Figure 40-1 shows a typical large medical *air compressor system.* In these systems, an electric motor is used to power a piston in a compression cylinder. On its downstroke, the piston draws air through a filter system with an inlet valve. On its upstroke, the piston compresses the air in the cylinder (closing the inlet valve) and delivers it through an outlet valve to a reservoir tank. Air from the reservoir tank is reduced to the desired working pressure by a pressure-reducing valve before being delivered to the piping system.

For medical gas use, air must be dry and free of oil or particulate contamination.[5] The most common method used for drying air is cooling to produce condensation. For avoidance of oil or particulate contamination, medical air compressors have air inlet filters and polytetrafluoroethylene (Teflon) piston rings as opposed to oil lubrication. Large medical air compressors must provide high flow (at least 100 L/min) at the standard working pressure of 50 *pounds per square inch gauge* (**psig**) for all equipment in use. The psig is the pressure read on the gauge. It reads the pressure above atmosphere pressure. See Chapter 6 for more information on this concept.

Smaller compressors (Figure 40-2) are available for bedside or home use. These compressors have a diaphragm or turbine that compresses the air and generally do not have a reservoir. This design limits the pressure and flow capabilities of these devices. For this reason, small compressors must never be used to power equipment that needs unrestricted flow at 50 psig, such as pneumatically powered ventilators (see Chapter 45). However, small diaphragm or turbine compressors are ideal for powering devices such as small-volume medication nebulizers (see Chapter 39).

FIGURE 40-2 Small portable compressor used with a hand-held nebulizer to aerosolize medication.

Carbon Dioxide

At STPD, CO_2 is a colorless and odorless gas with a specific gravity of 1.52 (approximately 1.5 times heavier than air).[1] CO_2 does not support combustion or maintain animal life. For medical use, CO_2 usually is produced by heating limestone in contact with water. The gas is recovered from this process and liquefied by compression and cooling. The FDA purity standard for CO_2 is 99%.[3]

Mixtures of O_2 and 5% to 10% CO_2 are occasionally used for therapeutic purposes, as noted in Chapter 41. Therapeutic uses include the management of singultus (hiccups), prevention of the complete washout of CO_2 during cardiopulmonary bypass, and regulation of pulmonary vascular pressures in some congenital heart disorders. However, CO_2 mixtures are more commonly used for the calibration of blood gas analyzers (see Chapter 19) and for diagnostic purposes in the clinical laboratory.

Helium

Helium (He) is second only to hydrogen as the lightest of all gases; it has a density at STPD of 0.1785 g/L. He is odorless, tasteless, nonflammable, and chemically and physiologically

inert. It is a good conductor of heat, sound, and electricity but is poorly soluble in water. Although He is present in small quantities in the atmosphere, it is commercially produced from natural gas through liquefaction to purity standards of at least 99%.[1,3]

He cannot support life, so breathing 100% He would cause suffocation and death. For therapeutic use, He must always be mixed with at least 20% O_2. **Heliox** (a gas mixture of O_2 and He) may be used clinically to manage severe cases of airway obstruction. Its low density decreases the work of breathing by making gas flow more laminar. He is discussed in more detail in Chapter 41.

RULE OF THUMB

He must always be combined with at least 20% O_2. The higher the concentration of O_2 used in a heliox mixture, the less likely it is that heliox would be beneficial. Heliox mixtures of less than 60% He are rarely used clinically.

Nitric Oxide

Nitric oxide (NO) is a colorless, nonflammable, toxic gas that supports combustion. It is produced by oxidation of ammonia at high temperatures in the presence of a catalyst. In combination with air, NO forms brown fumes of nitrogen dioxide (NO_2). Together, NO and NO_2 are strong respiratory irritants that can cause chemical pneumonitis and a fatal form of pulmonary edema. Exposure to high concentrations of NO alone can cause methemoglobinemia (see Chapter 41). High levels of methemoglobin can cause tissue hypoxia.

As discussed in Chapter 41, NO is approved by the FDA for use in the treatment of term and near-term infants for hypoxic respiratory failure. The American Academy of Pediatrics (AAP) published a policy statement recommending the use of NO in the care of term and near-term infants when mechanical ventilation is failing because of hypoxic respiratory failure. The AAP suggests that NO be used before extracorporeal membrane oxygenation.[6] A systemic review from the Cochrane database supports the recommendation that inhaled NO at 20 ppm may be beneficial in term and near-term infants who do not have a diaphragmatic hernia (see Chapter 34).[7] The use of inhaled NO in the treatment of premature neonates with hypoxic respiratory failure does not improve outcomes and may increase the risk for intracranial hemorrhage.[8]

Nitrous Oxide

Nitrous oxide (N_2O) is a colorless gas with a slightly sweet odor and taste that is used clinically as an anesthetic agent. Similar to O_2, N_2O can support combustion. However, N_2O cannot support life and causes death if inhaled in pure form. For this reason, inhaled N_2O must always be mixed with at least 20% O_2. N_2O is produced by thermal decomposition of ammonium nitrate.[1]

The use of N_2O as an anesthetic agent is based on its central nervous system depressant effect. However, only dangerously high levels of N_2O provide true anesthesia. N_2O/O_2 mixtures are almost always used in combination with other anesthetic agents.

Long-term human exposure to N_2O has been associated with a form of neuropathy. In addition, epidemiologic studies have linked chronic N_2O exposure with an increased risk for fetal disorders and spontaneous abortion.[1] On the basis of this knowledge, the National Institute for Occupational Safety and Health (a division of the Occupational Safety and Health Administration) set an upper exposure limit for hospital operating rooms of 25 ppm N_2O.[1]

STORAGE OF MEDICAL GASES

Medical gases are stored either in portable high-pressure cylinders or in large bulk reservoirs. Bulk reservoirs require a separate distribution system to deliver the gas to the patient.

Gas Cylinders

The containers used to store and ship compressed or liquid medical gases are high-pressure cylinders. The design, manufacture, transport, and use of these cylinders are carefully controlled by both industrial standards and federal regulations. Gas cylinders are made of seamless steel and are classified by the U.S. Department of Transportation (DOT) according to their fabrication method. DOT type 3A cylinders are made from carbon steel, and DOT type 3AA containers are manufactured with a steel alloy tempered for higher strength.[1]

Markings and Identification

Medical gas cylinders are marked with metal stamping on the shoulders that supplies specific information (Figure 40-3).[1,9] Although the exact location and order of these markings vary, the practitioner should be able to identify several key items of information.

The letters *DOT* or *ICC* (Interstate Commerce Commission) are followed by the cylinder classification (*3A* or *3AA*) and the normal filling pressure in pounds per square inch (psi). Below this information usually is the letter size of the cylinder (*E, G,* and so on) followed by the cylinder serial number. A third line provides a mark of ownership, often followed by the manufacturer's stamp or a mark identifying the inspecting authority. An abbreviation indicating the method of cylinder manufacturer is usually on the opposite side of the cylinder. Also in this area is information about the original safety test and dates of all subsequent tests.

Safety tests are conducted on each cylinder every 5 or 10 years, as specified in DOT regulations.[1,9] During these tests, cylinders are pressurized to five thirds of their service pressure. While the cylinder is under pressure, technicians measure cylinder leakage, expansion, and wall stress. The notation *EE* followed by a number indicates the elastic expansion of the cylinder in cubic centimeters under the test conditions. An asterisk (*) next to the test date indicates DOT approval for 10-year testing. A plus sign (+) means the cylinder is approved

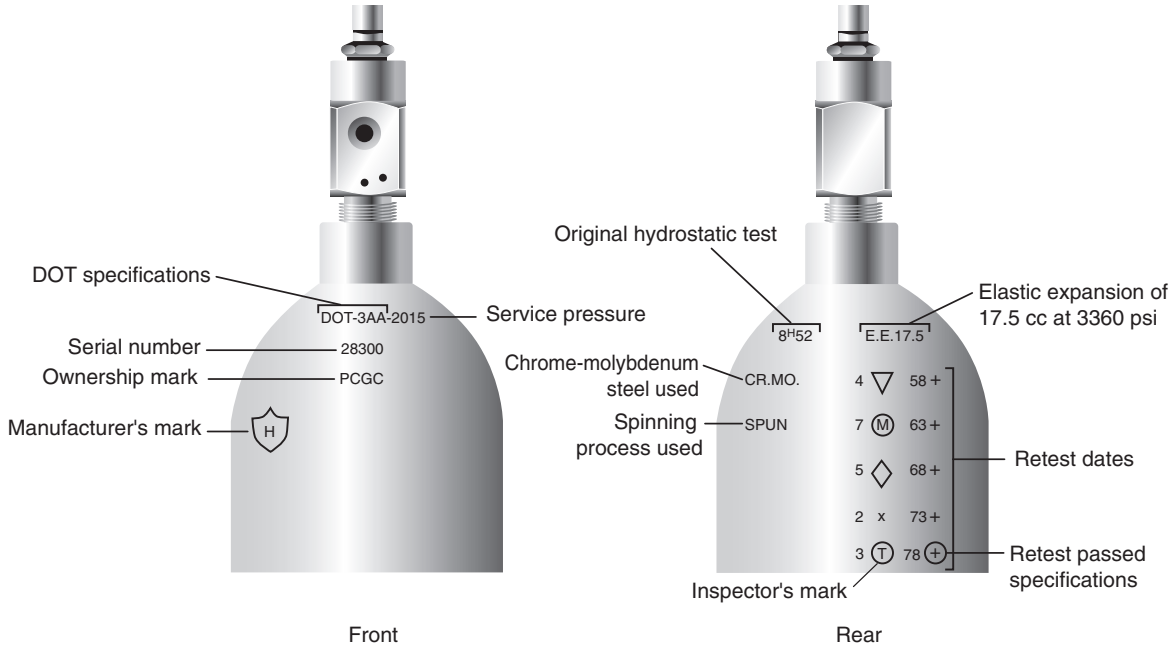

FIGURE 40-3 Typical markings of cylinders containing medical gases. Front and back views are for illustration purposes only; exact location and order of markings vary. *DOT,* Department of Transportation.

TABLE 40-2

Color Codes for Medical Gas Cylinders

Gas	United States	Canada
O_2	Green	White*
CO_2	Gray	Gray
N_2O	Blue	Blue
Cyclopropane	Orange	Orange
He	Brown	Brown
C_2H_4	Red	Red
CO_2-O_2	Gray/green	Gray/white
He-O_2	Brown/green	Brown/white
N_2	Black	Black
Air	Yellow*	Black/white
N_2-O_2	Black/green	Pink

*Vacuum systems historically are identified as white in the United States and yellow in Canada. For this reason, the Compressed Gas Association recommends that white not be used for any cylinders in the United States and that yellow not be used in Canada.
C_2H_4, Ethylene.

for filling to 10% greater than its service pressure. An approved cylinder with a service pressure of 2015 psi can be filled to approximately 2200 psi. After hydrostatic testing, cylinders are subjected to internal inspection and cleaning.

In addition to these permanent marks, all cylinders are color-coded and labeled for identification of their contents.[1,10] Table 40-2 lists the color codes for medical gases as adopted by the Bureau of Standards of the U.S. Department of Commerce.[10,11] For comparison, the color codes adopted by the Canadian Standards Association also are included. Color codes are not standardized internationally. For this reason, cylinder color should be used only as a guide. As with any drug agent, the cylinder contents always must be identified through careful inspection of the label. It has been reported that gas mixtures such as heliox can become unmixed.[12] To be absolutely sure about the O_2 concentration provided by a cylinder, the user must analyze the gas before administering it (see Chapter 19).

Cylinder Sizes and Contents

Letter designations are used for different sizes of cylinders (Figure 40-4). Sizes E through AA are referred to as "small cylinders" and are used most often for transporting patients and anesthetic gases. These small cylinders are easily identified because of their unique valves and connecting mechanisms. Small cylinders have a post valve and yoke connector. Large cylinders (F through H and K) have a threaded valve outlet (Figure 40-5).

Cylinder Safety Relief Valves

In a closed cylinder, any increase in gas temperature increases gas pressure. Should the temperature increase too much (as in a fire), the high gas pressure could rupture and explode the cylinder. To prevent this type of accident, all cylinders have high-pressure relief valves. These relief valves are of three basic designs: frangible disk, fusible plug, and spring-loaded. The *frangible metal disk* ruptures at a specific pressure. The *fusible plug* melts at a specific temperature. The *spring-loaded valve* opens and vents gas at a set high pressure. In each case, the activated valve vents gas from the cylinder and prevents pressure from becoming too high.

Most small cylinders have a fusible plug relief valve. Most large cylinders have a spring-loaded relief valve. These safety relief valves are always located in the cylinder valve stems.

Filling (Charging) Cylinders

How a cylinder is filled depends on whether its contents will be gaseous or liquid. Some gases stored in liquid form can remain at room temperature, but others must be maintained in a cryogenic (low-temperature) state.

Compressed Gases. A gas cylinder normally is filled to its service pressure (the pressure stamped on the shoulder) at 21.1° C (70° F). However, approved cylinders can be filled to 10% greater than service pressure.

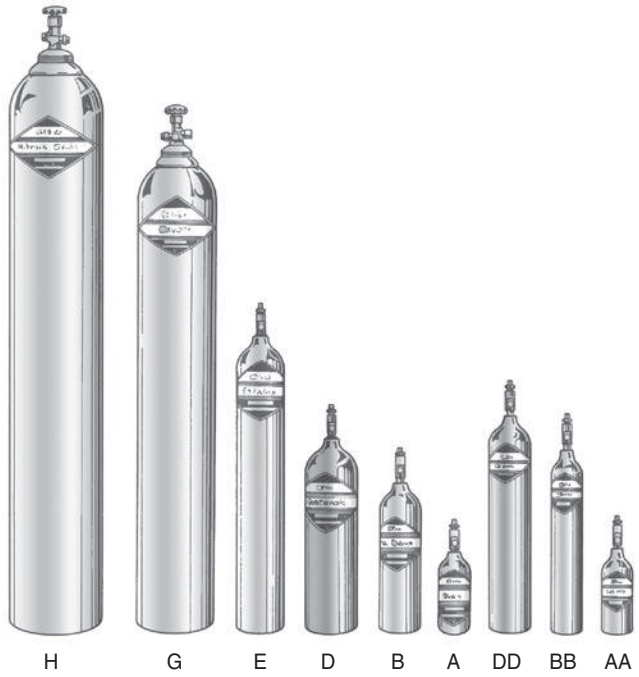

FIGURE 40-4 Cylinder sizes are identified by letter designations.

Liquefied Gases. Gases with critical temperatures greater than room temperature can be stored as liquids at room temperature (see Chapter 6). These gases include CO_2 and N_2O. Rather than being filled to filling pressure, cylinders of these gases are filled according to a specified filling density. The **filling density** is the ratio between the weight of liquid gas put into the cylinder and the weight of water the cylinder could contain if full. The filling density for CO_2 is 68%. This system allows the manufacturer to fill a cylinder with liquid CO_2 up to 68% of the weight of water that a full cylinder could hold. The filling density of N_2O is 55%.

Cylinder pressures for gases stored in the liquid phase are much lower than for gases stored in the gas phase. Because the liquid does not fill the entire volume of a cylinder, the space above the liquid surface contains gas in equilibrium with the liquid. The pressure in a liquid-filled cylinder equals the pressure of the vapor at any given temperature.

Pressure in a cylinder depends on the state of its contents. In a gas-filled cylinder, the pressure represents the force required to compress the gas into its smaller volume. In contrast, the pressure in a liquid-filled cylinder is the vapor pressure needed to keep the gas liquefied at the current temperature.

Measuring Cylinder Contents

Because of the previously described differences in the physical state of matter of compressed and liquid gases, different methods are needed to measure the contents of the cylinder.

Compressed Gas Cylinders. For gas-filled cylinders, the volume of gas in the cylinder is directly proportional to its pressure at a constant temperature. If a cylinder is full at 2200 psig, it will be half full when the pressure decreases to 1100 psig. To know how much gas is contained in a compressed gas cylinder, one needs only to measure its pressure.

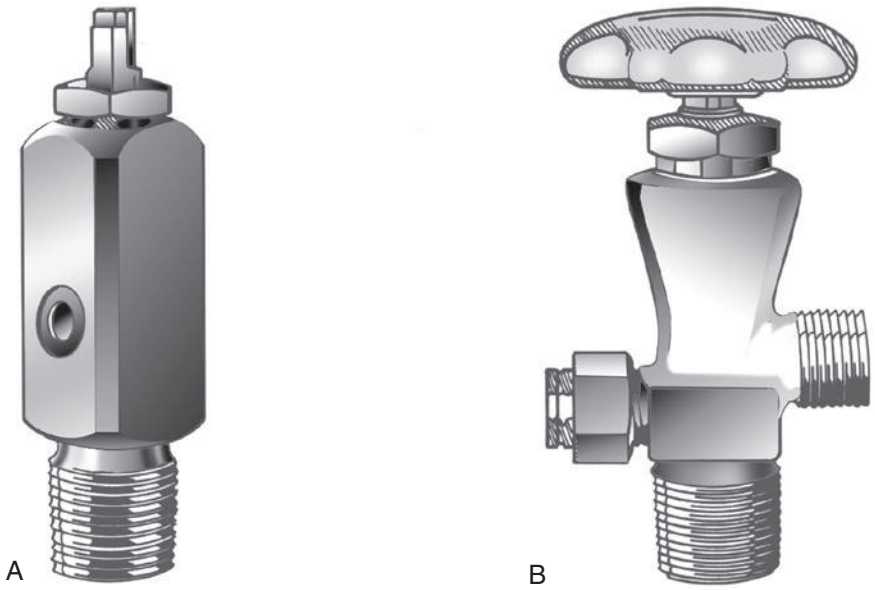

FIGURE 40-5 **A,** Post valve for yoke connector used with small cylinders (E through AA). **B,** Large, threaded valve outlet used with large cylinders (H/K, G, and M).

Liquid Gas Cylinders. In a liquid gas cylinder or container, the measured pressure is the vapor pressure above the liquid. This pressure bears no relationship to the amount of liquid remaining in the cylinder. As long as some liquid remains (and the temperature remains constant), the vapor pressure and the gauge pressure remain constant. When all the liquid is gone and the cylinder contains only gas, the pressure decreases in proportion to a reduction in volume. Monitoring the gauge pressure of liquid gas cylinders is useful only after all the liquid vaporizes. Weighing a liquid-filled cylinder is the only accurate method for determining the contents.

Figure 40-6 compares the behavior of compressed gas and liquid gas cylinders during use. The vapor pressure of liquid gas cylinders varies with the temperature of the contents. The pressure in an N_2O cylinder at 21.1° C (70° F) is 745 psig; at 15.6° C (60° F), the pressure decreases to 660 psig. As the temperature increases toward the critical point, more liquid vaporizes, and the cylinder pressure increases. If a cylinder of N_2O warms to 36.4° C (97.5° F) (its critical temperature), all the contents convert to gas. Only at this temperature and higher does the cylinder gauge pressure accurately reflect cylinder contents.

Estimating Duration of Cylinder Gas Flow

When a cylinder of therapeutic gas is used, it often is necessary to predict how long the contents will last at a given flow. The duration of flow of a cylinder can be estimated if the following are known: (1) the gas flow, (2) the cylinder size, and (3) the cylinder pressure at the start of therapy. For a given flow, the more gas a cylinder holds, the longer it lasts. The higher the gas flow, the shorter the cylinder emptying time. The duration of flow from a cylinder is directly proportional to the contents and inversely proportional to flow, as expressed in the following formula:

$$\text{Duration of flow} = \frac{\text{Contents}}{\text{Flow}}$$

The units commonly used in the United States for measurement of these quantities are not the same. Cylinder contents are generally specified in cubic feet or gallons, whereas gas flow normally is measured in liters. Table 40-3 provides the factors needed to convert these units.

Rather than memorizing various cylinder contents and constantly converting metric and English units, the user can quickly calculate duration of flow by using *cylinder factors*. Cylinder factors are derived for each common gas and cylinder size with the following formula:

$$\text{Cylinder factor (L/psig)} = \frac{\text{Cubic feet (full cylinder)} \times 28.3}{\text{Pressure (full cylinder) in psig}}$$

In the numerator of the previous equation, the English-metric conversion constant (28.3) is used to convert cubic feet to liters. Dividing the resulting volume by the pressure in a full cylinder

TABLE 40-3

Gas Volume Conversion Factors

Liters	Cubic Feet	Gallons
28.316	1	7.481
1	0.03531	0.2642
3.785	0.1337	1

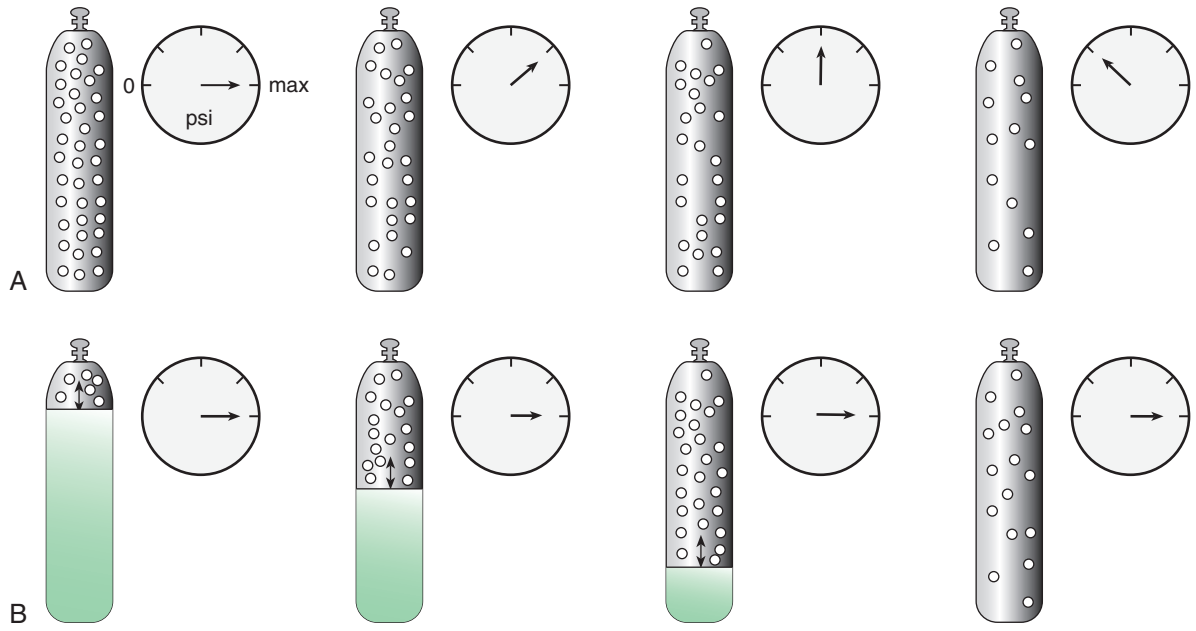

FIGURE 40-6 The content of a gas-filled cylinder **(A)** is directly proportional to the gas pressure. A pressure decrease of 50% indicates a loss of 50% of the contained gas. In a liquid-gas cylinder **(B),** gauge pressure is a measure of only the vapor pressure of gas in equilibrium with the liquid phase. This value remains constant at a given temperature as long as liquid is present. Only when all the liquid has vaporized, as the cylinder nears depletion, does the gauge pressure decrease proportionately to the terminal volume of remaining gas.

TABLE 40-4

Factors for Calculation of Cylinder Duration of Flow (Minutes)

Gas	CYLINDER SIZE			
	D	E	G	H and K
O_2, O_2/N_2, air	0.16	0.28	2.41	3.14
O_2/CO_2	0.20	0.35	2.94	3.84
He/O_2	0.14	0.23	1.93	2.50

yields the cylinder factor. The derived factor represents the volume of gas leaving a given cylinder for every 1-psig decrease in pressure. Table 40-4 provides cylinder factors for the therapeutic medical gases and common cylinder sizes.

When the factor for a given gas and cylinder is known, calculating the duration of flow is a simple matter of applying the following equation:

$$\text{Duration of flow (min)} = \frac{\text{Pressure (psig)} \times \text{Cylinder factor}}{\text{Flow (L/min)}}$$

A margin of safety must be allowed in estimation of cylinder duration of flow. This principle is especially important if the RT cannot be present during use and must return with a full cylinder. Some clinicians return 30 to 40 minutes before the calculated time; others compute duration of flow to a level of 300 to 500 psig rather than 0 psig (empty). Assuming the calculations are correct and there is no change in flow, both methods ensure an uninterrupted supply. The accompanying Rule of Thumb presents a shortcut for estimating cylinder duration of flow.

RULE OF THUMB

A full E O_2 cylinder running at 10 L/min lasts approximately 60 minutes (1 hour). A full H/K cylinder lasts at least 10 times longer (>10 hours). Use these two simple rules to estimate flow duration. For example, a half-full E O_2 cylinder running at 10 L/min lasts approximately 30 minutes, whereas a full H cylinder running at 5 L/min lasts more than 20 hours.

MINI CLINIC

Computing Cylinder Duration of Flow

PROBLEM: The RT needs to determine how long a G cylinder of O_2 with a gauge pressure of 800 psi set to deliver 8 L/min will last until empty.

SOLUTION: *Step 1:* Determine the cylinder factor for an O_2 G cylinder (see Table 40-4), which in this case is 2.41.

Step 2: Apply the duration of flow equation:

$$\text{Duration of flow (min)} = \frac{\text{Pressure (psig)} \times \text{Cylinder factor}}{\text{Flow (L/min)}}$$

$$\text{Duration of flow (min)} = \frac{800 \times 2.41}{8} = 241 \text{ minutes}$$

$$\text{(approximately 4 hours)}$$

Estimating Duration of Liquid Oxygen Cylinder Gas Flow

The only accurate method for determining the volume of gas in a liquid-filled cylinder is by weight. Because 1 L of liquid O_2 weighs 2.5 lb and produces 860 L of O_2 in its gaseous state, the amount of gas in a liquid O_2 cylinder can be calculated with the following formula:

$$\text{Amount of gas in cylinder} = \frac{\text{Liquid } O_2 \text{ weight (lb)} \times 860}{2.5 \text{ lb/L}}$$

After the amount of O_2 remaining in the cylinder is determined, the duration of the gas in minutes can be calculated with the following formula:

$$\text{Duration of gas (min)} = \frac{\text{Amount of gas in cylinder (L)}}{\text{Flow (L/min)}}$$

As with gaseous O_2 cylinders, a wide margin of safety is needed for estimation of cylinder duration. This margin of safety varies with the size of the portable O_2 unit or large storage container.

MINI CLINIC

Computing the Duration of a Liquid Oxygen Container

PROBLEM: The RT needs to estimate how long Mrs. Jones' portable liquid O_2 container will last if it contains 3 lb of liquid O_2 that supplies an O_2 delivery device running at 2 L/min.

SOLUTION: *Step 1:* Determine the amount of O_2 in the cylinder.

$$\text{Amount of gas in cylinder} = \frac{\text{Liquid } O_2 \text{ weight (lb)} \times 860}{2.5 \text{ lb/L}}$$

$$= \frac{3 \times 860}{2.5}$$

$$= 1032 \text{ L}$$

Step 2: Calculate the duration of the gas in the container.

$$\text{Duration of gas} = \frac{\text{Amount of gas in the cylinder (L)}}{\text{Flow (L/min)}}$$

$$= \frac{1032 \text{ L}}{2} = \frac{516 \text{ minutes}}{60 \text{ (min/hr)}}$$

$$= 8 \text{ hours } 36 \text{ minutes}$$

Gas Cylinder Safety

The following guidelines for cylinder safety are from the recommendations of the National Fire Protection Agency (NFPA)[2] and the Compressed Gas Association (CGA).[1,11] For ease of use, these safety guidelines are divided into cylinder storage, transport, and use.

Cylinder Storage. The following guidelines apply to cylinder storage:

- Store gas cylinders in racks or chain cylinders to the wall to prevent them from falling or becoming damaged.

- Store cylinders away from any combustible material.
- Store gas cylinders away from sources of heat. Keep the cylinder temperature less than 125° F (<51.7° C).
- Store flammable gases separately from gases that support combustion, such as air, O_2, and N_2O.
- If a cylinder is not in use, keep the protective cylinder cap in place.
- Do not store air compressors and gas cylinders together. A fire involving one or the other can damage both gas delivery systems.
- Contain and store cylinder supply systems in an enclosure constructed of a material with at least a 1-hour fire resistive rating that is well ventilated and well drained.
- Segregate full and empty cylinders; store them separately if possible.
- Place on each door or gate of the enclosure a sign that cautions the presence of an oxidizing gas and alerts against smoking. This sign must be readable from a distance of at least 5 ft (1.5 m).
- Store liquid O_2 containers in a cool, well-ventilated area because of the venting of small amounts of O_2 from these low-pressure containers. The venting of O_2 prevents these containers from overpressurizing because liquid O_2 is continuously converting to gaseous O_2.

Cylinder Transport. The following guidelines apply to cylinder transport:

- Use cylinder carts with a securing mechanism for transportation of cylinders.
- Keep the protective cylinder caps in place during transportation of cylinders.
- Protect gas cylinders from striking other cylinders or objects to avoid damaging the safety devices, valve stems, or the cylinder itself.
- Avoid dropping, dragging, or rolling cylinders in transport.
- Do not transport cylinders for use that are not appropriately labeled.

Cylinder Use. The following guidelines apply to cylinder use:

- Secure gas cylinders at the patient's bedside in a way that prevents them from falling. Secure cylinders to the wall with a chain, bind or chain them to a suitable cart, or support the cylinder with a stand.
- Do not use flammable materials, especially oil or grease, on regulators, cylinders, fittings, or valves. This restriction includes oily hands, rags, and gloves.
- Open the cylinder valve slightly to remove dust and dirt before attaching the regulator. When slightly opening the valve, ensure no one is in front of the valve. "Crack" the cylinder before bringing it to the patient's bedside.
- Never use cylinder valves or regulators that need repair.
- Do not alter or deface cylinder markings or color.
- Never place cylinders near sources of heat.
- Never secure cylinders to movable objects unless the object has an apparatus that can contain the cylinder safely.
- Ensure that the connection between the regulator and the cylinder valve is an **American standard safety system** (ASSS) for H and G cylinders and a **pin-index safety system** (PISS) for E cylinders.
- When O_2 is in use, post a "No Smoking" sign unless signs in the entrances are posted that prohibit smoking in the facility.

Bulk Oxygen

Large acute care facilities use large volumes of O_2 every day. To meet these needs, a centralized bulk storage and delivery system is required. By definition, bulk O_2 storage systems hold at least 20,000 ft^3 of gas, including the onsite unconnected reserves.[2] Bulk O_2 may be stored in either gaseous or liquid form, but liquid storage is most common. When needed, the O_2 flows from this central source throughout the facility through a piping system with outlets conveniently located.

A bulk O_2 system has several advantages over portable cylinders. Although initially expensive to construct, bulk O_2 systems are far less expensive over the long term. Bulk O_2 systems are less prone to interruption. These systems eliminate the inconvenience and hazard of transporting and storing numerous cylinders. Bulk O_2 systems regulate delivery pressures centrally, eliminating the need for separate pressure-reducing valves at each outlet. These systems also operate at low pressures, making them much safer than high-pressure cylinders.

Safety standards for bulk O_2 systems are set by the NFPA and are subject to further control by local fire and building codes.[2]

Gas Supply Systems

The three types of centrally located gas supply systems are an alternating supply system or cylinder **manifold** system, a cylinder supply system with reserve supply, and a bulk gas system with a reserve.[2] The *alternating supply* or *cylinder manifold system* consists of large (normally H or K size) cylinders of compressed O_2 banked together in series (Figure 40-7). This alternating supply system has two sides: a primary bank and a reserve bank. When the pressure in the primary bank decreases to a set level, a control valve automatically switches over to the reserve bank. When this occurs, the primary bank is taken offline, and the empty cylinders are replaced with full ones. The replenished primary bank becomes the reserve bank. Some large alternating supply systems are permanently fixed and are refilled on site by a supply truck. These cylinder manifold systems have pressure-reducing valves for regulation of delivered pressure and normally have low-pressure alarms. These alarms sound when reserve switchover occurs, and they warn of impending depletion or malfunction. Cylinder manifolds or alternating supply systems are used to supply O_2 from a central location in small facilities or to supply specialty gases, such as N_2O, to operating rooms (Figure 40-8).

A *cylinder supply system with a reserve* consists of a primary supply, a secondary supply, and a reserve supply. When the primary gas supply is depleted by the demand, this supply system automatically switches to the secondary supply. Master signal panels indicate that the changeover has occurred. This supply system operates in a manner similar to the alternating system except that this system has a reserve supply if primary

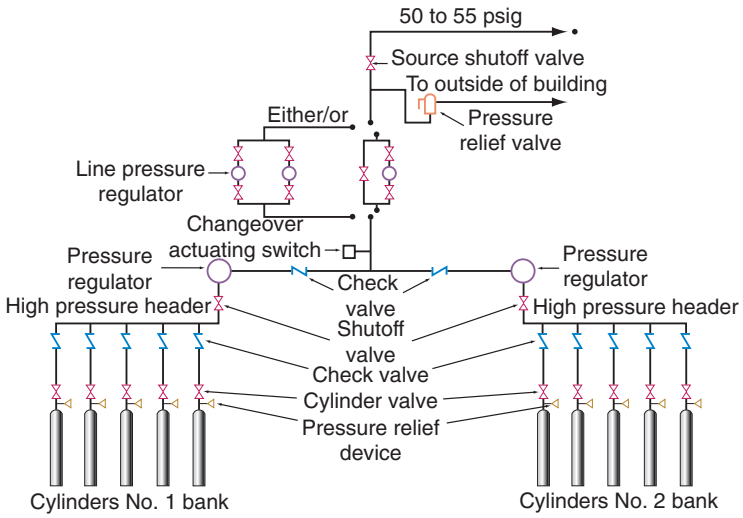

FIGURE 40-7 Gas cylinder manifold system. The alternating supply system is composed of primary and reserve banks, which alternate to charge the piping system. (Modified from Standard for nonflammable medical gas systems, NFPA No. 56F. Copyright 1973, National Fire Protection Association, Boston, MA.)

FIGURE 40-8 Alternating supply system of N_2O.

FIGURE 40-9 Large stand tank and reserve tank of liquid O_2 represents a typical bulk gas system with a reserve.

and secondary supplies become depleted. Liquid containers may be used as the primary and secondary gas sources, but the reserve supply usually is high-pressure gas cylinders. Gas cylinders are used as the reserve supply because low-pressure liquid containers lose approximately 3% of the supply per day.[2]

For economy, safety, and convenience, most large health care facilities use a *liquid bulk O_2 system*. A small volume of liquid O_2 provides a very large amount of gaseous O_2 and minimizes space requirements. However, along with this advantage comes a major problem. O_2 has a critical temperature well below room temperature (−118.6° C [−181.4° F]).[1] Liquid O_2 must continually be stored below this temperature, or it reverts to its gaseous state.

To stay in liquid form, O_2 is stored in large stand tanks (Figure 40-9) at relatively low pressure (<250 psig). These stand tanks are similar to giant thermos bottles, consisting of inner and outer steel shells separated by an insulated vacuum chamber (Figure 40-10). Because it eliminates heat conduction, the vacuum keeps the liquid O_2 below its critical temperature without refrigeration. When it flows through vaporizer coils exposed to ambient temperature, the liquid O_2 quickly converts back to a gas. With the O_2 in its gaseous form, the pressure is decreased to the standard working pressure of 50 psi by a

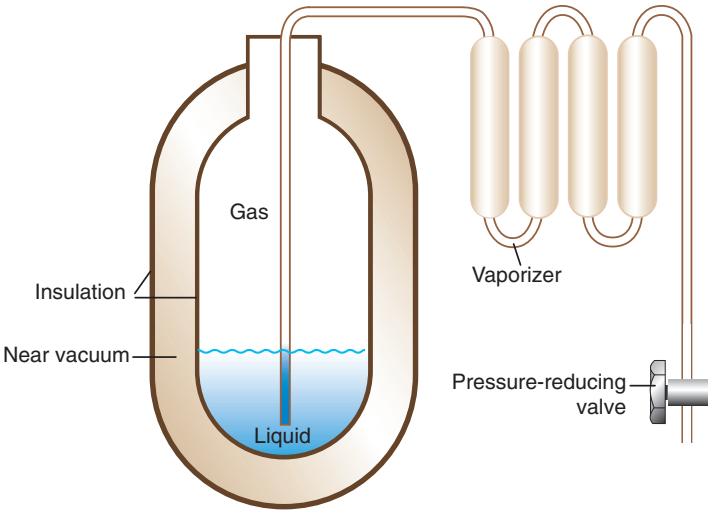

FIGURE 40-10 Liquid-O_2 stand tank (fixed station). (Modified from Cairo JM, Pilbeam SP: Mosby's respiratory care equipment, ed 8, St Louis, 2010, Mosby.)

pressure-reducing valve. A safety vent allows vaporized liquid O_2 to escape if warming causes cylinder pressure to increase above a set limit.

Smaller liquid cylinders are used for home O_2 supply. These cylinders come in several sizes and hold between ⅔ ft^3 and 1½ ft^3 of liquid O_2. Small liquid O_2 cylinders are refilled onsite by means of transfer of liquid O_2 from a large cylinder. Chapter 56 describes the use of these small liquid O_2 cylinders in the home.

Bulk Oxygen Safety Precautions

The NFPA sets standards for the design, construction, placement, and use of bulk O_2 systems.[2] A key provision in these standards is the requirement for a reserve or backup gas supply to equal the average daily gas usage of the hospital. To meet this requirement, most large facilities have a second, smaller liquid stand tank. Smaller facilities may use a cylinder gas manifold as the backup.

Failure of bulk O_2 supply systems has been reported with resultant major problems.[13-16] Failure of a bulk O_2 supply can be life-threatening to any patient receiving O_2 or gas-powered ventilatory support. For this reason, the respiratory care staff must be prepared. Adherence to an established protocol is a quick way to identify and prioritize all affected patients. When affected patients are identified, staff members move appropriate backup equipment to the bedside (e.g., portable cylinders, bag-valve-mask resuscitators). Trained personnel bypass the failed system and provide needed patient support, while engineers determine the cause of the failure and correct it.

DISTRIBUTION AND REGULATION OF MEDICAL GASES

Before it can be administered to a patient, a medical gas must be delivered to the bedside and the pressure reduced to a workable level. This is the primary function of gas distribution and regulation systems. Modern hospital gas distribution systems deliver bulk O_2 and compressed air to patient rooms and special care areas through an elaborate piping network. This network may include a vacuum source and, for surgical areas, N_2O. Patient transport still requires the use of portable cylinders. Whether delivery occurs by central bulk supply or cylinder, patient safety is always the primary aim. For this reason, RTs must be proficient in the use of both delivery systems.

Central Piping Systems

Structural standards for piping systems are established by the NFPA and are described in more detail elsewhere.[2] Figure 40-11 shows a simple central piping gas system. The gas pressure in a central piping system normally is reduced to the standard working pressure of 50 psi at the bulk storage location. A main alarm warns of decreases in pressure or interruptions in flow from the source. **Zone valves** (Figure 40-12) throughout the system can be closed for system maintenance or in case of fire. Wall or station outlets at the delivery sites allow connection of various types of equipment to the gas distribution system. Because most delivery outlets include O_2, air, vacuum, and possibly N_2O, special safety connectors are used to help prevent accidental misconnections.

Safety Indexed Connector Systems

One of the greatest risks in medical gas therapy is giving the wrong gas to a patient. Carefully reading the cylinder or outlet labels is the best way to avoid these accidents. However, human error does occur. For this reason, the industry has developed indexed safety systems for gas delivery and regulation equipment. These safety systems make misconnection between pieces of equipment nearly impossible. For example, an indexed safety system normally prevents connecting a cylinder of N_2O to an O_2 delivery system. Three basic indexed safety systems are used in the delivery and regulation of medical gases: (1) the American National Standard/Compressed Gas Association Standard for Compressed Gas Cylinder Valve Outlet and Inlet Connections, or the ASSS; (2) the **diameter-index safety system** (DISS); and (3) the pin index safety system (PISS).[17,18]

American Standard Safety System

Adopted in the United States and Canada, the ASSS provides standards for threaded high-pressure connections between large compressed gas cylinders (sizes F through H/K) and their attachments.[17] Specifications exist for more than 60 gases and gas mixtures. Figure 40-13 shows a typical ASSS connection between a threaded cylinder outlet and a pressure-reducing valve nipple. Use of the ASSS standards makes misconnections difficult because the size (bore) of the cylinder outlet and its threading differ based on the type of gas in the cylinder.

Because there are only 26 connections for the 62 listed gases and mixtures, each gas may not have a unique connection. Some gases have identical connections. Catalogues of cylinder equipment show the connection specifications for each type of

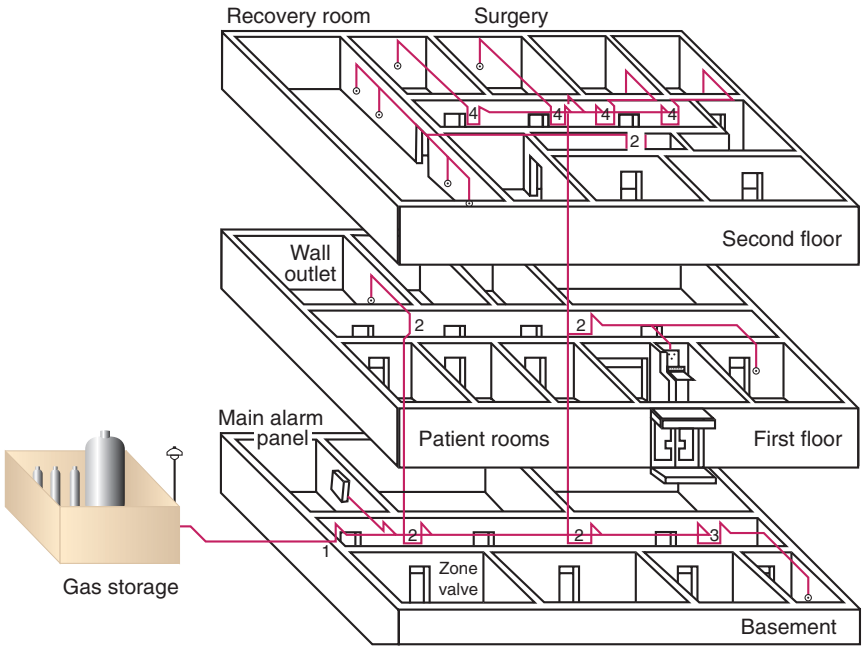

FIGURE 40-11 A hospital piping system. Numbers indicate zone valves.

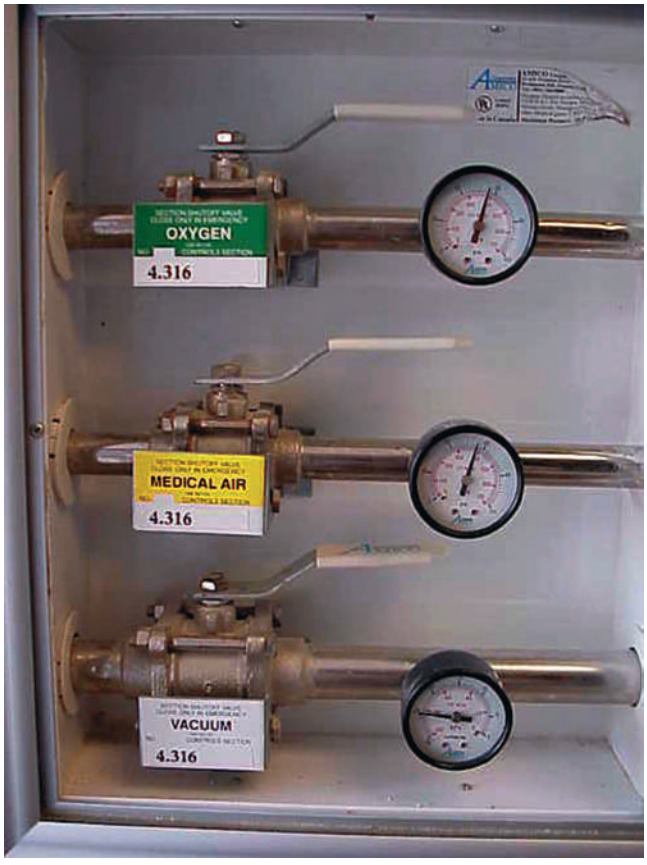

FIGURE 40-12 O_2, air, and vacuum zone valves.

cylinder and gas. A typical description for a large cylinder of O_2 is as follows: CGA-540 0.903-14NGO-RH-Ext. The connection for the threaded outlet of this cylinder is listed by the CGA as connection number 540. The outlet has a thread diameter (bore) of 0.903 inch; there are 14 threads per inch; and the

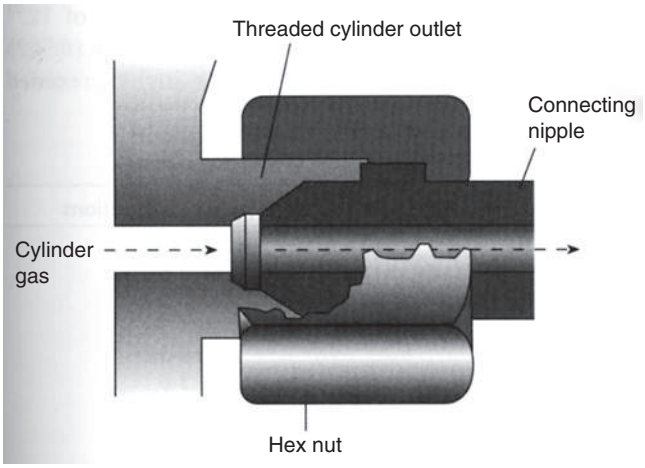

FIGURE 40-13 Typical American standard supply system connection used to attach a reducing valve to a large high-pressure cylinder. A hexagonal nut is held on the nipple of the reducing valve by a circular collar. The connection is made by (1) aligning the reducing valve nipple with the conical cylinder valve outlet and (2) tightening the reducing valve hex nut onto the threaded cylinder outlet. Different threading and cylinder outlet sizes make accidental misconnections difficult.

threads are right-handed (RH) and external (Ext). It generally is necessary to use only one or two outlet connections because most of the gases that are used by RTs are grouped within a few connector sizes. However, practitioners should be familiar with the classification scheme in general because expanding instrumentation and scope of services may bring RTs in contact with other gases and gas systems.

Pin-Index Safety System

Pin indexing is part of the ASSS but applies only to the valve outlets of small cylinders, up to and including size E. These

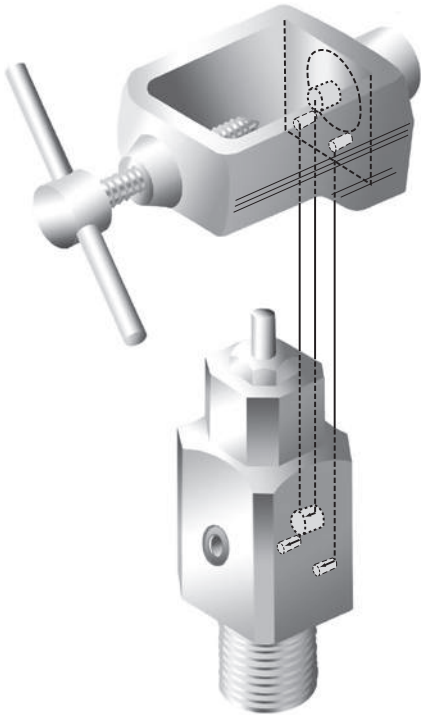

FIGURE 40-14 Yoke connector showing regulator inlet and pin-indexed safety system (for cylinders size AA to E).

cylinders have a yoke type of connection. Figure 40-14 illustrates the general structure of the pin-indexed yoke connection. The upper yoke fits over the lower valve stem. Two pins, projecting from the inner surface of the yoke connector, mate with two pinholes bored into the valve stem. Proper pin position aligns the small receiving nipple of the yoke with the recessed cylinder valve outlet. Tightening the hand screw on the yoke firmly seats the receiving nipple into the valve outlet. A nylon washer or bushing typically is used to ensure a leak-free connection.

Similar to the ASSS, the PISS helps prevent accidental misconnections between pieces of equipment. The exact positions of pins and pinholes vary for each gas. Unless the pins and holes align perfectly, the yoke nipple cannot seat in the recessed valve outlet. Six holes and pin positions constitute the total system. Because overlapping holes cannot be used, there are 10 possible pin combinations. Figure 40-15 is a diagram of the location of all six possible holes and their index numbers. Table 40-5 lists the gases included in the PISS system, including their index positions.

Diameter-Index Safety System

The ASSS and the PISS provide standards for high-pressure connections between cylinders and equipment; the DISS was established to prevent accidental interchange of low-pressure (<200 psig) medical gas connectors.[18] RTs typically find DISS connections (1) at the outlets of pressure-reducing valves attached to cylinders; (2) at the station outlets of central piping systems; and (3) at the inlets of blenders, flowmeters, ventilators, and other pneumatic equipment.

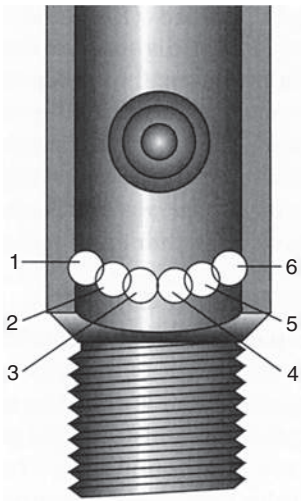

FIGURE 40-15 Location of the pin-index holes in the cylinder valve face for different gases. See Table 40-5 for pin-index hole locations for various gases.

TABLE 40-5

Pin-Index Hole Positions*

Gas	Pin Positions
O_2	2-5
O_2/CO_2 (CO_2 not >7%)	2-6
He/O_2 (He not >80%)	2-4
C_2H_4	1-3
N_2O	3-5
C_3H_6	3-6
He/O_2 (He > 80%)	4-6
O_2/CO_2 (CO_2 > 7%)	1-6
Air	1-5

*See Figure 40-15.
C_2H_4, Ethylene; C_3H_6, cyclopropane.

As shown in Figure 40-16, the DISS connection consists of an externally threaded body and a mated nipple with a nut. As the two parts are joined, the shoulders of the nipple and the bores of the body mate, with the union held together by a hand-tightened hex nut. Indexing is achieved by varying the dimensions of the borings and shoulders. There are 11 indexed DISS connections and 1 connection for O_2, for a total of 12.[18] The standard threaded O_2 connector (0.5625 inch in diameter and 18 threads per inch) preceded adoption of this safety system. Nonetheless, it has been assigned a DISS number of 1240.

Although O_2 and air are generally used from a central outlet, it may be necessary to administer other gases that have different DISS connections. To avoid stocking a large variety of pressure regulators, flowmeters, and connectors for special gas use, adapters can be used to convert various DISS connections so they can be used for different purposes. Using adapters to bypass a safety system carries the increased risk for misconnection. For this reason, RTs should exercise extreme caution

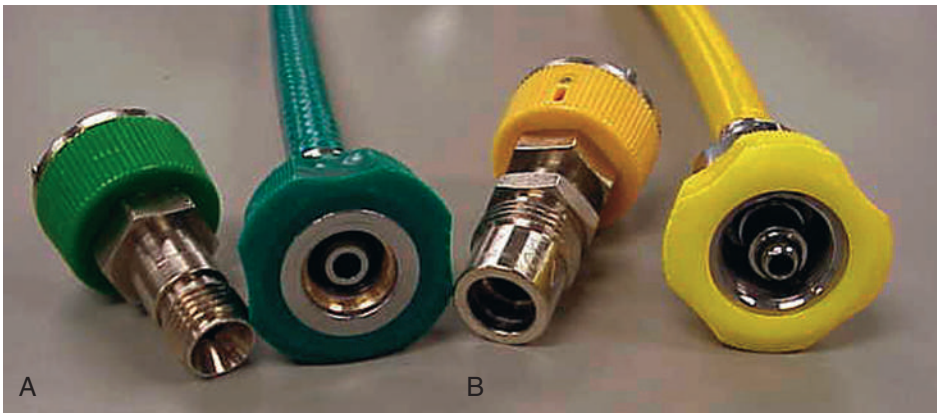

FIGURE 40-16 O_2 **(A)** and air **(B)** diameter index safety system (DISS) connections. The two shoulders of the nipple allow the nipple to unite only with a body that has corresponding borings. If the match is incorrect, the nut does not engage the body threads. The difference in the shoulders and bore between the O_2 **(A)** and air **(B)** DISS connections is evident.

when adapting equipment connections. Misconnections have occurred, with negative patient consequences.[13,19]

Quick-Connect Systems

Station outlets at the patient's bedside allow quick access to a bulk supply of O_2 and air or a vacuum source. Station outlets have DISS connections or quick-connect systems that are gas-specific or vacuum-specific. Various manufacturers have designed specially shaped connectors for each gas (Figure 40-17). Because each connector has a distinct shape, it does not fit into an outlet for another gas and each manufacturer has its own unique design. For this reason, connectors from different manufacturers are not interchangeable. As long as a facility is standardized for a single quick-connect system, this incompatibility is seldom a problem.

A variety of safety systems help prevent inadvertent misconnections between medical delivery systems and equipment. Figure 40-18 summarizes the use of and relationships between the ASSS, PISS, and DISS systems as applied to cylinder gases. Proficiency in the proper use of these systems is a basic skill of RTs.

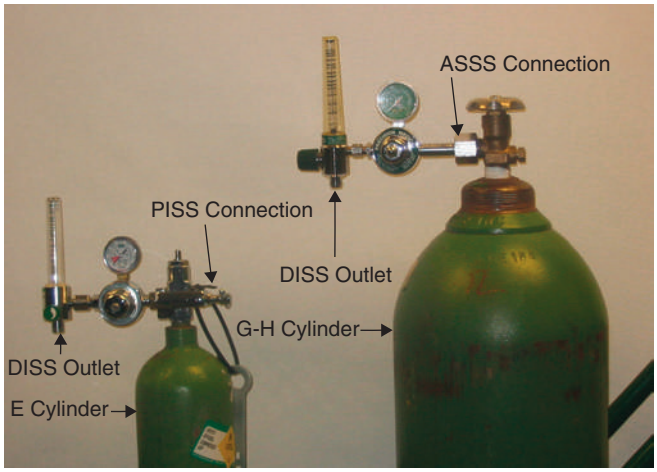

FIGURE 40-18 Comparison of safety systems used for compressed gases. The diameter-index safety system (DISS) connections are for low-pressure outlets (<200 psig). The American standard safety system (ASSS) provides for high-pressure connections with large cylinders. A variation of the ASSS entails a yoke and pin system (PISS) for connecting to small cylinders (AA through E).

Regulating Gas Pressure and Flow

Whatever the source of medical gas, for safe administration to a patient, the pressure and flow must be regulated. If the goal is solely a reduction in gas pressure, a **reducing valve** is used. For control of gas flow to a patient, a **flowmeter** is used. If control of both pressure and flow is needed, a regulator is used.

Cylinder gases such as O_2 and air exert a pressure that is much too high for use with respiratory care equipment. For use at the bedside, these high pressures must be reduced to a lower "working" level. In the United States, this working pressure is 50 psig. For bulk delivery systems with individual station outlets, built-in reducing valves decrease the delivered pressure to 50 psig. This standard pressure can be directly applied to power devices such as ventilators (see Chapter 45). However, if the goal is to control gas delivery to a patient for O_2 therapy or nebulized medication (see Chapters 39 and 41), a flowmeter also must be used.

High-Pressure Reducing Valves

The two basic types of high-pressure reducing valves are single-stage and multiple-stage. Reducing valves are available as preset or adjustable. Although all of these valves function on the same principle, the design, features, and use are different. This section differentiates preset reducing valves and adjustable reducing valves and discusses multiple-stage reducing valves.

Preset Reducing Valve. Figure 40-19 shows the basic design of a high-pressure preset reducing valve. High-pressure gas (2200 psig for O_2) enters through the valve *(A)*, with the inlet pressure displayed on the pressure gauge *(B)*. The body of the valve is divided into a high-pressure chamber *(C)* and an ambient-pressure chamber *(D)* by a flexible diaphragm *(E)*. Attached to the diaphragm in the ambient-pressure chamber is a spring *(F)*, which is fixed to the other side of the chamber. Also attached to the diaphragm, but in the high-pressure chamber, is a valve stem *(G)* that sits on the high-pressure inlet *(H)*. Gas flows through the valve inlet *(H)* into the high-pressure chamber and on to the gas outlet *(I)*. The pressure chamber is supplied with a safety vent *(L)* preset to 200 psig to release pressure in the event of malfunction.

The spring tension is calibrated to give when the pressure on the diaphragm exceeds 50 psig. When this happens, the valve stem is pushed forward and closes the high-pressure inlet, preventing further entry of gas into the reducing valve. However, as long as gas is allowed to escape from the pressure chamber through the outlet *(I)*, the inlet valve remains open and allows gas flow. The regulator maintains a balance between outlet flow and inlet pressure. Automatic adjustment of the diaphragm-spring combination keeps the pressure in the high-pressure chamber at a near-constant 50 psig—hence the name *preset*. Preset reducing valves are normally used in conjunction with high-pressure gas cylinders to decrease the pressure to the standard 50 psig used with most respiratory care equipment.

Adjustable Reducing Valve. Although most respiratory care equipment works at the standard 50 psig, some devices need variable pressures. To provide variable outlet pressures from a high-pressure gas source, an adjustable reducing valve is needed. Figure 40-20 shows the basic design of a high-pressure

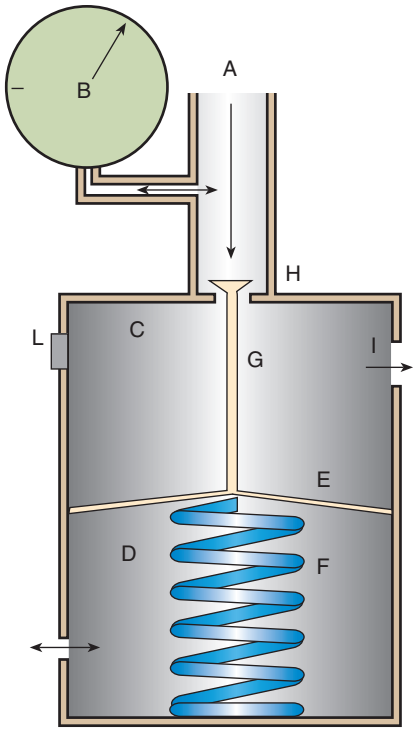

FIGURE 40-19 Preset high-pressure reducing valve.

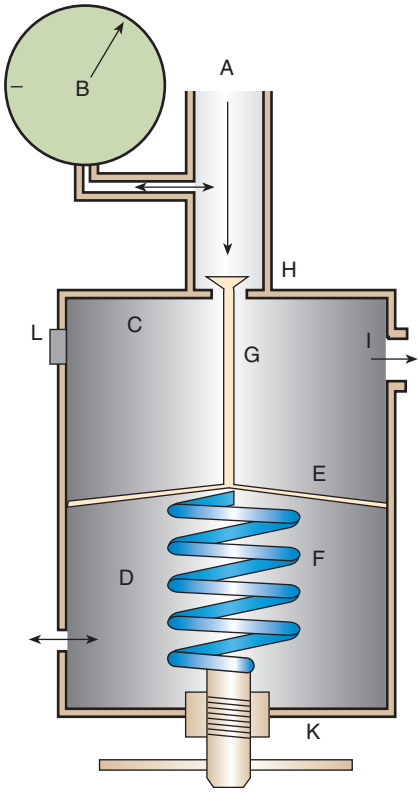

FIGURE 40-20 Adjustable high-pressure reducing valve.

adjustable reducing valve. As with the preset design, the inlet valve *(H)* remains open until the gas pressure exceeds the spring tension, displacing the diaphragm and blocking further gas entry. However, whereas the preset reducing valve provides a fixed pressure, the adjustable reducing valve allows a change in outlet pressure. Outlet pressure can be changed with a threaded hand control *(K)* attached to the end of the diaphragm spring. Changing the tension on the valve spring varies pressure over a wide range, usually between 0 psig and 100 psig.

The adjustable reducing valve commonly is used in combination with a Bourdon-type flow gauge (discussed later). The combination of a flowmeter with a reducing valve is called a **regulator.**

Multiple-Stage Reducing Valve. As the name suggests, a *multiple-stage reducing valve* reduces pressure in two or more steps. Multiple-stage reducing valves can be either preset or adjustable and can be combined with a flowmeter device as a true regulator. Two-stage reducing valves are used occasionally, and three-stage units are rarely needed. A two-stage reducing valve functions as two single-stage reducing valves working in series. Gas enters the first stage, where the pressure is reduced to an intermediate level (usually 200 to 700 psig). Gas then enters the second stage, where the pressure is decreased to working level (usually 50 psig). Because each pressure chamber has one safety relief vent, the user usually can determine the number of stages in a reducing valve by noting the number of relief vents present. Because they reduce pressure in multiple steps, these valves provide more precise and smooth flow control. However, they are larger and more expensive than single-stage reducing valves. For this reason, a multiple-stage reducing valve should be considered only if minimal fluctuations in pressure or flow are critical factors, as in research activities. For routine hospital work, single-stage reducing valves are satisfactory.

Proper Use of High-Pressure Reducing Valves. When a cylinder attached to a high-pressure reducing valve is open, gas undergoes rapid decompression followed by rapid recompression. Because the recompression is adiabatic (see Chapter 6), the gas temperature quickly increases. These rapid pressure and temperature changes may cause failure of the reducing valve. Rapid temperature changes can ignite combustible materials; this risk is increased in the presence of 100% O_2. Box 40-1 provides guidelines for minimizing the risk associated with setting up O_2 cylinders with a high-pressure reducing valve or regulator.[1]

Box 40-1 Safe Procedure for Setup of an Oxygen Cylinder and Reducing Valve or Regulator

1. Secure the cylinder according to the CGA guidelines. Verify the contents from the label that matches the color code and valve indexing.
2. Remove the protective cap or wrap, and inspect the cylinder valve to ensure that it is free of dirt, debris, and oil.
3. Warn any persons present that the cylinder valve is about to be "cracked" and that it will make some noise. Turn the cylinder valve away from persons present, stand to the side, and quickly open and close the valve. This removes any dust or small debris from the cylinder valve outlet.
4. Inspect the valve or regulator inlet for debris, dirt, and oil. Check the device label, and confirm that it is intended for high-pressure service and for use with the gas to be administered. O_2-reducing valves and regulators should have a label stating: *Oxygen: Use No Oil*.
5. After the valve or regulator inlet is confirmed to be free of contaminants, securely tighten (but do not force) the device onto the cylinder outlet. When making connections to the cylinder, use appropriate wrenches that are free of oil and grease. Never use pipe wrenches. Use only cylinder valve connections that conform to the ASSS and the PISS. Low-pressure connections must comply with the DISS or be noninterchangeable, low-pressure quick connects. Never connect fixed or adjustable orifices or metering devices directly to a cylinder without a pressure-reducing valve.
6. Confirm that the regulator or reducing valve is in the *off* or *closed* position, and slowly open the cylinder valve to pressurize the attached reducing valve or regulator. After pressurization has occurred, open the cylinder valve completely and turn it back one-fourth to one-half turn (this maneuver prevents a condition known as "valve freeze," in which the valve cannot be turned).

Low-Pressure Gas Flowmeters

As with drugs, giving a medical gas to a patient requires knowledge of the dosage being delivered. Physicians often prescribe O_2 dosage as a flow, in liters per minute. In addition, certain gas-mixing equipment requires accurate knowledge of input flows, sometimes involving two or more gases. Flowmeters allow the rate of gas flow to a patient to be set and controlled. When the gas source is a high-pressure gas cylinder, a regulator (reducing valve plus flowmeter) is required. However, when the source is a bulk central supply system, the pressure has already been reduced to 50 psig by the time it reaches the outlet stations; this eliminates the need for pressure reduction and requires only a flowmeter.

Three categories of flowmeters are used in respiratory care: the flow restrictor, the **Bourdon gauge,** and the **Thorpe tube.** The Thorpe tube has two different designs: pressure compensated or not pressure compensated (uncompensated). Although uncompensated Thorpe tubes are rare, they may still be used at some institutions. For this reason, the principles underlying each of the four types of flow metering devices are compared and contrasted.

Flow Restrictor. The flow restrictor is the simplest and least expensive flowmeter device. As shown in Figure 40-21, a flow restrictor consists solely of a fixed orifice calibrated to deliver a specific flow at a constant pressure (50 psig). The operation of the flow restrictor is based on the principle of flow resistance, as described in Chapter 6. Specifically, the flow of gas through a tube can be quantified with the following equation:

$$R = \frac{P_1 - P_2}{V}$$

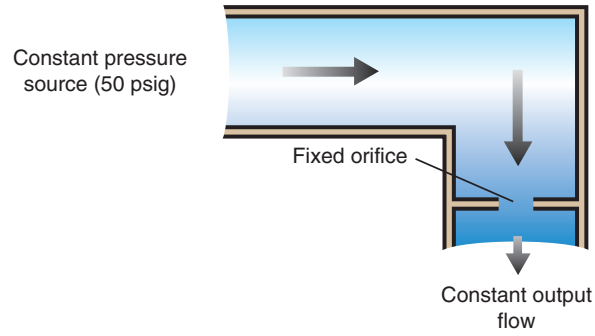

FIGURE 40-21 Flow restrictor.

FIGURE 40-22 Bourdon gauge regulator.

MINI CLINIC

Leaky Connections

PROBLEM: Following standard procedure, the RT attaches a pressure-reducing valve to an O_2 cylinder. When the RT opens the cylinder valve, gas leaking at or near the connection can be heard.

SOLUTION: A leak usually indicates that the connection between the pressure-reducing valve and the cylinder outlet is not tight. If the cylinder outlet is a standard ASSS threaded connector, the connection is either cross-threaded or not properly seated and tightened. To solve this problem, the RT closes the cylinder valve and removes and reattaches the pressure-reducing valve, taking care to thread the connection properly and to tighten with a wrench. If the cylinder outlet is a pin-indexed connector, the RT closes the cylinder valve and removes the pressure-reducing valve. The RT checks to ensure that the nylon washer is present, in good condition, and properly fitted. The RT then reattaches the pressure-reducing valve, taking care to seat the connection properly and to hand tighten. If the leak continues after these corrective actions, it is likely that the pressure-reducing valve is malfunctioning and should be replaced.

Rearranging the equation to solve for flow *(V)* yields the following:

$$V = \frac{P_1 - P_2}{R}$$

where *V* is the volumetric flow per unit time, P_1 is the pressure at the **upstream** point (point 1), P_2 is the pressure at the **downstream** point (point 2), and *R* is the total resistance to gas flow.

By design, a flow restrictor requires a source of constant pressure (usually 50 psig). As long as the source pressure remains fixed, $P_1 - P_2$ should stay constant. With a fixed-size orifice, the flow resistance *(R)* also remains constant. The rate of gas flow through a flow restrictor can be increased by increasing P_1 (upstream pressure) or by selecting a larger orifice size. Both fixed and adjustable orifice flow restrictors are used clinically. Commercially produced flow restrictors are calibrated at 50 psig. Table 40-6 summarizes the advantages and disadvantages of flow restrictors.

TABLE 40-6
Advantages and Disadvantages of Flow Restrictors

Advantages	Disadvantages
Low-cost, simple, reliable (no moving parts)	Different versions required for different flows
Cannot be set to incorrect flow	Accuracy varies with changes in source and downstream pressures
Can be used in any position (gravity-independent)	Cannot be used with high-resistance equipment

Bourdon Gauge. A Bourdon gauge (Figure 40-22) is a flowmeter device that is always used in combination with an adjustable pressure-reducing valve. Similar to the flow restrictor, the Bourdon gauge uses a fixed orifice. In contrast to the flow restrictor, the Bourdon gauge operates under variable pressures, as adjusted with the pressure-reducing valve. The Bourdon gauge is a fixed-orifice, variable-pressure flowmeter, so increasing the upstream pressure increases gas flow out of the device unless downstream pressure also increases.

As shown in Figure 40-23, a Bourdon gauge has a calibrated fixed orifice *(A)*, which creates outflow resistance. The gauge itself is attached with a connector *(B)* located proximal to the orifice. Inside the gauge is a curved, hollow, closed tube *(C)* that responds to pressure changes by changing shape. The force of gas pressure tends to straighten the tube, causing its distal end to move. This motion is transmitted to a gear assembly and indicator needle *(D)*. Although it changes based on pressure, the numbered scale is calibrated to read the needle movement in units of flow (liters per minute).

As with the flow restrictor with a fixed orifice, the output flow of the Bourdon gauge is proportional to the driving pressure. However, the Bourdon gauge provides a continuous range of flow, which the user adjusts by altering the driving pressure.

Although the gauge actually measures pressure changes, it displays the corresponding flow.

As with a flow restrictor, gravity does not affect a Bourdon gauge. The Bourdon gauge is the best choice when a flowmeter cannot be maintained in an upright position. This situation is common when a patient is being transported with a portable O_2 source. In these instances, keeping the E cylinder upright is seldom easy, and movement of both the O_2 supply and the patient is common. Combined with its continuous range of flows, this feature makes the Bourdon gauge the metering device of choice for patient transport.

The main disadvantage of the Bourdon gauge is its inaccuracy when pressure distal to the orifice (downstream pressures) changes. Specifically, if downstream pressure increases (as when high-resistance equipment is used), the pressure difference across the orifice and actual output flow decrease. However, the Bourdon gauge flow reading depends on upstream pressure, which stays constant. In this situation, the gauge reading is falsely higher than the actual delivered flow. Because it measures upstream pressure, the gauge registers flow even when the outlet is completely blocked (Figure 40-24). A user who needs accurate flow when using a device that creates high resistance should not select a Bourdon gauge. A compensated Thorpe tube should be used instead.

Integrated O_2 cylinders (Figure 40-25), including the Grab 'n Go System (Praxair, Danbury, CT), have combined the O_2 cylinder with a pressure regulator and an adjustable flow restrictor to meter O_2 flow. These portable O_2 systems eliminate the need for separate O_2 tanks, Bourdon gauge regulators, and O_2 keys or wrenches (needed to turn on standard E-cylinders). These integrated systems virtually eliminate problems and delays associated with incorrectly mounted regulators. The practitioner simply selects the flow on the flow-adjusting knob and connects the O_2 tubing to the system connection and the patient.

Thorpe Tube. The Thorpe tube flowmeter (Figure 40-26) is always attached to a 50-psig source, either a preset pressure-reducing valve or a bedside station outlet. Compared with the flow restrictor and the Bourdon gauge, the Thorpe tube functions as a variable-orifice, constant-pressure flowmeter, so

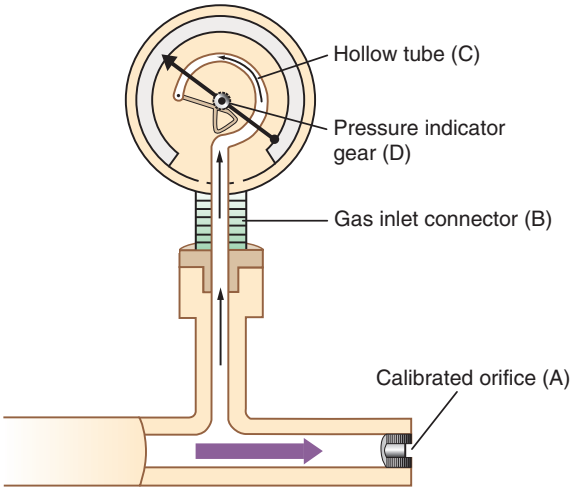

FIGURE 40-23 Components of a Bourdon pressure gauge. See text for more information.

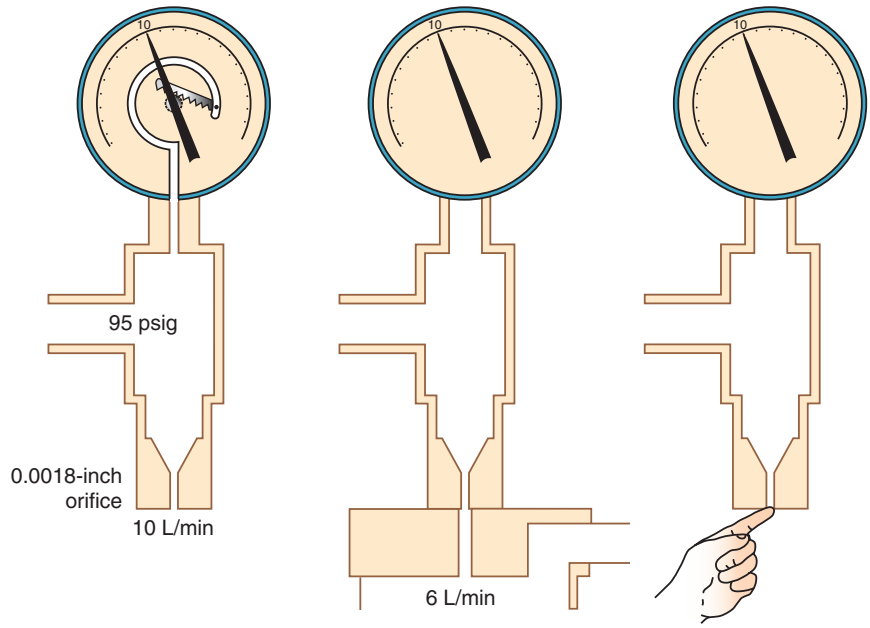

FIGURE 40-24 Bourdon performance when downstream pressures increase as a result of high-resistance equipment or blockage. *Left,* Normal state with fixed orifice and no downstream resistance results in an accurate flow reading. *Center,* High-resistance nebulizer increases downstream pressure, or back pressure. The result is a falsely high reading (10 L/min vs. actual flow of 6 L/min). *Right,* Complete blockage (zero flow) results in flow reading on gauge.

FIGURE 40-25 Grab 'n Go System (Praxair, Danbury, Connecticut).

FIGURE 40-26 Thorpe tube flowmeter.

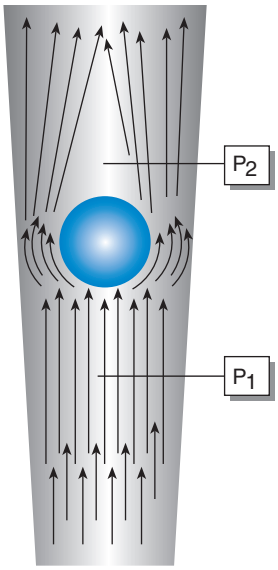

FIGURE 40-27 The position of the float in a Thorpe tube flowmeter is based on a balance between the force of gravity and the pressure difference ($P_2 - P_1$) across it, as determined by the variable-sized orifice between the float and the tube wall.

increasing the size of the orifice increases the gas flow. Figure 40-27 shows how a Thorpe tube works. The key component in this device is a tapered transparent tube that contains a float. The diameter of the tube increases from bottom to top. Gas flow suspends the float against the force of gravity. To read the flow, one simply compares the float position with an adjacent calibrated scale, normally calibrated in liters per minute.

Although the Bourdon gauge measures pressure, the Thorpe tube is used to measure true flow. Flow measurement involves the complex interaction of gravity and fluid dynamics. When gas begins to flow into a Thorpe tube, the initial pressure difference lifts the float. As the needle valve is opened, the float rises in the widening tube, the space available for flow around it increases, and resistance to flow decreases. The float ultimately stabilizes when the pressure difference across the float (an upward force) equals the opposing downward force of gravity.

As the needle valve of the flowmeter is opened, the increase in flow initially disrupts this balance, causing an increase in the pressure difference across the float. With the upward pressure difference greater than the downward force of gravity, the float rises. However, as the float rises, the available "orifice" increases in diameter. Flow resistance around the float decreases, and the pressure difference again equilibrates with gravity. The float position stabilizes at a higher level, proportionate to the greater flow around it.

Thorpe tubes come in two basic designs: pressure compensated and pressure uncompensated. The term *pressure compensation* refers to a design that prevents changes in downstream resistance, or back pressure, from affecting meter accuracy. All manufacturers now supply only pressure-compensated Thorpe tubes for administration of a medical gas. However, some ventilators and anesthesia machines still use uncompensated Thorpe tubes. For this reason, clinicians using these devices must understand the effect of back pressure on the accuracy of these devices. Downstream resistance increases when the user connects a flowmeter to certain types of equipment. Almost all therapy gas equipment produces some flow restriction. Devices such as jet nebulizers produce very high downstream resistance. Depending on their design, Thorpe tube flowmeters respond to resistance in one of two ways.

The *uncompensated* Thorpe tube flowmeter is calibrated in liters per minute but at atmospheric pressure (without restriction). Gas from a 50-psig source flows into the meter at a rate controlled by a needle valve located before the flow tube (Figure 40-28, *A*). When the user attaches flow-restricting equipment to the meter, downstream resistance increases, which increases pressure in the flow tube. As long as this pressure does not exceed 50 psig, gas continues to flow through the tube. However, the added downstream resistance increases the pressure in the flow tube above atmospheric pressure. At this higher pressure,

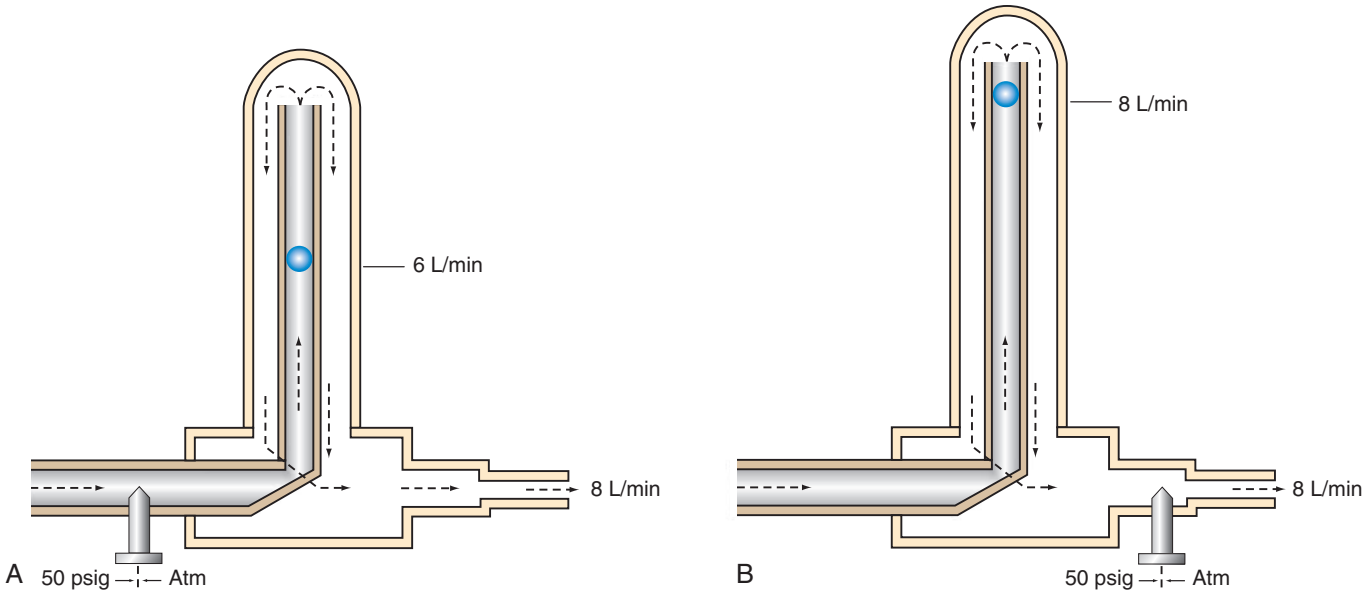

FIGURE 40-28 Comparison of pressure-uncompensated **(A)** and pressure-compensated **(B)** Thorpe tube flowmeters. In the pressure-uncompensated flowmeter, the flow-control valve is proximal to the meter, and the gauge records less than the actual output. In the pressure-compensated flowmeter, location of the valve distal to the meter correlates the gauge reading with the output.

a greater amount of gas flows through a given restriction than at atmospheric pressure so that the float at a given height on the scale indicates more gas flow through the tube than is actually occurring. Under these conditions, an uncompensated Thorpe tube falsely shows a flow lower than that actually delivered to the patient.[4]

In contrast, the scale of the compensated Thorpe tube flowmeter is calibrated at 50 psig instead of at atmospheric pressure. Its flow control needle valve is placed after (distal to) the flow tube (see Figure 40-28, *B*). The entire meter operates at constant 50-psig pressure. Knowing that the compensated Thorpe tube operates at 50 psig helps identify it. When a compensated Thorpe tube is connected to a 50-psig gas source with the needle valve closed, the float "jumps" and then returns to zero as the Thorpe tube is pressurized. Because the entire meter operates at constant pressure, an increase in downstream resistance increases pressure distal to the needle valve only. As long as the downstream pressure does not exceed 50 psig (in which case flow ceases), the position of the float accurately reflects actual outlet flow. For this reason, the pressure-compensated Thorpe tube is the preferred instrument in most clinical situations.

The only factor limiting the use of a pressure-compensated Thorpe tube is gravity. Because it is accurate only in an upright position, a Thorpe tube is not the ideal choice for patient transport. In these cases, the gravity-independent Bourdon gauge is a satisfactory alternative. Figure 40-29 summarizes the effects of downstream resistance, or back pressure, on the Bourdon gauge and pressure-compensated and uncompensated Thorpe tube flow metering devices.

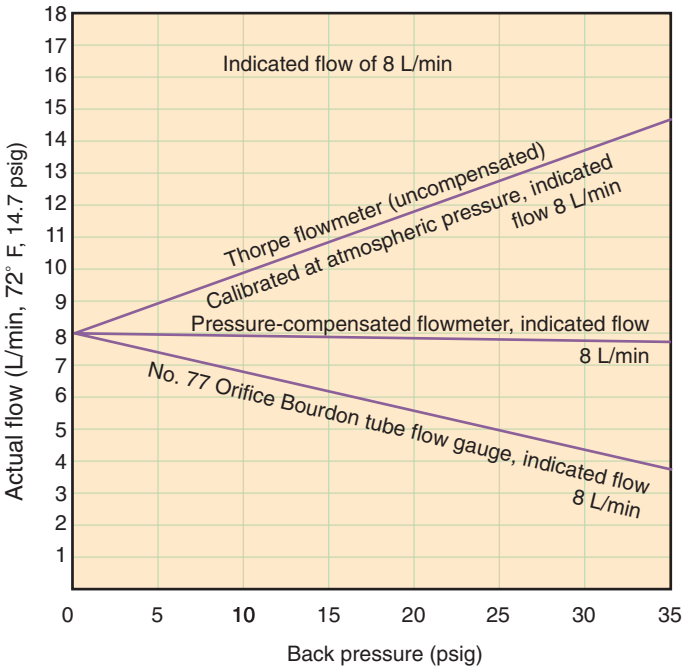

FIGURE 40-29 Comparative accuracy of flowmeter devices against increasing downstream pressure (back pressure). With the pressure-compensated Thorpe tube, indicated flow equals actual flow, regardless of downstream pressure. With the uncompensated Thorpe tube, indicated flow is progressively lower than actual flow as downstream pressure increases. With the Bourdon gauge, indicated flow is progressively higher than actual flow as downstream pressure increases. MINI CLINIC

Selection of Devices to Regulate Gas Pressure or Control Flow

PROBLEM: Three staff RTs are given three separate requests to set up O_2. (1) Mark has an order to transport Ms. Patel to radiology with O_2. (2) Carmen needs to set up a pneumatically powered ventilator with O_2 in the ambulatory clinic (where there are no O_2 outlets). (3) Monica has to set up O_2 therapy with a jet nebulizer for a patient in the intensive care unit (ICU). What equipment should RT select?

SOLUTIONS:

1. Because he has to transport a patient using O_2, Mark should select an E cylinder with an adjustable regulator that includes a Bourdon gauge (unaffected by gravity) or an integrated O_2 cylinder that includes an adjustable flow restrictor.
2. Because pneumatically powered ventilators require 50 psig and no central outlets are available, Carmen needs a preset (50 psig) reducing valve and a large G or H size O_2 cylinder.
3. Because all modern ICUs have central wall outlets for O_2, Monica need only select a flowmeter with the appropriate quick connect. A compensated Thorpe tube is required for metering flow through high-resistance equipment such as jet nebulizers.

SUMMARY CHECKLIST

- All therapy gases must contain at least 20% O_2; all such gases support combustion.
- Medical gases are stored either in portable high-pressure cylinders or in large centralized bulk reservoirs.
- For positive identification of the contents of a medical gas cylinder, the label must be carefully read.
- The pressure in a gas-filled cylinder indicates its contents; the pressure in a liquid-filled cylinder does not.
- To compute duration of flow (minutes) of a medical gas cylinder, multiply the cylinder pressure (pounds per square inch) by the cylinder factor, and divide the result by the set flow (liters per minute).
- Gas supply systems provide gas at 50 psig to outlets throughout a facility through a network of pipes. Such a system must include both zone valves for repairs or fire and alarms to warn of failure.
- Failure of a bulk gas supply system can threaten the lives of patients receiving O_2 therapy or being supported with pneumatically powered devices. A protocol must exist to deal with this emergency.
- Indexed safety systems help prevent misconnections between equipment. The ASSS provides high-pressure connections with large cylinders; the PISS does the same for small cylinders; and DISS connections are for low-pressure outlets, typically 50 psig.
- A reducing valve is used for reduction of gas pressure. A flowmeter is used for control of gas flow. A regulator is used for control of both pressure and flow.
- A flow restrictor is used to provide fixed low flows of O_2. A Bourdon gauge is used to meter flow during patient transport. A compensated Thorpe tube is used when accurate flows are needed with high-resistance equipment.

CHAPTER 41

Medical Gas Therapy

ALBERT J. HEUER

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe when oxygen (O_2) therapy is needed.
- Assess the need for O_2 therapy.
- Describe what precautions and complications are associated with O_2 therapy.
- Select an O_2 delivery system appropriate for the respiratory care plan.
- Describe how to administer O_2 to adults, children, and infants.
- Describe how to identify and correct malfunctions of O_2 delivery systems.
- Assess and monitor a patient's response to O_2 therapy.
- Describe how and when to modify or recommend modification of O_2 therapy.
- Describe how to implement protocol-based O_2 therapy.
- Identify the indications, complications, and hazards of hyperbaric O_2 therapy.
- Identify when and how to administer specialty therapeutic gases.

CHAPTER OUTLINE

KEY TERMS

atmospheric pressure absolute (ATA)
bronchopneumonia
bronchopulmonary dysplasia
croup
exudative
heliox therapy
high-flow system
high-flow nasal cannula (HFNC)
hyperbaric oxygen (HBO) therapy
low-flow system
neovascularization
neutral thermal environment (NTE)
nitric oxide (NO)
reservoir system
retinopathy of prematurity (ROP)

Gas therapy is the most common mode of respiratory care. Most medical gases are drugs. As with any drug, in consultation with the physician, respiratory therapists (RTs) recommend a dosage and delivery method for medical gases, initiate therapy, monitor the response, and alter therapy accordingly in relation to the patient care plan.

OXYGEN THERAPY

There is general agreement among clinicians about the proper use of O_2 therapy.[1-4] However, as the primary member of the health care team responsible for O_2 administration, the RT must be well versed in all aspects of its use in clinical practice.

General Goals and Clinical Objectives

The overall goal of O_2 therapy is to maintain adequate tissue oxygenation, while minimizing cardiopulmonary work. Clinical objectives for O_2 therapy are the following:

- Correct documented or suspected acute hypoxemia
- Decrease symptoms associated with chronic hypoxemia
- Decrease the workload hypoxemia imposes on the cardiopulmonary system

Correcting Hypoxemia

O_2 therapy corrects hypoxemia by increasing alveolar and blood levels of O_2. Correction of hypoxemia is the most tangible objective of O_2 therapy and the easiest to measure and document.

Decreasing Symptoms of Hypoxemia

In addition to relieving hypoxemia, O_2 therapy can help relieve the symptoms associated with certain lung disorders, including dyspnea.[5] O_2 therapy also may improve mental function among patients with chronic hypoxemia.[6]

Minimizing Cardiopulmonary Workload

The cardiopulmonary system compensates for hypoxemia by increasing ventilation and cardiac output. In cases of acute hypoxemia, supplemental O_2 can decrease demands on both the heart and the lungs. Patients with hypoxemia breathing air can achieve acceptable arterial oxygenation only by increasing ventilation. Increased ventilatory demand increases the work of breathing. In these cases, O_2 therapy can reduce both the high ventilatory demand and the work of breathing.

Patients with arterial hypoxemia can maintain acceptable tissue oxygenation only by increasing cardiac output. Because O_2 therapy increases blood O_2 content, the heart does not have to pump as much blood per minute to meet tissue demands. This reduced workload is particularly important when the heart is already stressed by disease or injury, as in myocardial infarction, sepsis, or trauma.

Hypoxemia causes pulmonary vasoconstriction and pulmonary hypertension. Pulmonary vasoconstriction and hypertension increase workload on the right side of the heart. For patients with chronic hypoxemia, this increased workload over the long-term can lead to right ventricular failure (cor pulmonale). O_2 therapy can reverse pulmonary vasoconstriction and decrease right ventricular workload.[7]

Clinical Practice Guideline

To guide practitioners in safe and effective patient care, the American Association for Respiratory Care (AARC) has developed and published clinical practice guidelines for O_2 therapy. Excerpts from the AARC guideline on O_2 therapy in acute care hospitals appear in Clinical Practice Guideline 41-1.[2] Additional AARC guidelines for O_2 therapy in the home or an extended care facility[3] and for selection of O_2 delivery devices for neonatal and pediatric patients[4] are provided in Chapters 53 and 56.

Assessing the Need for Oxygen Therapy

There are three basic ways to determine whether a patient needs O_2 therapy. The first is the use of laboratory measures to document hypoxemia. Second, a patient's need for O_2 therapy can be based on the specific clinical problem or condition. Third, hypoxemia has many manifestations, such as tachypnea, tachycardia, cyanosis, and distressed overall appearance, and therefore bedside assessment can identify such a need.

Laboratory measures for documenting hypoxemia include hemoglobin saturation and partial pressure of oxygen (PO_2), as determined by either invasive or noninvasive means (see Chapter 19). Threshold criteria defining hypoxemia with these measures are described in the AARC clinical practice guideline (see Clinical Practice Guideline 41-1).[2]

O_2 therapy is needed for patients with disorders associated with hypoxemia. Examples are postoperative patients; patients with carbon monoxide or cyanide poisoning, shock, trauma, or acute myocardial infarction; and some premature infants.[1,2,8]

Careful bedside physical assessment can disclose a patient's need for O_2 therapy. Table 41-1 summarizes the common respiratory, cardiovascular, and neurologic signs used in the detection of hypoxia. This information can be combined with more quantitative measures such as arterial blood gas results to confirm the need for supplemental O_2.

Precautions and Hazards of Supplemental Oxygen

Excerpts from the relevant AARC clinical practice guidelines (see Clinical Practice Guideline 41-1) outline the major precautions and hazards associated with administration of supplemental O_2.[2] Five of these hazards are common enough to warrant additional discussion.

TABLE 41-1

Clinical Signs of Hypoxia

Finding	Mild to Moderate	Severe
Respiratory	Tachypnea Dyspnea Paleness	Tachypnea Dyspnea Cyanosis
Cardiovascular	Tachycardia	Tachycardia, eventual bradycardia, arrhythmia
	Mild hypertension, peripheral vasoconstriction	Hypertension and eventual hypotension
Neurologic	Restlessness Disorientation Headaches Lassitude	Somnolence Confusion Distressed appearance Blurred vision Tunnel vision Loss of coordination Impaired judgment Slow reaction time Manic-depressive activity Coma

41-1 Oxygen Therapy

AARC Clinical Practice Guideline (Excerpts)

INDICATIONS

- Documented hypoxemia as evidenced by
  - PaO_2 less than 60 mm Hg or SaO_2 less than 90% in subjects breathing room air
  - PaO_2 or SaO_2 below desirable range for a specific clinical situation
- Acute care situations in which hypoxemia is suspected
- Severe trauma
- Acute myocardial infarction
- Short-term therapy or surgical intervention (e.g., postanesthesia recovery)

CONTRAINDICATIONS

- With a few exceptions, no specific contraindications to O_2 therapy exist when indications are present.
- Certain delivery devices are contraindicated, such as nasal cannulas and nasopharyngeal catheters in pediatric and neonatal patients with nasal obstruction.

PRECAUTIONS AND/OR POSSIBLE COMPLICATIONS

- PaO_2 greater than or equal to 60 mm Hg; ventilator depression may occur rarely in spontaneously breathing patients with elevated $PaCO_2$
- With FiO_2 greater than 0.5, absorption atelectasis, O_2 toxicity, or depression of ciliary or leukocyte function may occur
- In premature infants, PaO_2 greater than 80 mm Hg may contribute to retinopathy of prematurity
- In infants with certain congenital heart lesions such as hypoplastic left heart syndrome, high PaO_2 can compromise the balance between pulmonary and systemic blood flow
- In infants, O_2 flow directed at the face may stimulate an alteration in respiratory pattern
- Increased FiO_2 can worsen lung injury in patients with paraquat poisoning or patients receiving bleomycin
- During laser bronchoscopy or tracheostomy, minimal FiO_2 should be used to avoid intratracheal ignition
- Fire hazard increased in the presence of high FiO_2
- Bacterial contamination can occur when nebulizers or humidifiers are used

ASSESSMENT OF NEED

Need is determined by measurement of inadequate PaO_2 or SaO_2, or both, by invasive or noninvasive methods and the presence of clinical indicators.

ASSESSMENT OF OUTCOME

Outcome is determined by clinical and physiologic assessment to establish adequacy of patient response to therapy.

MONITORING

Patient

- Clinical assessment including but not limited to cardiac, pulmonary, and neurologic status
- Assessment of physiologic parameters (PaO_2, SaO_2, SpO_2) in any patient treated with O_2 (consider need or indication to adjust FiO_2 for increased levels of activity and exercise) in conjunction with the initiation of therapy or
  - Within 12 hours of initiation with FiO_2 less than 0.40
  - Within 8 hours with FiO_2 of 0.40 or greater (including postanesthesia recovery)
  - Within 72 hours in acute myocardial infarction
  - Within 2 hours for any patient with principal diagnosis of COPD
  - Within 1 hour for the neonate
- Appropriate O_2 therapy use protocol is suggested as a method to decrease waste and to realize increased cost savings

Equipment

- All O_2 delivery systems should be checked at least once per day
- More frequent checks by calibrated analyzer are necessary in systems
  - Susceptible to variation in FiO_2 (e.g., hood, high-flow blending systems)
  - Applied to patients with artificial airways
  - Delivering a heated gas mixture
  - Applied to patients who are clinically unstable or who require FiO_2 greater than 0.50
  - Equipment supplying supplemental O_2 to newborn or premature infants

For complete guidelines, see American Association for Respiratory Care: Clinical practice guideline: selection of an oxygen delivery device for neonatal and pediatric patients, Respir Care 47:707, 2002; and American Association for Respiratory Care: Clinical practice guideline: oxygen therapy for adults in the acute care facility, Respir Care 47:717, 2002.

Oxygen Toxicity

O_2 toxicity primarily affects the lungs and the central nervous system (CNS).[9-11] Two primary factors determine the harmful effects of O_2: PO_2 and exposure time (Figure 41-1). The higher the PO_2 and the longer the exposure, the greater the likelihood of damage. Effects on the CNS, including tremors, twitching, and convulsions, tend to occur only when a patient is breathing O_2 at pressures greater than 1 atm (hyperbaric pressure). Pulmonary effects can also occur with enriched O_2 environments at normal atmospheric pressures.

Table 41-2 summarizes the physiologic response to breathing 100% O_2 at sea level. A patient exposed to a high PO_2 for a prolonged period has signs similar to **bronchopneumonia**. Patchy infiltrates appear on chest radiographs and usually are most prominent in the lower lung fields.

Exposure to high PO_2 first damages the capillary endothelium. Interstitial edema follows and thickens the alveolar-capillary membrane. If the process continues, type I alveolar cells are destroyed, and type II cells proliferate. An **exudative** phase follows, resulting from alveolar fluid buildup, which leads

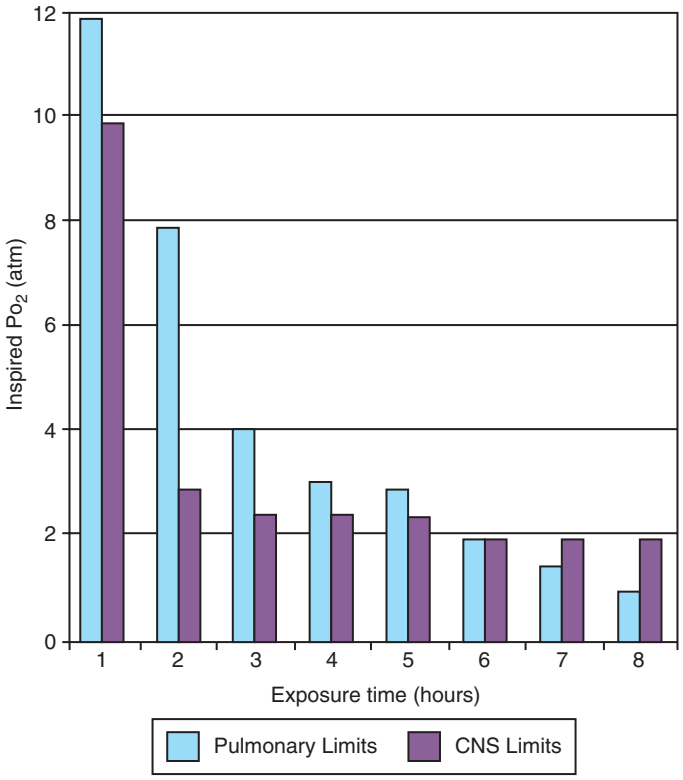

FIGURE 41-1 Relationship between PO_2 and exposure time causing O_2 toxicity.

TABLE 41-2

Physiologic Responses of Healthy Individuals to Exposure to 100% Inspired Oxygen

Exposure Time (hr)	Physiologic Response
0-12	Normal pulmonary function
	Tracheobronchitis
	Substernal chest pain
12-24	Decreasing vital capacity
25-30	Decreasing lung compliance
	Increasing $P(A\text{-}a)O_2$
	Decreasing exercise PO_2
30-72	Decreasing diffusing capacity

to a low ventilation/perfusion ratio, physiologic shunting, and hypoxemia. In the end stages, hyaline membranes form in the alveolar region, and pulmonary fibrosis and hypertension develop.

As the lung injury worsens, blood oxygenation deteriorates. If this progressive hypoxemia is managed with additional O_2, the toxic effects worsen (Figure 41-2). However, if the patient can be kept alive while fractional inspired oxygen concentration (FiO_2) is decreased, the pulmonary damage sometimes resolves.

The toxicity of O_2 is caused by overproduction of O_2 free radicals. O_2 free radicals are by-products of cellular metabolism. If unchecked, these radicals can severely damage or kill cells.[9]

In the presence of high PO_2, free radicals can overwhelm the body's normal antioxidant system and cause cell damage. Cell

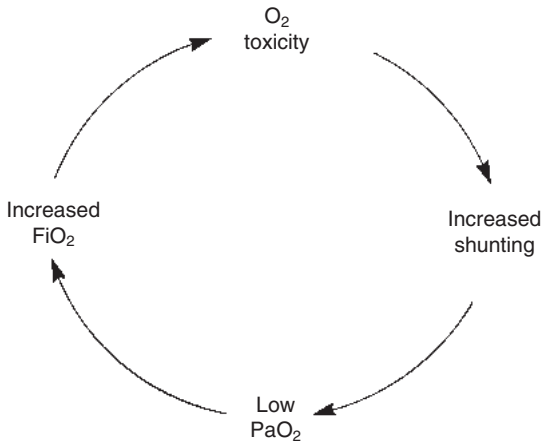

FIGURE 41-2 The vicious circle that can occur in managing hypoxemia with high FiO_2. High FiO_2 can be toxic to the lung parenchyma and cause further physiologic shunting. Increased shunting worsens the hypoxemia, necessitating higher FiO_2. (Modified from Flenley DC: Long-term oxygen therapy—state of the art. Respir Care 28:876, 1983.)

damage provokes an immune response and causes tissue infiltration by neutrophils and macrophages. These scavenger cells release inflammatory mediators that worsen the initial injury. At the same time, local neutrophils and platelets may release more free radicals, which continue the process.

Exactly how much O_2 is safe is the subject of debate (see the following Rule of Thumb). Results of most studies indicate that adults can breathe up to 50% for extended periods without major lung damage.[12] Rather than applying strict cutoffs, the goal always should be to use the lowest possible FiO_2 to achieve adequate tissue oxygenation.[13]

RULE OF THUMB

Avoiding Oxygen Toxicity

Limit patient exposure to 100% O_2 to less than 24 hours whenever possible. High FiO_2 is acceptable if the concentration can be decreased to 70% within 2 days and 50% or less in 5 days.

Because the growing lung may be more sensitive to O_2, more caution is needed with infants. High PO_2 also is associated with retinopathy of prematurity (ROP) and **bronchopulmonary dysplasia** in infants.

Regardless of approach, supplemental O_2 never should be withheld from hypoxic patients. Although the toxic effects of high O_2 concentrations can be serious, it is not FiO_2 but rather PO_2 that results in such harmful effects. If a patient needs a high FiO_2 to maintain adequate tissue O_2, the patient should receive it.

Depression of Ventilation

When breathing moderate to high O_2 concentrations, a very small percentage of patients with COPD and chronic hypercapnia may ventilate less.[14] Decreases in ventilation of nearly 20% have been observed in these patients with accompanying elevations in arterial partial pressure of carbon dioxide ($PaCO_2$) of

20 to 23 mm Hg.[15] However, this hypoventilation is not typical of patients with COPD and appropriate management of hypoxemia with supplemental O_2 should never be avoided in them.

The primary reason some patients with COPD hypoventilate when given O_2 is most likely suppression of the hypoxic drive. In these patients, the normal response to high partial pressure of carbon dioxide (PCO_2) is blunted, the primary stimulus to breathe being lack of O_2 as sensed by the peripheral chemoreceptors. The increase in the blood O_2 level in these patients suppresses peripheral chemoreceptors, depresses ventilatory drive, and elevates the PCO_2.[16,17] High blood O_2 levels may disrupt the normal ventilation/perfusion balance and cause an increase in dead space-to-tidal volume ratio (V_D/V_T) and in $PaCO_2$.[18]

Retinopathy of Prematurity

Retinopathy of prematurity (ROP), also called *retrolental fibroplasia,* is an abnormal eye condition that occurs in some premature or low-birth-weight infants who receive supplemental O_2. An excessive blood O_2 level causes retinal vasoconstriction, which leads to necrosis of the blood vessels. In response, new vessels form and increase in number. Hemorrhage of these delicate new vessels causes scarring behind the retina. Scarring often leads to retinal detachment and blindness.[19] ROP most often affects neonates up to approximately 1 month of age, by which time the retinal arteries have sufficiently matured. Excessive O_2 is not the only factor associated with ROP; other factors associated with ROP include hypercapnia, hypocapnia, intraventricular hemorrhage, infection, lactic acidosis, anemia, hypocalcemia, and hypothermia.

Because premature infants often need supplemental O_2, the risk of ROP poses a serious management problem. The American Academy of Pediatrics recommends keeping arterial PO_2 in an infant less than 80 mm Hg as the best way to minimize the risk of ROP.[8]

Absorption Atelectasis

FiO_2 greater than 0.50 presents a significant risk of absorption atelectasis.[20] Nitrogen normally is the most plentiful gas in both the alveoli and the blood. Breathing high levels of O_2 quickly depletes body nitrogen levels. As blood nitrogen levels decrease, the total pressure of venous gases rapidly decreases. Under these conditions, gases that exist at atmospheric pressure within any body cavity rapidly diffuse into the venous blood. This principle is used for removing trapped air from body cavities. Giving patients high levels of O_2 can help clear trapped air from the abdomen or thorax.

This same phenomenon can cause lung collapse, especially if the alveolar region becomes obstructed (Figure 41-3). Under these conditions, O_2 rapidly diffuses into the blood (see Figure 41-3, *A*). With no source for repletion, the total gas pressure in the alveolus progressively decreases until the alveolus collapses. Because collapsed alveoli are perfused but not ventilated, absorption atelectasis increases the physiologic shunt and worsens blood oxygenation.[20]

The likelihood of absorption atelectasis is greatest when present with other risk factors associated with low tidal volumes such as sedation, surgical pain, or CNS dysfunction. In these cases, poorly ventilated alveoli may become unstable when they lose O_2 faster than it can be replaced. The result is a more

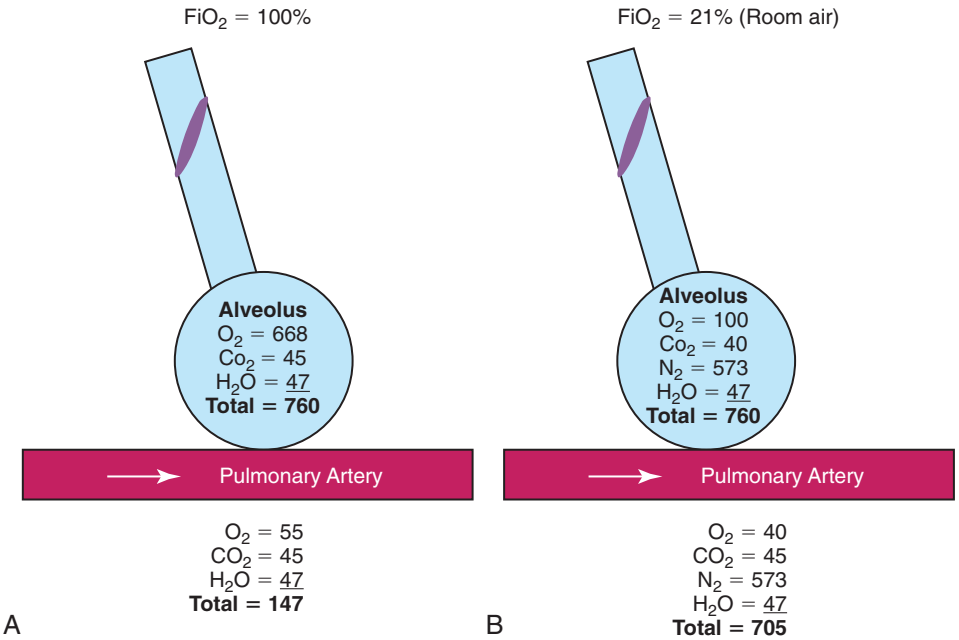

FIGURE 41-3 The development of atelectasis beyond blocked airways when breathing of 100% O_2 **(A)** and room air **(B).** In each case, the sum of the gas pressures in mixed venous blood (pulmonary artery) is less than in the alveoli. The pressure gradient is much greater when breathing 100% O_2 **(A),** causing more rapid diffusion from the alveoli. *Note:* The gas pressures in the room air alveolus will change slightly over time, but the total will remain close to 760 mm Hg.

gradual shrinking of the alveoli that may lead to complete collapse, even when the patient is not breathing supplemental O_2 (see Figure 41-3, *B*).

Fire Hazard

Despite numerous preventive measures, fires involving enriched O_2 environments continue to occur in health care facilities. Fires seem to pose the greatest risk in operating rooms and in association with selected respiratory procedures. During surgery and procedures such as tracheotomies, electronic scalpels and similar devices are often used while the patient is receiving supplemental O_2. To complicate matters, even higher O_2 concentrations may exist under surgical drapes.[21] Other situations associated with increased fire risk involve home care patients smoking while receiving low-flow O_2 and the use of aluminum O_2 regulators. Additionally, hyperbaric oxygen (HBO) therapy or therapy at increased atmospheric pressures (discussed later in this chapter) often involves the administration of supplemental O_2 and greatly increases fire risk.

Some simple strategies can be used to reduce the fire risk in health care facilities. Effectively managing the fire triangle of O_2, heat, and fuel is key. An essential component is always using the lowest effective FiO_2 for a given clinical situation. In addition, using scavenging systems to minimize O_2 buildup beneath sterile drapes during surgery or while performing tracheostomies can help reduce fire risk. Educating clinicians, patients, and caregivers on safe O_2 use is also important. Additionally, fire prevention protocols for HBO therapy should be strictly followed.[21]

Oxygen Delivery Systems: Design and Performance

Proper device selection requires in-depth knowledge of both the general performance characteristics of these systems and the individual capabilities.[22] O_2 delivery devices traditionally are categorized by design. Three basic designs exist: **low-flow systems**, **reservoir systems**, and **high-flow systems**. Enclosures are commonly identified as a fourth category. The design categories share functional characteristics, capabilities, and limitations.

Although design plays an important role in the selection of these devices, clinical performance ultimately determines how the device is used. The user judges the performance of an O_2 delivery system by answering two key questions: (1) How much O_2 can the system deliver (FiO_2 or FiO_2 range)? (2) Does the delivered FiO_2 remain fixed or vary under changing patient demands?[22]

Regarding the FiO_2 range, O_2 systems can be broadly divided into systems designed to deliver a low (<35%), moderate (35% to 60%), or high (>60%) O_2 concentration. Some designs can deliver O_2 across the full range of concentrations (21% to 100%).

Whether a device delivers a fixed or variable FiO_2 depends on how much of the patient's inspired gas it supplies. If the system provides all of the patient's inspired gas, FiO_2 remains stable. If the device provides only some of the inspired gas, the patient must draw the remainder from the surrounding air. In this case, the more the patient breathes, the more air dilutes the delivered O_2, and FiO_2 is lower. If the patient breathes less with this type of device, less air dilutes the O_2, and FiO_2 increases. A system that supplies only a portion of the inspired gas always provides a variable FiO_2.[23] FiO_2 supplied with such systems can vary widely from minute to minute and even from breath to breath.

Figure 41-4 shows these concepts as applied to low-flow, reservoir, and high-flow systems. With the low-flow system (see Figure 41-4, *A*) the patient's inspiratory flow often exceeds the flow delivered by the device; the result is air dilution *(shaded*

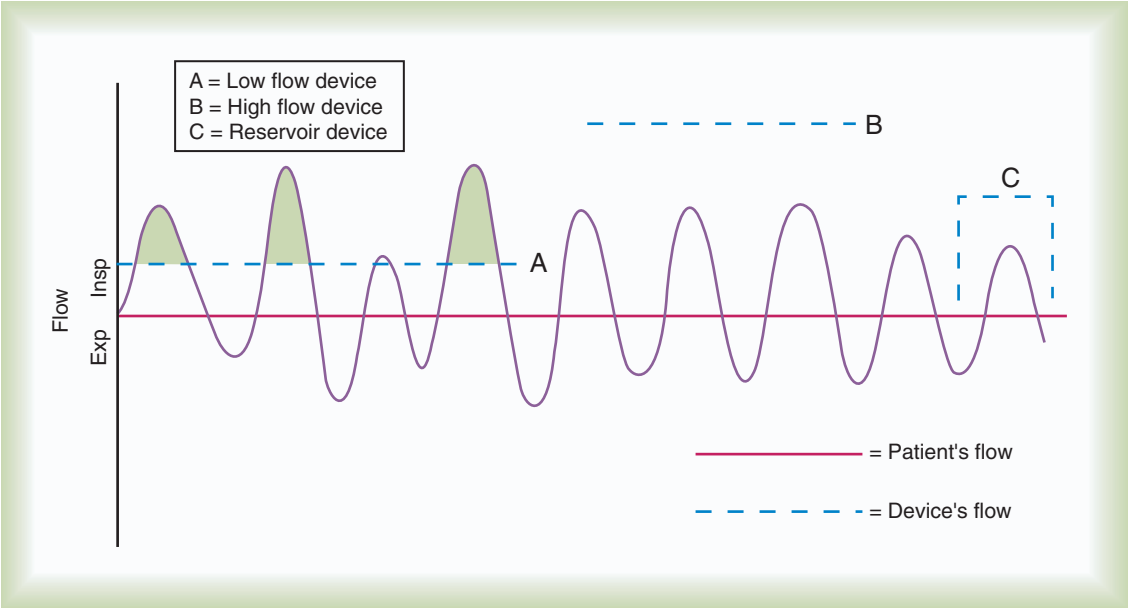

FIGURE 41-4 Differences between O_2 delivery systems. *A,* Low-flow device. *B,* High-flow device. *C,* Reservoir device.

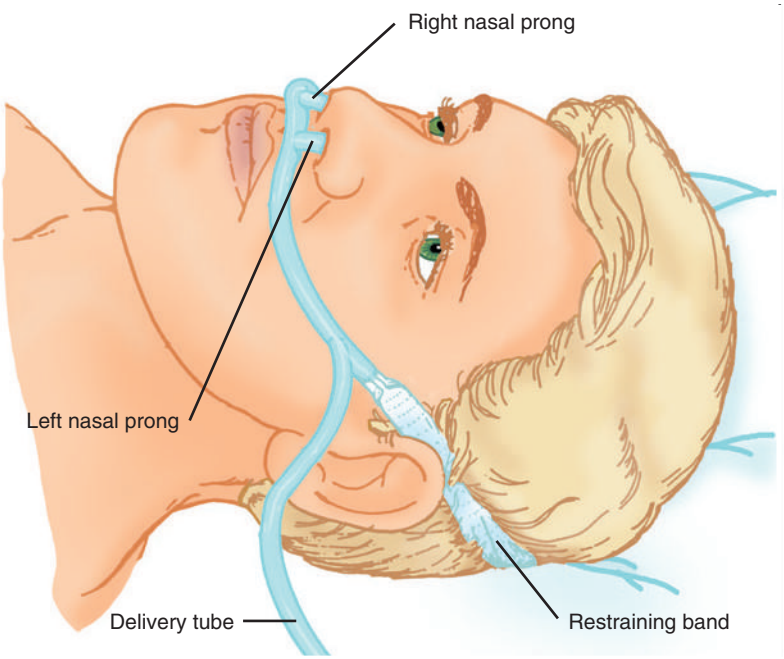

FIGURE 41-5 Nasal cannula.

areas). The greater the patient's inspiratory flow, the more air is breathed, and FiO_2 is lower. The high-flow system (see Figure 41-4, *B*) always exceeds the patient's flow and provides a fixed FiO_2. A fixed FiO_2 can be achieved with a reservoir system (see Figure 41-4, *C*), which stores a reserve volume (flow × time) that equals or exceeds the patient's tidal volume. For a reservoir system to provide a fixed FiO_2, the reservoir volume must always exceed the patient's tidal volume, and there cannot be any air leaks in the system. Table 41-3 outlines the general specifications for the common O_2 therapy systems in current use.

Low-Flow Systems

Typical low-flow systems provide supplemental O_2 directly to the airway at a flow of 8 L/min or less. Because the inspiratory flow of a healthy adult exceeds 8 L/min, the O_2 provided by a low-flow device is always diluted with air; the result is a low and variable FiO_2. Low-flow O_2 delivery systems include nasal cannula, nasal catheter, and transtracheal catheter.

Nasal Cannula. A nasal cannula is a disposable plastic device consisting of two tips or prongs approximately 1 cm long that are connected to several feet of small-bore O_2 supply tubing (Figure 41-5). The user inserts the prongs directly into the vestibule of the nose while attaching the supply tubing either directly to a flowmeter or to a bubble humidifier. In most cases, a humidifier is used only when the input flow is greater than 4 L/min.[2] However, flows greater than 6 to 8 L/min can cause patient discomfort.[22] Cannulas should not be used in newborns and infants if their nasal passages are obstructed, and flows generally should be limited to 2 L/min unless a specialized high-flow cannula system, discussed later in this chapter, is being used.[2] Table 41-3 lists the FiO_2 range, FiO_2 stability, advantages, disadvantages, and best use of a nasal cannula.

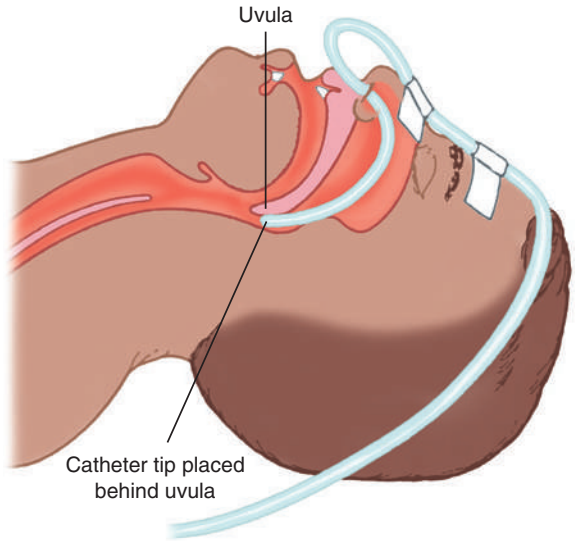

FIGURE 41-6 Placement of nasal catheter in the nasopharynx.

Nasal Catheter. The use of nasal catheters is generally limited to short-term O_2 administration during specialized procedures such as a bronchoscopy. A nasal catheter is a soft plastic tube with several small holes at the tip that is inserted by gently advancing it along the floor of either nasal passage and visualizing it just behind and above the uvula (Figure 41-6). Once in position, the catheter is taped to the bridge of the nose. If direct visualization is impossible, the catheter may be blindly inserted to a depth equal to the distance from the nose to the earlobe.

When placed too deep, the catheter can provoke gagging or swallowing of gas, which increases the likelihood of aspiration. In general, a nasal catheter should be replaced with a new one

TABLE 41-3

Overview of Oxygen Therapy Systems

Category	Device	Flow	FiO_2 Range	FiO_2 Stability	Advantages	Disadvantages	Best Use
Low flow	Nasal cannula	¼-6 L/min (adults) ≤2 L/min (infants)	22%-40%	Variable	Use on adults, children, infants; easy to use; disposable; low cost; well tolerated	Unstable, easily dislodged; high flow uncomfortable; can cause dryness, bleeding; polyps; deviated septum and mouth breathing may reduce FiO_2	Patient in stable condition who needs low FiO_2; home care patient who needs long-term therapy, low to moderate FiO_2 while eating
	Nasal catheter	¼-5 L/min	22%-45%	Variable	Use on adults, children, infants; good stability; disposable; low cost	Difficult to insert; high flow increases back pressure; needs regular changing; polyps, deviated septum may block insertion; may provoke gagging, air swallowing, aspiration	Procedures in which cannula is difficult to use (bronchoscopy); long-term care of infants
	Transtracheal catheter	¼-4 L/min	22%-35%	Variable	Lower O_2 use and cost; eliminates nasal and skin irritation; improved compliance; increased exercise tolerance; increased mobility; enhanced image	High cost; surgical complications; infection; mucous plugging; lost tract	Home care or ambulatory patients who need increased mobility or do not accept nasal O_2
	Reservoir cannula	¼-4 L/min	22%-35%	Variable	Lower O_2 use and cost; increased mobility; less discomfort because of lower flow	Unattractive, cumbersome; poor compliance; must be regularly replaced; breathing pattern affects performance	Home care or ambulatory patients who need increased mobility
	Simple mask	5-10 L/min	35%-50%	Variable	Use on adults, children, infants; quick, easy to apply; disposable; inexpensive	Uncomfortable; must be removed for eating; prevents radiant heat loss; blocks vomitus in unconscious patients	Emergencies; short-term therapy requiring moderate FiO_2; mouth breathing patients requiring moderate FiO_2
	Partial rebreathing mask	Minimum of 10 L/min (prevent bag collapse on inspiration)	40%-70%	Variable	Same as simple mask; moderate to high FiO_2	Same as simple mask; potential suffocation hazard	Emergencies; short-term therapy requiring moderate to high FiO_2
	Nonrebreathing mask	Minimum of 10 L/min (prevent bag collapse on inspiration)	60%-80%	Variable	Same as simple mask; high FiO_2	Same as simple mask; potential suffocation hazard	Emergencies; short-term therapy requiring high FiO_2
	Nonrebreathing circuit (closed)	>3 × V_E (prevent bag collapse on inspiration)	21%-100%	Fixed	Full range of FiO_2	Potential suffocation hazard; requires 50 psi air/O_2; blender failure common	Patients who need precise FiO_2 at any level (21%-100%)

High flow	AEM	Varies; should provide output flow >60 L/min	24%-50%	Fixed	Easy to apply; disposable, inexpensive; stable, precise FiO_2	Limited to adult use; uncomfortable, noisy; must be removed for eating; FiO_2 >0.40 not ensured; FiO_2 varies with back pressure	Patients in unstable condition who need precise low FiO_2
	Air-entrainment nebulizer	10-15 L/min input; should provide output flow of at least 60 L/min	28%-100%	Fixed	Provides temperature control and extra humidification	FiO_2 <0.28 or >0.40 not ensured; FiO_2 varies with back pressure; high infection risk	Patients with artificial airways who need low to moderate FiO_2
	Blending system (open)	Should provide output flow of at least 60 L/min	21%-100%	Fixed	Full range of FiO_2	Requires 50 psi air/O_2; blender failure or inaccuracy common	Patients with high VE who need high FiO_2
	High-flow nasal cannula system	Up to 50 L/min, or more (depending on system)	35%-90%	Generally fixed, depending on system, input flow, and patient breathing pattern	Wide range of FiO_2 and relative/absolute humidity; use on adults, children, infants	FiO_2 is often ensured but depends on system, input flow, and patient breathing pattern; infection risk	Patients of all ages with high or variable VE who need supplemental O_2, positive pressure and humidity
Enclosure	Oxyhood	≥7 L/min	21%-100%	Fixed	Full range of FiO_2	Difficult to clean, disinfect	Infants who need supplemental O_2
	Isolette	8-15 L/min	40%-50%	Variable	Provides temperature control	Expensive, cumbersome, unstable FiO_2 (leaks); difficult to clean, disinfect; limits patient mobility; fire hazard	Infants who need supplemental O_2 and precise thermal regulation
	Tent	12-15 L/min	40%-50%	Variable	Provides concurrent aerosol therapy	Expensive, cumbersome, unstable FiO_2 (leaks); requires cooling; difficult to clean, disinfect; limits patient mobility; fire hazard	Toddlers or small children who need low to moderate FiO_2 and aerosol

VE, Minute volume.

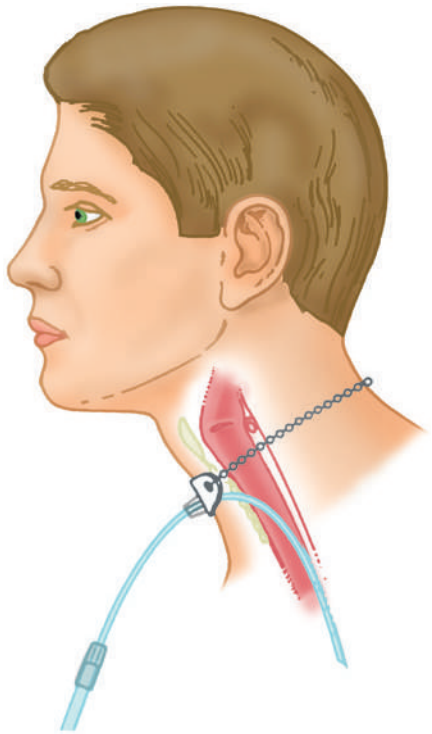

FIGURE 41-7 Transtracheal O_2 catheter.

(placed in the opposite naris) at least every 8 hours. Nasal catheters are inappropriate for neonatal patients. As a result of these notable limitations, nasal catheters are rarely used today.[4]

Transtracheal Catheter. A transtracheal O_2 catheter is a thin polytetrafluoroethylene (Teflon) catheter inserted into the trachea between the second and third tracheal rings (Figure 41-7), secured by a chain necklace. Standard tubing connected directly to a flowmeter provides the O_2 source flow.[24, 25] Because flow is so low, no humidifier is needed.

Because the transtracheal catheter resides directly in the trachea, O_2 builds up both there and in the upper airway during expiration. This process effectively expands the anatomic reservoir and increases the FiO_2 at any given flow. Compared with a nasal cannula, a transtracheal catheter needs about half of the O_2 flow to achieve a given arterial partial pressure of oxygen (PaO_2).[25] This reduced flow can be of great economic and practical benefit to patients needing continuous long-term O_2 therapy because it can greatly increase the duration of flow of portable O_2 systems. Transtracheal O_2 therapy can pose problems and risks, however, and these devices have not received widespread acceptance. Chapter 56 provides some additional details on maintaining transtracheal O_2 set-ups. Table 41-3 lists the FiO_2 range, FiO_2 stability, advantages, disadvantages, and best use of a transtracheal catheter.

Performance Characteristics of Low-Flow Systems

Low-flow nasal systems provide O_2 concentrations ranging from 22% at 1 L/min to 60% at 15 L/min.[2,3,22] The range of 22% to 45% cited in Table 41-3 is based on 8 L/min as the upper limit of comfortable flow. These wide FiO_2 ranges occur because the O_2 concentration delivered by a low-flow system varies with the amount of air dilution. The amount of air dilution depends on several patient and equipment variables. Table 41-4 summarizes these key variables and how they affect FiO_2 provided by low-flow systems.

Simple formulas exist for estimating FiO_2 provided by low-flow systems (see the accompanying Rule of Thumb). Given the large number of variables affecting FiO_2, however, the RT can never know precisely how much O_2 a patient is receiving with these systems. Without knowing the patient's exact FiO_2, the RT must rely on assessing the actual response to O_2 therapy.

TABLE 41-4

Variables Affecting FiO_2 of Low-Flow Oxygen Systems

Increases FiO_2	Decreases FiO_2
Higher O_2 input	Lower O_2 input
Mouth-closed breathing*	Mouth-open breathing*
Low inspiratory flow	High inspiratory flow
Low tidal volume	High tidal volume
Slow rate of breathing	Fast rate of breathing
Small minute ventilation	Large minute ventilation
Long inspiratory time	Short inspiratory time
High I:E ratio	Low I:E ratio

I:E, Inspiratory/expiratory.
*Cannula only.

RULE OF THUMB

Estimating FiO_2 Provided by Low-Flow Systems

For patients with a normal rate and depth of breathing, each 1 L/min of nasal O_2 increases FiO_2 approximately 4%. For example, a patient using a nasal cannula at 4 L/min has an estimated FiO_2 of approximately 37% (21 + 16).

Troubleshooting Low-Flow Systems

Common problems with low-flow O_2 delivery systems include inaccurate flow, system leaks and obstructions, device displacement, and skin irritation. The problem of inaccurate flow is greatest when low-flow flowmeters (≤3 L/min) are used. Given the trend toward assessment of outcome of O_2 therapy (with either blood gases or pulse oximetry), ensuring the absolute accuracy of O_2 input flow generally is not essential. Nonetheless, similar to all respiratory care equipment, flowmeters should be subjected to regular preventive maintenance and testing for accuracy. Equipment that fails preventive maintenance standards should be removed from service and repaired or replaced. Table 41-5 provides guidance on troubleshooting the most common clinical problems with nasal cannulas.

TABLE 41-5

Troubleshooting Common Problems With a Nasal Oxygen Cannula

Problem or Clue	Cause	Solution
No gas flow can be felt coming from the cannula	Flowmeter not on	Adjust flowmeter
	System leak	Check connections
Humidifier pop-off is sounding	Obstruction distal to humidifier	Find and correct the obstruction
	Flow is set too high	Use alternative device
	Obstructed naris	Use alternative device
Patient reports soreness over lip or ears	Irritation or inflammation caused by appliance straps	Loosen straps
		Place cotton balls at pressure points
		Use a different device
Mouth breathing	Habitual mouth breathing, blocked nasal passages	Switch to simple mask or venturi mask

FIGURE 41-8 Reservoir cannula.

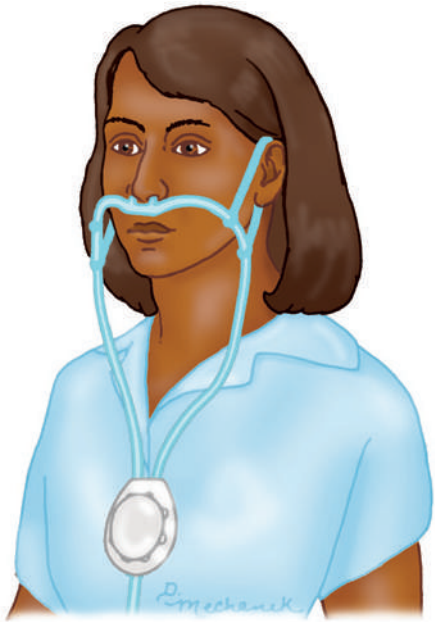

FIGURE 41-9 Pendant reservoir cannula.

Reservoir Systems

Reservoir systems incorporate a mechanism for gathering and storing O_2 between patient breaths. Patients draw on this reserve supply whenever inspiratory flow exceeds O_2 flow into the device. Because air dilution is reduced, reservoir devices generally provide higher FiO_2 than low-flow systems. Reservoir devices can decrease O_2 use by providing FiO_2 comparable with nonreservoir systems but at lower flow. Reservoir systems currently in use include reservoir cannulas, masks, and nonrebreathing circuits. In principle, enclosure systems, such as tents and hoods, operate as reservoirs surrounding the head or body.

Reservoir Cannula. Reservoir cannulas are designed to conserve O_2 and are an alternative to the pulse-dose or demand-flow O_2 systems described in Chapter 56. There are two types of reservoir cannula: nasal reservoir and pendant reservoir. Table 41-3 lists the FiO_2 range, FiO_2 stability, advantages, disadvantages, and best use of a reservoir cannula.

A nasal reservoir cannula operates by storing approximately 20 ml of O_2 in a small membrane reservoir during exhalation (Figure 41-8). The patient draws on this stored O_2 during early inspiration. The amount of O_2 available increases with each breath and decreases the flow needed for a given FiO_2. Although the device is comfortable to wear, many patients object to its appearance and may not always comply with prescribed therapy.

The pendant reservoir system helps overcome esthetic concerns by hiding the reservoir under the patient's clothing on the anterior chest wall (Figure 41-9). Although the device is less visible, the extra weight of the pendant can cause ear and facial discomfort.

At low flow, reservoir cannulas can reduce O_2 use 50% to 75%. A patient at rest who needs 2 L/min through a standard cannula to achieve an arterial oxygen saturation (SaO_2) greater than 90% may need only 0.5 L/min through a reservoir cannula to achieve the same blood oxygenation.[26] Although flow savings is predictable, factors such as nasal anatomy and breathing pattern can affect the performance of the device. For these devices to function properly at low flow, patients must exhale through the nose (this reopens or resets the reservoir membrane). In addition, exhalation through pursed lips may impair performance, especially during exercise. For these reasons, prescribed flow settings should be individually determined by clinical assessment, including SaO_2 monitoring.[26]

The low flow at which the reservoir cannula operates makes humidification unnecessary. Excess moisture can hinder proper action of the reservoir membrane.[26] Even regular use can cause membrane wear. For this reason, patients should replace the reservoir cannula approximately every 3 weeks.

Reservoir Masks. Masks are the most commonly used reservoir systems. There are three types of reservoir masks: (1) simple mask, (2) partial rebreathing mask, and (3) nonrebreathing mask. Table 41-3 lists the FiO_2 range, FiO_2 stability, advantages, disadvantages, and best use of each of these devices.

A simple mask is a disposable plastic unit designed to cover both the mouth and the nose (Figure 41-10). The body of the mask itself gathers and stores O_2 between patient breaths. The patient exhales directly through open holes or ports in the mask body. If O_2 input flow ceases, the patient can draw in air through these holes and around the mask edge.

The input flow range for an adult simple mask is 5 to 10 L/min. Generally, if flow greater than 10 L/min is needed for satisfactory oxygenation, use of a device capable of a higher FiO_2 should be considered. At a flow less than 5 L/min, the mask volume acts as dead space and causes carbon dioxide (CO_2) rebreathing.[27]

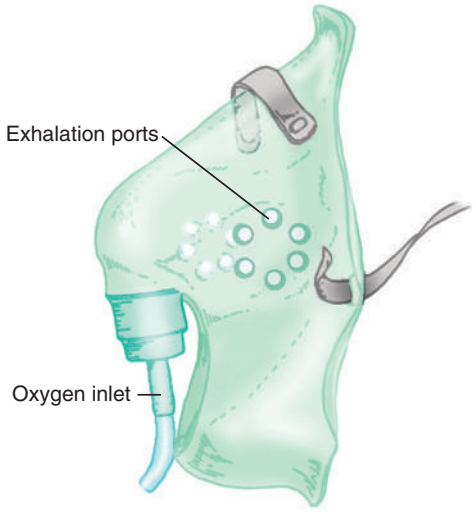

FIGURE 41-10 Simple O_2 mask.

Because air dilution easily occurs during inspiration through its ports and around its body, a simple mask provides a variable FiO_2. How much FiO_2 varies depends on the O_2 input flow, the mask volume, the extent of air leakage, and the patient's breathing pattern.[28]

As shown in Figure 41-11, a partial rebreathing mask and a nonrebreathing mask have a similar design. Each has a 1-L flexible reservoir bag attached to the O_2 inlet. Because the bag increases the reservoir volume, both masks provide higher FiO_2 capabilities than a simple mask. The key difference between these designs is the use of valves. A partial rebreathing mask has no valves (see Figure 41-11, *A*). During inspiration, source O_2 flows into the mask and passes directly to the patient. During exhalation, source O_2 enters the bag. However, because no valves separate the mask and the bag, some of the patient's exhaled gas also enters the bag (approximately the first third). Because it comes from the anatomic dead space, the early portion of exhaled gas contains mostly O_2 and little CO_2. As the bag fills with both O_2 and dead space gas, the last two-thirds of exhalation (high in CO_2) escapes out the exhalation ports of the mask. As long as the O_2 input flow keeps the bag from collapsing more than about one-third during inhalation, CO_2 rebreathing is negligible.

Although it can provide a higher FiO_2 than a simple mask (see Table 41-3), a standard disposable partial rebreathing mask is subject to considerable air dilution. The result is delivery of a moderate but variable FiO_2 dependent on the same factors as with a simple mask.

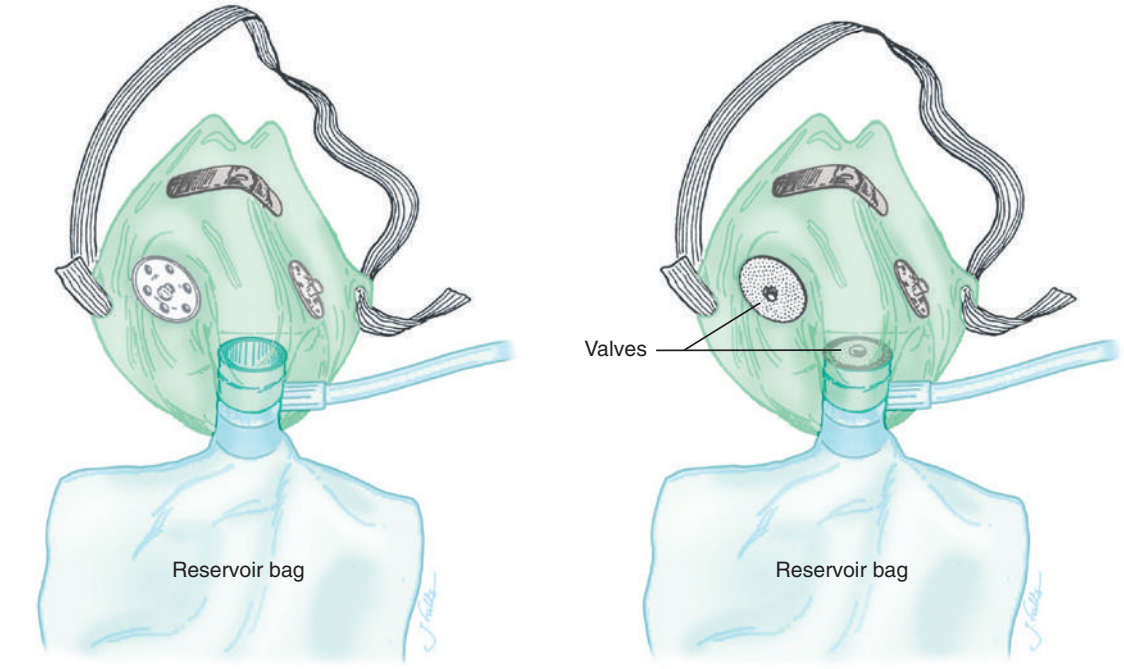

FIGURE 41-11 **A,** Partial rebreathing mask. **B,** Nonrebreathing mask.

A nonrebreathing mask, which is much more commonly used than a partial rebreathing mask, prevents rebreathing with one-way valves (see Figure 41-11, *B*). An inspiratory valve sits on top of the bag, and expiratory valves cover the exhalation ports on the mask body. During inspiration, slight negative mask pressure closes the expiratory valves, preventing air dilution. At the same time, the inspiratory valve on top of the bag opens, providing O_2 to the patient. During exhalation, valve action reverses the direction of flow. Slight positive pressure closes the inspiratory valve, which prevents exhaled gas from entering the bag. Concurrently, the one-way expiratory valves open and divert exhaled gas out to the atmosphere.

Because it is a closed system, a leak-free nonrebreathing mask with competent valves and enough flow to prevent more than one-third bag collapse during inspiration can deliver 100% source gas. As indicated in Table 41-3, however, modern disposable nonrebreathing masks normally do not provide much more than approximately 70% O_2.[22]

Large air leaks which occur both around the mask body and through the open (nonvalved) exhalation port can pose a problem. This open exhalation port is a common safety feature designed to allow air breathing if the O_2 source fails, but can result in air dilution (leakage) and a variable FiO_2 whenever inspiratory flow or volume are high.

Nonrebreathing Reservoir Circuit. A nonrebreathing circuit operates with the same design principles as a nonrebreathing mask. Although the nonrebreathing circuit requires an elaborate combination of equipment and supplies, it can be more versatile than a nonrebreathing mask because it provides a full range of FiO_2 (21% to 100%) and can be used for both intubated and nonintubated patients.[22] As shown in Figure 41-12, a typical nonrebreathing circuit incorporates a blending system to premix air and O_2. The gas mixture is warmed and humidified, ideally with a servo-controlled heated humidifier. Gas flows through large-bore tubing into an inspiratory volume reservoir, which includes a fail-safe inlet valve. The patient breathes through a closed airway appliance, in this case, a mask with one-way valves. A valved T-tube also can be used in the care of a patient with an endotracheal or a tracheostomy tube.

Troubleshooting Reservoir Systems. Common problems with reservoir masks include device displacement, system leaks and obstructions, improper flow adjustment, and skin irritation. Table 41-6 provides guidance on troubleshooting the most common clinical problems with reservoir masks.

High-Flow Systems

High-flow systems supply a given O_2 concentration at a flow equaling or exceeding the patient's peak inspiratory flow. An air-entrainment or a blending system is used. As long as the delivered flow exceeds the patient's flow, both systems can ensure a fixed FiO_2. The accompanying Rule of Thumb can help determine which devices truly qualify as high-flow systems.

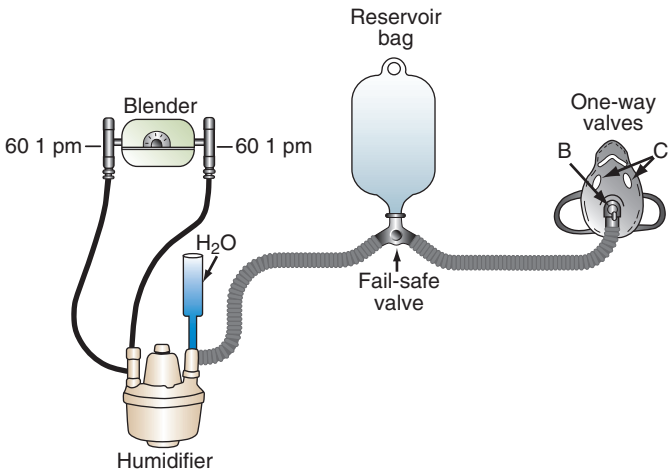

FIGURE 41-12 Nonrebreathing reservoir circuit with a valved face mask. Reservoir bag in combination with high-flow (0 to 100 L/min) flowmeters ensures delivery of set FiO_2. (Modified from Foust GN, Potter WA, Wilons MD, et al: Shortcomings of using two jet nebulizers in tandem with an aerosol face mask for optimal oxygen therapy, Chest 99:1346, 1991.)

TABLE 41-6

Troubleshooting Common Problems With Reservoir Masks

Problem or Clue	Cause	Solution
Patient constantly removes mask	Claustrophobia	Use alternative device
	Confusion	Restrain patient
No gas flow can be detected	Flowmeter not on	Adjust flowmeter
	System leak	Check connections
Humidifier pop-off is sounding	Obstruction distal to humidifier	Find and correct obstruction
	High input flow	Omit humidifier if therapy is short-term
	Jammed inspiratory valve	Fix or replace valve
Reservoir bag collapses when the patient inhales	Flow is inadequate	Increase flow
Reservoir bag remains inflated throughout inhalation	Large mask leak	Correct leak
	Inspiratory valve jammed or reversed	Repair or replace mask
Erythema develops over face or ears	Irritation or inflammation owing to appliance or straps	Reposition mask or straps
		Place cotton balls over ear pressure points
		Provide skin care

RULE OF THUMB

High-Flow Devices

To qualify as a high-flow device, a system should provide at least 60 L/min total flow. This flow criterion is based on the fact that the average adult peak inspiratory flow during tidal ventilation is approximately three times the minute volume. Because 20 L/min is close to the upper limit of sustainable minute volume for an ill person, a flow of 3 × 20, or 60 L/min, should suffice in most situations. In a few rare circumstances, flow must reach or exceed 100 L/min.

Principles of Gas Mixing. All high-flow systems mix air and O_2 to achieve a given FiO_2. These gases are mixed with air-entrainment devices or blending systems. Computations involving mixtures of air and O_2 are based on a modified form of the dilution equation for solutions:

$$V_F C_F = V_1 C_1 + V_2 C_2$$

In this equation, V_1 and V_2 are the volumes of the two gases being mixed; C_1 and C_2, the O_2 concentration in these two volumes; and V_F and C_F, the final volume and concentration of the resulting mixture.

Box 41-1 shows how to apply variations of this equation to compute (1) the final concentration of a mixture of air and O_2, (2) the air-to-O_2 ratio needed to obtain a given FiO_2, (3) the total output flow from an air-entrainment device, and (4) the amount of O_2 that must be added to a volume of air to obtain a given FiO_2. Clinical examples of these computations are provided in the accompanying Mini Clini boxes.

Box 41-1 Equations for Computing Oxygen Percentage, Ratio, and Flow

To compute the O_2 percentage of a mixture of air and O_2:

$$\%O_2 = \frac{(\text{Airflow} \times 21) + (O_2 \text{ flow} \times 100)}{\text{Total flow}} \quad \textbf{(Eq. 41-1)}$$

1. To compute the air-to-O_2 ratio needed to obtain a given O_2 percentage:

$$\frac{\text{Liters air}}{\text{Liters } O_2} = \frac{(100 - \%O_2)}{(\%O_2 - 21)} \quad \textbf{(Eq. 41-2)}$$

2. To compute the total output flow from an air-entrainment device (given the O_2 input):
   a. Compute the air-to-O_2 ratio (see Equation 41-2).
   b. Add the air-to-O_2 ratio parts.
   c. Multiply the sum of the ratio parts by the O_2 input flow.
3. To compute the flow of O_2 and air needed to obtain a given O_2 percentage at a given total flow:
   a. Compute the O_2 flow:

$$O_2 \text{ flow} = \frac{\text{Total flow} \times (O_2\% - 21)}{79} \quad \textbf{(Eq. 41-3)}$$

   b. Compute the airflow:

$$\text{Airflow} = \text{Total flow} - O_2 \text{ flow}$$

MINI CLINI

Conflicting Assessment Information

PROBLEM: A disoriented postoperative male patient breathing room air exhibits tachypnea, tachycardia, and mild cyanosis of the mucous membranes. Using a pulse oximeter, the RT measures the patient's oxyhemoglobin saturation as 90%. What should the RT recommend to the patient's surgeon?

Discussion: This is a classic example of how monitoring data and results of bedside assessment can conflict. Both the patient's condition and the observed clinical signs indicate hypoxemia, but the pulse oximeter indicates adequate oxygenation. In situations such as this, it is always better to err on the side of the patient and recommend O_2 therapy—treat the patient, not the monitor. This concept is particularly important in the use of monitoring technologies known to have limited accuracy, such as pulse oximetry (see Chapter 19).

MINI CLINI

Determining FiO_2 of an Air-Oxygen Mixture

PROBLEM: An air-entrainment device mixes at a fixed ratio of three volumes of air to each volume of O_2 (3:1 ratio). What is the resulting FiO_2?

Solution: Substituting air, O_2, and total (air + O_2) volumes into Equation 41-1:

$$\%O_2 = \frac{(\text{Airflow} \times 21) + (O_2 \text{ flow} \times 100)}{\text{Total flow}}$$

$$\%O_2 = \frac{(3 \times 21) + (1 \times 100)}{3 + 1}$$

$$\%O_2 = 41$$

An air-entrainment device that mixes three volumes of air with one volume of O_2 provides a gas mixture with FiO_2 of approximately 0.40.

Air-Entrainment Systems. Air-entrainment systems direct a high-pressure O_2 source through a small nozzle or jet surrounded by air-entrainment ports (Figure 41-13). The amount of air entrained at these ports varies directly with the size of the port and the velocity of O_2 at the jet. The larger the intake ports and the higher the gas velocity at the jet, the more air is entrained.

Because they dilute source O_2 with air, entrainment devices always provide less than 100% O_2. The more air they entrain, the higher the total output flow, but the delivered FiO_2 is lower. High flow is possible only when low O_2 concentration is delivered. For these reasons, air-entrainment devices function as true high-flow systems only at low FiO_2. If the flow output from an air-entrainment device decreases to less than a patient's inspiratory flow, air dilution occurs, and FiO_2 becomes variable.

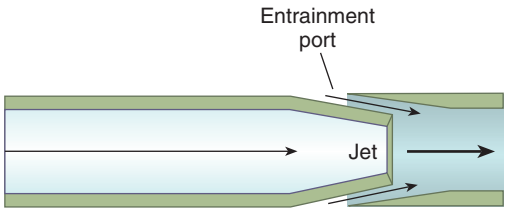

FIGURE 41-13 Basic components of an air-entrainment system. Pressurized gas passes through a nozzle or jet, beyond which are air-entrainment ports. Shear forces at the jet orifice entrain air into the primary gas stream, diluting the O_2 and increasing the total flow output of the device.

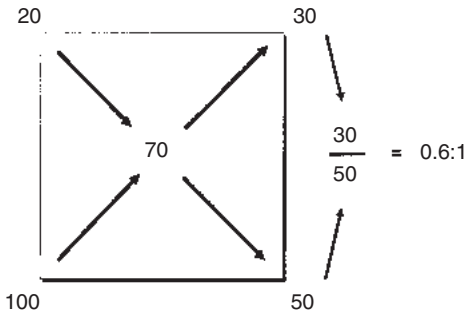

FIGURE 41-14 The magic box used to estimate air-to-O_2 ratio.

MINI CLINI

Computing Total Flow Output of an Air-Entrainment Device

PROBLEM: A patient is receiving O_2 through an air-entrainment device set to deliver 50% O_2. The input O_2 flow is set to 15 L/min. What is the total output flow of this system?

Solution: Step 1: Compute the air-to-O_2 ratio by substituting 50 for the $\%O_2$ in Equation 41-2:

$$\frac{\text{Liters air}}{\text{Liters } O_2} = \frac{(100 - \%O_2)}{(\%O_2 - 21)}$$

$$\frac{\text{Liters air}}{\text{Liters } O_2} = \frac{(100 - 50)}{(50 - 21)}$$

$$\frac{\text{Liters air}}{\text{Liters } O_2} = \frac{50}{29}$$

$$\frac{\text{Liters air}}{\text{Liters } O_2} = \frac{1.7}{1}$$

Step 2: Add the air-to-O_2 ratio parts:

$$1.7 + 1 = 2.7$$

Step 3: Multiply the sum of the ratio parts times the O_2 input flow:

$$2.7 \times 15\,\text{L/min} = 41\,\text{L/min}$$

An air-entrainment device set to deliver 50% O_2 that has an input flow of 15 L/min provides a total output flow of approximately 41 L/min.

FiO_2 provided by air-entrainment devices depends on two key variables: the air-to-O_2 ratio and the amount of flow resistance downstream from the mixing site. Changing the input flow of an air-entrainment device alters the total output flow but has little effect on delivered FiO_2. Generally, FiO_2 remains within 1% to 2% of that specified by the manufacturer, regardless of input flow.[29]

The size of the jet and entrainment ports of a device determines the air-to-O_2 ratio and the delivered FiO_2. The accompanying Mini Clini entitled Determining FiO_2 of an Air-Oxygen Mixture shows how to compute the FiO_2 provided by an air-entrainment system if the air-to-O_2 ratio is known.

A more common clinical problem arises when the total output flow from an air-entrainment system must be determined. As described in the previous Rule of Thumb, the total flow output of a system determines whether it truly performs as a high-flow device. The accompanying Mini Clini entitled Computing Total Flow Output of an Air-Entrainment Device shows how to determine the total output flow of an air-entrainment system.

Rather than using Equation 41-2 in Box 41-1 to compute air-to-O_2 ratio, many RTs derive quick estimates by using a simple mathematical aid called the ***magic box*** (Figure 41-14). To use the magic box, one draws a square and places 20 in the top left corner and 100 in the bottom left corner. One places the desired O_2 percentage in the center of the box (as in the case illustrated in Figure 41-14, 70%). One subtracts diagonally from lower left to the upper right (disregard the sign). One subtracts diagonally again from upper left to lower right (disregard the sign). The resulting numerator (30) is the value for air, and the denominator (50) is the value for O_2.

By convention, the air-to-O_2 ratio is expressed with the denominator (liters of O_2) set to 1. To reduce any ratio to a ratio of x:1, divide both the numerator and the denominator by the denominator. In the magic box example (also see Figure 41-14):

$$\frac{30}{50} = \frac{30/50}{50/50} = \frac{0.61}{1}$$

The magic box can be used only for estimation of air-to-O_2 ratio. For absolute accuracy, Equation 41-2 in Box 41-1 always should be used. Based on Equation 41-2, Table 41-7 lists the approximate air-to-O_2 ratios for several common O_2 percentages.

The other major factor determining the O_2 concentration provided by an air-entrainment device is downstream flow resistance. In the presence of flow resistance distal to the jet, the volume of air entrained always decreases. With less air being entrained, total flow output decreases, and the delivered O_2 concentration increases. More detail on this phenomenon is provided later in this chapter.[29]

The two most common O_2 delivery systems in which air entrainment is used are the air-entrainment mask (AEM) and the air-entrainment nebulizer.

Air-Entrainment (Venturi) Mask. The use of an O_2 mask with controlled FiO_2 by means of air entrainment was first reported in 1941 by Barach and Eckman.[30] The system provided relatively high FiO_2 (>40%) through the use of adjustable

air-entrainment ports that controlled the amount of air mixed with O_2. Almost 20 years later, Campbell[31] developed an entrainment mask that provided controlled, low FiO_2 and called the device a *venturi mask* or *venti-mask*.

As the name *venti-mask* suggests, the operating principle behind these devices has often been attributed to the Venturi principle (see Chapter 6). This assumption is incorrect.[32] Rather than having an actual Venturi tube that entrains air, these devices have a simple restricted orifice or jet through which O_2 flows at high velocity. Air is entrained by shear forces at the boundary of jet flow, not by low lateral pressures. The smaller the orifice, the greater the velocity of O_2, and more air is entrained.

TABLE 41-7

Approximate Air-to-Oxygen Ratios for Common Oxygen Concentrations*

Percentage O_2	Approximate Air-to-O_2 Ratio	Total Ratio Parts
100	0:1	1
80	0.3:1	1.3
70	0.6:1	1.6
60	1:1	2
50	1.7:1	2.7
45	2:1	3
40	3:1	4
35	5:1	6
30	8:1	9
29	10:1	11
24	25:1	26

*Total output flow (air + O_2) in L/min can be calculated by multiplying the total ratio parts by the O_2 input flow (L/min).

Figure 41-15 depicts a typical AEM, designed to deliver a range of low to moderate FiO_2 (0.24 to 0.40). The mask consists of a jet orifice or nozzle around which is an air-entrainment port *(top drawing)*. The body of the mask has several large ports, which allow escape of both excess flow from the device and exhaled gas from the patient. In this design, FiO_2 is regulated by selection and changing of the jet adapter. The smallest jet provides the highest O_2 velocity, the most air entrainment, and the lowest FiO_2 (0.24). The largest jet provides the lowest O_2 velocity, the least air entrainment, and the highest FiO_2 (0.40). Other AEM designs may vary both jet and entrainment port size to provide an even broader range up to 50% FiO_2. The aerosol entrainment collar fits over the air-entrainment ports (see later).

For controlled FiO_2 at flow high enough to prevent air dilution, the total output flow of an AEM must exceed the patient's peak inspiratory flow.[29] With an entrainment ratio exceeding 5:1, an AEM set to deliver less than 35% O_2 has little trouble meeting or exceeding the 60 L/min high-flow criterion (see previous Rule of Thumb). At settings greater than 35%, total AEM flow decreases significantly, and FiO_2 becomes variable. For example, when set to deliver 50% O_2, some AEMs provide 0.39 FiO_2.[32-34]

Air-Entrainment Nebulizer. Pneumatically powered air-entrainment nebulizers have most of the features of AEMs but have added capabilities, including additional humidification and temperature control. Humidification is achieved through

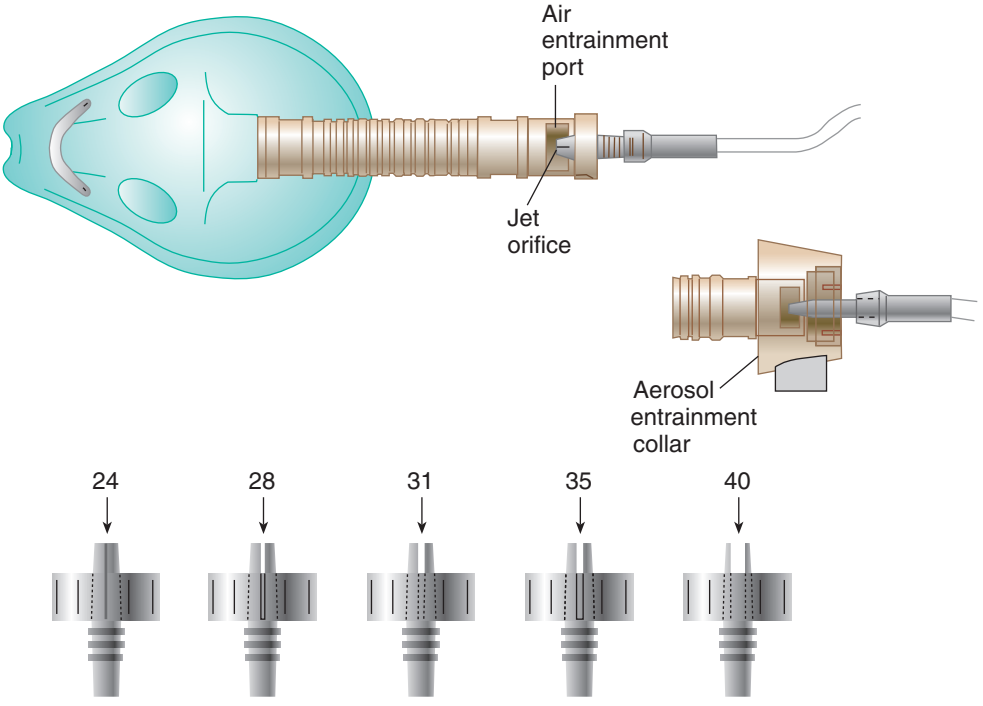

FIGURE 41-15 Typical AEM. FiO_2 is regulated by changing a jet adapter. The aerosol collar allows high humidity or aerosol entrainment from an air source. (Modified from Kacmarek RM: In-hospital O_2 therapy. In Kacmarek RM, Stoller J, editors: Current respiratory care, Toronto, 1988, BC Decker.)

production of aerosol at the nebulizer jet. Temperature control is provided by an optional heating element. In combination, these added features allow delivery of particulate water (in excess of needs for body temperature and pressure, saturated) to the airways. These devices are also widely known as *jet nebulizers* or *large volume nebulizers*.

Because of added humidification and heat control, air-entrainment nebulizers have been the traditional device of choice for delivering O_2 to patients with artificial tracheal airways. O_2 typically is delivered with a T tube or a tracheostomy mask. An alternative is to use an aerosol mask or a face tent to deliver an O_2 mixture via aerosol to patients with intact upper airways (Figure 41-16).[35]

AEMs can vary both jet and entrainment port size to obtain a given FiO_2; however, gas-powered nebulizers have a fixed orifice. Air-to-O_2 ratios can be altered only by varying entrainment port size. Disposable nebulizers usually have a continuous range of settings from 28% to 100%.[22]

Similar to AEMs, air-entrainment nebulizers perform as fixed-performance devices only when output flow meets or exceeds the patient's inspiratory demand. In contrast to AEMs, air-entrainment nebulizers do not allow easy increases in nebulizer output flow by means of an increase in O_2 input. With most nebulizer systems, the extremely small size of the jet needed for aerosol production limits the maximum O_2 input flow to 12 to 15 L/min at 50 psig. For example, the total output flow of an air-entrainment nebulizer set to deliver 40% O_2 ranges from 48 to 60 L/min. Although this amount may be adequate for most patients, it is insufficient for patients with very high inspiratory flow or minute volume.[35]

The actual FiO_2 received by patients may be affected by the choice of airway appliance. The FiO_2 delivered by face tent is consistently less than the set nebulizer concentration, especially at higher levels.[36]

Air-entrainment nebulizers should be treated as fixed-performance devices only when set to deliver low O_2 concentration (≤35%).[33] When a nebulizer is used to deliver a higher concentration of O_2, the output flow is insufficient to meet patient needs. There are two ways to assess whether the flow of an air-entrainment nebulizer meets the patient's needs. The first method is simple visual inspection. With this approach (generally used only with a T tube), the RT sets up the device to deliver the highest possible flow at the prescribed FiO_2 and observes the mist output at the expiratory side of the T tube. As long as mist can be seen escaping throughout inspiration, flow is adequate and the delivered FiO_2 is ensured.

The second way to assess the adequacy of nebulizer flow is to compare it with the patient's peak inspiratory flow. A patient's peak inspiratory flow during tidal breathing is at least three times minute volume. As long as the nebulizer flow exceeds this value, the delivered FiO_2 is ensured. If the patient's peak flow exceeds that provided by the nebulizer, the device functions as a low-flow system with variable FiO_2 (see the accompanying Mini Clini for an example).[35]

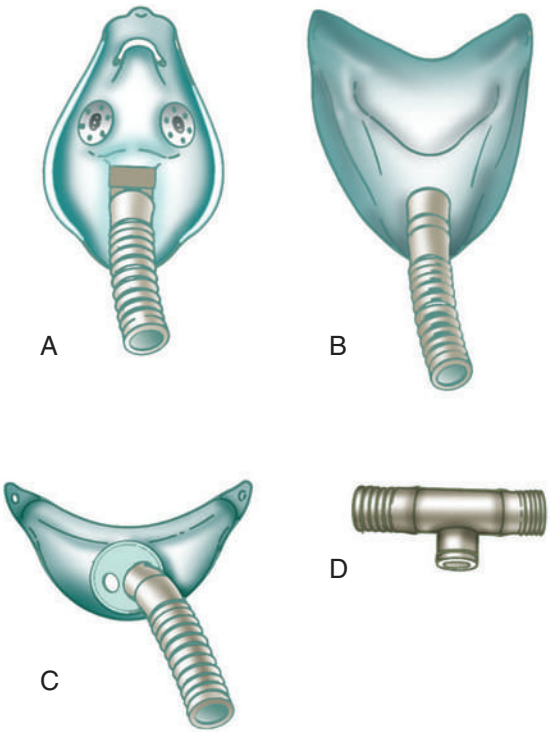

FIGURE 41-16 Devices for delivery of O_2 mixtures with aerosol. **A,** Aerosol mask. **B,** Face tent. **C,** Tracheostomy collar. **D,** T tube. (Modified from Kacmarek RM: In-hospital O_2 therapy. In Kacmarek RM, Stoller J, editors: Current respiratory care, Toronto, 1988, BC Decker.)

MINI CLINI

Computing Minimum Flow Needs

PROBLEM: A physician orders 40% O_2 through an air-entrainment nebulizer to a patient with a tidal volume of 0.6 L and a respiratory rate of 33 breaths/min. If maximum nebulizer input flow is 12 L/min, will the patient receive 40% O_2? If not, what total flow is needed to meet this patient's needs?

Solution: 1. Estimate the patient's inspiratory flow:

$$\text{Peak inspiratory flow} = \text{VE} \times 3 = (0.6 \times 33) \times 3 = 59.4 \text{ L/min}$$

2. Compute the total flow of the nebulizer:

$$\text{Sum of ratio parts}\,(3:1) \times \text{Input flow}\,(12 \text{ L/min}) = 48 \text{ L/min}$$

3. Compare value 1 with value 2 (patient with nebulizer):

$$59.4 \text{ L/min}\,(\text{patient}) > 48 \text{ L/min}\,(\text{nebulizer})$$

Under these conditions, the patient does not receive 40% O_2. To deliver a stable 40% O_2 concentration, the total flow would have to be at least 59.4 L/min.

Troubleshooting Air-Entrainment Systems. The major problem with air-entrainment systems is ensuring that the set FiO_2 actually is delivered to the patient. Problems usually do not occur when the devices are used to deliver low FiO_2 (<0.35). However, the design of these devices makes it difficult to provide even moderate FiO_2 at the high flow needed to ensure a set

O_2 concentration. The performance of all air-entrainment devices is affected by downstream resistance. The result can be inaccurate FiO_2 that makes delivery of a low O_2 concentration difficult with air-entrainment nebulizers.

Providing Moderate to High FiO_2 at High Flow. AEMs and air-entrainment nebulizers differ in ratio settings and input and output flow capabilities. Most AEMs can be set to deliver no more than 50% O_2. When set according to the manufacturer's specifications to provide much more than 35% O_2, AEMs simply do not generate enough flow to ensure the set FiO_2. The solution is to boost the total output flow. With AEMs, total output flow can be boosted with a simple increase in input flow. For a 35% AEM (5:1 ratio) with an input flow of 8 L/min, the total output flow is 48 L/min. This flow is insufficient to ensure 35% O_2 delivery to all patients. Simply increasing the input flow to 12 L/min boosts the output flow of the AEM by 50%, to 72 L/min. The new high flow ensures delivery of the set O_2 concentration to essentially all patients.

This solution is impossible with most air-entrainment nebulizers. Because the small jets in many of these devices limit O_2 flow to 12 to 15 L/min, the input flow cannot be increased beyond these levels. A few nebulizer models, such as the Theramist Barrel Nebulizer (Smiths Medical, London, England), supposedly can provide moderately high output flows of 54 L/min at FiO_2 80%. However, most air-entrainment nebulizers cannot because of the total flow-to-FiO_2 tradeoff. The five alternatives for boosting the FiO_2 capabilities in these situations are presented in Box 41-2.

The simplest approach to achieving higher FiO_2 with these devices is to add a 50- to 150-ml aerosol tubing reservoir to the expiratory side of the T tube (Figure 41-17). Given its simplicity, adding an open volume reservoir to the expiratory side of T tubes is standard procedure in most clinical settings. This approach can be used only in the treatment of intubated patients. Even then, the small reservoir size limits the ability of this system to ensure stable FiO_2, especially greater than 40%, and larger reservoirs can cause rebreathing.

Rather than a simple open reservoir, a closed reservoir or nonrebreathing system similar to that shown in Figure 41-12 can be used. These systems combine an inspiratory volume reservoir (usually a compliant 3- to 5-L anesthesia bag) with a one-way expiratory valve. Whenever patient flow exceeds nebulizer flow, the expiratory valve closes, and the patient draws additional gas from the reservoir. Although they can ensure delivery of the set O_2 concentration, these systems pose considerable hazards. If source flow stops for any reason, the patient can suffocate. For this reason, these systems must be equipped with an emergency inlet valve that allows room air breathing in the event of source gas failure.

The third approach to higher FiO_2 with air-entrainment nebulizers is to connect two or more devices together with a "wye" adapter (Figure 41-18).[22] Although a single air-entrainment nebulizer set at 60% (1:1 ratio) with a maximum input flow of 15 L/min has a total output flow of only 30 L/min, connecting two of these devices together doubles the total output flow to 60 L/min (the minimum needed for a high-flow device). This approach works well only for delivery of a concentration of 60% or less to patients with a minute volume less than 10 L/min.[35,36]

A fourth method for boosting FiO_2 provided by air-entrainment nebulizers is to set the device to a lower

Box 41-2 Increasing FiO_2 Capabilities of Air-Entrainment Nebulizers

- Add open reservoir to expiratory side of T tube
- Provide inspiratory reservoir with one-way expiratory valve
- Connect two or more nebulizers together in parallel
- Set nebulizer to low concentration; bleed-in O_2; analyze and adjust
- Use a commercial dual-flow system

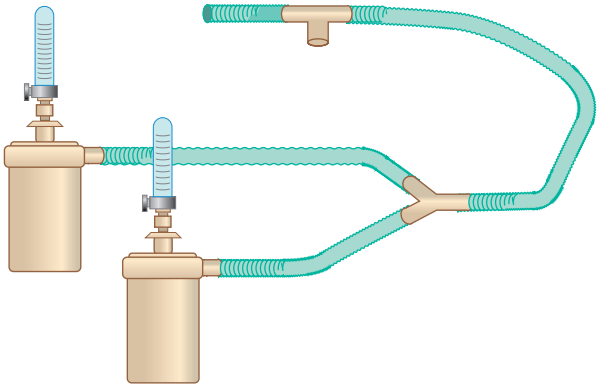

FIGURE 41-18 Use of two nebulizers in parallel to provide high FiO_2 at high flow.

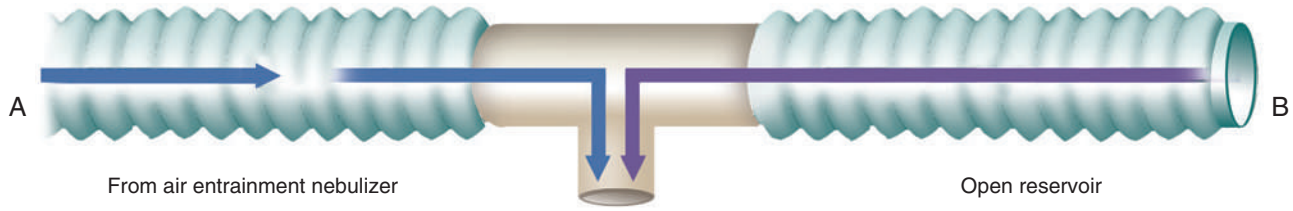

FIGURE 41-17 Use of an open volume reservoir to enhance delivered O_2 concentration with a T tube. From 50 to 150 ml of aerosol tubing is connected to the expiratory side of the T tube. **A,** When the patient inhales, gas at the set FiO_2 is drawn first through the inspiratory side of the circuit. **B,** If the patient's flow exceeds nebulizer flow, gas is drawn from the reservoir side. After the reservoir volume is fully tapped, room air is entrained, and FiO_2 decreases.

concentration than that prescribed (to generate high flow) while bleeding supplemental O_2 into the delivery tubing. This method increases both FiO_2 and total output flow. To achieve a specific FiO_2 the delivered concentration should be analyzed and the supplemental O_2 input flow adjusted until the desired concentration is achieved.

Commercial dual-flow systems entail a similar approach. One flow source powers the jet, while another flow source provides supplemental O_2. The Misty Ox (Vital Signs, Totowa, New Jersey) gas injection nebulizer is an example. This system is not an air-entrainment system because it does not depend on entrainment ports to increase total flow or O_2 concentration to the patient. Rather, it uses two flowmeters: one that operates the jet and one that feeds into the side of the jet manifold. The Misty Ox system can provide FiO_2 of 0.96 at a flow of 42 L/min and offers O_2 concentrations ranging from 0.21 to nearly 1.00.[35]

Problems With Downstream Flow Resistance. Any increase in flow resistance downstream from (distal to) the point of air entrainment alters the performance of all air-entrainment systems. Increased downstream flow resistance causes back pressure. The back pressure decreases both the volume of entrained air and the total flow output of these devices. With less air entrained, the delivered O_2 concentration increases; however, because total flow output also decreases, the effect on FiO_2 varies. High downstream flow resistance usually turns air-entrainment systems from high-flow (fixed) O_2 delivery systems into low-flow (variable) O_2 delivery systems incapable of delivering a precise and constant FiO_2.[29]

This problem explains why it is extremely difficult to deliver less than 28% to 30% O_2 with an air-entrainment nebulizer. The 5 to 6 ft (1.5 to 1.8 m) of aerosol tubing normally used with these devices produces enough flow resistance to decrease air entrainment and prevent a lower FiO_2.

A similar situation can occur when the entrainment ports of an air-entrainment device become obstructed (most common with AEMs). Delivered O_2 concentration increases, but total output flow decreases. The net effect usually is a variable FiO_2. The accompanying Mini Clini is an example of the effect of increased downstream flow resistance on the performance of an air-entrainment device.

High-Flow Nasal Cannula. A variation of the standard nasal cannula discussed earlier in this chapter is a **high-flow nasal cannula (HFNC)**. Various systems are available, including the Vapotherm Precision Flow System (Vapotherm, Exeter, New Hampshire), which can deliver both FiO_2 and relative humidity greater than 90% by using heated, humidified O_2 flows up to 40 L/min. HFNC units offered by other manufacturers such as Fisher and Paykel's Optiflow (Irvine, California) featured in Figure 41-19, have been shown to provide even higher flows of 50 L/min, as well as a maximum FiO_2 of more than 90%. These devices feature a variety of proprietary designs that facilitate the separate control of flow and humidified supplemental oxygen. The ability to maintain a consistent FiO_2 under varying patient breathing patterns makes these devices suitable for a great many patients. As a result, these systems have been shown to successfully treat moderate hypoxemia through a combination of the three main features: (1) delivery of a high FiO_2, (2) meeting or exceeding the patient's minute ventilation and therefore acting as a fixed oxygen delivery device, and (3) generating a distending positive airway pressure. Furthermore, the heated-humidity feature enables these systems to deliver highly humidified oxygen, thus preventing the drying effects that some high-flow devices have on the mucosa. This point and the less confining design of these devices generally mean that they are more comfortable and better tolerated by many patients than are alternative oxygen delivery devices. As a result, such devices have become a popular substitute for both traditional high-flow oxygen devices and continuous positive airway pressure setups for infants with disorders including bronchiolitis and bronchopulmonary dysplasia. Furthermore, HFNC devices are rapidly

MINI CLINI

Effect of Downstream Flow Resistance on Performance of an Air-Entrainment Device

PROBLEM: A tracheostomy patient is receiving O_2 therapy through a T tube attached to an air-entrainment nebulizer set at 35% O_2 with an input flow of 10 L/min. Over the past 30 minutes, the patient's SpO_2 has decreased from 93% to 88%. When assessing the patient, the RT finds that the large-bore delivery tubing of the nebulizer is partially obstructed with condensate and that aerosol mist at the T tube is not visible throughout inspiration. What is the likely problem, and what is the best solution?

Solution: The likely problem is a decrease in FiO_2 owing to the increased downstream resistance caused by the condensate. At 10 L/min input flow, the device was probably delivering approximately 60 L/min of 35% O_2 before the tubing became obstructed. Because aerosol mist is not visible at the T tube throughout inspiration, it is clear that the total output flow is no longer sufficient and that the patient is now diluting the delivered O_2 with room air. Draining the tubing solves this problem.

gaining popularity in treating patients of all ages with moderate hypoxemia.

Despite the fact that some earlier infection control concerns associated with older HFNC designs appear to have been largely overcome, a few limitations seem to persist. These include contraindications for use on patients with blocked nasal passages, problems from the inability to precisely determine and monitor the level of positive pressure actually applied to the airway, and in rare instances, nasal skin erosions, mainly in neonates and infants, from an improperly fitting cannula.[37]

MINI CLINI

Indications for High-Flow Nasal Oxygen

PROBLEM: A recently extubated patient experiencing moderate hypoxemia is having trouble tolerating a 50% venturi mask due to claustrophobia and airway dryness. When switched to a nasal cannula, his SpO_2 drops to 88%. The physician wants the patient SpO_2 to remain at 92% or higher and asks the RT what options are available for delivering moderate oxygen concentrations to this patient while maximizing patient comfort.

Solution: A high-flow nasal oxygen setup is able to provide a moderate to high and consistent FiO_2 through varying patient breathing patterns. In addition, features including a less-confining design and delivery of a highly humidified gas tend to make them better tolerated than many other oxygen delivery systems. Hence, in this instance, the RT should recommend a high-flow nasal oxygen setup.

Blending Systems. When air-entrainment devices cannot provide a high enough O_2 concentration or flow, use of a gas blending system should be considered. With a blending system, separate pressurized air and O_2 sources are input, and the gases are mixed either manually or with a precision valve (blender). This system allows precise control over both FiO_2 and total flow output. Most blending systems can provide flow much greater than 60 L/min, qualifying them as true fixed-performance delivery devices. For adults, gas is delivered from the blender either through an open system, such as an aerosol mask or T tube, or with a closed nonrebreathing system. For many patients requiring high FiO_2 and breathing spontaneously, this is the ideal setup, provided that the gas is humidified. The use of high-flow blended systems with heated humidity, as opposed to a heated aerosol, are very well tolerated by most patients, including patients with tracheostomies.

Mixing Gases Manually. When gases are mixed manually, separate air and O_2 flowmeters must be adjusted for the desired FiO_2 and flow (see the accompanying Mini Clini). For adults, this approach requires calibrated high-flow flowmeters (at least 60 L/min) and monitoring of delivered FiO_2.

Oxygen Blenders. Rather than manually mixing air and O_2, the RT more often uses an O_2 blender. Figure 41-20 shows the major components of a typical O_2 blender. Air and O_2 enter the blender and pass through dual pressure regulators that exactly match the two pressures. Gas flows to a precision proportioning valve. Because the two gas pressures at this point are equal, varying the size of the air and O_2 inlets provides precise control over the relative concentration.

An alarm system gives an audible warning when either source gas fails or the pressure decreases below a specified value.

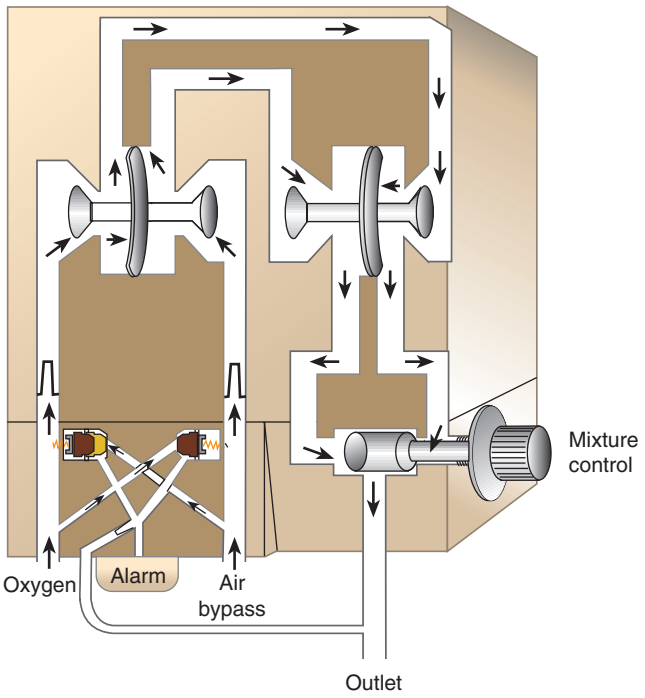

FIGURE 41-20 O_2 blending device. (Modified from McPherson SP: Respiratory therapy equipment, ed 3, St. Louis, 1985, Mosby.)

MINI CLINI

Manually Mixing Air and Oxygen to Achieve Specified Concentration at a Given Flow

PROBLEM: To mix air and O_2 manually to provide a patient with 50% O_2 at a total flow of 60 L/min, what O_2 and airflow would the RT set?

Solution: 1. Use Equation 41-3 to compute the O_2 flow:

$$O_2 \text{ flow} = \frac{\text{Total flow} \times (O_2\% - 21)}{79}$$

$$O_2 \text{ flow} = \frac{60 \times (50 - 12)}{79}$$

$$O_2 \text{ flow} = 22 \text{ L/min}$$

2. Compute the airflow:

$$\text{Airflow} = \text{Total flow} - O_2 \text{ flow}$$

$$\text{Airflow} = 60 - 22$$

$$\text{Airflow} = 38 \text{ L/min}$$

To provide a patient with 50% O_2 at a total flow of 60 L/min, blend 22 L of O_2 with 38 L of air.

Box 41-3 Procedure for Confirming Operation of an Oxygen Blender

1. Confirm that inlet pressures of air and O_2 are within manufacturer's specifications.
2. Test low air and O_2 alarms by disconnecting each source; also confirm safety bypass or crossover system.
3. Analyze O_2 concentration at 100%, 21%, and specified FiO_2.

The alarm system usually has a crossover or bypass feature whereby failure of one gas source causes the blender system to switch to the other. If the air source fails when delivering 60% O_2, the alarm sounds, and the blender switches over to delivery of 100% O_2.

Although they allow ideal control over both FiO_2 and flow, blenders are especially prone to inaccuracy and failure.[38,39] Hence, an operational check of any blender should be conducted before using it on a patient (Box 41-3). FiO_2 should be checked and confirmed with a calibrated O_2 analyzer at least once per shift.[2] When a blender is used in the care of a neonate, an O_2 analyzer should be kept in-line at all times. In the use of a nonrebreathing or closed delivery system, (1) all breathing valves should be inspected and tested before application to a patient, and (2) a fail-safe inspiratory valve should be included in the delivery system.

Enclosures. The concept of enclosing a patient in a controlled-O_2 atmosphere is among the oldest approaches to O_2 therapy. Entire rooms once were used for this purpose. With today's simpler airway devices, enclosures are generally used only in the care of infants and children. The primary types of O_2 enclosures used for infants and children are tents, incubators, and hoods.

Oxygen Tents. O_2 tents previously were the most common method of O_2 therapy in the treatment of both adults and children. Use of O_2 tents in both adults and children is rare at the present time. However, when they are used, it is common for tents to be air-conditioned or cooled with ice to provide a comfortable temperature within a plastic sheet canopy (Figure 41-21).

The main problem with tents is that frequent opening and closing of the canopy cause wide swings in O_2 concentration. Constant leakage makes a high FiO_2 impossible. In large tents, O_2 input flow of 12 to 15 L/min can provide only 40% to 50% O_2 levels. Comparable FiO_2 can be achieved in smaller pediatric or **croup** tents with flow of 8 to 10 L/min.

Hoods. An O_2 hood, also known as an *oxyhood,* is often the best method for administration of controlled O_2 therapy to infants. As shown in Figure 41-22, an O_2 hood covers only the head, leaving the infant's body free for nursing care. O_2 is delivered to the hood through either a heated air-entrainment nebulizer or a blending system with a heated humidifier. A minimum flow of 7 L/min should be set to prevent accumulation of CO_2.[40] Depending on the size of the hood, flow of 10 to 15 L/min may be needed to maintain a stable high O_2 concentration. Higher flow generally is not needed and may produce a harmful noise level and additional stress on neonatal patients.[41]

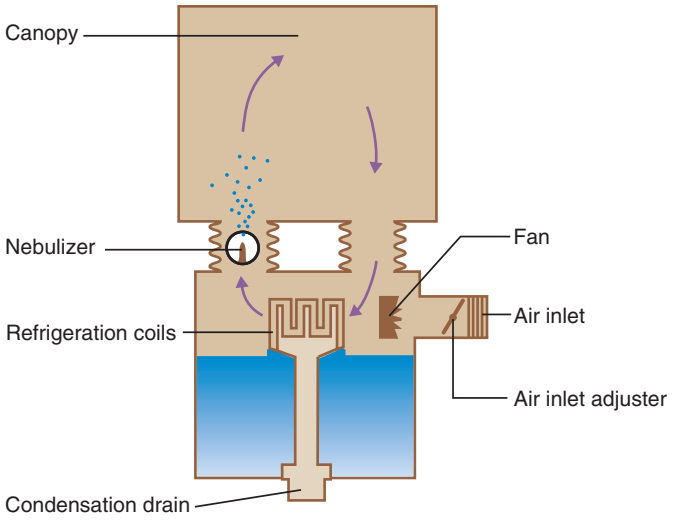

FIGURE 41-21 O_2 tent incorporating refrigeration coils for cooling. (Modified from Cairo JM: Mosby's respiratory care equipment, ed 9, St. Louis, 2014, Mosby.)

FIGURE 41-22 Infant O_2 hood. (Courtesy Utah Medical Products, Inc, Midvale, Utah.)

In the care of premature infants, it is especially important to ensure that the gas mixture is properly warmed and humidified and not directed toward the patient's face or head. Low temperatures or convection cooling produced by high flow over the head can cause heat loss and cold stress. In premature infants, cold stress can increase O_2 consumption and cause apnea.[42]

The temperature of gases provided to an infant in an O_2 hood should be precisely set to maintain a **neutral thermal environment (NTE)**. The NTE temperature varies according to an infant's age and weight. The NTE temperature for newborns weighing less than 1200 g is 95° F (35° C). For older infants weighing 2500 g or more, the NTE is lower, approximately 86° F (30° C).[42]

Incubators. Incubators, also known by the trade name Isolette (Dräger Medical AG & Co, Lübeck, Germany) are polymethyl methacrylate (Plexiglas) enclosures that combine servo-controlled convection heating with supplemental O_2 (Figure 41-23). When it is needed, supplemental humidity usually is provided with an external heated humidifier or nebulizer.

FIGURE 41-23 Infant isolette. (Courtesy Dräger Medical AG & Co, Lübeck, Germany.)

Supplemental O_2 can be administered with a direct connection between the incubator and a flowmeter that has a heated humidifier. In some units, a filtered air-entrainment device limits the delivered concentration to approximately 0.40. However, leaks and frequent opening of the isolette dilute the O_2 levels to much less than 40%. Blockage of the inlet filter can cause less air entrainment and a higher O_2 concentration.[42]

Given the highly variable O_2 concentration provided by these devices, the best way to control O_2 delivery to infants in an isolette is with an oxyhood. The oxyhood is placed over the infant's head inside the isolette. The O_2 concentration and gas temperature within the oxyhood, not in the isolette, must be assessed. It is ideal to monitor isolette or oxyhood O_2 concentration continuously (see later).[2,4]

Because hoods allow better FiO_2 control, and because servo-controlled radiant heating warmers are generally more convenient, Plexiglas isolettes are not as popular as they used to be. However, these devices are still the best choice for providing O_2 to infants in stable condition with a NTE.[42]

Other Oxygen Delivery Devices

Bag-Mask Devices. Bag-mask devices use a self-inflating bag and nonrebreathing valve features to provide up to 100% O_2. Bag-mask devices are often used in emergency life support and in critical care and are more completely discussed in Chapter 37.

Demand-Flow and Pulse-Dose Systems. Demand-flow or pulse-dose systems use a flow sensor and valve to synchronize gas delivery with inspiration. These devices can substantially extend duration of flow of a liquid or gaseous O_2 tank and are popular in alternative settings, as described in Chapter 56.

Box 41-4 Patient Factors in Selecting Oxygen Therapy Equipment

- Severity and cause of hypoxemia
- Patient age group (infant, child, adult)
- Degree of consciousness and alertness
- Presence or absence of tracheal airway
- Stability of minute ventilation
- Mouth breathing vs. nose breathing patient

Selecting a Delivery Approach

The RT is often involved in the initial selection of an appropriate delivery system. This generally involves making recommendations—on the basis of sound patient assessment—to initiate, change or discontinue the treatment regimen (see later section on Protocol-Based Oxygen Therapy).

The three *Ps*—*purpose, patient,* and *performance*—are used in the initial selection or recommendation of a change in O_2 delivery system. The goal is to match the performance characteristics of the equipment to both the objectives of therapy (purpose) and the patient's special needs.

Purpose

The general purpose or objective of all O_2 therapy is to increase FiO_2 sufficiently to correct arterial hypoxemia. Other objectives, including decreasing hypoxic symptoms and minimizing increased cardiopulmonary work, follow from this primary purpose.

Patient

Key patient considerations in selecting O_2 therapy equipment for use in acute care are summarized in Box 41-4. Knowledge of these factors helps guide the RT in selecting the appropriate equipment. For example, a simple mask at 5 to 6 L/min is probably more suitable than a nasal cannula at 4 L/min for a mouth breathing, mildly hypoxemic patient. An infant with moderate hypoxia and a normal airway usually needs an O_2 enclosure (hood or enclosed incubator).

Performance

O_2 systems vary according to actual FiO_2 delivered and stability of FiO_2 under changing patient demands. Generally, the more critically ill the patient, the greater the need for a stable, high FiO_2. Less acutely ill patients generally need a lower, less exact FiO_2. Table 41-8 lists guidelines for selecting an O_2 delivery system on the basis of the level and stability of the FiO_2 needed.

General Goals and Patient Categories

On the basis of overall consideration of the three *P*s, general goals can be set for several patient categories. In emergencies in which tissue hypoxia is suspected, patients should be given the

TABLE 41-8

Selection of an Oxygen Delivery System Based on Desired FiO_2 Level and Stability

Desired FiO_2 Level	DESIRED FiO_2 STABILITY	
	Fixed	Variable
Low (<35%)	AEM Air-entrainment nebulizer Blending system Isolette, incubator (infant)	Nasal cannula Nasal catheter Transtracheal catheter
Moderate (35%-60%)	Air-entrainment nebulizer Blending system Oxyhood (infant)	Simple mask Air-entrainment nebulizer Tent (child)
High (>60%)	Blending system Oxyhood (infant) High-flow nasal cannula	Partial rebreather Nonrebreather

highest FiO_2 possible—ideally 100%. This level can be achieved with a true high-flow or a closed reservoir system. The goal is the highest possible blood O_2 content. Clinical examples include respiratory or cardiac arrest, severe trauma, shock, carbon monoxide poisoning, and cyanide poisoning. Carbon monoxide and cyanide poisoning may necessitate HBO therapy (see later).

A critically ill adult patient with moderate to severe hypoxemia needs either a reservoir or a high-flow system capable of at least 60% O_2. Thereafter, changes in FiO_2 (and device) should be based on results of assessment of physiologic values. The goal is a PaO_2 greater than 60 mm Hg or oxyhemoglobin saturation greater than 90%.

In the care of adult patients in more stable condition but who are acutely ill with mild to moderate hypoxemia, a system capable of low to moderate O_2 concentration can be used. In these cases, stability of FiO_2 is not critical. Applicable devices include a nasal cannula at moderate flow or a simple mask. Common examples include patients in the immediately postoperative phase and patients recovering from acute myocardial infarction.

Adult patients with chronic lung disease and accompanying acute-on-chronic hypoxemia present a special case. In the care of these patients, the goal is to ensure adequate arterial oxygenation without depressing ventilation. Adequate oxygenation of these patients generally means SaO_2 of 85% to 92% with PaO_2 of 50 to 70 mm Hg.[31,43] These values usually are achieved with either low-flow nasal O_2 or a low-concentration (24% to 28%) AEM. The less stable the patient's condition, the greater the need for a high-flow AEM.[22]

Because of size, discomfort, and appearance, AEMs are less well tolerated than nasal cannulas for long-term therapy. In contrast to a cannula, an AEM must be removed for eating and drinking. Because even a short break in O_2 therapy can cause a rapid decrease in PaO_2 in some patients, these patients should be taught to switch to a nasal cannula whenever they must remove the mask.[22]

Lastly, it is sometimes necessary to modify O_2 delivery systems to facilitate patient transport. An example is a spontaneously breathing patient with a tracheostomy tube receiving a moderate FiO_2 via a blended system or an air-entrainment nebulizer connected to a tracheostomy mask. Given the impracticalities of transporting a patient on an air-entrainment nebulizer, it may be more suitable to connect a venturi adapter temporarily to provide the appropriate FiO_2 to the tracheostomy mask during the transport, and then reconnect them back to the original aerosol set-up immediately after the transport.

Box 41-5 Physiologic Effects of Hyperbaric Oxygen Therapy

- Bubble reduction (Boyle's law)
- Hyperoxygenation of blood and tissue (Henry's law)
- Vasoconstriction
- Enhanced host immune function
- Neovascularization

Protocol-Based Oxygen Therapy

O_2 therapy is ideally suited for a protocol. Bedside assessment of oxygenation by RTs and other clinicians has progressed to where it is more cost-effective and clinically appropriate to use a protocol rather than obtaining a new physician order for each change in FiO_2. An order for "O_2 therapy via protocol" permits O_2 therapy to be initiated, modified, or discontinued by the RT, provided that an assessment reveals that the patient meets previously approved clinical criteria. A well-designed O_2 protocol ensures the patient (1) undergoes initial assessment, (2) is evaluated for protocol criteria, (3) receives a treatment plan that is modified according to need, and (4) stops receiving therapy as soon as it is no longer needed.[44]

Figure 41-24 shows the decision algorithm underlying an O_2 therapy titration protocol developed at the Cleveland Clinic Foundation. In the algorithm, a pulse oximetry saturation (SpO_2) of 92% is the point at which therapy is to be initiated. The patient is assessed each shift for the need of supplemental O_2, which is adjusted depending on need. When the SpO_2 is consistently 92% or greater on room air, therapy is discontinued.

HYPERBARIC OXYGEN THERAPY

Hyperbaric oxygen (HBO) therapy is the therapeutic use of O_2 at pressures greater than 1 atm.[45-47] Pressures during HBO therapy usually are expressed in multiples of **atmospheric pressure absolute (ATA)**: 1 ATA equals 760 mm Hg (101.32 kPa). Most HBO therapy is conducted at pressures between 2 ATA and 3 ATA, although other pressures may be used, often based on U.S. Navy diving treatment tables.[46-48]

Physiologic Effects

The known physiologic effects of HBO therapy are summarized in Box 41-5.[45] These effects are mainly due to either high pressure or high O_2 tension in body fluids and tissues. In conditions

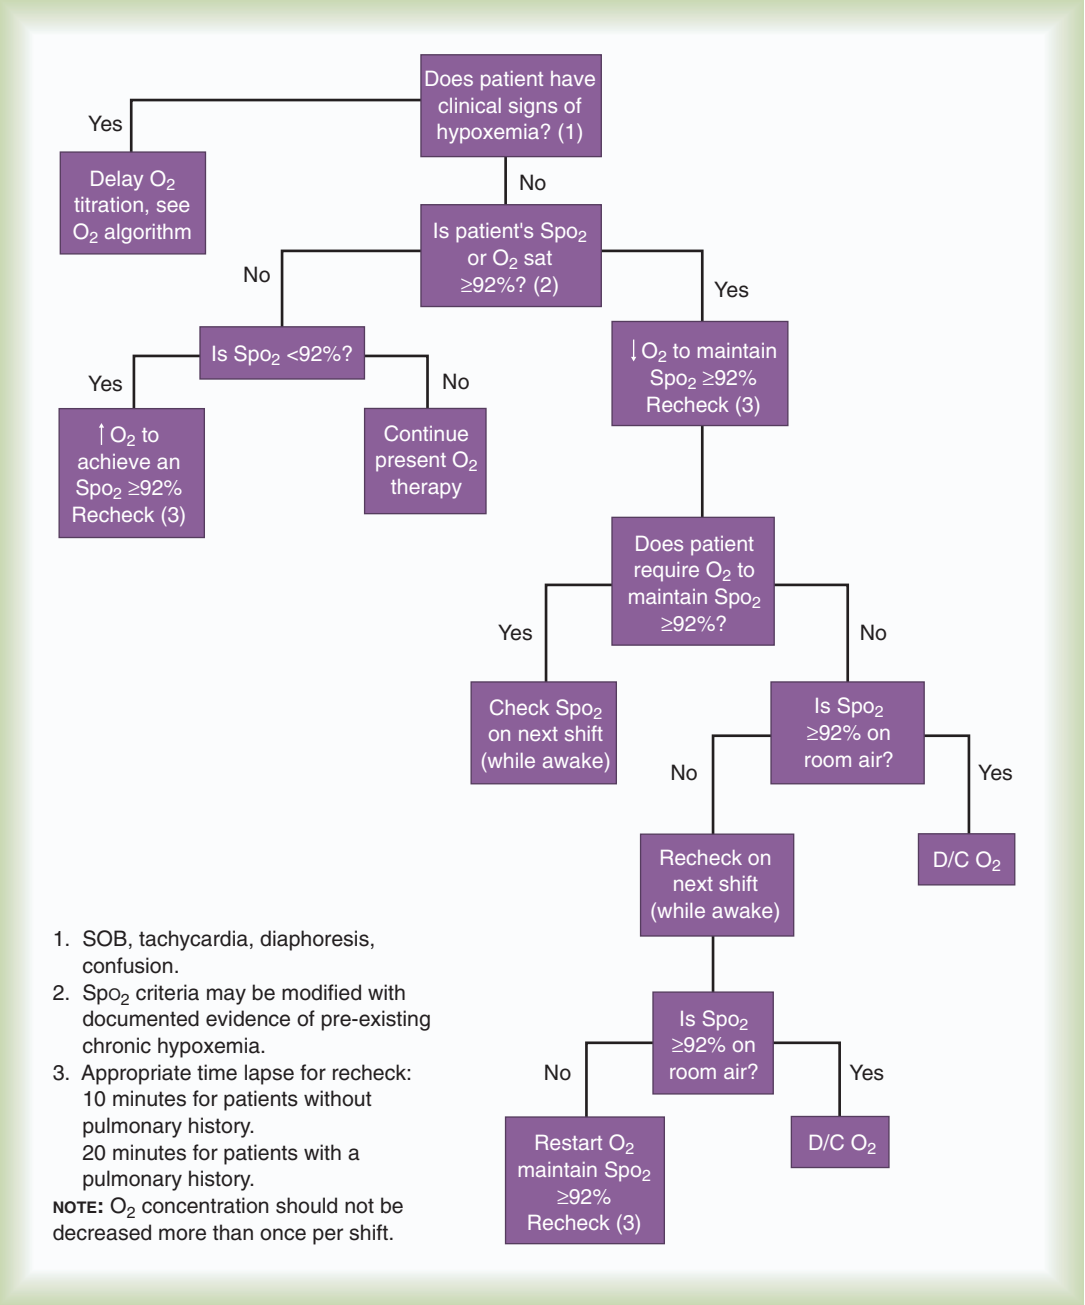

FIGURE 41-24 Protocol for titration of O_2 therapy. (Courtesy the Respiratory Therapy Section, Cleveland Clinic Foundation, Cleveland, Ohio.)

such as air embolism and decompression sickness, Boyle's law dictates that high pressure exerts a physical effect on air or nitrogen bubbles trapped in the blood or tissues, reducing their size, and minimizing potential harm. Because pressure is crucial in these cases, HBO treatments may be conducted at 6 ATA or more.[46,48]

The second beneficial effect of HBO is hyperoxia. When a patient is breathing room air, only a small amount of O_2 dissolves in the plasma (approximately 0.3 ml/dl). At 3 ATA, plasma contains nearly 7 ml/dl dissolved O_2, a level exceeding average resting tissue uptake.[46]

O_2 supply to the tissues affects the immune system, wound healing, and vascular tone. A tissue PO_2 of at least 30 mm Hg is necessary for normal cellular function. Damaged and infected tissues often have a lower PO_2. Increasing O_2 supply to these tissues can help restore both white blood cell function and antimicrobial activity.

Hyperoxia affects the cardiovascular system. HBO therapy causes generalized vasoconstriction and a small decrease in cardiac output. Although these changes may decrease blood flow to a region, this effect is more than offset by the increase in O_2 content. In conditions such as burns, cerebral edema, and

crush injuries, vasoconstriction may be helpful because it reduces edema and tissue swelling while maintaining tissue oxygenation.

Hyperoxia also helps form new capillary beds, a process called **neovascularization.** Although the exact mechanism is unknown, neovascularization is an essential component of tissue repair, especially in radiation-induced injuries.[46,47]

Study results suggest that HBO may be useful in many other conditions, including the management of stroke, wound healing, and treating stubborn soft tissue infections. Because HBO has emerged as a highly effective therapy for various conditions, its use in recent years has expanded.[49,50]

Methods of Administration

HBO is administered in either a multiplace or a monoplace chamber. A multiplace chamber is a large tank capable of holding a dozen or more people (Figure 41-25, *A*). Because patients are directly cared for by medical staff inside the tank, multiplace chambers have air locks that allow entry and exit without altering the pressure. The multiplace chamber is generally filled with air. If indicated, only the patient breathes supplemental O_2 (through a mask or another device). Because they can achieve pressures of 6 ATA or more, multiplace chambers are ideal for the management of decompression sickness and air embolism.[46-48]

A typical monoplace chamber consists of a transparent Plexiglas cylinder large enough only for a single patient (see Figure 41-25, *B*). During therapy, the cylinder O_2 concentration is kept at 100%. The patient need not wear a mask. Because of the high O_2 concentration, most electronic equipment cannot be used in a monoplace chamber. In addition, many ventilators do not function properly under the high atmospheric pressures. However, monitoring systems and ventilators can be adapted to allow treatment of a critically ill patient with hyperbaric pressure. Additionally, artificial airways suited to function properly under hyperbaric conditions should be used.[45]

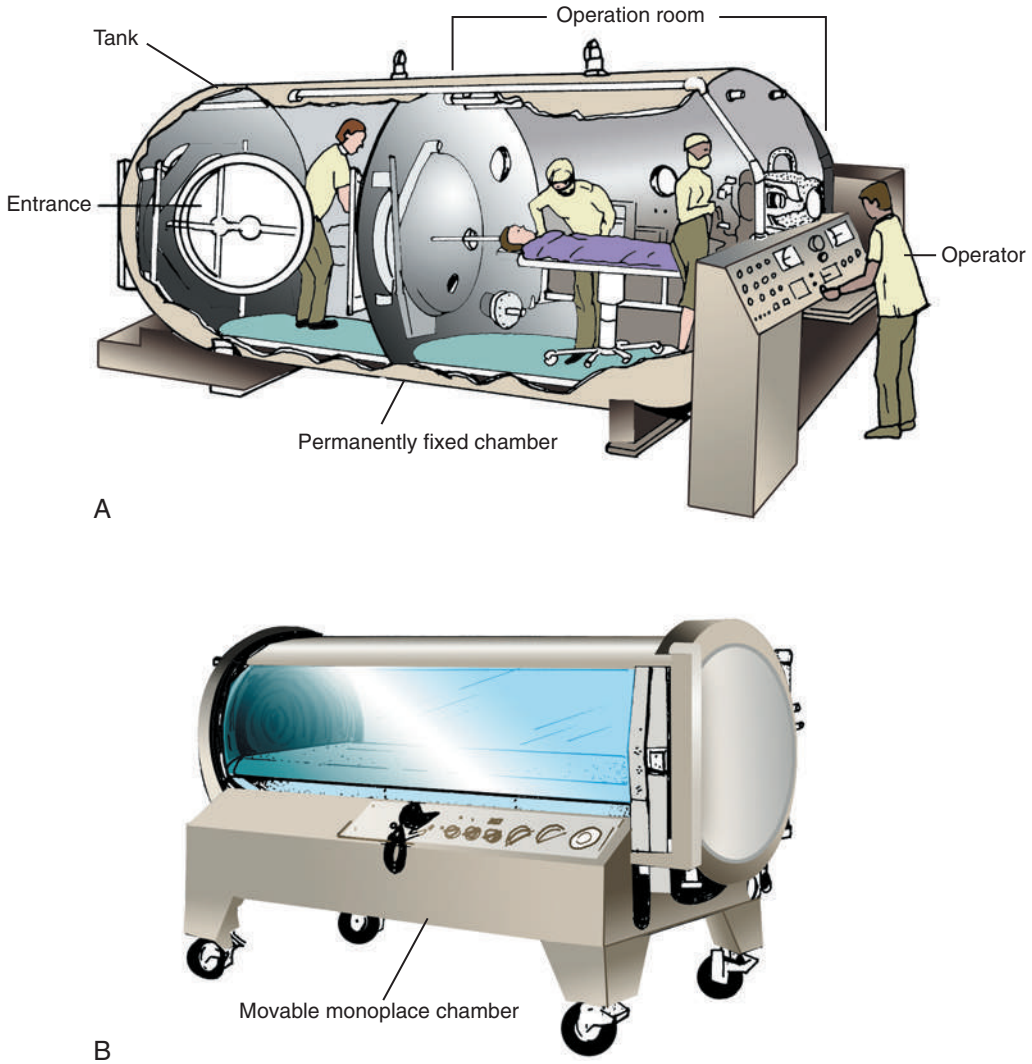

FIGURE 41-25 **A,** Fixed hyperbaric chamber. **B,** Monoplace chamber.

Box 41-6 Indications for Hyperbaric Oxygen Therapy

ACUTE CONDITIONS
- Decompression sickness
- Air or gas embolism
- Carbon monoxide and cyanide poisoning
- Acute traumatic ischemia (compartment syndrome, crush injury)
- Acute peripheral arterial insufficiency
- Intracranial abscesses
- Crush injuries and suturing of severed limbs
- Clostridial gangrene
- Necrotizing soft tissue infection
- Ischemic skin graft or flap

CHRONIC CONDITIONS
- Diabetic wounds of the lower extremities and other nonhealing wounds
- Refractory osteomyelitis
- Actinomycosis (chronic systemic abscesses)
- Radiation necrosis (HBO as an adjunct to conventional treatment)

Box 41-7 Criteria for Hyperbaric Oxygen Therapy for Acute Carbon Monoxide Poisoning

- History of unconsciousness
- Presence of neuropsychiatric abnormality
- Presence of cardiac instability or cardiac ischemia
- Carboxyhemoglobin level 25% (lower levels for children and pregnant women)

Box 41-8 Major Complications of Hyperbaric Oxygen Therapy

BAROTRAUMA
- Ear or sinus trauma
- Tympanic membrane rupture
- Alveolar overdistention and pneumothorax
- Gas embolism

OXYGEN TOXICITY
- CNS toxic reaction
- Pulmonary toxic reaction

OTHER
- Fire
- Sudden decompression
- Reversible visual changes
- Claustrophobia
- Decreased cardiac output

Indications

HBO has long been accepted as the primary treatment of divers with decompression sickness. Several other of the most common indications for HBO therapy are listed in Box 41-6.[45,47] The two most common acute conditions for which RTs administer HBO are air embolism and carbon monoxide poisoning.[45,48,51]

Air Embolism

Air embolism is a complication that can occur with certain cardiovascular procedures, lung biopsy, hemodialysis, and central line placement. HBO can decrease the size of air bubbles which may otherwise reach the cerebral or cardiac circulation and can cause symptoms or sudden death. Typical therapy for air embolism involves immediate pressurization in air to 6 ATA for 15 to 30 minutes. This step is followed by decompression to 2.8 ATA with prolonged O_2 treatment.[46-48]

Carbon Monoxide Poisoning

Carbon monoxide poisoning accounts for about half of all poisoning deaths in the United States. The condition of a patient with carbon monoxide poisoning improves quickly with HBO treatment because this treatment is the fastest way to remove carbon monoxide from the blood.[51] If a patient breathes air, it takes more than 5 hours to remove only one half of the carboxyhemoglobin in the blood. Breathing 100% O_2 reduces this "half-life" to 80 minutes. The half-life of carboxyhemoglobin under HBO at 3 ATA is only 23 minutes. Box 41-7 lists the major criteria for selecting patients with acute carbon monoxide poisoning for treatment with HBO.[51]

Complications and Hazards

Although the benefits of HBO are significant, this type of therapy also has significant risks. As a result, the benefits should be compared with the hazards before therapy is initiated. Common complications of HBO are listed in Box 41-8.[46] These complications are generally caused by high pressure, O_2 toxicity, fire, or worsening of certain existing conditions. The most frequent problems involve barotrauma to closed body cavities, such as the middle ear or sinuses. Pneumothorax and air embolism also are possible during HBO treatment but are rare in patients with normal lungs.

O_2 at high pressure can rarely be neurotoxic. Early signs of impending CNS toxicity include twitching, sweating, pallor, and restlessness, and later seizures and convulsions.[47]

In terms of pulmonary O_2 toxicity, HBO treatments do not normally expose patients to high PO_2 long enough to cause damage. However, HBO may have an additive effect on critically ill patients who receive high FiO_2 between HBO treatments.[46,47]

Avoiding fire and sudden decompression are primary safety concerns. Only 100% cotton fabric should be used to avoid fire from a static electrical discharge. Other ignition sources such as matches or lighters should never be brought into HBO chambers, and alcohol- or petroleum-based products, including makeup or deodorant, should never be used. Other potential hazards of HBO involve the aggravation of existing conditions, including diabetes, epilepsy, and hypertension. These concerns can be addressed by an appropriate history and chart review, close patient monitoring, and appropriate adjustment of therapy.

There are numerous relative contraindications for HBO, many of which relate to the potential complications and hazards noted earlier. Relative contraindications include inner ear infections and seizure disorders. Absolute contradictions include an untreated pneumothorax and congenital heart defects resulting in dependency on a patent ductus arteriosus for survival.[47]

Troubleshooting

Although fire hazards restrict the use of certain electronic equipment, some state-of-the-art monitors and ventilators with solid-state circuitry can be used within the chamber. This equipment allows intensive care of critically ill patients.[45]

In regard to ventilator use, reductions in delivered tidal volume should be expected and corrected. Additionally, tracheostomy or endotracheal tubes with foam or fluid-filled cuffs should generally be used to preserve cuff integrity under pressure. If not accounted for, reduced tidal volumes and leaks can lead to respiratory hypercapnia and acidosis. Hypercapnia can result in respiratory acidosis and can worsen CNS toxicity owing to cerebral vasodilation.[47] Generally, pressure-regulating and flow-regulating equipment used in a hyperbaric chamber must be specifically designed for operation or equipment appropriately modified to function properly in such conditions.

OTHER MEDICAL GAS THERAPIES

O_2 is not the only medical gas administered by RTs. The potent pulmonary vasodilator **nitric oxide (NO)**, and helium-O_2 mixtures are also among other medical gases administered by RTs.

Nitric Oxide Therapy

Mode of Action

NO gas is a colorless, odorless, highly diffusible, and lipid-soluble free radical that oxidizes quickly to nitrogen dioxide (NO_2) in the presence of O_2. NO is normally produced in small amounts within the human body and activates guanylate cyclase, which catalyzes the production of cyclic guanosine 3′,5′-monophosphate (cGMP). The end result is that increased cGMP levels cause vascular smooth muscle relaxation.[52] The therapeutic benefit of inhaled NO stems from improved blood flow to ventilated alveoli. The result is a reduction in intrapulmonary shunting, improvement in arterial oxygenation, and a decrease in pulmonary vascular resistance and pulmonary arterial pressure.

Indications

Inhaled NO has been approved by the U.S. Food and Drug Administration (FDA) for use in conjunction with mechanical ventilation, in treating term and near-term (>34 weeks) neonates with hypoxic (type I) respiratory failure with associated pulmonary hypertension. As a result of the clinical benefits of reduced pulmonary vascular resistance, improved oxygenation, and less need for a highly invasive method for increasing tissue oxygenation known as *extracorporeal membrane oxygenation,* inhaled NO is a mainstay therapy for near-term neonates with this type of respiratory failure.[53]

In adults, studies have shown that inhaled NO has been effective in treating pulmonary hypertension associated with acute respiratory distress syndrome (ARDS). However, these benefits seem to be short-lived, and no significant improvement in clinical outcomes, including ventilator days and mortality, have been shown to date. However, inhaled nitric oxide is frequently used for the management of patients with acute or chronic pulmonary hypertension as a result of pulmonary or cardiac disease and as a diagnostic tool for assessing pulmonary vascular responsiveness prior to heart transplantation or other cardiac surgical procedures. But because of the high cost of nitric oxide, and the lower cost of alternative drug therapies, including inhaled epoprostenol sodium (Flolan) and similar medications (discussed in Chapter 35), most try to avoid the use of nitric oxide. Inhaled NO in adults has not been approved by the FDA. Irrespective, the potential indications for inhaled NO are listed in Box 41-9.[53,54]

Dosing

The amount of NO needed to improve oxygenation or decrease pulmonary vascular pressure in neonates or adults is relatively low. The therapeutic range of NO is 2 to 20 ppm, and an initial dose of 20 ppm is commonly used. Treatment should be continued until underlying oxygenation desaturation has resolved. For many patients, dosages often can be reduced to less than 20 ppm at the end of 4 hours of initial treatment, as tolerated. At these levels, NO has minimal toxicity.[52-54]

Toxicity and Adverse Effects

Most of the toxic effects of NO are caused by its chemical by-products, especially NO_2. NO_2 is produced spontaneously whenever NO is exposed to O_2. NO_2 is more toxic than NO. Levels greater than 10 ppm can cause cell damage, hemorrhage, pulmonary edema, and death. The U.S. Occupational Safety and Health Administration has set the safety limit for NO_2 exposure at 5 ppm. Properly set up NO delivery systems safely and easily achieve this limit.[55]

Other harmful chemical by-products produced in reaction with NO include methemoglobin and peroxynitrite (produced when NO reacts with superoxide). Although it can occur with NO administration, methemoglobinemia probably is not a large problem considering the doses commonly used and the

- Delivery of a precise and stable dose of NO
- Limited production of nitrogen dioxide
- Accurate monitoring of NO and nitrogen dioxide levels
- Maintenance of adequate patient ventilation

required monitoring systems discussed later in this section. Peroxynitrite can cause severe cell damage; however, there is no hard evidence supporting its toxic effects during NO administration.

Potential adverse effects associated with NO therapy are listed in Box 41-10.[55] A poor or paradoxical response to NO has been observed in some patients. Of patients with ARDS, 40% do not have initial improvement in oxygenation with NO therapy, and some patients have experienced more severe hypoxemia (probably because of a worsening ventilation/perfusion imbalance when no shunt was present). NO inhibits platelet agglutination; however, no significant increase in bleeding time has been reported in NO trials with human subjects. Because it can quickly reduce right ventricular afterload, NO may increase left ventricular filling pressure in some patients. In the presence of congestive heart failure, this effect could cause or worsen pulmonary edema. Concerns involving increased left heart pressures also account for inhaled NO being contraindicated for neonates with certain cardiac and vascular anomalies such as coarctation of the aorta.[53] In certain patients, the withdrawal of NO has resulted in development of hypoxemia and pulmonary hypertension, perhaps worse than they were before therapy was started. This phenomenon is known as a *rebound effect*. This rebound effect occurs because the administration of nitric oxide depresses the body's normal production of NO. When NO is finally discontinued, FiO_2 frequently needs to be initially increased then slowly reduced to baseline.[52]

Although NO has been used safely with other drugs and treatments such as dopamine, steroids, surfactant, and high-frequency ventilation, the interaction of NO with other medications is still being studied. One investigational area may involve the study of patients receiving both inhaled NO and other NO-related compounds such as nitroglycerin and the possible development of methemoglobinemia or systemic hypotension.[54]

Methods of Administration

NO is administered to mechanically ventilated patients through a system with the capability for operator-determined concentration of NO in the breathing gas, a constant concentration throughout the breathing cycle, and a concentration that does not cause generation of excessive inhaled NO_2. Features of an ideal NO delivery system are listed in Box 41-11.

The INOmax® DS_{IR}® Plus (Delivery System-Infrared) (Ikaria, Hampton, New Jersey) shown in Figure 41-26 provides these features.[54,56] The INOmax DS_{IR} Plus delivers INOmax (nitric oxide) for inhalation into the inspiratory limb of the patient's breathing circuit in a manner that provides a constant dose of NO, as preset by the clinician, throughout inspiration. This configuration tracks the ventilator flow waveforms and delivers

FIGURE 41-26 INOmax DS Plus (Delivery System-Plus) delivery system for administration of NO to mechanically ventilated patients. (Courtesy Ikaria, Hampton, New Jersey.)

a synchronized and proportional dose of NO through the injector module into the ventilator circuit. A monitoring system continuously displays inspired FiO_2, NO_2, and NO. The INOmax DS_{IR} Plus employs several alarm systems to alert clinicians, including alarms for high and low NO and FiO_2 and high NO_2. Other alarms notify clinicians when the source gas (INOmax) pressure is low, or if there is a monitoring failure. The device also informs clinicians when high calibrations for the monitoring system are due; low calibrations are performed automatically by the device without requiring user intervention.[57]

The delivery system entails the use of cylinder mixtures of NO containing up to 800 ppm of NO with the balance being nitrogen. This high concentration of NO is diluted by gases in the ventilator circuit before delivery to the patient. Because adding NO to the circuit decreases the FiO_2 (up to 10 percent at 80 ppm), O_2 concentration must be continuously monitored downstream from the titration site.

The INOmax DS_{IR} Plus can also be interfaced with several specialty ventilators including high-frequency oscillators, jet ventilators, and anesthesia machines. Inhaled NO has also been used with noninvasive ventilation. Other special considerations apply, and resources such as ventilator procedure manuals and department policy and procedures should be reviewed to help ensure proper setup and patient safety.[56]

The administration of inhaled NO to spontaneously breathing patients is also possible. The INOmax DS_{IR} Plus has been validated with high- and low-flow nasal cannula systems and some nasal CPAP systems.[56]

Withdrawing Therapy

Care must be taken when NO therapy is withdrawn to prevent the rebound effect. First, the NO level should be reduced to the lowest effective dose (ideally ≤5 ppm). Second, the patient's condition should be hemodynamically stable, and the patient should be able to maintain adequate oxygenation while breathing a moderate FiO_2 (≤0.4) on low levels of positive end expiratory pressure. Third, the patient should be hyperoxygenated (FiO_2 0.6 to 0.7) just before discontinuation of NO inhalation. Close monitoring of patients and use of these measures usually avoid an increase in pulmonary artery pressure and hypoxemia with withdrawal of nitric oxide.[53]

Helium-Oxygen Therapy

Indications

The value of helium as a therapeutic gas is based solely on its low density. As detailed in Chapter 6, when flow is turbulent, driving pressure varies with the square of the flow. Because flow in the large airways is mainly turbulent, breathing a low-density gas mixture can decrease the driving pressure needed to move gas in and out of this area. With less pressure needed to move gas through the large airways, the patient's work of breathing decreases. However, this effect is limited to large airway obstruction (flow in the small airways is not turbulent).

Helium-O_2 has been used for more than 70 years as an adjunct tool in the management of large airway obstruction.[58] **Heliox therapy** has been shown to be effective in treating acute obstructive disorders.[59,60] Either alone or combined with other therapies such as bronchodilators, helium-O_2 therapy has been shown to decrease the respiratory rate, the level of dyspnea, and the need for intubation and mechanical ventilation in patients with reversible obstructive disorders.[61] Specifically, heliox therapy has yielded promising results in the management of acute upper airway obstruction of varying origin,[62] postextubation stridor in pediatric trauma patients,[63] acute severe asthma, and croup.[64]

Guidelines for Use

Because it is inert and unable to support life, helium always must be mixed with at least 20% O_2. The most common combination is 80% helium and 20% O_2. From the standpoint of its ability to oxygenate, this mixture is comparable to air, but helium is used in place of nitrogen. Although air has a density of 1.293 g/L, the density of an 80% helium mixture is 0.429 g/L. For a comparable flow through constricted large airways, this low-density mixture can dramatically decrease the work of breathing.

Most commonly, premixed, commercial heliox cylinders are used at the bedside. These premixed cylinders are commonly available in an 80:20 or a 70:30 combination. The 70% helium and 30% O_2 mixture has a density of 0.554 g/L and can provide additional O_2 for the management of the hypoxemia that can occur with large airway obstruction. Other combinations such as 60:40 and 65:35 mixtures are being examined and show promising results.[61,65]

The low-density benefit of heliox is the same attribute that presents challenges in selecting a delivery device. Because helium is highly diffusible, administration through low-flow systems such as a nasal cannula tends not to deliver sufficient concentrations to treat obstructive disorders in adults. However, heliox administered via cannulas with an adequate seal at the nares has shown to be effective in some infants.[66] Irrespective, heliox should generally be delivered to most spontaneously breathing patients via a tight-fitting nonrebreathing mask with a fully functional valved exhalation port. The delivery system should be high flow, sufficient to meet or exceed the patient's minute ventilation requirements. Closed systems with demand valves and reservoirs or the use of demand regulators has proved to be suitable for delivering heliox to patients with artificial airways. Ideally, an O_2 analyzer should be used to confirm the FiO_2 of the heliox mixture output flowing to the patient and all such patients should be closely monitored, including with a pulse oximetry.[67]

Helium mixtures can be given through a cuffed tracheal airway with a positive pressure ventilator. However, the performance of ventilators in delivering heliox tends to vary significantly by model, and only some of them have received FDA clearance for such use. Consequently, RTs should ensure that an appropriate ventilator is being used to administer heliox, determine if a conversion factor is needed to adjust settings, and ensure that the patient is monitored closely while such an approach is being used.[68] Pressure measurements on mechanical ventilators are always accurate during the use of heliox but

volume measurements can be grossly inaccurate if the ventilator is not calibrated to a heliox mixture.

Blenders have also been used to administer heliox. When a blender is used, the 80:20 heliox is generally attached to the air inlet, and an O_2 analyzer is placed downstream. However, because the accuracy of blenders tends to vary, the system's FiO_2 readings should first be tested, and the difference between the set and actual FiO_2 should be known.

Heliox has also been combined with bronchodilator therapy to treat acute obstructive disorders such as status asthmaticus. Heliox improves aerosol deposition mainly because of a reduction in turbulence and less impaction and medication loss. Because of the low density of heliox, when a nebulizer is driven by heliox, the liter flow must be increased from the customary 6 L/min to 10 to 12 L/min to achieve the same volume of aerosol generated per unit of time.

When heliox is given alone or as part of nebulization, the RT should realize that a typical hospital O_2 flowmeter is inaccurate because of the lower density of helium. Flowmeters calibrated for helium should be used to ensure accurate delivery. However, correction factors are available for O_2 flowmeters. The correction for an 80:20 helium-O_2 mixture is 1.8; this means that for every 10 L/min indicated flow, 10 × 1.8, or 18 L/min, of the 80:20 mixture actually leaves the flowmeter. For delivery of a specific flow from an 80:20 helium-O_2 source, the RT sets the flowmeter to the desired flow divided by 1.8. If a flow of 9 L/min of an 80:20 helium-O_2 mixture is needed, the RT sets the flowmeter to 9/1.8, or 5 L/min. Factors for any other mixture can be calculated if needed. The factor for a 70:30 helium-O_2 mixture is 1.6.

In addition to special flow considerations, the RT should use an O_2 analyzer to monitor heliox (actually O_2) concentrations continuously between the source of the mixture and the patient. The basis for this recommendation is that the gas is either helium or O_2, and if the FiO_2 is known, assuming there are no leaks, the remaining gas is helium. This monitoring helps ensure that the patient is receiving the therapeutic benefits of a less dense gas while maintaining the appropriate FiO_2.

Troubleshooting and Hazards

The low density of helium mixtures makes them poor vehicles for aerosol transport. High-density bland water aerosols are difficult to deliver with helium mixtures. The low density of helium mixtures also makes coughing less effective. If the patient can develop an effective cough, this problem can be rectified by means of washing out the helium before coughing.

The most common side effect of helium is a benign one. When a patient is breathing a helium mixture, the spoken word is badly distorted at a pitch so high as to make it almost unintelligible. This effect is caused by the passage of a low-density gas through the vocal cords on exhalation.

A more serious problem is hypoxemia associated with breathing helium mixtures.[66,69] Although this problem may have been caused by using too low an O_2 concentration (20%), there is another possibility. Very rarely, some commercial helium-O_2 cylinders stored for long periods of time have been found to contain these gases in an unmixed, or separated, state. The only way to avoid this potential hazard is to analyze the O_2 concentration coming from the cylinder before administering the gas.

As clinical applications for heliox have expanded, other hazards have emerged. One potential problem is volume-induced lung injury when heliox is administered via a mechanical ventilator. This risk can be addressed by using only ventilators approved by the FDA for heliox administration. In addition, the lower density of helium-O_2 mixtures may result in greater variability in medication delivery to the airways. Careful patient monitoring during such therapy can help minimize this concern. Another rare but possible problem is hypothermia to infants receiving heliox via an oxyhood. This risk results from the high thermal conductivity of helium and can be avoided by warming and humidifying the heliox gas.[66]

Carbon Dioxide–Oxygen (Carbogen) Therapy

Although rarely used, CO_2-O_2 mixtures (carbogen) have been employed to treat hiccups, carbon monoxide poisoning, and some neonates with congenital cardiac anomalies, and to prevent complete washout of CO_2 during cardiopulmonary bypass and extracorporeal gas exchange. More recently, it has been investigated as a treatment for hearing loss and seizures. However, the application of carbogen in clinical settings has been quite limited given the potential adverse effects of hypoxemia, premature ventricular contractions, hypertension, and muscle twitching.[70]

Carbogen is supplied in compressed gas cylinders as either 5%:95% or 7%:93% CO_2-O_2 mixtures. It can be administered to patients with a snug-fitting nonrebreathing mask, with a flow sufficient to prevent the reservoir from collapsing during inhalation. Because of the potential adverse effects, patients receiving carbogen should be monitored closely, especially at 7%:93% mixtures. If any significant adverse effects are noted, the therapy should be stopped.[70]

SUMMARY CHECKLIST

- O_2 therapy is used to (1) correct acute hypoxemia, (2) decrease the symptoms of chronic hypoxemia, and (3) decrease cardiopulmonary workload.
- The need for supplemental O_2 can be assessed with laboratory measures, clinical history, and bedside patient evaluation.
- In the care of adults, children, and infants older than 28 days, O_2 therapy is indicated if PaO_2 is less than 60 mm Hg or SaO_2 is less than 90%.
- Exposure to 100% O_2 for more than 24 hours should be avoided whenever possible; high FiO_2 is acceptable if the concentration can be decreased to 0.70 within 2 days and to 0.50 or less in 5 days.
- Concern that O_2 therapy can cause hypoventilation should never preclude administration of O_2 to a patient in need. Prevention of hypoxia always is the first priority.

- If an O_2 delivery system provides all of a patient's inspired gas, FiO_2 remains stable. If the device provides only part of the inspired gas, air dilutes the O_2, and FiO_2 can vary.
- O_2 provided with low-flow devices such as a nasal cannula always is diluted with air; the result is a low and variable FiO_2.
- Reservoir devices can provide higher FiO_2 than low-flow systems or can be used to conserve O_2.
- To avoid rebreathing, a flow of at least 5 L/min should be used with O_2 masks; for reservoir masks with bags, the flow must be sufficient to prevent bag collapse.
- A nonrebreathing reservoir circuit can provide a full range of FiO_2 (21% to 100%) at any needed flow to both intubated and nonintubated patients.
- High-flow systems supply a given O_2 concentration at a flow of at least 60 L/min.
- A high-flow nasal cannula can be useful in treating moderate hypoxemia, especially for patients who don't tolerate oxygen masks and need supplemental humidity.
- Because entrainment devices dilute source O_2 with air, they always provide less than 100% O_2. The more air entrained, the higher the total flow, but the delivered FiO_2 is lower.
- Air-entrainment nebulizers should be treated as fixed-performance devices only when set to deliver low O_2 concentration (≤35%).
- One way to achieve high FiO_2 with air-entrainment nebulizers is to connect two or more devices together in parallel.
- Back pressure decreases both the volume of entrained air and the total flow output of air-entrainment devices.
- A blending system allows precise control over FiO_2 and total flow output; most blending systems qualify as true fixed-performance delivery devices.
- An operational check of an O_2 blender should always be conducted before the device is used.
- O_2 therapy enclosures are used mainly in the care of children and infants. Problems include limited and highly variable FiO_2 and temperature control.
- The three Ps—purpose, patient, and performance of the device—should be considered in the selection or recommendation of an O_2 delivery system.
- In HBO therapy, O_2 is administered at a pressure greater than 1 atm for management of conditions such as air embolism and carbon monoxide poisoning.
- Inhaled NO improves blood flow to ventilated alveoli, reduces intrapulmonary shunting, improves arterial oxygenation, and decreases pulmonary vascular resistance and pulmonary arterial pressure.
- Heliox mixtures are used to reduce the work of breathing in large airways obstruction. The low density of heliox makes standard O_2 flowmeters inaccurate and provides inaccurate volume and flow measurement on ventilators not calibrated for its use.
- Carbogen is used in the management of some neonates with congenital heart disease, to treat hiccups and to prevent complete washout of CO_2 during cardiopulmonary bypass or extracorporeal gas exchange.

CHAPTER 42

Lung Expansion Therapy

DANIEL F. FISHER

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the various causes of atelectasis.
- Identify which patients need lung expansion therapy.
- Define the clinical findings seen in atelectasis.
- Describe how lung expansion therapy works.
- List the indications, hazards, and complications associated with the various modes of lung expansion therapy.
- Describe the primary responsibilities of the respiratory therapist in planning, implementing, and evaluating lung expansion therapy.

CHAPTER OUTLINE

KEY TERMS

atelectasis
compression atelectasis
continuous positive airway pressure (CPAP)
deep breathing/directed cough
gas absorption atelectasis
incentive spirometry (IS)
intermittent positive airway pressure breathing (IPPB)
lobar atelectasis
noninvasive ventilation (NIV)
positive expiratory pressure (PEP)

Pulmonary complications are common serious problems seen in patients who have undergone thoracic or abdominal surgery.[1,2] Such complications include **atelectasis** (alveolar collapse), pneumonia, and acute respiratory failure. These respiratory problems can be minimized or avoided if proper respiratory care is implemented during the perioperative period. The most common form of therapy used in high-risk patients is lung expansion therapy.

Lung expansion therapy encompasses a variety of respiratory care procedures designed to prevent or correct atelectasis. The most common modalities include **deep breathing/directed cough**, **incentive spirometry (IS)**, **continuous positive airway pressure (CPAP)**, **positive expiratory pressure (PEP)**, **intermittent positive airway pressure breathing (IPPB)**, and early patient mobilization. The common purpose that all of these techniques share is improving pulmonary function by maximizing alveolar recruitment and optimizing airway clearance.

Various lung expansion therapies can be effective in preventing or correcting atelectasis in selected patients.[1] There is no one specific method to apply in a given situation because no advantage of any one method has been established. In fact, evidence suggests that patient preference is as important as the chosen therapy.[3] The most efficient use of resources is a primary concern with any plan to apply lung expansion therapy.

All of the following therapies share a common goal, to increase functional residual capacity (FRC). In other words, all of these supplemental techniques are designed to simulate a deep breath or sigh. In consultation with the prescribing

physician, the RT should assist in identifying patients most likely to benefit from lung expansion therapy, recommend and initiate the appropriate and most efficient therapeutic approach, monitor the patient's response, and alter the treatment regimen as needed.

CAUSES AND TYPES OF ATELECTASIS

Although atelectasis can occur from a large variety of problems, this chapter focuses on the two primary types associated with postoperative or bedridden patients who are breathing spontaneously without mechanical assistance: (1) gas absorption atelectasis and (2) compression atelectasis. **Gas absorption atelectasis** can occur either when there is a complete interruption of ventilation to a section of the lung or when there is a significant shift in ventilation/perfusion ($\dot{V}/\dot{Q}$). Gas distal to an obstruction is absorbed by blood passing through the pulmonary capillaries, which eventually causes partial collapse of the nonventilated alveoli. When ventilation is compromised in a larger airway or bronchus, **lobar atelectasis** can develop.

Compression atelectasis occurs when the transthoracic pressure (the pressure difference between the body surface and the alveoli) exceeds the transalveolar pressure (the pressure difference between the alveoli and pleural space).[2,4,5] Compression atelectasis is primarily caused by mechanisms that increase this pressure gradient. This situation is common with general anesthesia, with the use of sedatives and bed rest, and when deep breathing is painful, as when broken ribs are present or surgery has been performed on the upper abdominal region. Weakening or impairment of the diaphragm can also contribute to compression atelectasis. Compression atelectasis also results from fluid overload. It is a common cause of atelectasis in hospitalized patients. It may occur in combination with gas absorption atelectasis in a patient with excessive airway secretions who breathes with small tidal volumes for a prolonged period.

Factors Associated With Causing Atelectasis

Patients who have difficulty taking deep breaths without assistance include those with significant obesity, patients with neuromuscular disorders, patients under heavy sedation, and patients who have undergone upper abdominal or thoracic surgery. Diaphragmatic position and function is the major contributor to the onset of atelectasis. In an anesthetized patient, there is a cephalad (toward the head) shift of the diaphragm. For patients who are supine and breathing spontaneously, the lower, dependent portion of the diaphragm performs the most movement. The opposite occurs in patients who are paralyzed—the upper portion of the diaphragm is involved in movement.[4,5] Patients undergoing lower abdominal surgery are at relatively less risk for developing atelectasis than patients undergoing upper abdominal or thoracic surgery. Neuromuscular injury patients are prone to respiratory complications, the most common of which is atelectasis. Atelectasis can occur in any patient who cannot or does not take deep breaths periodically and in patients who are restricted to bed rest for any reason.[6] Atelectasis is one of the leading causes of hypoxemia after abdominal surgery and may account for 24% of deaths within 6 days of surgery.[7] It is good clinical practice to consider atelectasis during assessment of postoperative patients.

Impairment of the function of pulmonary surfactant can also have an impact on the development of atelectasis. Surfactants decrease the surface tension of the walls of the alveoli. When there is deterioration of the function of this vital protein, the relative increase in surface tension can cause alveoli to collapse.[5]

Most postoperative patients also have problems coughing effectively because of their reduced ability to take deep breaths. An ineffective cough impairs normal clearance mechanisms and increases the likelihood of retained secretions, which could lead to the development of absorption atelectasis and pneumonia in a patient with excessive mucus production. Patients with a history of lung disease that causes increased mucus production (e.g., chronic bronchitis) are most prone to develop complications in the postoperative period. Similarly, a significant history of cigarette smoking should alert the RT to the high risk for respiratory complications with surgery. Such patients must be identified in the preoperative period and considered strong candidates for airway clearance and lung expansion therapy. Elective surgery for these patients may need to be postponed in some cases until such therapies can be included in the treatment plan. Lung expansion therapy in the postoperative period may help improve clearance of secretions by improving the effectiveness of coughing and secretion removal.

RULE OF THUMB

The closer the incision is to the diaphragm, the greater the risk for postoperative atelectasis. Patients with a history of inadequate nutritional intake, as shown by an albumin level less than 3.2 mg/dl, have an increased risk for pulmonary complications in the postoperative period. This increased risk is most likely due to inadequate strength of the inspiratory muscles to maintain a normal VC.

Laproscopic surgery uses a fiberoptic bundle with small incisions to perform the procedure. Use of this technique has gained widespread acceptance in gastrointestinal procedures because of shortened recovery time, less pain for the patient, and smaller incisions. All of this also lessens the opportunities for development of postoperative pulmonary complications.[8,9] Some studies have shown there is a slightly higher cost both monetarily and in personel time for laparoscopic procedures when compared with open incisions. The benefit of this procedure is the shortened recovery time and fewer complications.[8]

CLINICAL SIGNS OF ATELECTASIS

RTs must be able to recognize the clinical signs of atelectasis in patients so that appropriate therapy can be implemented in a

MINI CLINI

Risk Factors for Atelectasis

PROBLEM: The RT is called to evaluate a 47-year-old obese man admitted to the hospital for upper abdominal surgery. He has a 60 pack-year smoking history and is scheduled for surgery tomorrow morning. Examination reveals bilateral inspiratory and expiratory coarse crackles and expiratory wheezes. He is alert and oriented with normal vital signs. His past medical history is positive for diabetes and kidney stones. What factors are present that predispose this patient for postoperative atelectasis, and what treatment plan should the RT recommend?

Discussion: Several important risk factors are present in this patient. The three most important are positive smoking history, obesity, and the site of surgery (upper abdomen). The findings of adventitious lung sounds and positive smoking history are very suggestive of a current pulmonary problem that would probably require bronchial hygiene and bronchodilators before surgery. Delaying the surgery may be necessary if significant secretion retention is present. Postoperatively, this high-risk patient would need careful monitoring for risks of atelectasis.

timely fashion. The patient's medical history often provides the first clue in identifying atelectasis. Recent upper abdominal or thoracic surgery in any patient should suggest possible atelectasis. A history of chronic lung disease or cigarette smoking or both provides additional evidence that the patient is prone to respiratory complications after major surgery or prolonged bed rest.

The physical signs of atelectasis may be absent or very subtle if the patient has minimal atelectasis. When the atelectasis involves a more significant portion of the lungs, the patient's respiratory rate increases proportionally. Fine, late-inspiratory crackles may be heard over the affected lung region. These crackles are produced by the sudden opening of distal airways with deep breathing. Bronchial-type breath sounds may be present as the lung becomes more consolidated with atelectasis. Diminished breath sounds are common when excessive secretions block the airways and prevent transmission of breath sounds. Tachycardia may be present if atelectasis leads to significant hypoxemia.

RULE OF THUMB

There is a direct relationship between the spontaneous respiratory rate and the degree of atelectasis present. Typically, as atelectasis progresses, respiratory rate increases proportionally.

The chest radiograph is often used to confirm the presence of atelectasis. The atelectatic region of the lung has increased opacity. Evidence of volume loss is present in patients with significant atelectasis. Direct signs of volume loss on the chest film include displacement of the interlobar fissures, crowding of the pulmonary vessels, and air bronchograms. Indirect signs include elevation of the diaphragm; shift of the trachea, heart, or mediastinum; pulmonary opacification; narrowing of the space between the ribs; and compensatory hyperexpansion of the surrounding lung.

LUNG EXPANSION THERAPY

All modes of lung expansion therapy increase lung volume by increasing the transpulmonary pressure (P_{TP}) gradient. As detailed elsewhere in this text (Chapters 46 and 51), P_{TP} gradient represents the difference between the alveolar pressure (P_{alv}) and the pleural pressure (P_{pl}):

$$P_{TP} = P_{alv} - P_{pl}$$

With all else being constant, the greater the P_{TP} gradient, the more that the alveoli expand.

As depicted in Figure 42-1, the P_{TP} gradient can be increased by either (1) decreasing the surrounding P_{pl} (see Figure 42-1, *A*) or (2) increasing the P_{alv} (see Figure 42-1, *B*). A spontaneous deep inspiration increases the P_{TP} gradient by decreasing the P_{pl}. The application of positive pressure to the lungs increases the P_{TP} gradient by increasing the pressure inside the lung (P_{alv}).

All lung expansion therapies use one of these two approaches. IS enhances lung expansion via a spontaneous and sustained decrease in P_{pl}. Positive airway pressure techniques increase P_{alv} in an effort to expand the lung. Positive pressure lung expansion therapies may apply pressure during inspiration only (as in IPPB), during expiration only (as in PEP and flutter valves), or during both inspiration and expiration (CPAP). Although all of these approaches are used in lung expansion therapy, the methods that decrease P_{pl} (e.g., IS) have more of a physiologic effect than the methods that increase P_{alv} and often are most effective. IS and other patient-directed therapies require an alert, cooperative patient who is capable of taking a deep breath.

The goal of any lung expansion therapy should be to implement a plan that provides an effective strategy in the most efficient manner. Staff time and equipment are the two major issues related to efficiency. For a patient with minimal risk of postoperative atelectasis, deep breathing exercises, frequent repositioning, and early ambulation are usually effective and can be done with minimal coaching and time from clinicians

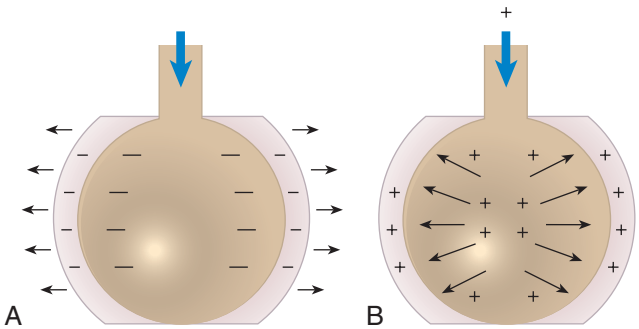

FIGURE 42-1 Transpulmonary pressure gradients with spontaneous inspiration **(A)** and positive pressure inspiration **(B).**

and without equipment.[5] For a patient at high risk for atelectasis (e.g., a patient undergoing upper abdominal surgery), IS is usually instituted. The additional staff time and equipment are justified in this high-risk group. Positive pressure therapy requires significantly more staff time and equipment and is reserved for high-risk patients who cannot perform IS techniques.

Incentive Spirometry

The purpose of IS is to coach the patient to take a sustained maximal inspiratory (SMI) effort resulting in a decrease in P_{pl} and maintaining the patency of airways at risk for closure. Because of its simplicity, IS has been the mainstay of lung expansion therapy for many years. IS devices are designed to mimic natural sighing by encouraging patients to take slow, deep breaths simulating a yawn or sigh. IS can be performed using devices that provide visual cues to patients when the desired inspiratory flow or volume has been achieved. Incentive spirometry was first described in 1972, which led to the development of a visual feedback device in 1973.[10]

The desired volume and number of repetitions to be performed are initially set by the RT or other qualified caregiver. The inspired volume goal is set on the basis of predicted values or observation of initial performance. The true benefit from IS is best achieved by repeated use and proper technique.[11] The American Association for Respiratory Care (AARC) has developed and published a clinical practice guideline on IS; excerpts from this guideline appear in Clinical Practice Guideline 42-1.

42-1 Incentive Spirometry

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS
- Presence of conditions predisposing to the development of pulmonary atelectasis (upper abdominal surgery, thoracic surgery, surgery in patients with COPD)
- Presence of pulmonary atelectasis
- Presence of restrictive lung defect associated with quadriplegia or dysfunctional diaphragm

CONTRAINDICATIONS
- Patient cannot be instructed or supervised to ensure appropriate use of device
- Patient cooperation is absent, or patient is unable to understand or demonstrate proper use of device
- Patient is unable to deep breathe effectively (e.g., with VC <10 ml/kg or IC <⅓ predicted)
- Presence of an open tracheal stoma is not a contraindication but requires adaptation of the spirometer

HAZARDS AND COMPLICATIONS
- Ineffective unless closely supervised or performed as ordered
- Inappropriate as sole treatment for major lung collapse or consolidation
- Hyperventilation
- Barotrauma (emphysematous lungs)
- Discomfort secondary to inadequate pain control
- Hypoxia owing to break in mask O_2 therapy
- Exacerbation of bronchospasm
- Fatigue

ASSESSMENT OF NEED
- Surgical procedure involving upper abdomen or thorax
- Conditions predisposing to atelectasis, including immobility, poor pain control, and abdominal binders
- Presence of neuromuscular disease involving respiratory musculature

ASSESSMENT OF OUTCOME
- Absence of or improvement in signs of atelectasis
- Decreased respiratory rate
- Resolution of fever
- Normal pulse rate
- Absence of crackles or presence of or improvement in previously absent or diminished breath sounds
- Normal chest radiograph
- Improved PaO_2 and decreased alveolar-arterial O_2 tension gradient
- Increased VC and peak expiratory flows
- Return of FRC or VC to preoperative values, in absence of lung resection
- Improved inspiratory muscle performance (e.g., attainment of preoperative flow and volume levels, increased FVC)

MONITORING
Direct supervision of every patient performance is unnecessary after the patient has demonstrated mastery of technique; however, preoperative instruction, volume goals, and feedback are essential to optimal performance.
- Observation of patient performance and use
- Frequency of sessions
- Number of breaths per session
- Inspiratory volume or flow goals achieved and 3- to 5-second breath hold maintained
- Effort and motivation
- Periodic observation of patient compliance with technique, with additional instruction as necessary
- Device within reach of patient and patient encouraged to perform independently
- New and increasing inspiratory volumes established each day
- Vital signs

**For complete guidelines, see American Association for Respiratory Care: Clinical practice guidelines: incentive spirometry. Respir Care 56:1600, 2011.*

Physiologic Basis

An SMI is functionally equivalent to performing a functional residual capacity (FRC) to inspiratory capacity (IC) maneuver, followed by a breath hold. Figure 42-2 compares the alveolar and P_{pl} changes occurring during a normal spontaneous breath and an SMI during IS.

During the inspiratory phase of spontaneous breathing, the decrease in P_{pl} caused by expansion of the thorax is transmitted to the alveoli. With P_{alv} now negative, a pressure gradient is created between the airway opening and the alveoli. This transrespiratory pressure gradient causes gas to flow from the airway into the alveoli. Within certain limits, the greater the transrespiratory pressure gradient, the more that lung expansion occurs.

Indications

Indications for IS are listed in Box 42-1. The primary indication for IS is to treat existing atelectasis. IS may also be used as a preventive measure when conditions exist that make the development of atelectasis likely.[7]

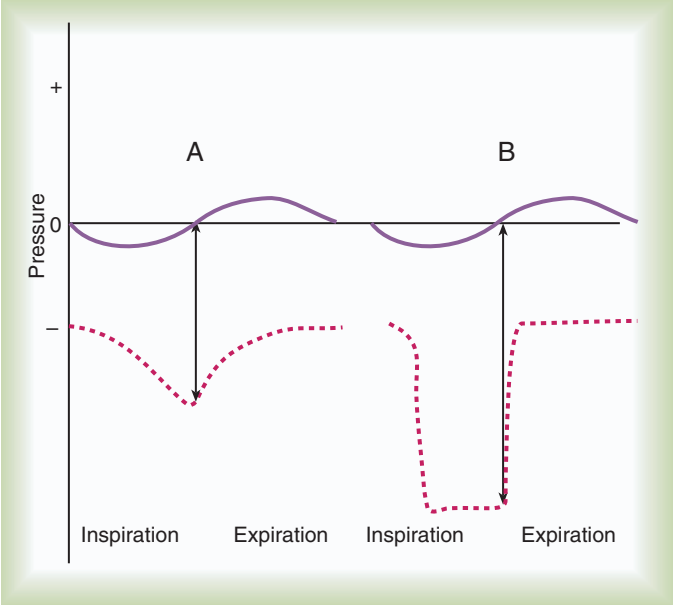

FIGURE 42-2 Alveolar *(solid lines)* and pleural *(dotted lines)* pressure changes during spontaneous breathing *(A)* and SMI *(B)*. Note the difference in P_{TP} gradients *(double arrows)*.

Box 42-1 Indications for Incentive Spirometry

- Presence of pulmonary atelectasis
- Presence of conditions predisposing to atelectasis
  - Upper abdominal surgery
  - Thoracic surgery
  - Surgery in patients with COPD
- Presence of a restrictive lung defect associated with quadriplegia or dysfunctional diaphragm

Contraindications

IS is a simple and relatively safe modality. For this reason, contraindications are few (Box 42-2).

Hazards and Complications

Given its normal physiologic basis, IS presents few major hazards and complications; those that can occur are listed in Box 42-3. Acute respiratory alkalosis is the most common problem and occurs when the patient performs IS too rapidly, or if the prescribed frequency of therapy is mismatched.[12] Dizziness and numbness around the mouth are the most frequently reported symptoms associated with respiratory alkalosis. This can be easily corrected with careful instruction and monitoring of the patient. Discomfort with deep inspiratory efforts secondary to pain is usually the result of inadequate pain control in a postoperative patient. Appropriate pain control prior to and during therapy is important.

Equipment

The equipment needed for SMI is typically simple, portable, and inexpensive. Although advances in technology have produced more complex devices, there is no evidence that these devices produce any better outcomes than their lower cost, disposable counterparts.

IS devices can generally be categorized as volume-oriented or flow-oriented. True volume-oriented devices measure and visually indicate the volume achieved during an SMI. The most popular true volume-oriented IS devices employ a bellows that rises according to the inhaled volume. When the patient reaches a target inspiratory volume, a controlled leak in the device allows the patient to sustain the inspiratory effort for a short period (usually 5 to 10 seconds). Because the bellows types of IS devices are bulky and large, smaller devices that indirectly indicate volume based on flow through a fixed orifice have been

Box 42-2 Contraindications for Incentive Spirometry

- Patient cannot be instructed or supervised to ensure appropriate use of device
- Patient cooperation is absent, or patient is unable to understand or demonstrate proper use of device
- Patients unable to deep breathe effectively (VC <10 ml/kg *or* IC <⅓ predicted)

Box 42-3 Hazards and Complications of Incentive Spirometry

- Hyperventilation and respiratory alkalosis
- Discomfort secondary to inadequate pain control
- Pulmonary barotrauma
- Exacerbation of bronchospasm
- Fatigue

FIGURE 42-3 Volumetric incentive spirometer. (Courtesy DHE Healthcare, Canastota, NY.)

FIGURE 42-4 Flow-oriented incentive spirometer. (From DeWit, S: Fundamental concepts and skills for nursing, ed 2, St Louis, 2004, Saunders.)

developed. These devices sacrifice accurate measurement of the inhaled volume to achieve portability and smaller size (Figure 42-3).

Flow-oriented devices measure and visually indicate the degree of inspiratory flow (Figure 42-4). This flow can be equated with volume by assessing the duration of inspiration or time (flow × time = volume). Both flow-oriented and volume-oriented devices attempt to encourage the same goal for the patient: a sustained maximal inspiratory effort to prevent or correct atelectasis. There is no benefit of one type of IS over the other.

Box 42-4 Potential Outcomes of Incentive Spirometry

- Absence of or improvement in signs of atelectasis
- Decreased respiratory rate
- Normal pulse rate
- Resolution of abnormal breath sounds
- Normal or improved chest radiograph
- Improved PaO_2 and decreased $PaCO_2$
- Increased SpO_2
- Increased VC and peak expiratory flows
- Restoration of preoperative FRC or VC
- Improved inspiratory muscle performance and cough
- Attainment of preoperative flow and volume levels
- Increased FVC

Administration

The successful application of IS involves three phases: planning, implementation, and follow-up. Because many of the components of this process are similar to those previously described, we highlight only the key points and differences in approach.

Preliminary Planning. During preliminary planning, the need for IS should be determined by careful patient assessment. Once the need is established, planning should focus on selecting specific therapeutic outcomes. Box 42-4 lists potential outcomes that can be considered for patients receiving IS.

Patients scheduled for upper abdominal or thoracic surgery should be screened before undergoing the surgical procedure. Assessment conducted at this point helps to identify patients at high risk for complications and allows determination of their baseline lung volumes and capacities. This approach provides an opportunity to orient high-risk patients to the procedure before undergoing surgery, increasing the likelihood of success when IS is provided after surgery.

Implementation. Successful IS requires effective patient teaching. The RT should set an initial goal that is attainable by the patient yet requires a moderate effort. Setting an initial goal that is too low for the patient results in little incentive and an ineffective maneuver, at least initially. The patient should be instructed to inspire slowly and deeply to maximize the distribution of ventilation.

The RT should observe the patient perform the initial inspiratory maneuvers and ensure the patient uses correct technique. Correct technique calls for diaphragmatic breathing at slow to moderate inspiratory flows. Demonstration is probably the most effective way to assist patient understanding and cooperation. Both the operation of the device and the proper breathing technique can be explained easily when the RT uses himself or herself as an example, and much trial and error can be avoided.

Many patients have difficulty with the slow inspiration followed by the breath hold. Nonetheless, patients should be encouraged to try not to breathe in too fast or slowly and to attempt a brief breath hold.

A normal exhalation should follow the breath hold, and the patient should be given the opportunity to rest as long as needed before the next SMI maneuver. Some patients in the early

postoperative stage may need to rest for 30 seconds to 1 minute between maneuvers. This rest period helps avoid a common tendency by some patients to repeat the maneuver at rapid rates, causing respiratory alkalosis. The goal is not rapid, partial lung inflation but intermittent, maximal inspiration.

The exact number of sustained maximal inspirations needed to reverse or prevent atelectasis is not known and probably varies according to the patient's clinical status. However, because healthy individuals average about 6 sighs per hour, an IS regimen should probably aim to ensure a minimum of 5 to 10 SMI maneuvers each hour.[12]

Follow-up. Assessing the patient's performance is vital to ensuring achievement of goals. To do so, the RT should make return visits to monitor treatment sessions until the correct technique and appropriate effort are achieved. Suggested monitoring activities for IS are outlined in Box 42-5.

After the patient has demonstrated mastery of technique, IS may be performed with minimal supervision. For patients with a neuromuscular disease or spinal injury, the use of a mechanical cough device (in-exsufflator) may provide a similar therapeutic objective. There is a lack of supporting data that IS has an effect of preventing or reversing pulmonary complications in post cardiac surgery patients, or those patients who have recently had upper abdominal surgery.[10,13] This is not implying that the therapy does not work, but strengthens the need to have more robust studies to evaluate this modality.

Noninvasive Ventilation

Noninvasive ventilation (NIV) provides breathing support to patients with inadequate ability to ventilate. NIV has been documented to have beneficial effects for patients who may need periodic, short-term support or patients who are experiencing exacerbations of pulmonary disease. NIV offers some benefits over traditional, invasive ventilation owing to lower infection risk and reduced need for sedation because of the absence of an artificial airway. NIV is discussed in detail elsewhere (Chapter 49). In addition, variations of NIV, including IPPB and PEP therapy, can be potentially valuable lung expansion tools and are discussed in the following sections.

Box 42-5 Monitoring Patients Receiving Incentive Spirometry

Observe patient performance and use:

- Frequency of sessions
- Number of breaths per session
- Volume and flow goals achieved
- Breath hold maintained
- Effort and motivation
- Periodic observation of patient compliance, with additional instruction as needed
- Device within reach of patient and patient encouraged to perform independently
- New and increasing inspiratory volumes established each day
- Vital signs and breath sounds

Intermittent Positive Airway Pressure Breathing

Physiologic Basis

IPPB is a specialized form of NIV used for relatively short treatment periods (approximately 15 minutes per treatment). The intent of IPPB, unlike NIV, is not to provide full ventilatory support but to provide machine-assisted deep breaths assisting the patient to deep breathe and stimulate a cough. This section discusses the use of IPPB as a modality for the treatment of atelectasis.

IPPB has historically consisted of providing an aerosol under positive pressure, augmenting the patient's own inspiratory efforts and thus resulting in a larger tidal volume (V_T) than could be spontaneously generated. The effectiveness of IPPB as an enhancement for aerosol delivery has been shown to be incorrect. In fact, IPPB does not improve aerosol deposition at all.[3] The AARC CPG for IPPB even recommends a 10-fold increase in medication dosage when compared with other aerosol delivery methods.[14] Lung volumes are increased in IPPB because $P_{alv} > P_{pl}$. Depending on the mechanical properties of the lung, P_{pl} may exceed atmospheric pressure during a portion of inspiration. As with spontaneous breathing, the recoil force of the lung, stored as potential energy during the positive pressure breath, causes a passive exhalation. As gas flows from the alveoli out to the airway opening, P_{alv} decreases to atmospheric level, while P_{pl} is restored to its normal subatmospheric range (Figure 42-5). The AARC has developed and published a clinical practice guideline for IPPB; excerpts from this guideline appear in Clinical Practice Guideline 42-2.

Indications

Although IPPB is not an effective aerosol delivery system, periodic sessions of positive pressure ventilation provided noninvasively can be useful in the treatment of pulmonary complications

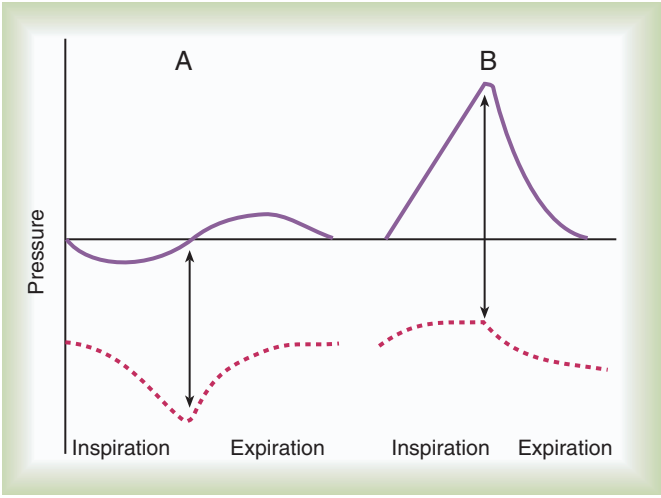

FIGURE 42-5 Alveolar *(solid lines)* and pleural *(dotted lines)* pressure changes during spontaneous breathing *(A)* and IPPB *(B)*. Note the difference in P_{TP} gradients *(double arrows)*.

42-2 Intermittent Positive Pressure Breathing

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

- Need to improve lung expansion
- Presence of clinically significant pulmonary atelectasis when other forms of therapy (e.g., IS) have been unsuccessful or the patient cannot cooperate
- Inability to clear secretions adequately because of pathology that severely limits the ability to ventilate or cough effectively and failure to respond to other modes of treatment
- Need for short-term noninvasive ventilatory support for hypercapnic patients (as an alternative to intubation and continuous ventilatory support)
- Need to deliver aerosol medication
- Although some authors oppose the use of IPPB in the treatment of severe bronchospasm (e.g., acute asthma), we recommend a careful, closely supervised trial of IPPB when treatment using other techniques (metered dose inhaler [MDI] or nebulizer) has been unsuccessful
- IPPB may be used to deliver aerosol medications to patients with ventilatory muscle weakness or fatigue or chronic conditions in which intermittent noninvasive ventilatory support is indicated.

CONTRAINDICATIONS

Although no absolute contraindications to use of IPPB therapy (except tension pneumothorax) have been reported, a patient with any of the following should be carefully evaluated before a decision is made to initiate IPPB therapy:

- ICP >15 mm Hg
- Hemodynamic instability
- Recent facial, oral, or skull surgery
- Tracheoesophageal fistula
- Recent esophageal surgery
- Active hemoptysis
- Nausea
- Air swallowing
- Active, untreated tuberculosis
- Radiographic evidence of bleb
- Singultus (hiccups)

HAZARDS AND COMPLICATIONS

- Increased airway resistance
- Barotrauma, pneumothorax
- Nosocomial infection
- Hyperventilation or hypocapnia
- Hemoptysis
- Hyperoxia when O_2 is the gas source
- Gastric distention
- Secretion impaction (inadequate humidity)
- Psychological dependence
- Impedance of venous return
- Exacerbation of hypoxemia
- Hypoventilation
- Increased $\bar{V}/\dot{Q}$ mismatch
- Air trapping, auto-PEEP, overdistended alveoli

ASSESSMENT OF NEED

- Presence of clinically significant atelectasis
- Reduced timed volumes or VC (e.g., FEV_1 <65% predicted, FVC <70% predicted, maximum voluntary ventilation <50% predicted, or VC <10 ml/kg) precluding an effective cough
- Neuromuscular or skeletal disorders associated with decrease in lung volumes and capacities
- Fatigue or muscle weakness with impending respiratory failure
- Presence of acute, severe bronchospasm or exacerbated COPD that fails to respond to other therapy (consider MDI with spacer or holding chamber first)
- With demonstrated effectiveness, the patient's preference for a positive pressure device should be honored

ASSESSMENT OF OUTCOME

- A minimum delivered tidal volume of at least one-third of predicted IC ($\frac{1}{3} \times 50$ ml/kg) has been suggested
- FEV_1 or peak flow increase
- Cough more effective with treatment
- Secretion clearance enhanced as a consequence of deep breathing and coughing
- Chest radiograph improved
- Breath sounds improved
- Favorable patient subjective response

MONITORING

Items from the following list should be chosen as appropriate for the specific patient:

- Machine performance (trigger sensitivity, peak pressure, flow settings, FiO_2, inspiratory time, expiratory time, plateau pressure, PEEP)
- Respiratory rate and volume
- Peak flow or FEV_1/FVC
- Pulse rate and rhythm from electrocardiogram if available
- Patient subjective response to therapy (pain, discomfort, dyspnea)
- Sputum production (quantity, color, consistency, and odor)
- Mental function
- Skin color
- Breath sounds
- Blood pressure
- Arterial hemoglobin saturation by pulse oximetry (if hypoxemia is suspected)
- ICP in patients for whom ICP is of critical importance
- Chest radiograph

**For complete guidelines, see American Association for Respiratory Care: Intermittent positive pressure breathing—2003 revision and update. Respir Care 48:540, 2003.*

or exacerbations of lung disease.[12,15-17] CPAP or NIV may be the more appropriate treatments for patients with clinically diagnosed atelectasis unresponsive to other therapies, such as IS. IPPB should not be used as a single treatment modality for a patient with absorption atelectasis because of excessive airway secretions. Appropriate systemic hydration and airway clearance techniques should be used to assist in removal of excessive secretions.

In concept, IPPB treatment should provide the patient with augmented tidal volumes, achieved with minimal effort. There is no data to support the use of IPPB as a method of preventing or expanding atelectasis. However both the use of CPAP and NIV have shown promise in the management of postoperative respiratory complications.[7,18]

Contraindications

There are several clinical situations in which IPPB should not be used (Box 42-6). With the exception of untreated tension pneumothorax, most of these contraindications are relative. As with all procedures, a sound knowledge of the patient's condition tempered with good clinical insight should guide the RT in the decision-making process. A patient with any of the conditions listed in Box 42-6 should be carefully evaluated before a decision is made to begin IPPB therapy.

Hazards and Complications

As with any clinical intervention, certain hazards and complications are associated with IPPB. These potential problems should be addressed in the initial stages of planning for IPPB. In addition, hazards and complications must be considered throughout the course of therapy as part of the process of assessing the patient for unwanted side effects. The most common complication associated with IPPB is the inducement of respiratory alkalosis. Respiratory alkalosis is induced when the patient hyperventilates during the treatment. Deep, fast breathing leads to a sharp decrease in PCO_2 and an equally marked increase in arterial pH. The patient usually feels light-headed and numb around the mouth. Arrhythmias are also possible if the alkalosis is severe or if the patient has significant heart disease. This problem is easily avoided through proper coaching of the patient before and during treatment.

Another potential complication of IPPB is gastric distention; this occurs when gas from the IPPB device passes directly into the esophagus. Gastric distention is uncommon in an alert patient but is a significant risk for a neurologically obtunded patient. Normally, the esophagus does not open until a pressure of about 20 to 25 cm H_2O has been reached. Gastric distention represents the greatest risk in patients receiving IPPB at high pressures. The major hazards and complications of IPPB are listed in Box 42-7.

Administration

Effective IPPB requires careful preliminary planning, individualized patient assessment and implementation, and thoughtful follow-up. In all three phases of the process, the RT should work closely with the prescribing physician to determine patient need, select the appropriate therapeutic approach, and assess patient progress toward predefined clinical outcomes.

Preliminary Planning. During preliminary planning, the need for IPPB is determined, and desired therapeutic outcomes are established. The outcomes chosen for a patient are based on diagnostic information that supports the need for IPPB therapy. In addition, therapeutic outcomes should be as explicit and measurable as possible. Box 42-8 lists potential accepted and

Box 42-6 Clinical Situations Contraindicating Intermittent Positive Airway Pressure Breathing Therapy

- Tension pneumothorax
- ICP >15 mm Hg
- Hemodynamic instability
- Active hemoptysis
- Tracheoesophageal fistula
- Recent esophageal surgery
- Active, untreated tuberculosis
- Radiographic evidence of blebs
- Recent facial, oral, or skull surgery
- Singultus (hiccups)
- Air swallowing
- Nausea

Box 42-7 Hazards and Complications of Intermittent Positive Airway Pressure Breathing

- Increased airway resistance and work of breathing
- Barotrauma, pneumothorax
- Nosocomial infection
- Hypocarbia
- Hemoptysis
- Gastric distention
- Impaction of secretions (associated with inadequately humidified gas mixture)
- Psychologic dependence
- Impedance of venous return
- Exacerbation of hypoxemia
- Hypoventilation or hyperventilation
- Increased mismatch of ventilation and perfusion
- Air trapping, auto-PEEP, overdistention

Box 42-8 Potential Outcomes of Intermittent Positive Airway Pressure Breathing Therapy

- Improved VC
- Increased FEV_1 or peak flow
- Enhanced cough and secretion clearance
- Improved chest radiograph
- Improved breath sounds
- Improved oxygenation
- Favorable patient subjective response

desired outcomes of IPPB therapy. Not all the outcomes listed in Box 42-8 apply to every patient. For example, for a patient exhibiting clinical signs and symptoms of postoperative atelectasis, the following outcomes might be set: improved patient comfort, increased aeration on auscultation, decreased respiratory rate and work of breathing, and improvement in the chest radiograph.

Evaluating Alternatives. Before starting IPPB, the RT and prescribing physician must determine therapeutic objectives for the treatment and whether simpler and less costly methods might be as effective in achieving the desired outcomes.

Baseline Assessment. Before beginning therapy, a baseline patient assessment should be conducted. This information helps individualize the treatment and allows objective evaluation of the patient's subsequent response to therapy. Together with the patient's medical history, this baseline assessment also alerts the RT to possible problems or hazards associated with administering IPPB to the patient. The baseline assessment includes a general evaluation of the patient's clinical status and a specific assessment related to the chosen therapeutic goals. The general assessment, common to all patients for whom IPPB is ordered, includes (1) measurement of vital signs, (2) observational assessment of the patient's appearance and sensorium, and (3) breathing pattern and chest auscultation.

Discontinuation and Follow-up

Depending on the goals of therapy and condition of the patient, IPPB treatments typically last 10 to 15 minutes. Follow-up activities include posttreatment assessment of the patient, recordkeeping, and equipment maintenance.

Posttreatment Assessment. At the end of a treatment session, the patient assessment is repeated. As with the baseline assessment, this follow-up evaluation has two components. The general follow-up evaluation of the patient's clinical status should focus on determining any pertinent changes in vital signs, sensorium, and breath sounds, with emphasis on identifying possible untoward effects. The more specific follow-up assessment provides information relevant to evaluating progress toward achieving the chosen goals of therapy.

Treatment frequency should be determined by assessing patient response to therapy (Box 42-9). For acute care patients, orders should be reevaluated based on patient response to therapy at least every 72 hours or with any change of patient status.

Other Therapies

There are other therapies available to the respiratory therapist with the aim of secretion clearance and possible treatment of postoperative pulmonary complications: intrapulmonary percussive ventilation (IPV), and high-frequency chest wall compression (HFCWC). There is a lack of supporting evidence for the effectiveness of either of these therapies, although each is similar to techniques previously discussed within this chapter. IPV is similar to IPPB with a high respiratory rate, and HFCWC is similar to CPT using a pneumatic vest that the patient wears. These modalities are mentioned for completeness, although the evidence supporting them is low-level, or anectdotal.[3,19]

Box 42-9 Monitoring Intermittent Positive Airway Pressure Breathing Therapy

MACHINE PERFORMANCE
- Sensitivity

- Pulse rate and rhythm (from electrocardiogram if available)
- Sputum quantity, color, consistency, and odor
- Mental function
- Skin color
- Breath sounds
- Blood pressure
- SpO_2 (if hypoxemia is suspected)
- ICP (in patients for whom ICP is important)
- Chest radiograph (when appropriate)
- Subjective response to therapy

*Items should be chosen as appropriate for the specific patient.

Positive Airway Pressure Therapy

Similar to IPPB, positive airway pressure (PAP) adjuncts use positive pressure to increase the P_{TP} gradient and enhance lung expansion. In contrast to IPPB, PAP therapy requires no complex machinery. Some methods do not even need a source of pressurized gas.

Physiologic Basis

There are three current approaches to PAP therapy: PEP, flutter, and CPAP. All three techniques are effective in treating atelectasis in most postsurgical patients.[20,21] Because PEP and flutter are used most often as part of airway clearance, they are described in Chapter 43. This chapter describes the intermittent use of CPAP for the treatment of atelectasis.

PEP and flutter valves create expiratory positive pressure only, whereas CPAP maintains a positive airway pressure throughout both inspiration and expiration. Figure 42-6 compares the alveolar and P_{pl} changes occurring during a normal spontaneous breath (Figure 42-6, *A*) and CPAP (see Figure 42-6, *B*). As can be seen, CPAP elevates and maintains high alveolar and airway pressures throughout the full breathing cycle; this increases P_{TP} gradient throughout both inspiration and expiration. Typically, a patient on CPAP breathes through a pressurized circuit against a threshold resistor, with pressures maintained between 5 cm H_2O and 20 cm H_2O. To maintain system pressure throughout the breathing cycle, CPAP requires a source of pressurized gas.

The following factors involving PAP, flutter, and CPAP therapy contribute to the beneficial effects: (1) recruitment of

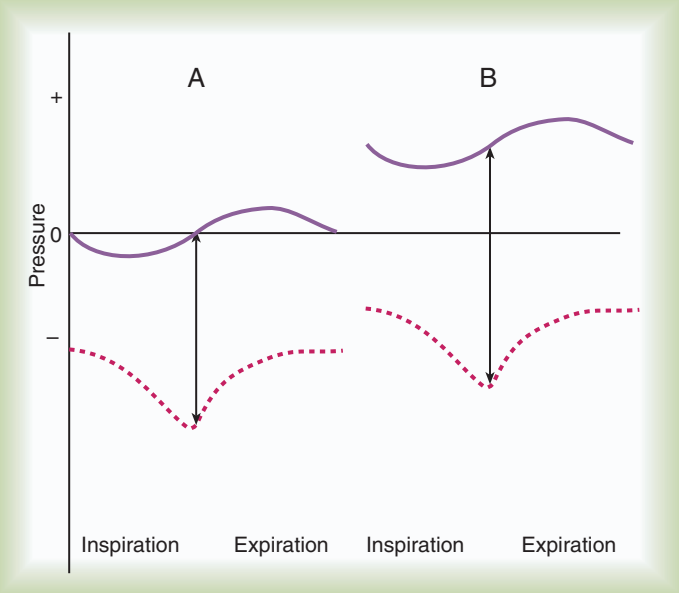

FIGURE 42-6 Alveolar *(solid lines)* and pleural *(dotted lines)* pressures during spontaneous breathing *(A)* and CPAP *(B)*. Note the difference in P_{TP} gradients *(double arrows)*.

collapsed alveoli via an increase in FRC, (2) decreased work of breathing secondary to increased compliance or elimination of intrinsic positive end expiratory pressure (PEEP), (3) improved distribution of ventilation through collateral channels (e.g., pores of Kohn), and (4) increase in the efficiency of secretion removal.

Indications

Although evidence exists to support the use of CPAP therapy in the treatment of postoperative atelectasis, as with all mechanical techniques, the duration of beneficial effects appears limited. The corresponding increase in FRC may be lost within 10 minutes after the end of the treatment. For this reason, it has been suggested that CPAP should be used on a continuous basis until the patient recovers.

CPAP by mask also has been used to treat cardiogenic pulmonary edema. In such patients, CPAP reduces venous return and cardiac filling pressures, which is helpful in reducing pulmonary vascular congestion. Lung compliance is improved, and the work of breathing is decreased.

Contraindications

Intermittent use of CPAP for the correction of atelectasis is contraindicated when certain clinical situations exist. A patient who is hemodynamically unstable is unlikely to tolerate CPAP for even a short period. A patient who is suspected to have hypoventilation is not a good candidate for CPAP because it does not ensure ventilation, but the patient may be an ideal candidate for consideration of NIV. Other problems that may indicate CPAP is not an appropriate therapy include nausea, facial trauma, untreated pneumothorax, and elevated intracranial pressure (ICP).

Hazards and Complications

Most hazards and complications associated with CPAP are caused by either the increased pressure or the apparatus. The increased work of breathing caused by the apparatus can lead to hypoventilation and hypercapnia. In addition, because CPAP does not augment spontaneous ventilation, patients with an accompanying ventilatory insufficiency may hypoventilate during application. Barotrauma is a potential hazard of CPAP and is more likely to occur in a patient with emphysema and blebs. Gastric distention may occur especially if CPAP values greater than 20 cm H_2O are needed. This condition may lead to vomiting and aspiration in a patient with an inadequate gag reflex.

Equipment

CPAP is most commonly delivered using either specialized CPAP machines (Figure 42-7), or ventilators. These devices allow for a more consistent level of positive pressure and provide the benefit of some level of patient monitoring. In the case where ICU-level ventilators are used, this includes monitoring of respiratory rate, airway pressures, and alarms. In the event of a disconnect, or if the patient becomes apneic, the ventilator can provide a measure of safety not realized with a high-flow system and resistor valve.

Administering Intermittent Continuous Positive Airway Pressure

As with all respiratory care, effective CPAP therapy requires careful planning, individualized patient assessment and implementation, and thoughtful follow-up.

Planning. During planning, the need for PAP therapy should be determined, and desired therapeutic outcomes should be set. Specifically, an improvement in breath sounds, improvement in vital signs (e.g., lower respiratory rate), resolution of abnormal radiograph findings, and restoration of normal oxygenation all would indicate that the therapy has achieved its goal.

Procedures. Whether used on an intermittent or continuous basis, CPAP is a complex and potentially hazardous approach to patient management. As with all therapies, the appropriate CPAP level for a patient must be determined on an individual basis. Initial application and monitoring require a broader range of knowledge and skill than required for simpler modes of lung expansion therapy.

Monitoring and Troubleshooting

CPAP poses a danger of hypoventilation. Experience with long-term CPAP shows that patients must be able to maintain adequate excretion of carbon dioxide on their own if the therapy is to be successful. For these reasons, patients receiving CPAP must be closely and continuously monitored for untoward effects. In addition, it is vital that the CPAP device be equipped with a means to monitor the pressure delivered to the airways and alarms to indicate the loss of pressure owing to system disconnect or mechanical failure. There should also be a device allowing for excessive pressure to be released (pop-off). These are essential components of any CPAP device.

FIGURE 42-7 Various CPAP systems. See text for description.

The most common problem with PAP therapies is system leaks. When using a mask, a tight seal must be maintained to keep pressure levels above atmospheric levels. Any significant leaks in the system result in the loss of PAP. Because a tight seal requires a tight-fitting mask, pain and irritation may occur in some patients, especially if the therapy is prolonged.

The development of new CPAP units and improvement on the interface itself have addressed some of the comfort issues and correction of leakage associated with CPAP. The RT must also ensure that the flow is adequate to meet the patient's needs with the use of CPAP systems. Flow adjustments are made by carefully observing the airway pressure. Flow generally can be considered adequate when the system pressure decreases no more than 1 to 2 cm H_2O during inspiration.

SELECTING AN APPROACH

The best approach for achieving a given clinical goal is always the safest, simplest, and most effective method for an individual patient. Selecting an approach for lung expansion therapy requires in-depth knowledge of both the methods available and the specific condition and needs of the patient being considered for therapy.

Figure 42-8 presents a sample protocol for selecting an approach to lung expansion therapy. As indicated in the algorithm, the patient first must meet the criteria for therapy by having one or more of the indications previously specified. For patients meeting the inclusion criteria, the RT first determines the degree of alertness. Because an obtunded patient cannot be expected to cooperate with IS or PEP or EPAP therapy, IPPB or NIV is initiated with appropriate monitoring.

For a patient having no difficulty with secretions, if the VC exceeds 15 ml/kg of lean body weight or the IC is greater than 33% of predicted, IS is given. If either the VC or the IC is less than these threshold levels, IPPB is initiated, with the pressure gradually manipulated from the initial setting to deliver at least 15 ml/kg.

If excessive sputum production is a compounding factor, a trial of PEP therapy is substituted for IS. Based on patient response, bronchodilator therapy and bronchial hygiene measures may be added to this regimen. If monitoring fails to reveal improvement and atelectasis persists, a trial of CPAP should be considered. Because evidence of the effectiveness of CPAP is still contradictory, its use should be limited to treating atelectasis after alternative approaches have been tried without success.

Early Mobilization of the ICU Patient

Whether or not to keep critically ill patients on complete bed rest is being critically examined in the literature.[22-25] The complications of prolonged bed rest include cardiovascular, pulmonary, gastrointestinal, and skin integrity issues. Pulmonary issues include those that have been the focus of this chapter: development of atelectasis, pneumonia, and pulmonary emboli (PE).[23-25] Rates of early mobilization for ICU patients have been

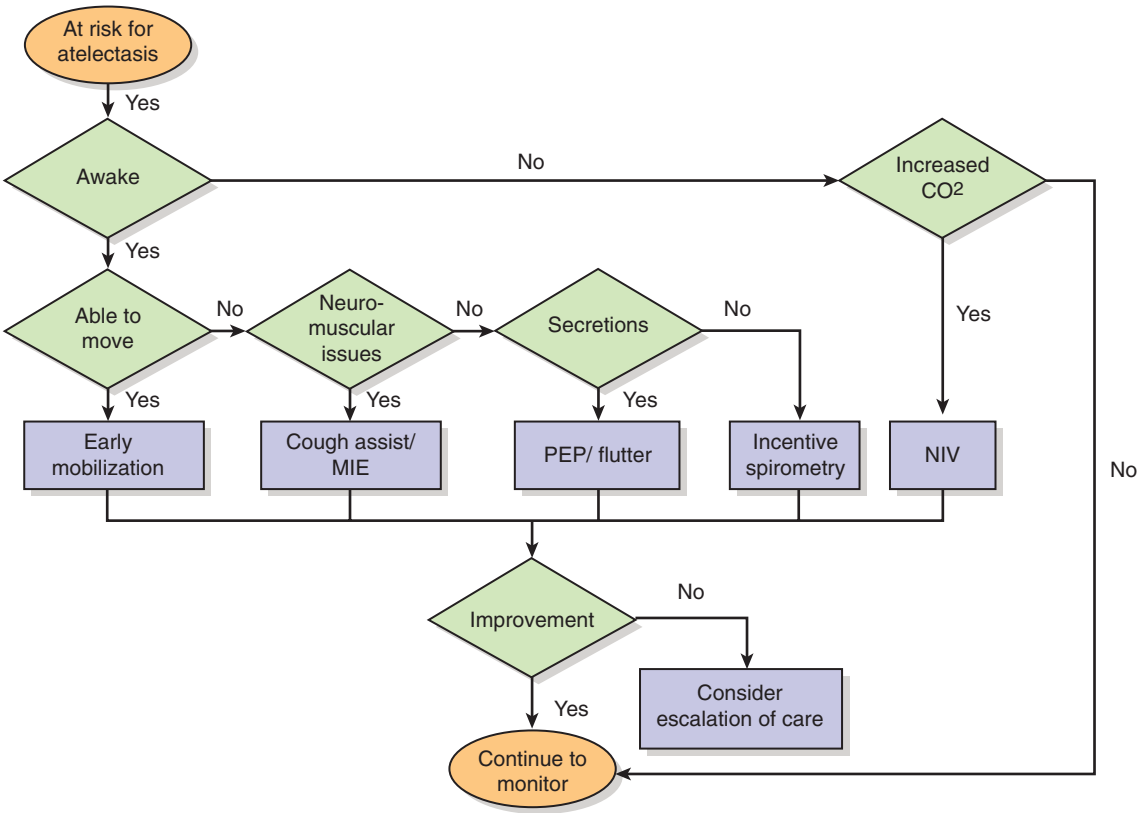

FIGURE 42-8 Protocol for selecting an approach for lung expansion therapy. See text for details.

increasing in both Europe and the United States along with the emphasis on decreasing morbidity in the ICU. Mobilization does not only include walking, but also sitting, standing, and getting out of bed into a chair. As the patient changes body position, his or her breathing changes as well as gas distribution within the lung. Improvements in ventilation result in less alveolar collapse.

Because of the beneficial pulmonary effects from early mobilization of the post–adbominal surgery patient, it has been suggested that mobilization should be considered as early as the day of surgery.[26] Recently, there has been a shift in the mindset that critically ill patients should be on complete bedrest. With the increasing knowledge of the benefits of early mobilization, the paradigm must change from thinking that a patient is too sick to get out of bed, to one in which we must think that a patient is too sick to stay in bed.[25]

In order to move the patient from the bed, it is important that they are not completely sedated. Along with early mobilization, there are other benefits of lighter sedation, and even "sedation vacations" when all sedation for the patient is temporarily discontinued in order to re-assess the need for sedation. Having a patient who is able to respond to the caregiver allows for better pain control with decreased risk of sedation-related complications.[27,28]

Although early mobilization does not classify as a procedure, it does have distinct benefits in decreasing morbidity and mortality. Early mobilization is the only true multidisciplinary approach requiring the various members of the health care team (respiratory therapist, nurse, physical therapist) to be present at the same time.

SUMMARY CHECKLIST

- Atelectasis is caused by persistent ventilation with small tidal volumes or by resorption of gas distal to obstructed airways.
- Patients who have undergone upper abdominal or thoracic surgery are at greatest risk for atelectasis.
- A history of lung disease or significant cigarette smoking increases the risk for atelectasis.
- Patients with atelectasis usually have rapid, shallow breathing; fine, late-inspiratory crackles; and abnormalities on chest radiograph.
- Lung expansion therapy corrects atelectasis by increasing the P_{TP} gradient; this can be accomplished by deep spontaneous breaths or by the application of positive pressure.
- The most common problem associated with lung expansion therapy is the onset of respiratory alkalosis, which occurs when the patient breathes too quickly.
- RTs are responsible for implementing, monitoring, and documenting results of lung expansion therapy.

CHAPTER 43

Airway Clearance Therapy (ACT)

DAVID L. VINES AND DONNA D. GARDNER

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the normal airway clearance mechanisms and the factors that impair their function.
- Identify pulmonary diseases associated with abnormal secretion clearance.
- State the goals and clinical indications for airway clearance therapy.
- Describe the proper technique and potential benefit of each of the following:
  - Chest physical therapy
  - Directed coughing and related expulsion techniques
  - Vibratory positive expiratory pressure therapy
  - High-frequency positive airway pressure devices
  - High-frequency compression/oscillation devices
  - Mobilization and exercise
- Evaluate a patient's response to airway clearance therapy.
- Modify airway clearance therapies on the basis of patient response.

CHAPTER OUTLINE

KEY TERMS

active cycle of breathing technique (ACBT)
autogenic drainage (AD)
bronchiectasis
chest physical therapy (CPT)
ciliary dyskinetic syndromes
forced expiratory technique (FET)
Hertz (Hz)
high-frequency chest wall compression (HFCWC)
high-frequency positive airway pressure devices (HFPAP)
huff coughing
inspissation
intrapulmonary percussive ventilation (IPV)
mechanical insufflation-exsufflation (MIE)
mucous plugging
oscillation
positive expiratory pressure (PEP)
splinting

Airway clearance therapy uses noninvasive techniques designed to assist in mobilizing and removing secretions to improve gas exchange.[1,2] Historically, the term **chest physical therapy (CPT)** described the primary techniques used to assist with clearing secretions from the airways. Today there are numerous options related to airway clearance including CPT, breathing retraining techniques, positive expiratory therapy (PEP), vibratory PEP, high-frequency positive pressure devices, high-frequency chest wall compression devices, and various exercise protocols.[1-4] This chapter focuses on airway clearance therapies or techniques used to mobilize secretions and noninvasively assist in their removal. The primary *invasive* method for removing airway secretions is suctioning, and is discussed in Chapter 36. Successful outcomes in airway clearance techniques require knowledge of normal and abnormal physiology, understanding of how clearance devices work, careful patient evaluation, rigorous application of evidence-based methods, and ongoing assessment targeted at achieving therapeutic goals.[1-6]

PHYSIOLOGY OF AIRWAY CLEARANCE THERAPIES (ACT)

To apply airway clearance therapies (ACT) properly, one first must understand how normal airway clearance mechanisms work and what can impair their function.

Normal Clearance

Normal airway clearance requires patent airways, a functional mucociliary escalator, adequate hydration, and effective coughs.[4,6] The mucociliary clearance happens from the larynx down to the respiratory bronchioles. Mucus is produced by secretory (Clara, goblet, and serous) cells and submucosal glands.[6] Ciliated epithelial cells move this mucus via a coordinated wave of ciliary motion toward the trachea and larynx, where secretions can be swallowed or expectorated. Healthy individuals produce 10 to 100 mL of secretions in the airway on a daily basis that are cleared by this mucociliary escalator.[1,4,6]

The cough is one of the most important protective reflexes.[1,2,4,6] Coughing clears the larger airways of excessive mucus and foreign matter, assists normal mucociliary clearance, and helps ensure airway patency. As shown in Figure 43-1, there are four distinct phases to a normal cough: *irritation, inspiration, compression,* and *expulsion*. In the initial irritation phase, an abnormal stimulus provokes sensory fibers in the airways to send impulses to the medullary cough center in the brain. This stimulus normally is inflammatory, mechanical, chemical, or thermal. Infection is a good example of an *inflammatory* process that can stimulate a cough. Foreign bodies can provoke a cough through *mechanical* stimulation. Inhaling irritating gases (e.g., cigarette smoke) can result in coughing through *chemical* stimulation. Finally, cold air may cause *thermal* stimulation of sensory nerves, producing a cough.

When these afferent impulses are received, the cough center generates a reflex stimulation of the respiratory muscles to initiate a deep inspiration (the second phase). In normal adults, this inspiration averages 1 to 2 L.

During the third or compression phase, reflex nerve impulses cause glottic closure and a forceful contraction of the expiratory muscles. This compression phase is normally about 0.2 second and results in a rapid increase in pleural and alveolar pressures, often greater than 100 mm Hg.

At this point, the glottis opens, initiating the expulsion phase. With the glottis open, a large pressure gradient between the lungs and the atmospheric pressure exists. Together with the continued contraction of the expiratory muscles, this pressure gradient causes a violent, expulsive high velocity of airflow from the lungs. This high-velocity gas flow, combined with dynamic airway compression, creates huge shear forces that displace mucus from the airway walls into the air stream. Mucus

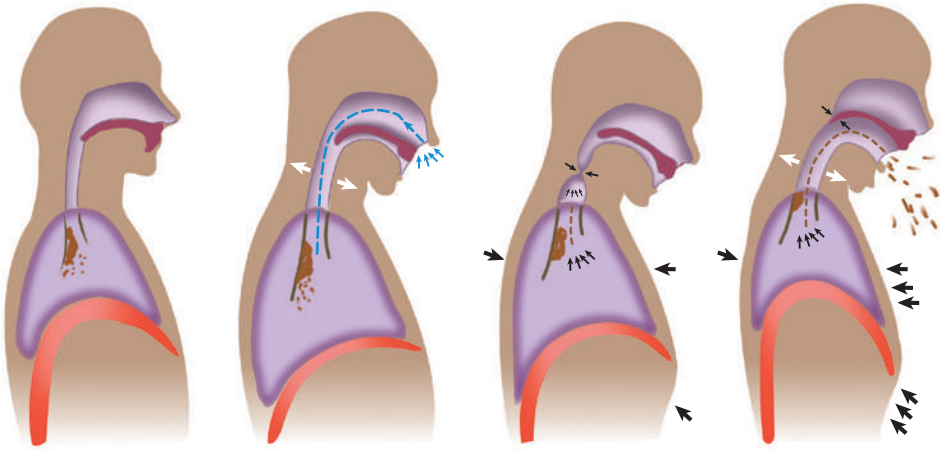

FIGURE 43-1 The cough reflex. (Modified from Cherniack RM, Cherniack L: Respiration in health and disease, ed 3, Philadelphia, 1983, WB Saunders.)

and foreign material are expelled from the lower airways to the upper airway, where they can be expectorated or swallowed.

Abnormal Clearance

Any abnormality that alters airway patency, mucociliary function, strength of the inspiratory or expiratory muscles, thickness of secretions, or effectiveness of the cough reflex can impair airway clearance leading to retention of secretions.[1,2,4-7] In addition, some therapeutic interventions, especially interventions used in critical care, such as an endotracheal tube, can result in abnormal clearance.

Retention of secretions can result in full or partial airway obstruction. Full obstruction, or **mucous plugging**, can result in atelectasis which causes hypoxemia due to shunting. A partial obstruction restricts airflow, increasing work of breathing and possibly leading to air trapping, lung overdistention, and ventilation/perfusion ($\dot{V}/\dot{Q}$) imbalances. In the presence of pathogenic organisms, retention of secretions can also lead to infections. Infectious processes provoke an inflammatory response and the release of chemical mediators. These chemical mediators, including leukotrienes, proteases, and elastases, can damage the airway epithelium and increase mucus production, resulting in a vicious cycle of worsening airway clearance.[6]

In patients with retained secretions, interference with one of the four phases of cough can result in ineffective airway clearance. This occurs in patients post thoracic or upper abdominal surgery, in the intensive care unit, or with neuromuscular diseases (NMD) such as amyotrophic lateral sclerosis (ALS), myasthenia gravis (MG), or spinal cord injuries.[4,7] Table 43-1 provides examples of factors that can impair the normal cough reflex.

As indicated in Box 43-1, additional factors can impair airway clearance in critically ill patients with artificial airways, the most important of which is the airway itself.[8] The presence of the tube in the trachea increases mucus secretion, and the cuff of the tube mechanically blocks the mucociliary escalator. In addition, movement of the tube tip and cuff can cause erosion of the tracheal mucosa leading to further impairment of the mucociliary escalator. The endotracheal tube also impairs the compression phase of the cough reflex by preventing closure of the glottis (see Table 43-1). Although suctioning is used to aid secretion clearance, it too can cause damage to the airway mucosa and impair mucociliary transport. Inadequate humidification can cause thickening or **inspissation** of secretions, mucous plugging, and airway obstruction.[9] High fractional inspired oxygen (FiO_2) concentrations can impair cilia function, resulting in retained secretions. Retained secretions can lead to acute tracheobronchitis. Several common drugs, including some general anesthetics and narcotic-analgesics, may also depress mucociliary transport.[10]

TABLE 43-1

Mechanisms Impairing Cough Reflex

Phase	Examples of Impairments
Irritation	Anesthesia
	CNS depression
	Narcotic-analgesics
Inspiration	Pain
	Neuromuscular dysfunction
	Pulmonary restriction
	Abdominal restriction
Compression	Laryngeal nerve damage
	Artificial airway
	Abdominal muscle weakness
	Abdominal surgery
Expulsion	Airway compression
	Airway obstruction
	Abdominal muscle weakness
	Inadequate lung recoil (e.g., emphysema)

CNS, Central nervous system.

Diseases Associated With Abnormal Clearance

Several diseases are associated with abnormal airway clearance, including diseases affecting airway patency, composition and production of mucus, ciliary structure and function, and normal cough reflex.[1,2,4,6,7] Internal obstruction or external compression of the airway lumen can impair airway clearance. Examples include foreign bodies, tumors, and congenital or acquired thoracic anomalies such as kyphoscoliosis. Internal obstruction also can occur with mucus hypersecretion, inflammatory changes, or bronchospasm that narrows the lumen. Examples include asthma, chronic bronchitis, and/or acute infections.

Diseases that alter normal mucociliary clearance also can cause retention of secretions. In cystic fibrosis (CF) the solute concentration of the mucus is altered because of abnormal sodium and chloride transport.[5,6] This alteration increases the viscosity of mucus and impairs its movement up the respiratory tract. Although less common, there are several conditions in which the respiratory tract cilia do not function properly.[6] These **ciliary dyskinetic syndromes** also can contribute to ineffective airway clearance. **Bronchiectasis** is permanently damaged and dilated airways that are prone to obstruction due to retained secretions.[6,11] Bronchiectasis is a common finding in CF and ciliary dyskinetc syndromes.[11,12]

Mucociliary function may be normal, but lack of an effective cough alters airway clearance leading to retained secretions,

Box 43-1 Causes of Impaired Mucociliary Clearance in Intubated Patients

- Endotracheal or tracheostomy tube
- Tracheobronchial suction
- Inadequate humidification

- Opiates
- Narcotics
- Underlying pulmonary disease

mucous plugs, obstructions, and atelectasis. The most common conditions affecting the cough reflex are musculoskeletal and NMDs,[6,7] including muscular dystrophy, ALS, spinal muscular atrophy, myasthenia gravis, poliomyelitis, and cerebral palsy (see Chapter 32).

GENERAL GOALS AND INDICATIONS

The primary goal of airway clearance therapy is to assist the patient to mobilize and remove retained secretions. Removal of these retained secretions may improve gas exchange, promote alveolar expansion, and reduce the work of breathing. Box 43-2 lists general indications for ACT.[1,2,4,7]

Airway Clearance Therapy for Acute Conditions

Patients with acute conditions in whom ACT may be indicated include (1) acutely or chronically ill patients with copious secretions; (2) patients with retained secretions or ineffective cough (coarse crackles, worsening oxygenation and/or ventilation, volume loss on chest radiograph); and possibly (3) patients with acute lobar atelectasis or (4) patients with $\dot{V}/\dot{Q}$ abnormalities.[13] In treating acute respiratory conditions, inhaled bronchodilator therapy before airway clearance therapy may improve the overall effectiveness of the treatment both by opening the airways and by increasing the mucociliary activity.[6] For acute pulmonary infections, inhaled antibiotics after airway clearance therapy can lead to improved deposition of the antibiotic.[14] Acute conditions for which airway clearance therapy is probably not indicated include (1) routine care of COPD, (2) pneumonia without clinically significant sputum production, (3) routine postoperative care, and (4) uncomplicated asthma.[1]

Airway Clearance Therapy for Chronic Conditions

Airway clearance therapy has proved effective in secretion clearance and improving pulmonary function in chronic conditions associated with copious sputum production, including CF, bronchiectasis, and ciliary dyskinetic syndromes, and COPD patients with retained secretions.[1,2,4,5,14] Generally, sputum production must exceed 20 to 30 ml/day for airway clearance therapy to improve secretion removal significantly.[2]

Box 43-2 Indications for Airway Clearance Therapy

ACUTE CONDITIONS
- Copious secretions
- Inability to mobilize secretions
- Ineffective cough

CHRONIC CONDITIONS
- CF
- Bronchiectasis
- Ciliary dyskinetic syndromes
- COPD patients with retained secretions

MINI CLINI

Assessing a Patient's Cough Clearance

PROBLEM: The RT is called by a nurse to determine a care plan to assist a patient who is having difficulty clearing secretions. The patient is an alert, obese, 45-year-old man who underwent general anesthesia and surgery for gallbladder removal 3 hours earlier. Physical signs indicate retention of secretions, but there is no history of lung disease. Auscultation reveals coarse expiratory crackles. The patient is breathing spontaneously, however, his breathing is shallow and he has a very weak cough. Visual clues indicate the patient has severe pain in the epigastric area. The patient was given an injection of morphine to assist with the pain 1 hour earlier.

Discussion: Even without lung disease, it is no surprise that this patient is having difficulty clearing secretions. Recent anesthesia and the narcotic-analgesic potentially are impairing his cough. In addition, obesity (abdominal restriction), weakness, and pain are impairing the inspiration, compression, and expulsion phases of his cough effort.

The patient should immediately be started on an ACT and hyperinflation or lung expansion therapies. Judicious use of pain medication, coinciding with therapies, should continue. Cough instruction including incisional splinting should be part of the plan. Early mobilization should be considered. Although the most common postoperative complication is atelectasis, pneumonia may also occur. The head of the patient's bed should be elevated at least to 30 to 45 degrees to minimize the risk of aspiration.

RULE OF THUMB

Patients with copious secretions (20 to 30 mL/day) or inability to mobilize and expectorate secretions may benefit from airway clearance therapy.

Airway Clearance Therapy to Prevent Retention of Secretions

Airway clearance therapy has been used as preventive therapy in various disorders. Current evidence is not supportive of this approach.[1,3] The best-documented preventive uses of airway clearance therapy include (1) body positioning and patient mobilization to prevent retained secretions in acutely ill patients and (2) ACT combined with physical activity to maintain lung function in patients with CF.[1,3,5] Other preventive applications of airway clearance therapy have not proved to be useful.[1,3,5]

DETERMINING THE NEED FOR AIRWAY CLEARANCE THERAPY

Effective airway clearance therapy requires proper initial and ongoing patient assessment (Chapter 16). Formulation of the respiratory care plan depends on review of the patient's medical

Box 43-3 Initial Assessment of Need for Airway Clearance Therapy

history and interview for current symptoms, physical assessment, laboratory testing (including pulmonary function tests), and radiologic evaluation. Box 43-3 lists the key factors that must be considered when assessing a patient's need for airway clearance therapy.[1,2,5] Physical findings such as a loose, ineffective cough; labored breathing pattern; decreased or bronchial breath sounds; coarse inspiratory and expiratory crackles; tachypnea; tachycardia; or fever may indicate a potential problem with retained secretions.

AIRWAY CLEARANCE METHODS

Five general approaches to ACT, which can be used alone or in combination, include (1) CPT; (2) coughing and related expulsion techniques (including manual insufflation-exsufflation [MIE]); (3) positive airway pressure (PAP) adjuncts (**positive expiratory pressure [PEP]**, vibratory PEP, high-frequency positive airway pressure devices); (4) high-frequency compression/oscillation methods; and (5) mobilization and physical activity. Table 43-2 provides a brief description and limitations associated with these airway clearance therapies. Appropriate use of these techniques requires an understanding of their underlying principles, relative efficacy, and methods of application.

Chest Physical Therapy

CPT has long been considered a standard of care in patients with CF. Evidence suggests that these therapies benefit mucus transport and assist in the expectoration of secretions.[1,2,4,5] This therapy includes postural drainage (PD) and percussion or vibration.

CPT involves the use of positioning, gravity, and mechanical energy to help mobilize secretions. PD places the body in various positions that are intended to drain secretions from each of the patient's lung segments into the central airways, where they can be removed by cough or suctioning.[4,5] This drainage is accomplished by simply placing the segmental bronchus to be drained in a more vertical position, permitting gravity to assist in the process. Positions generally are held for 3 to 15 minutes (longer in special situations such as CF) and modified as the patient's condition and tolerance warrant.[13] Cough methods are used with CPT and are discussed separately.

The indications for CPT (and other ACT) in a patient are copious secretions, inability to mobilize and expectorate the secretions, and pulmonary disorders associated with retained secretions (CF, bronchiectasis, and ciliary dyskinetic syndromes).[1,2,4,5] This therapy does require a trained caregiver's assistance for it to be performed correctly. CPT may be most effective in conditions characterized by excessive sputum production that is not cleared by deep breathing and coughing. For maximum effect with PD, head-down positions should exceed 25 degrees below horizontal.[14,15] If the patient can not be placed in appropriate positions for the areas affected, other ACT should be considered. In spontaneously breathing patients, frequency should be determined by assessing patient response to therapy. Critically ill patients, especially patients being mechanically ventilated, should have their positions changed every 2 hours.[16]

Technique

On the basis of a preliminary assessment of the patient and review of the physician's order, the RT should identify the appropriate lobes and segments for drainage. The RT may need to choose a different method for ACT in patients with unstable cardiovascular status, hypertension, cerebrovascular disorders, or dyspnea. To avoid gastroesophageal reflux and the possibility of aspiration, treatment times should be scheduled before or at least 2 hours after meals or tube feedings.[10] If the patient assessment indicates that pain may hinder treatment implementation, the RT should consider coordinating the treatment regimen with prescribed pain medication. Contraindications for CPT are listed in Box 43-4.

Before positioning, the procedure (including adjunctive techniques) should be explained to the patient. The RT should inspect for incisions, monitoring leads, intravenous tubing, and oxygen (O_2) therapy equipment connected to the patient and, if necessary, make adjustments to ensure continued function during the procedure or choose a different ACT method. Before starting, during, and after the procedure, the RT should measure the patient's vital signs, auscultate the chest, and measure SpO_2 if hypoxemia is suspected. These simple assessments serve as baseline measurements for monitoring the patient's response during the procedure and can assist in determining outcomes. The following items should also be monitored before, during, and after CPT: subjective responses (pain, discomfort, dyspnea, response to therapy), arrhythmias, breathing pattern, sputum production (quantity, color, consistency, odor), skin color, and ICP if monitored.[13]

TABLE 43-2

Techniques and Devices Used for Airway Clearance Therapy

Techniques/Devices	Description	Potential Limitations
Chest Physiotherapy (CPT) includes Percussion and Postural Drainage	Manually striking the chest wall with cupped hands in a rhythmic fashion or vibrating it with a mechanical device to loosen secretions from the airways and propel them forward while placing the patient in various positions so gravity can assist in draining the secretions from lung segment to larger airways to be cleared.	There is no age limitation but it requires help of a caregiver. CPT's effectiveness may be dependent on appropriate positioning, and patients with shortness of breath may not tolerate Trendelenburg position. Patients are unable to perform concurrent aerosol therapy.
Active Cycle of Breathing	The patient alternates cycles of deep breathing, relaxed breathing, and forced expiration technique to mobilize secretions.	Begin to introduce the concept at 3 to 4 years of age and continue coaching until approximately 10 years of age. It is difficult to perform during exacerbations or when patients are unable to take a deep breath.
Autogenic Drainage	The patient uses series of breathing patterns from a low volume that loosens secretions to start, then a normal tidal volume breath to begin to move secretions, and finally a larger volume breath at higher peak flows to move secretions into the larger airways so they can be expelled with a cough.	Patients need to be approximately 10 to 12 years of age to perform correctly. It requires a coordinated breathing effort from the patients. It is difficult to perform during exacerbations or when patients are unable to take a deep breath.
Mechanical Insufflator-Exsufflator (MIE)	This device applied with a mask provides inspiratory positive airway pressure to augment the patient's tidal volume and then switches to a negative pressure to assist with expulsion of secretions.	Usually requires an additional caregiver. May worsen airway collapse in obstructive disorders. It is contraindicated when untreated pneumothorax, hemodynamic instability, increased intracranial pressure, recent maxillofacial surgery or trauma, active hemoptysis, or ruptured tympanic membrane exists or is suspected.
Positive Expiratory Pressure (PEP) or Vibratory PEP	The PEP devices use a fixed or variable orifice expiratory flow resistor to generate expiratory pressures of 10 to 20 cm H_2O as the patient actively exhales through the device. Vibratory or oscillatory PEP incorporates flow interruptions during the active expiration to create flow oscillations in addition to the PEP.	It is limited to children and adults who can take a deep breath and generate high enough flow rates to create PEP and vibrations. It is contraindicated when untreated pneumothorax, hemodynamic instability, increased intracranial pressure, recent maxillofacial surgery or trauma, active hemoptysis, or ruptured tympanic membrane exists or is suspected.
High-Frequency Positive Airway Pressure Devices or Intrapulmonary Percussive Ventilation (IPV)	IPV devices provide short, rapid positive airway pressure pulses as the patient breathes in and actively exhales against these pulsations to loosen secretions and move then forward. If patients don't actively exhale, exhalation occurs due to chest wall's elastic recoil.	It is limited to children and adults. It is contraindicated when untreated pneumothorax, hemodynamic instability, increased intracranial pressure, recent maxillofacial surgery or trauma, active hemoptysis, or ruptured tympanic membrane exists or is suspected.
High-Frequency Chest Wall Compression (HFCW)	High-frequency, small volumes are applied to the chest wall through a vest. These pulses of air create chest wall compressions that result in small expiratory flows in the airways that move secretions forward.	Used in children that are at least 2 to 3 years of age. Indwelling catheters and chest tubes should be avoided when this device is used.
Mobilization and Physical Activity	Physical activity that results in increased tidal ventilation, heart rate, and cardiac output, and improved physical conditioning.	Patients' medical condition must be such that they can safely participate in physical exercise, or medical supervision would be required to monitor for desaturations. Patients with reactive airways have a risk of developing bronchospasms.

Modified from Volsko T: Airway clearance therapy: finding the evidence. Respir Care 58(10):1669–1678, 2013.

Figure 43-2 depicts the primary positions used to drain the various lung lobes and segments. Generally, to obtain the proper head-down position, the RT must lower the head of the bed by at least 16 to 18 inches to achieve the desired 25-degree angle. In the ambulatory care setting, a tilt table can be used in lieu of a hospital bed. A tilt table allows precise positioning at head-down angles up to 45 degrees. When angles this large are used, shoulder supports must be provided to prevent the patient from sliding off the tilt table.

After the patient is positioned, the RT confirms the patient's comfort and ensures proper support of all joints and bony areas with pillows or towels. The indicated position is maintained for a minimum of 3 minutes if tolerated and longer if good sputum production results. Between positions, pauses for relaxation and

Box 43-4 Contraindications to the Use of CPT

The decision to use postural drainage requires assessment of potential benefits vs potential risks. Therapy should be provided for no longer than necessary to obtain the desired therapeutic results. Listed contraindications are relative unless marked as absolute *(A)*.

Positioning: All positions are contraindicated for:

- Head and neck injury until stabilized *(A)*
- Active hemorrhage with hemodynamic instability *(A)*
- Intracranial pressure (ICP) greater than 20 mm Hg
- Recent spinal surgery or acute spinal injury
- Active hemoptysis
- Empyema
- Bronchopleural fistula
- Pulmonary edema associated with congestive heart failure
- Aged, confused, or anxious patients who do not tolerate position changes
- Pulmonary embolism
- Rib fracture, with or without flail chest
- Surgical wound or healing tissue
- Large pleural effusions

Trendelenburg position contraindicated for:

- Recent gross hemoptysis related to recent lung carcinoma treated surgically or with radiation therapy
- ICP greater than 20 mm Hg
- Uncontrolled hypertension
- Distended abdomen
- Patients in whom increased ICP is to be avoided (e.g., neurosurgery, aneurysms, eye surgery)
- Uncontrolled airway at risk for aspiration (tube feeding or recent meal)
- Esophageal surgery

External manipulation of the thorax contradinciations (in addition to contraindications previously listed):

- Subcutaneous emphysema
- Recent epidural spinal infusion or spinal anesthesia
- Recently placed transvenous pacemaker or subcutaneous pacemaker
- Lung contusion
- Osteomyelitis of the ribs
- Coagulopathy
- Recent skin grafts, or flaps, on the thorax
- Burns, open wounds, and skin infections of the thorax
- Suspected pulmonary tuberculosis
- Bronchospasm
- Osteoporosis
- Complaint of chest wall pain

Excerpts from the American Association for Respiratory Care: Clinical practice guideline: postural drainage therapy. Respir Care 36:1418, 1991.

breathing control are useful and can help prevent hypoxemia. Because postural drainage therapy can increase O_2 consumption, critically ill patients should be given supplemental O_2 during the procedure if SpO_2 decreases.

During the procedure, the patient is continually observed for any side effects or complications. Moderate changes in vital signs are expected during treatment. Table 43-3 lists complications and recommended interventions. Significant problems may require immediate intervention.

MINI CLINI

Postural Drainage, Percussion, and Vibration

PROBLEM: A physician's progress note indicates a potential bacterial pneumonia localized to a patient's right middle lobe. The patient has coarse breath sounds on the right midlung and a nonproductive cough. The physician orders CPT four times daily "until radiograph clears." What positions should the RT select for postural drainage, and where should the RT provide percussion?

Discussion: The correct position for draining the right middle lobe would be head down (foot of bed raised about 12 inches), with the patient rotated about 45 degrees left from supine (modified left side-lying position). Percussion should be performed on the right anterior chest wall, between the fourth and sixth ribs (see Chapter 16 for external anatomic landmarks).

Also, the RT should ensure that the patient uses appropriate coughing technique during and after positioning. When using the head-down position, the patient should avoid strenuous coughing because this markedly increases intracranial pressure. Rather, the patient should use the forced expiration technique (described later in this chapter). Generally, total treatment time should not exceed 15 minutes for a routine treatment and 30 minutes for extended treatment. Both the patient and the RT should understand that postural drainage does not always result in the immediate production of secretions. More often, secretions are simply mobilized toward the trachea for easier removal by coughing. If the procedure causes vigorous coughing, have the patient sit up until the cough subsides.

After the procedure, the patient is repositioned to the pretreatment position, and the RT ensures the patient's stability and comfort. Immediate posttreatment assessment includes repeat vital signs, confirmation of satisfactory arterial saturation, chest auscultation, and questioning the patient regarding his or her subjective response to the procedure.

RULE OF THUMB

Generally, whenever you observe any patient adverse effects or complications during postural drainage, follow the "triple S rule": **stop** the therapy, return patient to original resting position, and **stay** with the patient until he or she is **stabilized**.

Outcome Assessment

Specific outcome criteria indicating a positive response to postural drainage are listed in Box 43-5. Generally, achievement of one or more of these outcomes indicates that the therapy is meeting its objectives and should be continued. Not all criteria are required to justify continuing postural drainage. Because

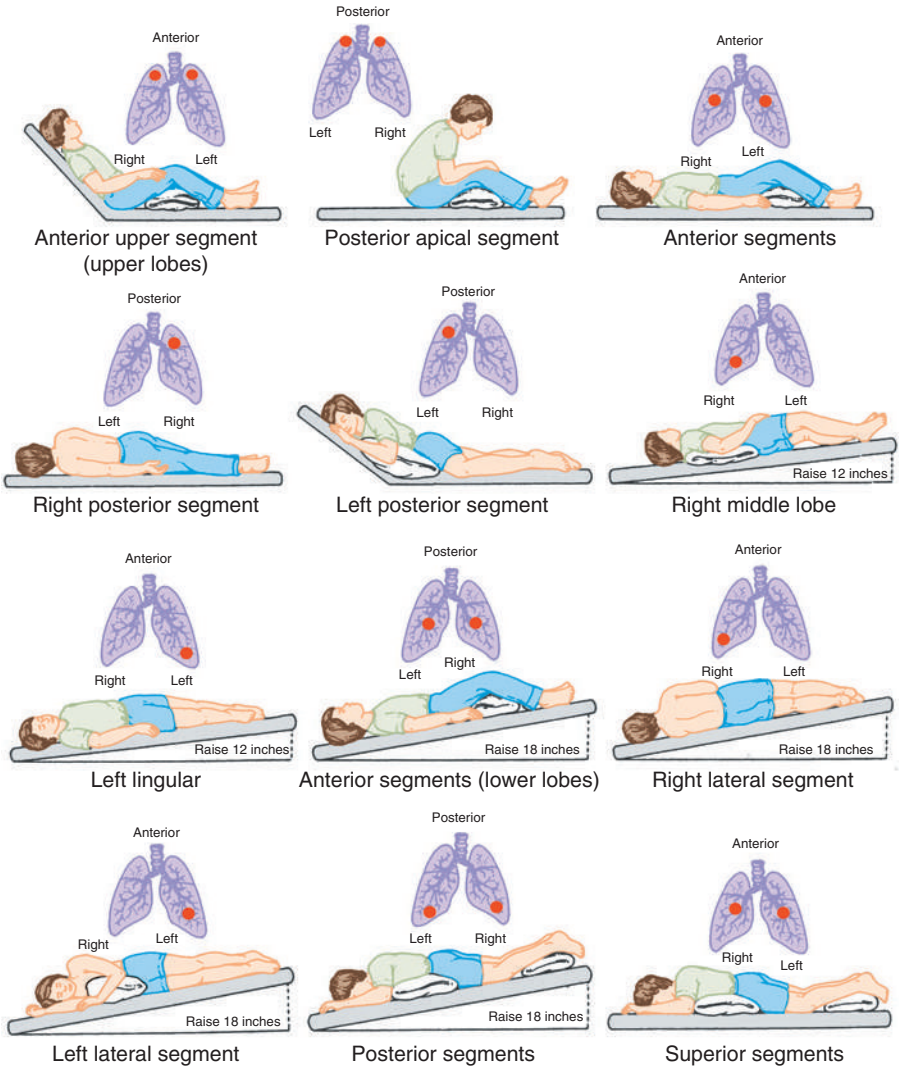

FIGURE 43-2 Patient positions for postural drainage. (Modified from Potter PA, Perry AG: Fundamentals of nursing: concepts, process and practice, ed 4, St Louis, 1997, Mosby.)

TABLE 43-3

Complications of Postural Drainage Therapy and Recommended Interventions

Complication	Action to Be Taken/Possible Intervention
Hypoxemia	Administer higher FiO_2 during procedure if potential for or observed hypoxemia exists. If patient becomes hypoxemic during treatment, administer 100% O_2, stop therapy immediately, return patient to original position, and consult physician
Increased intracranial pressure	Stop therapy, return patient to original resting position, and consult physician
Acute hypotension during procedure	Stop therapy, return patient to original resting position, and consult physician
Pulmonary hemorrhage	Stop therapy, return patient to original resting position, and call physician immediately. Administer O_2 and maintain an airway until physician responds
Pain or injury to muscles, ribs, or spine	Stop therapy that appears directly associated with pain or problem, exercise care in moving patient, and consult physician
Vomiting and aspiration	Stop therapy, clear airway and suction as needed, administer O_2, maintain airway, return patient to previous resting position, and contact physician immediately
Bronchospasm	Stop therapy, return patient to previous resting position, and administer or increase O_2 delivery while contacting physician. Administer physician-ordered bronchodilators
Arrhythmias	Stop therapy, return patient to previous resting position, and administer or increase O_2 delivery while contacting physician

Box 43-5 Assessment Outcomes after CPT

The following items represent individual criteria that indicate a positive response to therapy (and support continuation of therapy). Not all criteria are required to justify continuation of therapy (e.g., a ventilated patient may not have sputum production >30 ml/day but have improvement in breath sounds, chest radiograph, or increased compliance or decreased resistance).

- Change in sputum production
- Change in breath sounds of lung fields being drained
- Patient subjective response to therapy
- Change in vital signs
- Change in chest radiograph
- Change in arterial blood gas values or O_2 saturation
- Change in ventilator variables

Excerpts from the American Association for Respiratory Care: Clinical practice guideline: postural drainage therapy. Respir Care 36:1418, 1991.

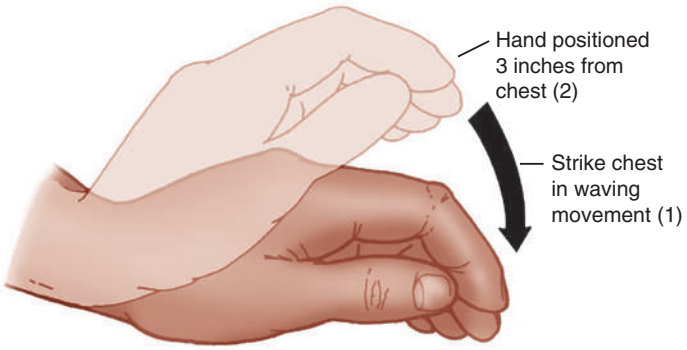

FIGURE 43-3 Movement of cupped hand at wrist, to percuss chest.

FIGURE 43-4 Hand placement for CPT. (From Harkreader H, Hogan M, Thobaben M: Fundamentals of nursing, caring and clinical judgment, ed 3, St Louis, 2007, Saunders.)

secretion clearance is affected by patient hydration, the RT may need to wait for at least 24 hours after optimal systemic hydration has been achieved to see any evidence of increased sputum production. In the interim, tracheobronchial clearance may be enhanced in some patients by adding bland aerosol therapy.[17,18]

Breath sounds may seem to "worsen" after therapy by changing from diminished breath sounds before therapy to coarse crackles. This change is due to the loosening of secretions and their movement into the larger airways, an intended purpose of the therapy. These coarse crackles should clear after coughing or suctioning.

In terms of the patient's subjective response to therapy, the patient should be encouraged to report any pain, discomfort, shortness of breath, dizziness, or nausea during or after therapy. Any of these adverse effects may be grounds for either modifying or stopping treatment. Patient reports of easier clearance or increased volume of secretions after therapy support continuing therapy.

On the basis of assessment results, CPT orders should be reevaluated for need at least every 2 to 3 days for hospitalized patients. Patients receiving home care should be reevaluated at least every 3 months or whenever their status changes.

Documentation and Follow-Up

The chart entry should include the positions used, time of treatment, patient tolerance, pre and post vital signs and breath sounds, subjective and objective indicators of treatment effectiveness (including amount, color, and consistency of sputum produced), and any adverse effects observed.

Percussion and Vibration

Percussion and vibration involve application of mechanical energy to the chest wall by the use of either hands or various electrical or pneumatic devices. Both methods are designed to augment secretion clearance.[14] In theory, percussion should help loosen secretions from the tracheobronchial tree, making them easier to remove by coughing or suctioning. The effectiveness of percussion as an adjunct to postural drainage remains unclear.[2,3] This controversy is due to variability in practice and the difficulty related to performing these trials since percussion is only a part of the treatment regimen.

Manual Percussion. The therapist performs manual percussion with his or her hands in a cupped position, with fingers and thumb closed (Figure 43-3). This technique compresses air between the hand and chest wall. This technique should be applied against a thin layer of cloth, such as a hospital gown or bed sheet to help improve patient comfort. This technique involves the therapist's cupped hands rhythmically striking the chest wall in a waving motion, using both hands alternately in sequence with the elbows partially flexed and wrists loose (see Figure 43-3). Slower, more relaxing rates are better tolerated by the patient and the therapist. This technique requires practice to determine the appropriate force and maintain a rhythmic pattern during this therapy (Figure 43-4). Ideally, the RT should percuss back and forth in a circular pattern over the localized area for 3 to 5 minutes. Care should be taken to avoid tender areas or sites of trauma or surgery, and one should never percuss

FIGURE 43-5 Example of an electrically powered mechanical percussor. (Courtesy General Physiotherapy, Inc. St Louis, MO.)

directly over bony prominences, such as the clavicles, vertebrae or sternum. Hands should be positioned parallel to the ribs.

Mechanical Percussion and Vibration. Mechanical vibration sometimes is used as an alternative to manual percussion in acutely ill patients with chest wall discomfort or injury. Various electrical and pneumatic devices have been developed to generate and apply the energy waves used during percussion and vibration. Typically, these devices have both a frequency and a percussion force control (Figure 43-5). Most units provide frequencies up to 20 to 50 cycles per second (20 to 50 Hz). Other sonic or acoustic devices may provide up to 120 **Hertz (Hz)**. Noise, excess force, and mechanical failure all are potential problems. Electrical devices also pose a potential shock hazard. These devices have the advantage of reducing fatigue on the caregiver and can deliver consistent rates, rhythms, and impact forces.[14] These devices may improve hospitalized patients' compliance, especially when chest wall discomfort or injury is present. However, there is no firm evidence that such devices are more effective than manual techniques. For this reason, the selection of manual or mechanical methods should be based on individual patient factors such as age, condition, and tolerance which are similar to other ACT modalities.[4]

Coughing and Related Expulsion Techniques

Most airway clearance therapies help only to move secretions into the central airways. Clearance of these secretions requires either coughing or suctioning. In this respect, an effective cough (or alternative expulsion measure) is an essential component of all ACT. These expulsion methods are also useful in obtaining sputum specimens for diagnostic analysis.

RULE OF THUMB

Clinicians should coach an effective cough with most airway clearance techniques to fully clear secretions.

Directed Cough

Directed cough is a deliberate maneuver that is taught, supervised, and monitored. It aims to assist in creating a productive cough in patients unable to clear secretions with an effective spontaneous cough.

In patients with copious secretions, directed coughing is an effective clearance method clearing secretions from the central, but not peripheral, airways.[1,2,19,20] In addition to aiding in the removal of retained secretions from central airways, it should be a routine part of all ACT and may be helpful in obtaining sputum specimens for diagnostic analysis.[19]

Box 43-6 lists the relative contraindications and potential complications associated with directed cough. These patients should be monitored for pain, discomfort, dyspnea, pulse rate, cardiac rhythm (if electrocardiogram is available), breath sounds, pulse oximetry if desaturation is suspected, breathing pattern, skin color, sputum production, and ICP if elevated. To determine the effectiveness of directed cough techniques, therapists should evaluate the patient for any of the following outcome changes: increased sputum production, decreased pulse and respiratory rate, clearing of the breath sounds, improved oxygen saturation, and possibly clearing of infiltrates on the chest radiograph.[19]

Box 43-6 Directed Cough

CONTRAINDICATIONS

Directed cough is rarely contraindicated. The contraindications listed must be weighed against potential benefit in deciding to eliminate cough from the care of the patient. Listed contraindications are relative:

- Inability to control possible transmission of infection from patients suspected or known to have pathogens transmittable by droplet nuclei (e.g., *Mycobacterium tuberculosis*)
- Presence of elevated ICP or known intracranial aneurysm
- Presence of reduced coronary artery perfusion, such as in acute myocardial infarction
- Acute unstable head, neck, or spine injury
- Manually assisted directed cough with pressure to the epigastrium may be contraindicated in the presence of increased potential for regurgitation or aspiration, acute abdominal pathology, abdominal aortic aneurysm, hiatal hernia, pregnancy, bleeding diathesis, or untreated pneumothorax
- Manually assisted directed cough with pressure to the thoracic cage may be contraindicated in the presence of osteoporosis or flail chest

HAZARDS AND COMPLICATIONS

- Reduced coronary artery perfusion
- Reduced cerebral perfusion
- Incontinence
- Fatigue
- Rib or costochondral fracture
- Headache
- Visual disturbances, including retinal hemorrhage
- Bronchospasm
- Muscular damage or discomfort
- Incisional pain, evisceration
- Anorexia, vomiting
- Gastroesophageal reflux
- Spontaneous pneumothorax
- Pneumomediastinum
- Subcutaneous emphysema
- Cough paroxysms
- Chest pain
- Central line displacement

Excerpts from the American Association for Respiratory Care: Clinical practice guideline: directed cough. Respir Care 38:495, 1993.

Standard Technique. After the clinical need for directed coughing has been established, the RT should assess the patient for any factors that could limit the success of directed cough and relative contraindications. An effective directed cough is impossible with unresponsive, paralyzed, or uncooperative patients. In addition, some patients with severe COPD or severe restrictive disorders (including neurologic, muscular, or skeletal abnormalities) may be unable to generate an effective spontaneous cough. Pain, systemic dehydration, tenaciously thick secretions, artificial airways, or use of central nervous system depressants can also impact efforts to implement an effective directed cough. If any of these limitations exist, the RT should recommend an alternative to directed cough such as an assisted cough, which is discussed later in this chapter.

Patient education is a critical part of developing an effective directed cough. The three most important aspects in teaching a patient to have an effective cough are (1) instruction on proper positioning, (2) instruction on breathing control, and (3) exercises to strengthen the expiratory muscles.[21] These activities are modified according to the patient's underlying clinical problem.

First, patients are taught to assume a sitting position with one shoulder rotated inward and the head and spine slightly flexed to aid exhalation and allow easy thoracic compression. It is difficult to generate an effective cough in the supine position. The patient's feet should be supported to provide abdominal and thoracic support for the patient. If the patient is unable to sit up, the RT should raise the head of the bed and ensure that the patient's knees are slightly flexed with the feet braced on the mattress.

Breathing control measures help ensure that the inspiration, compression, and expulsion phases of the cough are maximally effective and coordinated. For effective inspiration, the patient should be taught to inspire slowly and deeply through the nose, using the diaphragm. In patients with copious amounts of sputum, such breaths alone may stimulate coughing by loosening secretions in the larger airways.

After confirming that the patient can take a good, deep inspiration, the RT has the patient bear down against the glottis, in much the same manner as would occur with straining when lifting weights or during a bowel movement. For patients with pain or patients subject to bronchial collapse, it is probably best that they be shown how to "stage" their expiratory effort into two or three short bursts. For these patients, this method is generally less fatiguing and more effective in producing sputum than a single violent expulsion. Effective breathing control and effective coughing are best taught by demonstration. The RT demonstrates the various phases of the cough sequence while emphasizing the correct technique. The RT explains how to avoid common errors, such as simple throat clearing.

Proper positioning and breathing control alone may not result in an effective cough and clear secretions. This limitation often is due to weak breathing muscles. Muscle weakness is common in patients with neuromuscular disease, patients with COPD, and patients needing long-term ventilatory support. These muscles may atrophy due to disease progression, lack of appropriate nutrition, or lack of use during mechanical ventilation. In these cases, either suctioning or using the **mechanical insufflation-exsufflation (MIE)** device may be effective in clearing these secretions.

Modifications to Directed Cough Technique. Modifying the normal directed cough to the needs of the individual patient may lead to a productive cough effort. Good clinical examples of the need to modify directed cough are seen in surgical patients, patients with COPD, and patients with neuromuscular disorders.

In surgical patients, preoperative training in deep breathing and directed cough can help prepare the patient for the postoperative regimen. This preparation can minimize the anxiety related to pain that commonly impairs an effective cough in these patients. In addition, coordinating the coughing sessions with prescribed pain medication and **splinting** the operative site can enhance these sessions. The RT can use his or her hands to support the area of incision during the expiratory phase of the cough. Eventually, the patient can learn to use a pillow or blanket roll to splint the incision site. The **forced expiratory technique (FET)** (discussed subsequently) may also be valuable in these patients.

In some patients with COPD, the high pleural pressures during a forced cough may compress the smaller airways and limit the cough's effectiveness. In this situation, the patient is placed in the sitting position previously described. The patient is instructed to take in a moderately deep breath slowly through the nose. To help enhance expulsion, the patient should exhale with moderate force through pursed lips, while bending forward. This forward flexion of the thorax enhances expiratory flow by upward displacement of the abdominal contents. After three or four repetitions of this maneuver, the patient is encouraged to bend forward and initiate short staccato-like bursts of air. This technique relieves the strain of a prolonged hard cough, and the staccato rhythm at a relatively low velocity minimizes airway collapse. These staccato-like bursts of air against an open glottis are referred to as *huffing*.[1,2,21] With this technique the patient is instructed to make the sound "huff, huff, huff" rapidly with the mouth and glottis open. **Huff coughing** is also referred to as FET.

Forced Expiratory Technique

As stated above, FET consists of one or two forced expirations of middle to low lung volume without closure of the glottis, followed by a period of diaphragmatic breathing and relaxation.[19] The goal of this method is to help clear secretions with less change in pleural pressure and less likelihood of bronchiolar collapse. To help keep the glottis open during FET, the patient is taught to phonate or "huff" during expiration. The period of diaphragmatic breathing and relaxation following the forced expiration is essential in restoring lung volume and minimizing fatigue. Comparative clinical studies on the effectiveness of FET have shown favorable results. The technique is particularly useful in patients prone to airway collapse during normal coughing, such as patients with COPD, CF, or bronchiectasis.[1,2,21]

Manual Assisted Cough

Patients with neuromuscular conditions present a special challenge in cough management. These patients typically are unable to generate the forceful expulsion needed to move secretions toward the trachea.[23] If this problem results in retained secretions, there are only three options: (1) placement of an artificial airway and removal of secretions by tracheobronchial suctioning (see Chapter 36), (2) manually assisted cough, and/or (3) MIE.

Manually assisted cough is external application of pressure to the thoracic cage or epigastric region, coordinated with forced exhalation.[19] In this technique, the patient takes as deep an inspiration as possible, assisted as needed by the application of positive pressure via a self-inflating bag or intermittent positive pressure breathing device. At the end of the patient's inspiration, the RT begins exerting pressure on the lateral costal margins or epigastrium. This pressure increases the force of compression throughout expiration; this mimics the normal cough mechanism by generating an increase in the velocity of the expired air and may be helpful in moving secretions toward the trachea, where they can be removed by suctioning. Assisted cough with pressure to the lateral costal margins is contraindicated in patients with osteoporosis or flail chest.[19] Assisted cough using epigastric pressure is contraindicated in unconscious patients with unprotected airways, in pregnant women, and in patients with acute abdominal pathology, abdominal aortic aneurysm, or hiatal hernia.[19]

MINI CLINI

Modifications to Directed Cough

PROBLEM: A patient who has been diagnosed with ALS who has been attending your multidisciplinary clinic for the last few years returns for a follow-up visit. The patient states she has noticed her cough is not as powerful as it has been and that she is "winded" when walking distances. The respiratory therapist assesses the patient and finds: pulse rate of 80, respiratory rate of 24, and breath sounds of scattered wet crackles in both lungs. The patient performs spirometry and maximum inspiratory and expiratory pressure maneuvers (MIP/MEP). Her FVC is 70% of predicted, MIP is negative 50 cm H_2O and MEP is 55 cm H_2O sitting, and MIP is negative 40 cm H_2O and MEP is 40 cm H_2O supine. The therapist reviews the values from the previous visit 3 months earlier and finds FVC was 75% of predicted and MIP was a negative 65 cm H_2O and the MEP was 70 cm H_2O both sitting and supine.

Discussion: Based on this assessment, the patient's lung volumes and muscle strength have declined. She also has retained secretions and would benefit from airway clearance therapy and possibly MIE to assist with secretion removal. The patient began high-frequency chest wall compressions to mobilize these secretions and MIE to assist in expectorating the secretions. This therapy should take place a minimum of twice a day.

Active Cycle of Breathing Technique

To emphasize that FET should include breathing exercises, the originators of this technique modified the procedure and renamed it the **active cycle of breathing technique (ACBT)**.[14,24] ACBT consists of repeated cycles of breathing control, thoracic expansion, and FET (Box 43-7). *Breathing control* involves gentle diaphragmatic breathing at normal tidal volumes for 5 to 10 seconds with relaxation of the upper chest and shoulders. This phase is intended to help prevent bronchospasm. The thoracic expansion exercises involve deep inhalation, approaching vital capacity, with relaxed exhalation, which may be accompanied by percussion, vibration, or compression. The *thoracic expansion* phase is designed to help loosen secretions, improve the distribution of ventilation, and provide the volume needed for FET. The subsequent FET moves secretions into the central airways. Postoperative patients may require splinting at the thoracic or abdominal incision site. Although ACBT can be performed in the sitting position, it is most beneficial when combined with postural drainage. When ACBT is compared with similar methods of secretion clearance, studies indicate that ACBT can provide comparable results in terms of both sputum production and distribution of ventilation.[24,25] ACBT is not useful with young children (<2 years old) or critically ill patients. Caution should be taken in patients with reactive airways during ACBT.

Autogenic Drainage

Autogenic drainage (AD) is another modification of directed coughing, designed as an airway clearance mechanism that can be performed independently by trained patients.[7,11,14,24] During AD, the patient uses diaphragmatic breathing to mobilize secretions by varying lung volumes and expiratory airflow in three distinct phases (Figure 43-6).[14,24] For maximum benefit, the patient should be in the sitting position. Patients are taught to control their expiratory flows to prevent airway collapse while trying to achieve a mucous "rattle" rather than a wheeze. Coughing should be suppressed until all three breathing phases are completed.

In patients with CF, AD provides sputum clearance comparable to PDPV but is less likely to produce O_2 desaturation. In addition, AD seems to be tolerated better by patients and has the advantage of being performed without assistance from a caregiver.[2,21,24-26]

Box 43-7 Active Cycle of Breathing Technique Sequence

1. Relaxation and breathing control
2. Three or four thoracic expansion exercises
3. Relaxation and breathing control
4. Repeat three to four thoracic expansion exercises
5. Repeat relaxation and breathing control
6. Perform one or two FETs (huffs)
7. Repeat relaxation and breathing control

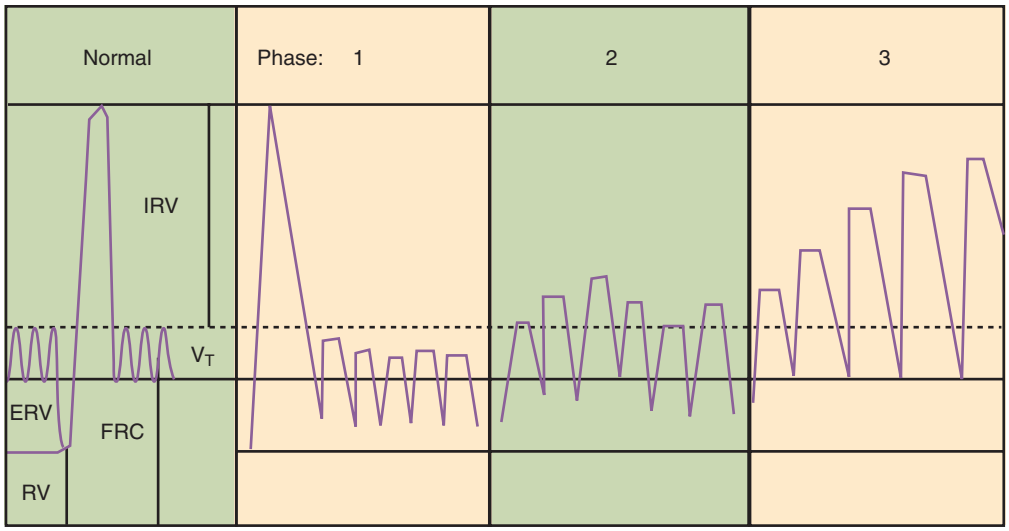

FIGURE 43-6 Spirogram of lung volumes during three phases of autogenic drainage. Phase 1 involves a full inspiratory capacity maneuver, followed by breathing at low lung volumes. This phase is designed to "unstick" peripheral mucus. Phase 2 involves breathing at low to middle lung volumes to collect mucus in the middle airways. Phase 3 is the evacuation phase, in which mucus is readied for expulsion from the large airways. (Modified from Hardy KA, Anderson BD: Respir Care Clin North Am 2:323, 1996.)

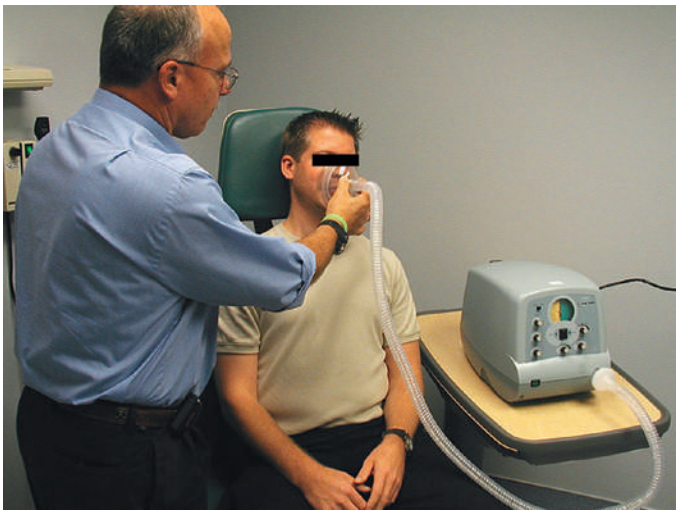

FIGURE 43-7 MIE device. (From Mason R, Broaddus V, Martin T, et al: Murray & Nadel's textbook of respiratory medicine, ed 10, Philadelphia, 2010, Saunders.)

Mechanical Insufflation-Exsufflation

The MIE device (also called *cough-assist device* or "coughlator") has gained popularity in its use to manage secretions in patients with certain neuromuscular disorders (Figure 43-7).[2,7,14] The reason is growing evidence that MIE helps prevent respiratory complications in patients with neuromuscular disorders by helping them generate sufficient expiratory flow rates needed for effective secretion clearance.[1,7,27]

NMD patients who are not able to demonstrate a peak cough flow greater than 180 L/min or not able to generate an effective cough may benefit from MIE.[7] The AARC clinical practice guideline for ACT recommends cough assist techniques when peak cough flows are less than 270 L/min in NMD patients.[1]

The MIE device delivers a positive pressure breath of 30 to 50 cm H_2O over a 1- to 3-second period via a face mask or artificial airway. The airway pressure is abruptly reversed to −30 to −50 cm H_2O and maintained for 2 to 3 seconds. Peak expiratory "cough" flows obtained with this device are in the normal range (mean 7.5 L/sec); far better than can be achieved with manually assisted coughing. Expiratory flows remain high in the immediate postexsufflation period, indicating that MIE does not promote airway collapse. Newer MIE devices have incorporated oscillation during inspiration or expiration to assist in mobilizing secretions.

A typical treatment session with the MIE consists of about five cycles (inspiration and expiration) followed by a period of normal spontaneous or assisted breathing (to avoid hyperventilation). This process is repeated five or more times until secretions are cleared from the airway and the patient is able to either suction or spit them out.

MIE via an oronasal mask is effective, provided that there is no fixed airway obstruction or glottic collapse during exsufflation. For patients with severe restrictive disease and NMD who are not able to take deep breaths, insufflation pressures should be increased gradually based on the patient and their assessment to avoid chest wall muscle strains. Abdominal distention is infrequent and reduced by decreasing airway pressures during insufflation, not exsufflation. The effectiveness of MIE in persons with airway obstructions such as COPD is less clear, and MIE may be detrimental because it may increase the amount of air trapping and auto-PEEP.[2]

Precautions should be observed using MIE with patients with known cardiac instability. It may be beneficial to monitor heart rate and O_2 saturation closely in these patients. MIE is contraindicated in patients with a history of bullous emphysema or previous barotraumas such as pneumothorax or pneumomediastinum.

Positive Airway Pressure Adjuncts

PAP adjuncts are used to help mobilize secretions and treat atelectasis. As adjuncts for airway clearance, these methods are usually paired with other airway clearance techniques such as directed cough. Indications for PAP adjuncts are similar to those listed early for all ACT. These devices elevate airway pressure and may also be beneficial in treating atelectasis. See Chapter 42 to review the use of these methods to treat atelectasis. Box 43-8 lists the contraindications and potential complications associated with PAP adjuncts. As with other ACT, these patients should be monitored for pain, discomfort, dyspnea, pulse rate, cardiac rhythm (if electrocardiogram is available), breath sounds, pulse oximetry if desaturation is suspected, breathing pattern, skin color, sputum production, fatigue, and ICP if elevated. To determine the effectiveness of PAP adjuncts, the therapist should evaluate the patient for increased sputum production, decreased pulse and respiratory rate, clearing of the breath sounds, improved oxygen saturation, and possibly clearing of infiltrates on the chest radiograph.[28] The following discussion will focus on the use of PAP devices for secretion clearance.

Box 43-8 Positive Airway Pressure (PAP) Adjuncts for Airway Clearance Therapy

CONTRAINDICATIONS

Although no absolute contraindications to the use of PAP adjuncts have been reported, the following should be carefully evaluated before initiating therapy:

- Patients unable to tolerate increased work of breathing (acute asthma, COPD)
- Intracranial pressure (ICP) greater than 20 mm Hg
- Hemodynamic instability
- Acute sinusitis
- Active hemoptysis
- Untreated pneumothorax
- Known or suspected tympanic membrane rupture or other middle ear pathology
- Recent facial, oral, or skull surgery or trauma
- Epistaxis
- Esophageal surgery
- Nausea

HAZARDS AND COMPLICATIONS INCLUDE

- Pulmonary barotraumas
- Increased ICP
- Cardiovascular compromise (myocardial ischemia, decreased venous return)
- Skin breakdown and discomfort from mask
- Air swallowing, vomiting, and aspiration
- Claustrophobia
- Increased work of breathing that may lead to hypoventilation and hypercapnia

Excerpts from the American Association for Respiratory Care: Clinical practice guideline: use of PAP adjuncts to bronchial hygiene therapy. Respir Care 38:516, 1993.

Positive Expiratory Pressure (PEP) and Vibratory PEP

PEP therapy involves active expiration against a fixed orifice flow resistor or variable orifice threshold resistor capable of developing pressures of 10 to 20 cm H_2O. Most fixed orifice devices allow adjustment of the orifice size to achieve a targeted PEP level. In theory, PEP therapy helps move secretions into the larger airways by providing a constant back-pressure that prevents airway collapse during expiration and the airway behind the mucus fills via collateral ventilation. A subsequent huff or FET maneuver may allow the patient to generate the flows needed to expel mucus from blocked airways.

PEP devices are available as PEP only or vibrator PEP. Vibrator or oscillator PEP devices provide rapid fluctuations in airway pressure as the patient exhales. The frequency of the vibrations has been reported to range from 10 to 30 Hz with amplitudes ranging from 20 to 100 torr at flows of 10 and 25 L/min.[29] Clinical studies of PEP and vibratory PEP therapy improved secretion clearance in hospitalized,[3] CF,[2,5,30,31] and COPD patients with secretion retention,[1] but is not beneficial in preventing postoperative atelectasis.[1] Generally, compared with other airway clearance methods (PDPV, AD, ACBT) in patients with CF, PEP therapy provides comparable mucociliary clearance, with the added advantages of being potentially self-administered and cost-effective.[2,32] Patients may prefer PEP over CPT.[5] PEP therapy cannot be used in young children (<3 years old). Patients must also be able to take a deep breath (>10-12 mL/kg) to generate adequate pressure, oscillations, and prolonged exhalations.

There are several available PEP and vibratory PEP devices on the market and manufacturer instructions on recommended application are included with each device (Figure 43-8). Most of these are single-use commercial devices. A general clinical procedure for application of PAP therapy is presented in Box 43-9.[16] Regardless of the equipment used, it is important that actual intended PEP levels are reached so initial monitoring of patient for correct use is essential.

Common strategies for PEP therapy vary, with frequency determined by assessment of patient response. Studies provide conflicting results related to the amount of time and intervals of therapy sessions during acute exacerbations associated with CF and COPD. Twice to four times daily are common frequencies used for PEP therapy.[28] Aerosol drug therapy may be added to a PEP session using either an in-line hand-held nebulizer or a metered dose inhaler attached to the one-way valve inlet of the system. The combination of aerosol drug therapy with PEP seems to improve the efficacy of bronchodilator administration because of better distribution to the peripheral airways.[17] Some PEP devices can be modified to incorporate a mask for patients with ALS, toddlers, or stroke patients who are unable to use a mouthpiece.

High-frequency vibrations or **oscillations** refer to the rapid vibratory movement of small volumes of air back and forth in the respiratory tract. At frequencies of 12 to 25 Hz these oscillations are thought to physically loosen secretions and move them toward the larger airways, which enhances airway

FIGURE 43-8 Positive expiratory devices: **A,** Flutter. **B,** TheraPEP. **C,** Acapella (Choice is used for a range of flows. Green is used for flows higher than 15 L/min. Blue is used for flows less than 15 L/min.). **D,** Aerobika. **E,** RC-Cornet.

Box 43-9 Clinical Procedure for Positive Airway Pressure Therapy

1. Assess need for PAP therapy and design a treatment program to accomplish treatment objectives.
   a. Bring equipment to bedside and provide initial therapy to patient, adjusting pressure settings to meet patient need.
   b. After initial patient treatment or training, communicate treatment plan to physician and nurse, and provide instruction to nursing staff if required.
2. Explain purpose of PAP therapy to patient; teach patient "huff" (directed cough procedure).
3. Instruct patient to:
   a. Sit comfortably.
   b. If using a mask, apply it tightly but comfortably over the nose and mouth. If mouthpiece is used, place lips firmly around it and breathe through mouth.
   c. Take in a breath that is larger than normal, but do not completely fill lungs.
   d. Exhale actively, but not forcefully, creating a PAP of 10 to 20 cm H_2O during exhalation (determined with manometer during initial therapy sessions). Length of inhalation should be approximately one-third of the total breathing cycle (inspiratory-to-expiratory ratio of 1:3 to 1:4).
   e. Perform 10 to 20 breaths.
   f. Remove the mask or mouthpiece, and perform two or three "huff" coughs; rest as needed.
   g. Repeat above cycle four to eight times, not to exceed 20 minutes.
4. Evaluate patient for the ability to self-administer.
5. When appropriate, teach patient to self-administer. Observations on several occasions of proper technique, uncoached, should precede allowing the patient to self-administer without supervision.
6. When patients are also receiving bronchodilator aerosol, administer in conjunction with PAP therapy by placing a nebulizer in line with the PAP device.
7. When PAP device is visibly soiled, rinse it with sterile water and shake or air dry; leave within reach at patient's bedside in a clear plastic bag.
8. Send the PAP device (if single-patient use) home with the patient, or discard it on discharge. If device is nondisposable, send in-house for high-level disinfection.
9. Document in the patient's medical record procedures performed (including device, settings used, pressure developed, number of breaths per treatment, and frequency), patient response to therapy, patient teaching provided, and patient ability to self-administer.

clearance. There are two general approaches: airway application of oscillation methods such as vibratory PEP discussed above or **high-frequency positive airway pressure devices (HFPAP)**, or external (chest wall) application referred to as **high-frequency chest wall compression (HFCWC)**. It is thought that the mucus moves as a result of the vibrations of the airways crated when the oscillation frequency resembles the resonance frequency of the pulmonary system.[22,29]

High-Frequency Positive Airway Pressure Devices

High-frequency positive airway pressure devices are also referred to as **intrapulmonary percussive ventilation (IPV)**.

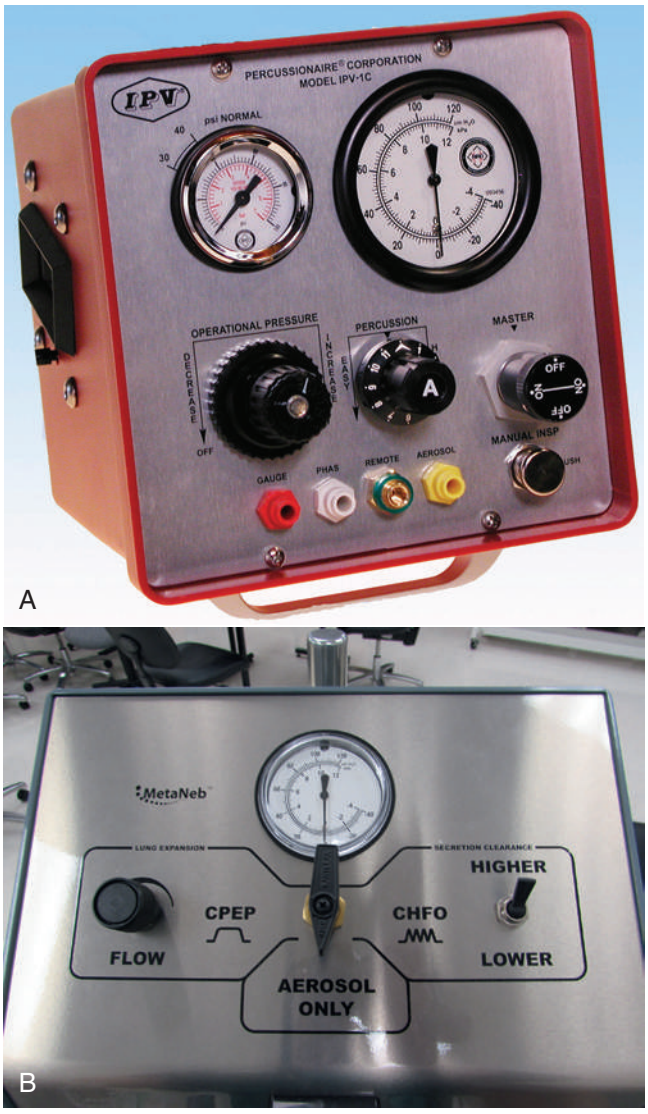

FIGURE 43-9 Intrapulmonary Percussive Ventilator, IPV. (Courtesy Percussionaire, SandPoint, Idaho, and MetaNeb.)

HFPAP or IPV devices (Figure 43-9) use a pneumatic device to deliver a rapid series of pressurized gas minibursts at rates of 100 to 225 cycles per minute (1.7 to 5 Hz) to the airway. During the percussive cycle, the patient can inhale and exhale through the device as this oscillating airway pressure is applied. These devices also deliver aerosolized medication, and rely on chest wall recoil or an active patient exhalation. Comparative studies show that IPV is equivalent to other airway clearance strategies in enhancing sputum expectoration in patients.[2,3,5] The therapy is well tolerated by stable patients and may provide a more effective alternative for airway clearance in patients unable to take a deep inspiration.

High-Frequency Chest Wall Oscillation

High-frequency chest wall oscillation (HFCWO) devices are passive oscillatory devices. These devices use a two-part system: (1) a variable air-pulse generator and (2) a nonstretch inflatable

vest that wraps around the patient's entire torso (Vest Airway Clearance Systems, Hill-Rom Services, Inc., Batesville, IN). See Figure 43-10. Either one or two large-bore tubing(s) connect the vest to the air-pulse generator. Table 43-4 lists the devices, air-pulse waveforms, and hose configurations. The generator inflates and deflates the vest, creating pressure pulses against the thorax resulting in chest wall oscillations and moving secretions forward. These devices are used in hospital or home settings. The therapy is typically performed for a 30-minute session 2 to 6 times per day at oscillatory frequencies between 5 to 25 Hz. These therapy sessions depend on patient need and response.

Clinical trials with HFCWO have reported better or equivalent secretions clearance compared to other ACT in CF patients.[2,5] Studies in other populations have shown some improvement, as measured by patient perception, increased compliance, or outcome.[7,22]

The Biphasic Cuirass Ventilation (BCV) device is an alternative to the vest devices. This device may be used to provide noninvasive ventilation and/or cough assist. It uses a chest cuirass or shell that encompasses the anterior chest wall. The shell is connected to the generator that controls both phases of the respiratory cycle. The chest wall will expand when the negative pressure is applied. This device is capable of a frequency range between 1 and 999 oscillations per minute, I:E ratios of 1:6 and 6:1 and inspiratory and expiratory pressures of −70 to 70 cm H_2O. The recommended application is two sets of cycles that include a few minutes at a frequency between 600 and 700 at an I:E of 1:1, followed by a higher frequency at an inverse I:E ratio.[22] The therapy will ultimately depend on the patient's response.

Exercise, Mobilization and Physical Activity

Immobility is a major factor contributing to complications in chronic disease and hospitalized patients. Early mobilization is recommended to reduce complications in hospitalized patients and is recommended as adjunctive therapy along with another ACT in CF to aid airway clearance and overall health benefits.[1,5,33,34] Physical activity may also improve lung function, exercise tolerance, quality of life, and adherence to therapy.[5] For more on the use of exercise in ambulatory patients with severe lung disease see Chapter 55.

SELECTING AIRWAY CLEARANCE TECHNIQUES

Selection Factors

Box 43-10 specifies many factors therapists should consider when selecting an airway clearance strategy. The correct application and patient motivation to perform the ACT are critical components regardless of the setting. No ACT is successful if it is abandoned by the patient. Likewise, no routine strategy is likely to be followed without results. In this regard, increased sputum production, less shortness of breath, and perhaps improved physical activity are a few outcomes that can be used to motivate patients and gain their ongoing cooperation.

Age, disease process, available resources, and patient preference often affect the choice of ACT. Patient and caregiver goals

Box 43-10 Key Factors in Selecting an Airway Clearance Strategy

- Patient's motivation
- Patient's goals
- Patient's ability to comprehend—literacy and cognition levels
- Patient's physical limitations
- Physician/caregiver goals
- Effectiveness of technique
- Ease of learning and teaching
- Skill of therapists
- Patient fatigue associated or work required to use device
- Need for assistance to use the equipment
- Limitations of technique based on disease type and severity
- Costs (direct and indirect)
- Desirability of combining methods

for treatment should be discussed jointly, with the intent of choosing the method that best fits the patient's goals and lifestyle. The RT's skill and patience in teaching the ACT is also a factor in determining the therapy's success. The patient's learning needs and barriers to learning should also be considered.

Because patients reject methods that are fatiguing, this should be considered in method selection. In addition, the patient's disease either may suggest the best approach or may impose certain limitations that preclude using a particular method. Cost is a critical factor in selecting all treatment strategies. There are multiple inexpensive options that are effective. Patient or caregiver education also plays an important role in the therapy's effectiveness (see Chapter 54).

MINI CLINI

Recommending Airway Clearance Strategies

PROBLEM: The RT is asked to evaluate and recommend an appropriate airway clearance therapy regimen for a 7-year-old active girl with CF who is being cared for in her home by elderly grandparents.

Discussion: Generally, appropriate secretion clearance strategies for this patient include exercise, vibratory PEP, CPT, ACBT, HFCWO, and IPV. CPT would be difficult to implement in this patient's home setting (elderly caregivers), so emphasis should be placed on either vibratory PEP with ACBT or HFCWO and FET. An exercise plan should also be incorporated into the overall strategy. Dietary and medication considerations are also important.

Protocol-Based Airway Clearance

Numerous RT-driven protocols have been published for airway clearance therapy. All of these protocols involve rigorous assessment of the patient both to establish preliminary need and to determine continuation of or modification in therapy. Figure 43-11 is an algorithm used in one such protocol. Changes in therapy occur throughout and are based on the patient's response and therapist's evaluation.

SUMMARY CHECKLIST

- Normal airway clearance requires a patent airway, a functional mucociliary escalator, and an effective cough.
- Patients with copious secretions (20 to 30 mL/day) or inability to mobilize and expectorate secretions may benefit from airway clearance therapy.
- The primary goal of airway clearance therapy is to help mobilize and remove retained secretions, improve gas exchange, and reduce the work of breathing.
- Retained secretions can increase the work of breathing, cause air trapping, worsen $\dot{V}/\dot{Q}$ imbalance, promote atelectasis and shunting, and increase the incidence of infection.
- Disorders associated with abnormal secretion clearance include foreign bodies, tumors, congenital or acquired thoracic anomalies, asthma, chronic bronchitis, CF, bronchiectasis, and acute infections.
- Musculoskeletal and neurologic disorders can impair coughing and lead to mucous plugging, airway obstruction, and atelectasis.
- Both mechanical and treatment factors impair mucociliary clearance in intubated patients.
- Clinical signs consistent with retained secretions include ineffective cough, absent or increased sputum production, a labored breathing pattern, abnormal or adventitious lung sounds (e.g., coarse crackles, decreased breath sounds), tachypnea, tachycardia, and fever.
- Turning promotes lung expansion, improves oxygenation, and prevents retention of secretions.
- Postural drainage involves placing the segmental bronchus to be drained in a vertical position relative to gravity and holding the position for 3 to 15 minutes.
- Cough methods must be modified in surgical patients, patients with COPD, and patients with neuromuscular disorders.
- FET, or huff cough, consists of one or two forced expirations of middle to low lung volume without closure of the glottis, followed by a period of diaphragmatic breathing and relaxation.
- ACBT consists of repeated cycles of breathing control, thoracic expansion, and FET.
- During AD, the patient uses diaphragmatic breathing to mobilize secretions by varying lung volumes and expiratory airflow in three distinct phases.
- MIE involves delivery of a positive pressure breath followed by the quick application of negative pressure; positive expiratory flows exceed flows developed by manually assisted coughing.
- PEP or vibratory therapy is a self-administered clearance technique involving active expiration against a variable-flow resistance, followed by FET; patients frequently prefer PEP over other methods.
- At high frequencies (12 to 25 Hz), airway oscillations enhance cough clearance of secretions.
- Airway oscillations can be created externally (HFCWC) or at the airway opening (flutter valve, IPV).
- Adding physical activity to mobilization and coughing enhances mucus clearance, improves overall aeration and $\dot{V}/\dot{Q}$ matching, and improves pulmonary function.
- If performed correctly, no airway clearance therapy has been proven better than another.
- Numerous factors must be considered in trying to select the best airway clearance strategy for a given patient.

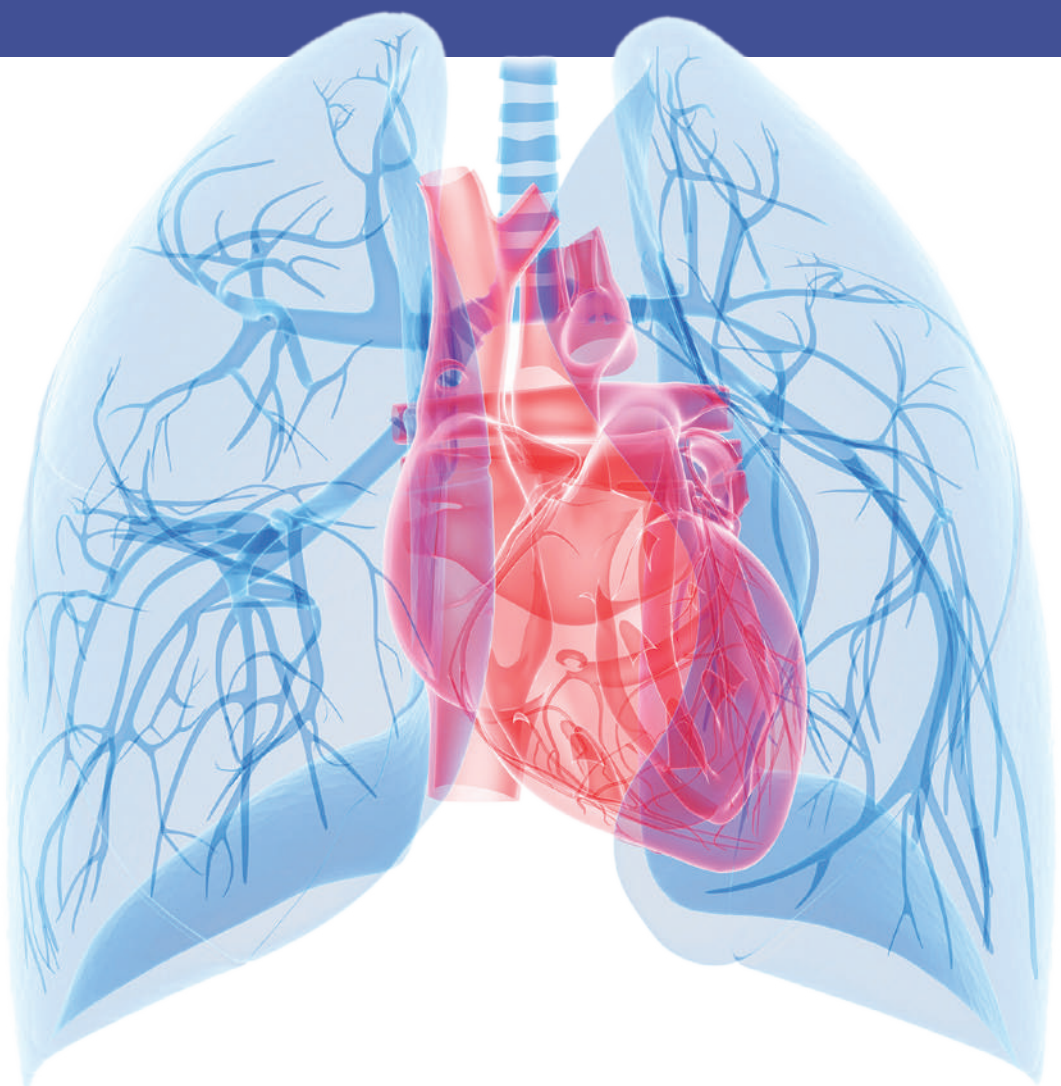
SECTION VI

ACUTE AND CRITICAL CARE



CHAPTER 44

Respiratory Failure and the Need for Ventilatory Support

LOUTFI S. ABOUSSOUAN

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Define acute respiratory failure.
- Differentiate between hypoxemic respiratory failure (type I) and hypercapnic respiratory failure (type II).
- Discuss the causes of acute respiratory failure.
- Discuss the differences between chronic respiratory failure and acute-on-chronic respiratory failure.
- Identify the complications of respiratory failure.
- Discuss the indications for ventilatory support.
- Discuss general management principles of hypoxemic and hypercapnic respiratory failure.
- Discuss indications for noninvasive ventilation.

CHAPTER OUTLINE

KEY TERMS

auto-PEEP
barotrauma
dynamic hyperinflation
hypercapnic respiratory failure (type II)
hypoxemic respiratory failure (type I)
maximum expiratory pressure (MEP)
maximum inspiratory pressure (MIP)
maximum voluntary ventilation (MVV)
muscle fatigue
noninvasive ventilation (NIV)
orthodeoxia
platypnea
positive end-expiratory pressure (PEEP)
pressure control ventilation
respiratory alternans
sniff nasal inspiratory pressure
tension-time index
work of breathing

Respiratory failure is a clinical problem that all respiratory care practitioners must be skilled at identifying, assessing, and treating. The mortality of patients requiring intensive care unit (ICU) admission with respiratory failure was 44% in 1995, and only marginally improved to 34.5% in 2010.[1,2] The need for oxygen (O_2) delivery, mechanical ventilation, and other modalities in the management of such patients makes the respiratory therapist's (RT) role indispensable.

Respiratory failure is the "inability to maintain either the normal delivery of O_2 to the tissues or the normal removal of carbon dioxide (CO_2) from the tissues"[3] and often results from an imbalance between respiratory workload and ventilatory strength or endurance. Criteria for respiratory failure based on arterial blood gases (ABGs) were established by Campbell[4] and generally define *failure* as arterial partial pressure of oxygen (PaO_2) less than 60 mm Hg (also referred to as **hypoxemic** or **type I respiratory failure**), alveolar partial pressure of carbon dioxide ($PaCO_2$) greater than 50 mm Hg (**hypercapnic** or **type II respiratory failure**), or both, in otherwise healthy individuals breathing room air at sea level. Respiratory failure can be an acute or a chronic process. Hypercapnic respiratory failure is also known as *ventilatory failure* or "bellows" failure. Patients with baseline acid-base derangement (e.g., chronic obstructive pulmonary disease [COPD], neuromuscular disease, thoracic or parenchymal restrictive lung disease) may be chronically hypercapnic and in chronic ventilatory failure. Although ABG analysis is helpful in distinguishing hypoxemic (type I) and hypercapnic (type II) respiratory failure, many patients in acute respiratory failure develop both hypoxemia and hypercapnia.

HYPOXEMIC RESPIRATORY FAILURE (TYPE I)

The primary causes of hypoxemia are the following:

- Ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch
- Shunt
- Alveolar hypoventilation
- Diffusion impairment
- Perfusion/diffusion impairment
- Decreased inspired O_2
- Venous admixture

These entities are briefly discussed here and are discussed in more detail in Chapters 11 and 12.

Ventilation/Perfusion Mismatch

There are regions in healthy lungs where ventilation and perfusion are not evenly matched, so it seems logical that this is the most common cause of hypoxemia. RTs are familiar with this concept through the work of West,[5] which described a high $\dot{V}/\dot{Q}$ ratio at the apex of the lungs and a low ratio at the bases. This concept can be oversimplified and stated as there being more air than blood at the apexes and more blood than air at the bases.

Pathologic $\dot{V}/\dot{Q}$ mismatch occurs when disease disrupts this balance, and hypoxemia results (Figure 44-1, *A*). Most commonly, areas of low $\dot{V}/\dot{Q}$ ratio are seen in which ventilation is compromised despite adequate blood flow. Obstructive lung diseases are frequent causes. The bronchospasm, mucous plugging, inflammation, and premature airway closure that signal asthmatic or emphysematous exacerbations worsen ventilation and create $\dot{V}/\dot{Q}$ mismatch. Infection, heart failure, and inhalation injury may lead to partially collapsed or fluid-filled alveoli, also resulting in decreased ventilation and reduced blood O_2 levels.

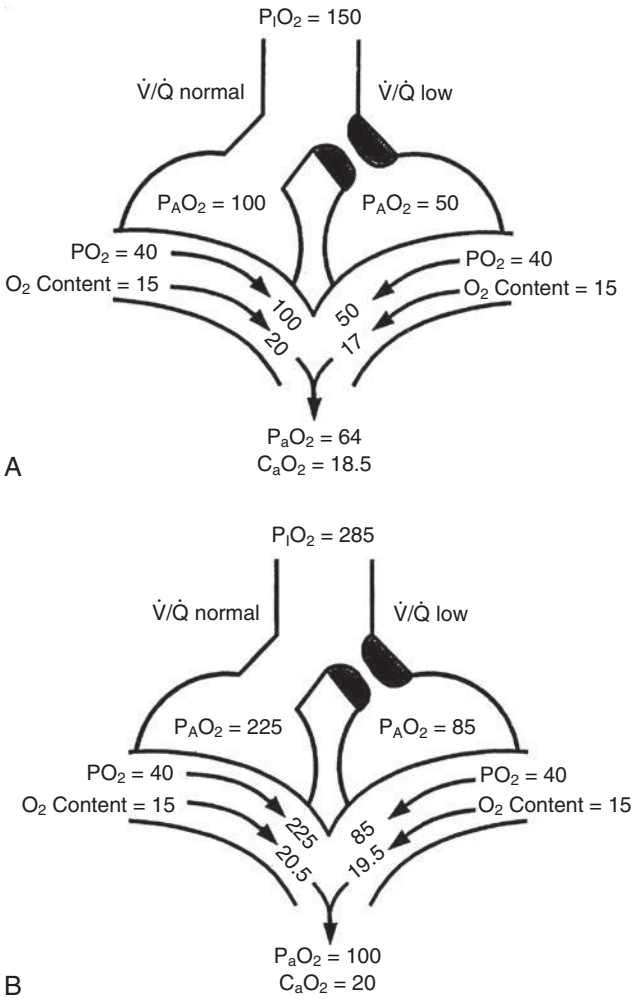


FIGURE 44-1 Hypoxemia caused by $\dot{V}/\dot{Q}$ mismatch showing the effect of supplemental O_2. $\dot{V}/\dot{Q}$ is normal on the left side of each idealized lung unit and low on the right. Only O_2 exchange is shown, and $P(A - a)O_2$ is assumed to be zero. **A,** With room air, not enough O_2 reaches the poorly ventilated alveolus to saturate its capillary blood fully. **B,** With 40% O_2, PaO_2 in this alveolus is increased enough to make capillary PO_2 nearly normal. PaO_2 in the mixed blood from the two capillaries is determined by the average of the O_2 contents of the two streams of blood, not by the PaO_2 values. (Modified from Pierson DJ, Kacmarek RM: Foundations of respiratory care, New York, 1992, Churchill Livingstone.)

Clinical Presentation

Because patients present with hypoxemia, the initial goal is always to treat the low PaO_2 or SpO_2 (arterial O_2 saturation by pulse oximeter). $\dot{V}/\dot{Q}$ mismatch responds to supplemental O_2

(see Figure 44-1, *B*). Hypoxemia commonly manifests with dyspnea, tachycardia, and tachypnea, but these are very nonspecific findings. However, patient observation is extremely valuable. The use of accessory muscles of respiration (scalene, pectoralis major, and sternomastoid) is an important sign that normal diaphragmatic inspiration is inadequate. In an elderly, cachectic, or barrel-chested individual who is leaning forward on his or her arms, COPD is the likely diagnosis. Nasal flaring may be present. Lower extremity edema is more indicative of cardiac failure as the cause of hypoxemia. Cyanosis may be peripheral and primarily due to decreased blood flow. Central cyanosis, seen most easily as a bluish tint around the lips, occurs when greater than 5 g/dl of unsaturated hemoglobin is present. This finding is more common in patients with polycythemia but may be subject to wide observer variability. More severe hypoxemia can lead to significant central nervous system (CNS) dysfunction, ranging from irritability to confusion to coma.

Auscultation and percussion are very useful when added to patient observation. Bilateral wheezing, especially in a young patient in respiratory distress, often identifies the bronchospasm of asthma. Upper airway disease or fluid-filled airways may also result in wheezing. Breath sounds that are diminished bilaterally with increased resonance on percussion are common in emphysema. Unilateral abnormalities are significant. Wheezing in one lung may identify an endobronchial lesion, whereas the absence of breath sounds and decreased resonance on one side of the chest may reflect collapse, infection, edema, or effusion as potential causes of $\dot{V}/\dot{Q}$ mismatch. Discordant exam findings with increased resonance on percussion and decreased breath sounds on the same side may signal a pneumothorax. Unilateral crackles and decreased resonance on percussion generally indicate an alveolar filling process (mass, infection, fluid).

Radiographically, $\dot{V}/\dot{Q}$ mismatch can manifest as a "black" radiograph, with large or hyperinflated lungs as in the case of obstructive disease. A "white" chest radiograph is evident when alveoli are partially occluded. The "blackness" or "whiteness" of the lung fields on the plain chest radiograph has important diagnostic value in assessing a patient with acute respiratory failure.

Shunt

Shunt is an extreme version of $\dot{V}/\dot{Q}$ mismatch in which there is no ventilation to match perfusion ($\dot{V}/\dot{Q} = 0$). About 2% to 3% of the blood supply is shunted via the bronchial and thebesian veins that feed the lungs and heart; this is normal anatomic shunt. Pathologic anatomic shunt occurs as a result of right-to-left blood flow through cardiac openings (e.g., atrial or ventricular septal defects) or in pulmonary arteriovenous malformations. Physiologic shunt leads to hypoxemia when alveoli collapse or are filled with fluid or exudate. Common etiologies of physiologic shunting include atelectasis, pulmonary edema, and pneumonia. In contrast to $\dot{V}/\dot{Q}$ mismatch, shunt does not respond to supplemental O_2 because the gas-exchange unit (the alveolus) is not open (Figure 44-2, *A*).

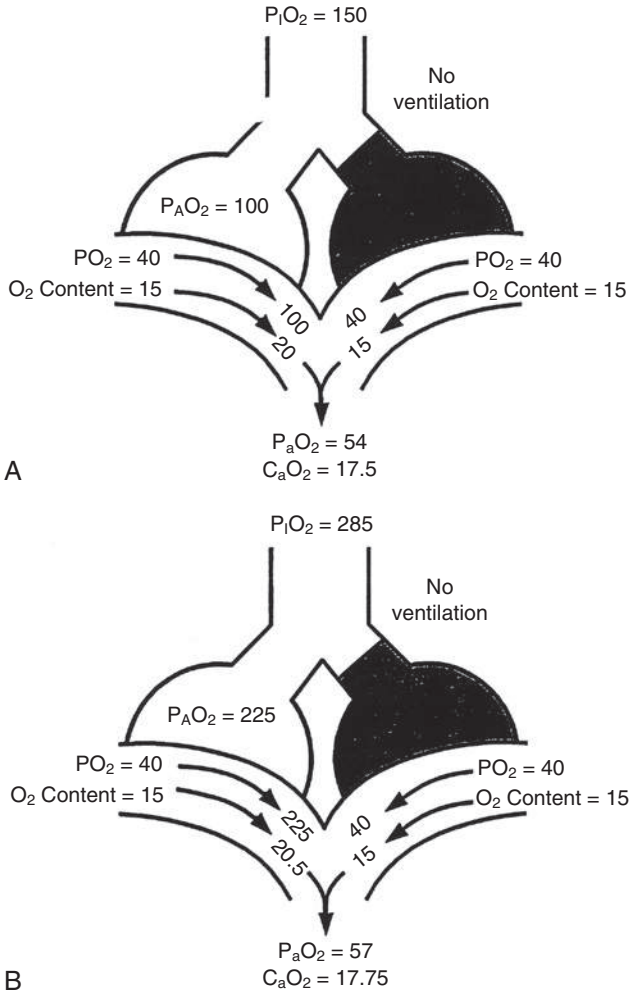

FIGURE 44-2 Alveolar-capillary diagram of intrapulmonary (capillary) shunting showing why supplemental O_2 fails to correct hypoxemia. Only O_2 exchange is shown, and $P(A - a)O_2$ is assumed to be zero. **A,** With room air, although blood leaving the normal alveolar-capillary unit is normally saturated, blood passing the capillary on the right "sees" no O_2 because its alveolus is unventilated, and it leaves the unit unsaturated. When the two streams of blood mix, the resulting PaO_2 is determined by the average of the O_2 contents, not by the PO_2 values. **B,** Addition of 40% O_2 fails to correct the hypoxemia because O_2 content is not significantly increased in the normal unit, and capillary blood in the unventilated unit still "sees" no O_2. Even 100% O_2 could not completely reverse the oxygenation defect in this example; this is very different from the effect with low $\dot{V}/\dot{Q}$ as illustrated in Figure 44-1. (Modified from Pierson DJ, Kacmarek RM: Foundations of respiratory care, New York, 1992, Churchill Livingstone.)

Clinical Presentation

The clinical presentation and patient observations in shunting are very similar in many ways to the presentation of $\dot{V}/\dot{Q}$ mismatch. Bilateral or unilateral crackles are common owing to the alveolar filling process. Unilateral absence of breath sounds may indicate significant collapse, mass, or effusion; these conditions require treatment before oxygenation can improve. The parenchyma on chest radiograph may be "white" with physiologic

causes of shunting as may occur in the acute respiratory distress syndrome (ARDS). Anatomic shunts may be harder to diagnose as the chest radiograph may appear normal, but can be diagnosed by using 100% O_2 breathing techniques, contrast-enhanced echocardiography, macroaggregated albumin scanning, or pulmonary angiography.[6] Shunt is differentiated from $\dot{V}/\dot{Q}$ mismatch by the lack of increase in PO_2 as fractional inspired oxygen (FiO_2) is increased (see Figure 44-2, *B*).

Alveolar Hypoventilation

Alveolar hypoventilation is discussed subsequently in the section on hypercapnic respiratory failure (Type II).

Diffusion Impairment

Diffusion refers to movement of gas across the alveolar-capillary membrane along a pressure gradient. Although diffusion impairment is rarely a cause of significant hypoxemia at rest, its effects become more pronounced with exercise, which limits the time for gas exchange. Diffusion impairment in interstitial lung disease (e.g., pulmonary fibrosis, asbestosis, sarcoidosis), in which the thickening and scarring of the interstitium undermine normal gas exchange, may contribute 20% to 30% of the widening in the alveolar-arterial O_2 gradient during exercise.[7] Emphysema, with its inherent alveolar destruction, also has subnormal transfer of O_2 and CO_2 between the alveolus and the capillary. The reduced ventilation in both diseases implies that $\dot{V}/\dot{Q}$ mismatch also plays a role in the resulting hypoxemia.

Pulmonary vascular abnormalities can also lead to diffusion impairment. Anemia, pulmonary hypertension, and pulmonary embolus all may reduce capillary blood flow, resulting in diminished gas transfer.

Clinical Presentation

Signs and symptoms are related to the specific disease. Interstitial lung disease may be the diagnosis of a dyspneic patient with a dry cough and fine, basilar crackles on auscultation, and clubbing of the nail beds. Rheumatologic manifestations may be present if the underlying cause is a connective tissue disorder. Joint abnormalities, Raynaud disease, and *telangiectasia* (a vascular lesion formed by dilation of a group of small blood vessels) may be observed. The pallor of anemia can be a clue to poor gas exchange, although chronic hypoxemia may lead to polycythemia and possibly cyanosis. Pulmonary hypertension may manifest with signs of right-sided heart failure, such as edema, jugular venous distention, and a louder pulmonary component of the second heart sound.

Diffusion impairment can also manifest with multiple, varied radiographic forms. The hyperinflated, dark radiograph of emphysema was mentioned earlier. Interstitial disease may manifest with reduced lung volumes with interstitial markings. Enlarged right ventricle and pulmonary arteries may be evident in secondary pulmonary hypertension.

Perfusion/Diffusion Impairment

Perfusion/diffusion impairment is a cause of hypoxemia in individuals with liver disease complicated by the hepatopulmonary syndrome.[6] In this condition, right-to-left intracardiac shunt combines with dilated pulmonary capillaries resulting in impaired gas exchange because the normal alveolar partial pressures of O_2 may be insufficient to drive the O_2 molecules to the center of the dilated pulmonary vasculature. Cirrhosis is the most common liver disease, and portal hypertension is usually present. Although shunt is a component of the syndrome, significant supplemental O_2 can overcome the hypoxemia, so this is commonly called a *perfusion/diffusion defect.*

Clinical Presentation

Obvious signs of liver disease (e.g., ascites, jaundice, and spider nevi) may or may not be present. Digital clubbing can occur in hepatopulmonary syndrome. **Platypnea**, which is the sensation of dyspnea when moving to the upright position from the supine position, may be a patient complaint. **Orthodeoxia**, an actual decrease in the measured O_2 level, may parallel this subjective sensation.

Decreased Inspired Oxygen

Also clinically uncommon, hypoxemia may develop when the inspired O_2 is less than body requirements. The most common situation is at high altitude, where hypoxemia occurs not because of a decrease in the fraction of oxygen in the ambient air (which remains 21%) but from barometric pressure decreases, which results in a decrease in the partial pressure of inspired O_2. Even with pressurized airplanes, air travelers with chronic hypoxemia may still need supplemental O_2.[8] Similarly, mountain climbers sometimes require O_2 masks. Cases of patient-O_2 disconnects and delivery of an incorrect gas source are also included in this category.

Inspired O_2 less than 21% can be used diagnostically and therapeutically. The Hypoxia Altitude Simulation Test replicates inspired partial pressure of O_2 (PiO_2) during air travel by asking the potential traveler to inhale a hypoxic mixture. Inhaling at FiO_2 of 15% replicates the PiO_2 found at an altitude of 8000 feet (108 mm Hg). For a lower altitude of 5400 feet, an equivalent FiO_2 of 17% can be calculated.[8] Infants with certain cyanotic congenital heart defects (e.g., hypoplastic left ventricle) may benefit from FiO_2 below room air level. In the preoperative state, low FiO_2 helps to prevent pulmonary dilation and the excessive pulmonary blood flow, which could flood the lungs.

Clinical Presentation

The signs and symptoms of hypoxemia may be present, with the cause related to the patient environment such as the altitude.

Venous Admixture

A decrease in mixed venous O_2 increases the gradient by which O_2 needs to be stepped up as it passes through the lungs and can contribute to the development of hypoxemia. Congestive heart failure with low cardiac output is the most common cause of low mixed venous O_2, owing to increased peripheral extraction of O_2, and there are therefore other, more important coexisting determinants of hypoxemia, such as $\dot{V}/\dot{Q}$ mismatch and

shunting.[3] Other causes include low hemoglobin concentration and increased O_2 consumption. A low mixed venous O_2 may have a significant effect on the ultimate arterial O_2 tension in the presence of lung disease.

Clinical Presentation

Signs and symptoms of congestive heart failure or underlying lung disease, or both, may be present and typically overshadow the clinical presentation.

Differentiating the Causes of Acute Hypoxemic Respiratory Failure

It is important to recognize the physiologic basis of each of the three main causes of hypoxemic respiratory failure (hypoventilation, $\dot{V}/\dot{Q}$ mismatch, and shunt). Hypoventilation differs from the other causes in manifesting with a normal alveolar-to-arterial PO_2 difference [$P(A-a)O_2$] indicating normal lung parenchyma (Table 44-1). A clinical determination of this difference is made by subtracting PaO_2 from PAO_2 (partial pressure of alveolar O_2) derived from the alveolar air equation:

$$PAO_2 = FiO_2(P_B - P_{H_2O}) - PaCO_2/R$$

where P_B is barometric pressure, P_{H2O} is water vapor tension, and R is the respiratory exchange ratio (0.8).

The $P(A-a)O_2$ ranges from 10 mm Hg in young patients to approximately 25 mm Hg in elderly patients while breathing room air (see the accompanying Rule of Thumb). In patients with hypoxemia caused by hypoventilation, treatment can be focused on improving ventilation because the hypoxemia is purely a result of alveolar displacement of O_2 by elevated CO_2.

RULE OF THUMB

The mean alveolar-to-arterial difference [$P(A-a)O_2$] in PO_2 increases slightly with age and can be estimated with the following equation:

Mean age-specific $P(A-a)O_2 = (age/4) + 4$

Example: A 76-year-old person living at sea level:

$P(A-a)O_2 = (76/4) + 4 = 19 + 4 = 23$ mm Hg

A $\dot{V}/\dot{Q}$ mismatch and shunt both result in elevated $P(A-a)O_2$ levels, indicating that the resultant hypoxemia is due to an abnormality of lung tissue, requiring treatment to address that abnormality. When the RT encounters an increased $P(A-a)O_2$, a $\dot{V}/\dot{Q}$ mismatch and shunt can be differentiated by means of O_2 administration (see Figures 44-1 and 44-2). A significant response to applying even small amounts of O_2 identifies $\dot{V}/\dot{Q}$ mismatch as the cause of hypoxemia because altered $P(A-a)O_2$ has not been totally obliterated. True shunt shows little or no improvement in oxygenation even with 100% FiO_2 (see Table 44-1). As a result, treatment of intrapulmonary shunt must be directed toward opening collapsed alveoli or clearing fluid or exudative material before O_2 can be beneficial at below toxic levels. Testing to rule out anatomic shunt should be done in the right clinical setting (e.g., clear or black parenchyma on the chest radiograph).

TABLE 44-1

Differentiating the Cause of Hypoxemia

Cause	$P(A-a)O_2$	Response to Increased FiO_2
Hypoventilation	Normal	Marked
Shunt	Increased	Minimal
$\dot{V}/\dot{Q}$ mismatch	Increased	Marked

HYPERCAPNIC RESPIRATORY FAILURE (TYPE II)

Hypercapnic respiratory failure (type II), also known as *pump, bellows* or *ventilatory failure,* is characterized by an elevated $PaCO_2$, creating an uncompensated respiratory acidosis (whether acute or acute-on-chronic). $PaCO_2$ and alveolar ventilation ($\dot{V}_A$) are inversely related, meaning that alveolar and arterial PCO_2 levels are doubled when alveolar ventilation is halved. This is illustrated by the metabolic hyperbola relationship:

$$PaCO_2 = (0.863\ \dot{V}CO_2)/\dot{V}_A$$
$$\dot{V}_A = MV\ (1 - V_D/V_T)$$

where $\dot{V}_A$ is alveolar ventilation (L/min), MV is minute ventilation, V_D/V_T is dead space-to-tidal volume ratio, and $\dot{V}CO_2$ is CO_2 production (ml/min).

This equation demonstrates a rectangular hyperbola relation between the $PaCO_2$ and ventilation (Figure 44-3). Patients with chronic hypercapnia and low ventilation are on a steeper section of the metabolic hyperbola such that a minor drop in ventilation results in a significant increase in $PaCO_2$, making them more susceptible to developing a sudden, further increase in $PaCO_2$ in the context of even minor respiratory exacerbations. Additionally, with chronically elevated arterial $PaCO_2$, the ventilatory response to a further increase in $PaCO_2$ is more blunted.[9] This leads to an *acute ventilatory failure superimposed on chronic ventilatory failure.*

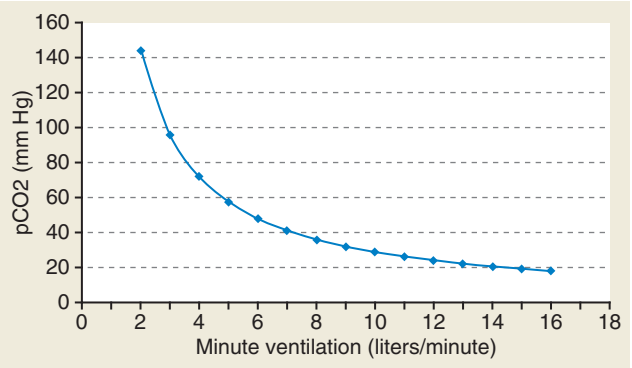

FIGURE 44-3 The metabolic hyperbola. Due to the hyperbolic relationship between the pCO_2 and ventilation, a minor drop of ventilation occurring at an already low minute ventilation results in a significantly greater increase in the pCO_2 relative to an equivalent drop occurring at a higher minute ventilation.

MINI CLINI

Differentiating Causes of Hypoxemia

PROBLEM: Two patients present with the following ABG values at sea level:

Patient A		Patient B	
pH	7.45	pH	7.21
$PaCO_2$	33 mm Hg	$PaCO_2$	72 mm Hg
PaO_2	40 mm Hg	PaO_2	53 mm Hg
HCO_3^-	22 mEq/L	HCO_3^-	28 mEq/L
SaO_2	70%	SaO_2	81%
FiO_2	0.21	FiO_2	0.21

1. Define the respiratory condition indicated by each ABG analysis.
2. What is the $P(A-a)O_2$ for each blood gas?
3. Identify the type of respiratory failure in each case.
4. In which case would administration of 100% FiO_2 help determine therapy?

Discussion:

1. Patient A exhibits uncompensated respiratory alkalosis with hypoxemia. Patient B exhibits partially compensated respiratory acidosis with hypoxemia.
2. Patient A:
   $PAO_2 = 0.21\ (760 - 47) - 33/0.8 = 108$ mm Hg
   $PaO_2 = 40$ mm Hg
   $P(A-a)O_2 = 108 - 40 = 68$ mm Hg on room air
   Patient B:
   $PAO_2 = 0.21\ (760 - 47) - 72/0.8 = 60$ mm Hg
   $PaO_2 = 53$ mm Hg
   $P(A-a)O_2 = 60 - 53 = 7$ mm Hg on room air
   The normal values for $P(A-a)O_2$ range from 10 mm Hg in young people to approximately 25 mm Hg in elderly people while breathing room air.
3. Patient A has hypoxemic respiratory failure (type I) as characterized by below-normal PaO_2 (40 mm Hg). $PaCO_2$ is also below normal (33 mm Hg), indicating hyperventilation is occurring in an effort to improve the oxygenation. Patient B has hypercapnic respiratory failure (type II) as characterized by above-normal $PaCO_2$ (72 mm Hg) indicating hypoventilation (ventilatory failure) is occurring. There is also an elevation of HCO_3^- (28 mEq/L), indicating that the acute ventilatory failure is superimposed on chronic ventilatory failure. This patient is also hypoxemic (53 mm Hg).
4. Patient A has hypoxemic respiratory failure with $P(A-a)O_2$ of 68 mm Hg, which is well above normal, indicating an oxygenation defect. The administration of 100% O_2 in this case would help to determine the cause of the defect. Significant response to 100% FiO_2 would point to $\dot{V}/\dot{Q}$ mismatch as the cause, whereas shunt would be implicated if PaO_2 did not respond to the increase in delivered O_2. In the latter condition, some form of PEEP would be necessary to improve gas exchange by improving functional residual capacity. Patient B has hypercapnic respiratory failure (ventilatory failure) with hypoxemia, but with $P(A-a)O_2$ of 7 mm Hg, which is within the normal range. A pure ventilatory defect is the cause of hypoxemia, and administration of 100% FiO_2 would not help to determine therapy. Depending on the full patient scenario, this patient may require non-invasive mechanical ventilation or intubation and invasive mechanical ventilation to restore normal acid-base status.

Similarly, this relationship shows that $PaCO_2$ may increase as dead space (V_D/V_T) rises or as CO_2 production ($\dot{V}CO_2$) increases. Additionally, a change in the $\dot{V}/\dot{Q}$ distribution of the lung toward lower ratios not only causes hypoxemia, as shown in Figures 44-1 and 44-2, but also to a lesser extent can cause an elevation of $PaCO_2$ by reducing the CO_2 discharge from the pulmonary circulation to the alveoli. However, increased dead space, increased $\dot{V}CO_2$, and shifts in the $\dot{V}/\dot{Q}$ distribution toward lower ratios all are usually matched by a corrective increase in ventilation because respiratory control mechanisms tend to maintain the $PaCO_2$ constant. The following sections describe mechanisms of hypercarbia caused by an imbalance between CO_2 exposure (external or internal) and CO_2 clearance (central and respiratory effector mechanisms). Hypoxemia may often accompany pump failure simply because of the displacement of alveolar PO_2 (PAO_2) by the increased $PaCO_2$ from alveolar hypoventilation. This situation is identified on a room air ABG assessment by a normal $P(A-a)O_2$ as discussed previously. The presence of an increased $P(A-a)O_2$ indicates that concomitant hypoxemia is present, most likely as a result of $\dot{V}/\dot{Q}$ mismatch or shunt. The disorders responsible for hypercapnic respiratory failure (ventilatory failure) are discussed next.

Insidious Exposure

Although most cases of increased $PaCO_2$ are due to hypoventilation, an insidious exposure can occur in certain situations.

Clinical Presentation

These insidious exposures follow unusual clinical scenarios including defective CO_2 scrubbers in the settings of anesthesia machines or life-support systems in scuba units, airtight chambers, spacecrafts, or submersible crafts. Occupational exposures also occur in spelunkers in caves (from groundwater seepage), individuals who work with dry ice (dry ice is a solid form of CO_2), miners, and firefighters.

Increased Carbon Dioxide Production

Fever, agitation, exertion, shivering, hypermetabolism, and excess caloric intake all can result in an increase in $\dot{V}CO_2$, with consequent hypercapnia in patients with additional impairment in respiratory control and effector mechanisms.

Clinical Presentation

The most common clinical scenario involving increases in CO_2 production probably involves mechanically ventilated patients with an already compromised lung function, in whom attempts to liberate from artificial ventilation are complicated by type II respiratory failure. Recognition and management of fever, agitation, hypermetabolic states, and excess caloric intake, particularly with carbohydrate-rich enteral solutions, may contribute to a favorable outcome.

Impairment in Respiratory Control

Both central (medullary) and peripheral (aortic and carotid bodies) chemoreceptors responding to CO_2 tension and O_2 tension stimulate the drive to breathe.[9] This ventilatory drive can be diminished by various factors, such as drugs (overdose or sedation), bilateral carotid endarterectomy with incidental resection of the carotid bodies, brainstem lesions, diseases of the CNS (multiple sclerosis, Parkinson disease, or elevated intracranial pressure), hypothyroidism, morbid obesity (e.g., obesity-hypoventilation), and sleep apnea. Other, less common potential causes include metabolic alkalosis, metabolic encephalopathy, malnutrition, and sleep deprivation.[10] Patients at risk of having a decreased ventilatory drive usually can be identified by their clinical situation (e.g., CNS insult, overdose of sedative medications), and the clinician should be attentive to reversible causes.

Clinical Presentation

The hallmark of the clinical scenario of decreased ventilatory drive is bradypnea and perhaps ultimately apnea. A respiratory rate is usually no less than 12 breaths/min in adults. Drug overdose or a brain disorder can manifest with an altered level of consciousness ranging from merely lethargic to obtunded and comatose, with decreased respirations. Evidence of drug use by history or toxicity screen confirms the diagnosis of drug overdose. Evidence of head trauma and brain computed tomography (CT) scan abnormalities are important in the diagnosis of a brain disorder. Although hypothyroidism classically manifests with fatigue, weight gain, hyporeflexia, and constipation, it can progress to significant hypoventilation and myxedema coma. Patients with obesity-hypoventilation may have a rapid, shallow breathing pattern, which results from decreased compliance and microatelectasis. Although these patients may also have nighttime sleep apnea, daytime $PaCO_2$ is also elevated because of a decrease in the drive to breathe or an increase in the **work of breathing**.[11] See Figure 44-3 for the relationship between PCO_2 and minute volume.

Impairment in Respiratory Effectors

Neurologic Diseases

The lungs inhale and exhale under the guidance of the CNS. In some patients, the CNS signal does not reach its goal, resulting in neuromuscular dysfunction. Examples include spinal trauma, motor neuron disease in which lesions of the anterior horn cells may gradually lead to progressive ventilatory failure (e.g., amyotrophic lateral sclerosis or poliomyelitis), motor nerve disorders (including Guillain-Barré syndrome and Charcot-Marie-Tooth disease), disorders of the neuromuscular junction (e.g., myasthenia gravis and botulism), and muscular diseases (including muscular dystrophy, myositis, critical care myopathy, and metabolic disorders).[12]

Clinical Presentation. Although hypercapnia may be a common end point, these diseases have varied clinical presentations. Patient observation is a key skill. Drooling, dysarthria, and weak cough are common bulbar signs in amyotrophic lateral sclerosis and myasthenia gravis. As muscle wasting and weakness become more severe, diaphragmatic insufficiency develops, and supine paradoxical breathing is common.[13] Guillain-Barré syndrome commonly manifests with lower extremity weakness progressing to the respiratory muscles in one-third of patients.[14] Weak cough and gag may be seen, which can threaten airway patency and lead to microatelectasis, hypoxemia, and uncompensated respiratory acidosis. Myasthenia gravis does not always result in respiratory failure.[15] These diseases are quite different in clinical course, but there is much overlap in their presentations, and they commonly result in respiratory **muscle fatigue** and failure and elevated $PaCO_2$.

Increased Work of Breathing

Despite normal respiratory drive, nerve transmission, and neuromuscular response, hypercapnic respiratory failure can still occur if the imposed workload cannot be overcome.[3,16] Most commonly, this situation occurs when increased dead space accompanies COPD, or elevated airway resistance accompanies asthma. Both of these obstructive airway diseases may increase respiratory work requirements excessively secondary to the presence of intrinsic **positive end-expiratory pressure (auto-PEEP)**. Increased workload can also result from thoracic abnormalities such as pneumothorax, rib fractures with a flail chest, pleural effusions, and other conditions creating a restrictive burden on the lungs. Finally, requirements for increased minute ventilation can arise when increased CO_2 production accompanies hypermetabolic states, such as in extensive burns.

Clinical Presentation. The RT must be alert to the possibility of respiratory failure when a heavy load is imposed on the respiratory system. Patients with asthma or COPD should present with hyperventilation in an exacerbation, but if breathing becomes more rapid but shallow, it may indicate impending failure. This increased V_D/V_T ratio leads to hypercapnia because the significant airway obstruction does not resolve with treatment. Diminished breath sounds in a young patient with asthma likewise can be an ominous sign. Irritability, confusion, and ultimately coma are possible signs in worsening hypercapnia, as they are in hypoxemic respiratory failure. More subtle findings include muscle tremor owing to catecholamine release and papilledema resulting from cerebral vasodilation in states of elevated arterial PCO_2.[17]

In summary, hypercapnic (type II) respiratory failure, also known as *ventilatory failure*, develops when ventilation is impaired secondary to intrinsically or extrinsically increased CO_2 exposure; impairment in respiratory control; or impairment in respiratory effector mechanisms, including neurologic

TABLE 44-2

Causes of Respiratory Failure

Type I (Hypoxemic)	Type II (Hypercapnic)			
	Increased Exposure	Impaired Respiratory Control	Neurologic Disease	Increased Work of Breathing
ARDS	Extrinsic	Drug overdose	Spinal cord trauma	Obstructive lung disease
Pulmonary embolism	Defective CO_2 scrubbers (anesthesia or life-support systems)	Bilateral endarterectomy with carotid body resection	Motor neuron	COPD
Pulmonary edema	Occupational exposure (miners, spelunkers, dry-ice workers, firemen)	Central sleep apnea	Poliomyelitis	Asthma
Septic shock	Intrinsic	Hypocapnia	Amyotrophic lateral sclerosis	Upper airway obstruction
Pulmonary infection	Fever	Cheyne-Stokes	Motor nerve	Obesity-hypoventilation
Viral	Shivering	Acromegaly	Phrenic nerve	Pneumothorax
Bacterial	Hypermetabolism	Hypothyroid	Guillain-Barré	Severe burns
Fungal	Agitation	Brainstem lesions	Charcot-Marie-Tooth	Chest wall disorders
Inhalation	Excess caloric intake	Cerebrovascular accident	Neuromuscular junction	Kyphoscoliosis
Smoke		Encephalitis	Myasthenia gravis	Ankylosing spondylitis
Chemical		Multiple sclerosis	Botulism	
Water		Parkinson disease	Muscular	
Pleural effusion		Metabolic alkalosis	Muscular dystrophy	
Interstitial lung disease		Primary alveolar hypoventilation	Myositis	
Obstructive lung disease		(Ondine's curse)	Myopathy	
Aspiration		Congenital central hypoventilation	Acid maltase	
Primary pulmonary hypertension		Carotid body resection Obesity-hypoventilation	Metabolic	

disease or pulmonary and chest wall disorders associated with increased work of breathing (Table 44-2).

CHRONIC RESPIRATORY FAILURE (TYPE I AND TYPE II)

For some patients with pulmonary disease and respiratory failure, the condition has developed over weeks to months to years and has become a chronic state, allowing compensatory adaptive mechanisms to develop. Most commonly, chronic hypercapnic respiratory failure accompanying COPD or obesity-hypoventilation syndrome elicits a renal response, and the kidneys retain bicarbonate to elevate the blood pH. However, this compensatory metabolic alkalosis would not be expected to restore the pH to normal. Chronic hypercapnic respiratory failure is also known as *chronic ventilatory failure*.

RULE OF THUMB

Chronic and acute hypercapnic respiratory failure can be differentiated by the severity of change in pH.[16]

- Acute hypercapnic failure (acute ventilatory failure): pH decreases 0.08 for every 10-mm Hg increase in $PaCO_2$
- Chronic hypercapnic failure (chronic ventilatory failure): pH decreases 0.03 for every 10-mm Hg increase in $PaCO_2$

Similarly, polycythemia may result from prolonged hypoxemic respiratory failure (e.g., sleep apnea) when O_2 delivery to the tissues is compromised, and erythropoietin levels increase to elicit erythrocytosis. Hemoglobin also releases O_2 more easily as the O_2 dissociation curve shifts to the right in the face of acidosis. Finally, O_2 delivery to the brain is enhanced when hypercapnia results in increased cerebral blood flow.[17]

Acute-on-Chronic Respiratory Failure

Chronic respiratory failure can be complicated by acute setbacks that create acute-on-chronic respiratory failure. Patients with chronic hypercapnic respiratory failure are at significant risk for this condition, as indicated by the fact that COPD is now the third leading cause of death in the United States.[18] Acute-on-chronic respiratory failure can also be the presenting manifestation of neuromuscular disease in the setting of a concurrent pulmonary infection.[19] Most common precipitating factors include bacterial or viral infections, congestive heart failure, pulmonary embolus, pneumothorax, chest wall dysfunction, and medical noncompliance.[19-21] In these patients, the presence of respiratory failure cannot be judged by the normal ABG criteria but by a significant change from the baseline $PaCO_2$ to a level having the potential for morbidity and mortality.

Treatment goals include normalizing pH (avoiding mechanical ventilation if possible), elevating SaO_2 to 90% (if hypoxemia is also present), improving airflow, treating infection,

monitoring and maintaining fluid status, and preventing or treating complications as necessary.[16,20,21] Deaths are less due to respiratory failure, and more associated with dysfunction of other organs, older age, significant baseline disease, a severe precipitating illness, severity of acidosis, and presence of complications.[22] Episodes of acute respiratory failure in these patients seem to have a significant long-term influence with mortality rates reaching 45% within the year after an exacerbation requiring mechanical ventilation and tracheostomy.[23]

Patients with chronic hypoxemic respiratory failure (type I) are at similar risk for acute deterioration of hypoxemia. Infection and heart failure can result in worsening of the tenuous oxygenation status of patients with interstitial pulmonary fibrosis or primary pulmonary hypertension.

Complications of Acute Respiratory Failure

Although respiratory failure is life-threatening by itself, complications frequently arise that can add significantly to morbidity and mortality. Especially in patients with ARDS, more deaths are due to complications (e.g., sepsis, multiorgan failure) than to the primary disease.[24] Modern ICUs with sophisticated mechanical ventilation can prolong but may not preserve life. Pulmonary complications such as emboli, **barotrauma**, and infection may be secondary to treatment strategies such as catheters, mechanical ventilation, and endotracheal tubes. A wide array of nonpulmonary complications may develop, including bacteremia, malnutrition, psychosis secondary to prolonged ICU stays, cardiac disorders (e.g., arrhythmias, hypotension), gastrointestinal ailments (e.g., hemorrhage, dysmotility), and renal disturbances (e.g., acute renal failure, positive fluid balance).

Clinical Presentation

Clinically, a patient with respiratory muscle fatigue shows an initially increased respiratory rate followed by *bradypnea* (slowed respiratory rate) and apnea as fatigue ensues. **Respiratory alternans**, which is a phasic alternation between rib cage and abdominal breathing, may also occur. Opinions vary on the sensitivity and specificity of abdominal motion paradox in patients with respiratory muscle weakness, but at least some investigators suggest that respiratory muscle paradox is an early sign (see Chapter 16). When ventilatory failure is full-blown, ABG results show hypercapnia with acidosis. As mentioned earlier, the presence of hypercapnia with acidosis can also indicate that the respiratory center is not responding properly.[25]

Tachypnea is the cardinal sign of increased work of breathing. Tachypnea occurs when the respiratory center increases breathing frequency in an attempt to lessen respiratory excursion and reduce the amount of work performed by the respiratory muscles.[26] Overall workload is reflected in the minute volume needed to maintain normocapnia.

Indications for Ventilatory Support

For each type of oxygenation and ventilatory failure, the goal of mechanical ventilation is either to support the patient until the underlying problem resolves or to maintain support of the patient with chronic ventilatory problems. These goals may be achieved by improving alveolar ventilation and arterial oxygenation, increasing lung volume, or reducing work of breathing.[27] This section discusses the indications for mechanical ventilation for hypoxemic (type I) and hypercapnic (type II) respiratory failure. Hypoxemic respiratory failure is divided into processes that require short-term and long-term ventilatory support. Hypercapnic respiratory failure is broken down into

MINI CLINI

Acute or Chronic Hypercapnic Respiratory Failure

PROBLEM: A 55-year-old man presents to the emergency department complaining of increased shortness of breath and yellow-green sputum production for 1 week. He is alert and oriented. He has a 60 pack-year smoking history. Vital signs are blood pressure 165/90 mm Hg, pulse 120 beats/min, respirations 25 breaths/min, and temperature 100.5° F oral.

ABG values on room air are as follows:

pH	7.28
$PaCO_2$	70 mm Hg
PaO_2	35 mm Hg
HCO_3^-	36 mm Hg
SaO_2	66%

1. Define the respiratory condition indicated by the ABG results.
2. What is the $P(A - a)O_2$?
3. What type of respiratory failure is present?
4. What kind of therapy is indicated?

Discussion

1. The ABG values indicate a partially compensated respiratory acidosis with hypoxemia.
2. $PAO_2 = 0.21\ (760 - 47) - 70/0.8 = 62$ mm Hg
   $PaO_2 = 35$ mm Hg
   $P(A - a)O_2 = 62 - 35 = 27$ mm Hg on room air
3. This is hypercapnic respiratory failure (type II), also known as *ventilatory failure*. However, in acute failure, the pH decreases 0.08 for every 10-mm Hg increase in $PaCO_2$. In this patient, $PaCO_2$ has increased 30 mm Hg (70 – 40), and the pH has decreased 0.12. The pH would be expected to decrease 0.24 (3 × 0.08) if this were acute ventilatory failure. This is a case of acute-on-chronic failure. HCO_3^- of 36 mEq/L (normal 22 to 26 mEq/L) also indicates renal compensation has occurred, which takes days to achieve. $P(A - a)O_2$ is 27 mm Hg, which is above normal, indicating that hypoxemia cannot be explained fully by hypoventilation.
4. Because the patient is alert, conservative therapy to improve lung function is indicated. O_2 administration to achieve SaO_2 of at least 90% is required. If PaO_2 does not respond to O_2 administration, shunt is present, and positive airway pressure may be necessary. Antibiotics are indicated for the probable infection (fever, discolored sputum), and bronchopulmonary hygiene (bronchodilators, steroids, cough assist) is indicated to improve ventilation.

unstable ventilatory drive, muscle fatigue, excessive work of breathing, and alveolar hypoventilation.

Parameters Indicating Need for Ventilatory Support

Although various measurements have been proposed to help decide if a patient needs mechanical ventilation, the clinical status of the patient is the most important criterion. Table 44-3 and the discussion that follows review common physiologic indicators for initiating support by the underlying cause of respiratory failure.

Hypoxemic Respiratory Failure. Severe, refractory hypoxemia is a common indication for intubation and ventilator support. Table 44-3 lists different measures of hypoxemia that have been used to assess the need for ventilatory support. Most commonly, PaO_2 is compared with FiO_2 as with the PaO_2/FiO_2 ratio or the alveolar-arterial O_2 difference [$P(A-a)O_2$]. Indicators of profoundly impaired oxygenation suggesting the need for intubation, high inspired O_2 administration, and PEEP include $P(A-a)O_2$ value of 350 mm Hg on FiO_2 of 1.0 or a PaO_2/FiO_2 value of less than 200. These values are useful for all causes of hypoxemic respiratory failure (type I) but cannot help distinguish if the process is a readily reversible one, such as pulmonary edema or atelectasis, or a process that resolves more slowly, such as acute lung injury. Frequently, patients have a combination of hypoxemic and hypercapnic respiratory failure.

Hypercapnic Respiratory Failure (Ventilatory Failure). As previously discussed, hypercapnic (type II) respiratory failure or ventilatory failure can be caused by increased ventilatory dead space, increased CO_2 production, or decreased alveolar ventilation. All of these processes cause an increase in $PaCO_2$.[25] Assessment of the pH allows a determination of whether the problem is acute or chronic. Chronic hypoventilation is compensated by the kidneys' retention of bicarbonate, although this response requires several days. The following example shows the importance of pH in interpreting the significance of elevated $PaCO_2$.

	Patient A	Patient B
$PaCO_2$	60 mm Hg	60 mm Hg
Serum HCO_3^-	25 mEq/L	36 mEq/L
pH	7.25	7.38

Although both patients in this example have the same level of hypercapnia, only patient A exhibits acute ventilatory failure with an elevated $PaCO_2$ but normal serum bicarbonate (25 mEq/L). Patient B has a compensated respiratory acidosis from chronic hypercapnic respiratory failure, as indicated by the normal pH and elevated serum bicarbonate (36 mEq/L). This condition is also known as *chronic ventilatory failure*. The distinction between acute and chronic ventilatory failure is very important in respiratory care and emphasizes the need to use both $PaCO_2$ and pH as indicators for ventilatory support. The trend in pH and $PaCO_2$ values is also useful in assessing the effects of therapies in correcting acute ventilatory failure.

Significance of Elevated Alveolar Partial Pressure of Carbon Dioxide. Because elevated $PaCO_2$ increases ventilatory drive in healthy subjects, the existence of hypoventilation suggests other problems with the respiratory apparatus. Specifically, the presence of acute respiratory acidosis indicates one of three major problems: (1) The respiratory center is not responding normally to elevated $PaCO_2$; (2) the respiratory center is responding normally, but the signal is not getting through to the respiratory muscles; or (3) despite normal neurologic response mechanisms, the lungs and chest bellows are incapable of providing adequate ventilation because of parenchymal lung disease or muscular weakness.[28]

TABLE 44-3

Physiologic Indicators for Ventilatory Support, Classified by Mechanism Underlying Respiratory Failure

Mechanism	Normal Values	Support Indicated
Inadequate Alveolar Ventilation		
$PaCO_2$ (mm Hg)	35-45	>55
pH	7.35-7.45	<7.20
Inadequate Lung Expansion		
Tidal volume (V_T) ml/kg	5-8	<5
Vital capacity (VC) ml/kg	65-75	<10
Respiratory rate	12-20	>35
Inadequate Muscle Strength		
Maximum inspiratory pressure (cm H_2O)	–80-100	≥–20
Vital capacity (VC, ml/kg)	65-75	<10
Maximum voluntary ventilation (MVV, L/min)	120-180	<2× VE
Increased Work of Breathing		
Minute ventilation ($\dot{V}_E$)	5-6	>10
V_D/V_T (%)	0.25-0.40	>0.6
Hypoxemia		
$P(A-a)O_2$ on 100% O_2 (mm Hg)	25-65	>350
PaO_2/FiO_2	350-450	<200

VE, Minute ventilation.

ASSESSMENT OF RESPIRATORY FATIGUE, WEAKNESS, FAILURE, AND WORK OF BREATHING

Respiratory Muscle Weakness

Respiratory muscle weakness refers to the decreased capacity of a rested muscle to generate force and decreased endurance.[29] Respiratory muscle weakness occurs most commonly in patients with neuromuscular disease. Other conditions that lead to muscle weakness by increasing demand include COPD, kyphoscoliosis, and obesity.

The most commonly used tests to assess respiratory muscle strength at the bedside are **maximum inspiratory pressure (MIP)** and **maximum expiratory pressure (MEP)**,[30] forced vital capacity, and **maximum voluntary ventilation (MVV)** (see Table 44-3). MIP of –30 cm H_2O or less (more negative)

usually indicates adequate respiratory muscle strength to continue spontaneous breathing, but the overall trend needs to be considered. This consideration is especially important in patients with myasthenic crisis or Guillain-Barré syndrome, where values of MIP that are becoming less negative may be the only clue to impending respiratory failure. The MVV maneuver can be performed at the bedside with a hand-held spirometer, but its use in the critical care setting is limited because substantial patient cooperation is required. The **sniff nasal inspiratory pressure** may also be used to assess inspiratory muscle strength. Advantages include ease of performance even in patients with advanced disease and its prognostic value.[31]

Respiratory Muscle Fatigue

Fatigue is usually defined as a condition in which there is loss of the capacity to develop force or velocity of a muscle resulting from muscle activity under load, which is reversible by rest.[32] Fatigue can be assessed by measuring the loss of force in response to repeated stimulations. It can be caused by both specific demands placed on the muscle and reduced supply of necessary nutrients. The demand on a muscle is increased by increased work of breathing, increased strength of muscle contraction, and decreased muscle efficiency. Hypoxemia, decreased inspiratory muscle blood flow, poor nutrition, and inability of a muscle to extract energy from supplied substrates can lead to fatigue as well.[29]

There are three types of respiratory **muscle fatigue**. (1) Central muscle fatigue is an exertion-induced, reversible decrease in central respiratory drive; (2) transmission muscle fatigue is an exertion-induced, reversible impairment in the transmission of neural impulses; and (3) contractile muscle fatigue is a reversible impairment in the contractile response to a neural impulse in an overloaded muscle.[28]

Respiratory Failure

Respiratory failure is an unfavorable imbalance between a respiratory workload, on the one hand, and ventilatory muscle strength and endurance, on the other hand. The **tension-time index** takes into account the fact that respiratory muscle endurance depends both on the magnitude of the respiratory load in relation to respiratory strength (P_{di}/P_{dimax}) and on the duration of the inspiratory effort in relation to total breath time (the duty cycle, or T_i/T_{tot}). This index (P_{di}/P_{dimax}) × (T_i/T_{tot}) determines whether a respiratory load can be tolerated without development of failure: Values less than 0.15 are generally tolerated for a long period, whereas indices greater than 0.18 usually result in fatigue and respiratory failure within 45 minutes.[33] Comparing the spontaneous minute ventilation with MVV is also a helpful index because fatigue and failure are both likely to occur if the minute ventilation exceeds 60% of MVV.[34]

These closely related concepts of weakness, fatigue, and failure usually overlap and can result in acute or chronic respiratory failure. Respiratory muscle weakness can predispose to ventilatory muscle fatigue. Whether fatigue consistently leads to failure has historically been the subject of much debate.[35] In one study, weaning failure was not accompanied by fatigue of the diaphragm despite the presence of diaphragm weakness.[36] Alternatively, fatigue of the diaphragm lasting for 24 hours is reliably present after hyperventilation at 60% of MVV or greater until task failure.[34,37]

Work of Breathing

Work of breathing is the amount of pressure needed to move a given volume into the lung with a relaxed chest wall. Excessive work of breathing is the most common cause of respiratory muscle fatigue. Work of breathing is due to physiologic work and imposed work. Physiologic work involves overcoming the elastic forces during inspiration and overcoming the resistance of the airways and lung tissue. Normal work of breathing is 0.3 to 0.6 J/L. Airway and pulmonary parenchymal abnormalities can increase the physiologic work of breathing. In intubated patients, sources of imposed work of breathing include the endotracheal tube, ventilator circuit, and **auto-PEEP** secondary to **dynamic hyperinflation** with airflow obstruction, as is commonly seen in a patient with COPD.[26] Increased work of breathing can also be an impediment to weaning.[38] Measurement of work of breathing with an esophageal balloon catheter and a flow transducer has been used to determine work of breathing and break it down into physiologic and imposed components.[38] Kirton and colleagues[39] showed that 96% of patients with a physiologic work of breathing less than 0.8 J/L were successfully weaned and extubated from ventilatory support.

CHOOSING A VENTILATORY SUPPORT STRATEGY FOR DIFFERENT CAUSES OF RESPIRATORY FAILURE

The remainder of this chapter briefly discusses current ventilatory strategies for hypoxemic and hypercapnic respiratory failure. The clinical application of specific modes of mechanical ventilation is described in Chapters 45 and 48, and noninvasive ventilation (NIV) is reviewed in more detail in Chapter 49. When it has been determined that the patient needs ventilatory support, the initial decision is whether to intubate or to ventilate noninvasively. In the acute setting, this decision is sometimes based on the underlying process, the type of respiratory failure, and how rapidly the underlying process can be reversed.

Noninvasive Ventilation

A consensus report supports the use of noninvasive support of ventilation to reduce the morbidity and possibly the mortality of both hypoxemic and hypercarbic respiratory failure.[40] In this context, **noninvasive ventilation (NIV)** can be defined as any mode of ventilatory support that is provided without endotracheal intubation, encompassing continuous positive airway pressure (CPAP) alone or in combination with any mode of pressure-limited or volume-limited ventilation.[40] NIV can improve hypoxemia and hypercarbia via several mechanisms including but not limited to (1) compensating for the inspiratory threshold load imposed by intrinsic PEEP,[41] (2) supplementing a reduced tidal volume,[42] (3) partial or complete unloading of the respiratory muscles,[42] (4) reducing venous

return and left ventricular afterload,[43,44] (5) alveolar recruitment,[45] (6) preventing intermittent narrowing and collapse in patients with concomitant obstructive sleep apnea hypopnea syndrome by acting as a pneumatic splint during sleep,[46] and (7) improving lung function (particularly functional residual capacity) and daytime gas exchange in obstructive sleep apnea hypopnea syndrome.[47] NIV currently has indications in both acute[48] and chronic[49] respiratory failure.

Noninvasive Ventilation in Acute Conditions

Exacerbations of Chronic Obstructive Pulmonary Disease

NIV is considered to be a standard of care in patients with exacerbations of COPD.[50] For instance, NIV combined with usual care in exacerbations of COPD reduces treatment failure (defined as mortality, need for intubation, or intolerance) such that the number needed to treat (NNT) to prevent 1 treatment failure was 5, intubations (NNT = 5), mortality (NNT = 8), complications (NNT = 3), and hospital length of stay by about 3 days.[50]

Recommendations are to initiate NIV when the $PaCO_2$ is greater than 45 mm Hg but before the development of severe acidosis in the course of a COPD exacerbation.[50] Otherwise, in patients with mild COPD exacerbations (pH >7.35), NIV was no more effective than standard medical therapy.[51] Nearly 50% of the patients did not tolerate NIV.[51]

Cardiogenic Pulmonary Edema

NIV is a recommended option in the management of acute respiratory failure in the setting of cardiogenic pulmonary edema. Studies showed that either CPAP or NIV in these patients significantly reduced dyspnea score, heart rate, acidosis, and hypercapnia within the first hour after the start of treatment.[52,53] In the largest study, mortality, rates of intubation, rate of admission to the critical care unit, or mean length of hospital stay were not improved,[52] but smaller trials showed decreased intubation and mortality rates with NIV.[53] Selection and methodologic criteria may explain the difference, see Chapter 49.

Acute Asthma

Studies have shown that NIV in asthma associated with acute respiratory failure progressively improved pH and $PaCO_2$ over 12 to 24 hours, reduced the respiratory rate, improved lung function, resolved the attack faster, and reduced the need for hospitalization.[54-55] Despite those promising results, the use of NIV in status asthmaticus remains controversial, and large, prospective, randomized controlled trials are needed to confirm the role of NIV in that setting.[56]

Acute Lung Injury and Acute Respiratory Distress Syndrome

NIV in the settings of acute lung injury and ARDS has been disappointing with a 50% to 84% failure rate.[57-59] A prospective study showed that NIV was successful in improving gas exchange and avoiding intubation in 54% of patients, with consequent reduction in ventilator-associated pneumonia and lower ICU mortality rate.[60] Factors that may be associated with NIV failure in these settings include the presence of shock, metabolic acidosis, severe hypoxemia, a Simplified Acute Physiology Score (SAPS) II greater than 34, and a PaO_2/FiO_2 less than 175 after 1 hour of NIV.[58-60]

Noninvasive Ventilation in Chronic Conditions

Obesity-Hypoventilation Syndrome

Obesity-hypoventilation syndrome refers to the presence of daytime hypercapnia ($PaCO_2$ > 45 mm Hg) in obese individuals when no other cause of hypoventilation is present. Factors associated with daytime hypercapnia include body mass index, the presence of nocturnal apnea hypopnea, mean overnight O_2 saturation, and severity of restrictive pulmonary function.[11] Average volume-assured pressure support, a form of NIV in which pressure support is automatically adjusted to reach a set tidal volume, lowers $PaCO_2$ compared with bilevel positive airway pressure alone but without improving oxygenation, sleep quality, or quality of life.[61]

Stable Chronic Obstructive Pulmonary Disease

NIV in patients with severe COPD and $PaCO_2$ greater than 46 mm Hg improves survival, but adherence to NIV is low, some quality of life indices appear to show worsening with NIV, and there was no reduction in hospitalization rates,[62] perhaps owing to selection of inspiratory pressures that were insufficient to reduce hypercapnia. For instance, compared with low-intensity NIV (mean inspiratory positive airway pressure 14 cm H_2O, backup rate 8/min), the use of settings that aimed to reduce $PaCO_2$ maximally (mean inspiratory positive airway pressure 29 cm H_2O with backup rate 17.5/min) increased the daily use of NIV by 3.6 hr/day and improved exercise-related dyspnea, daytime $PaCO_2$, forced expiratory volume in 1 second, vital capacity and health-related quality of life.[63]

Neuromuscular Diseases and Thoracic Cage Abnormalities

Several studies show that even in progressive neuromuscular disorders, NIV can prolong survival, improve quality of life, enhance cognitive function, and reduce pneumonia and hospitalization rates.[12] Other NIV techniques using rocking beds, pneumobelts, and negative pressure ventilation are much less frequently used and are becoming less easily available.

Invasive Ventilatory Support

Patients with profound hypoxemia from a process that is expected to resolve slowly, such as acute lung injury, usually require intubation and mechanical ventilation. Other indications for intubation include conditions where NIV may be poorly tolerated or even deleterious, such as the presence of upper airway obstruction, inability to clear secretions and protect airway, inability to achieve a proper mask fit, and intolerance of the intervention. Both hypoxemic and hypercarbic

MINI CLINI

Indications for Continuous Positive Airway Pressure versus Continuous Mechanical Ventilation With Positive End Expiratory Pressure

PROBLEM: A patient in the ICU is severely tachypneic and hypoxemic. The respiratory rate is 30 breaths/min. On approximately 50% O_2 by mask at sea level, PaO_2 is 50 mm Hg, $PaCO_2$ is 30 mm Hg, pH is 7.51, and HCO_3^- is 23 mEq/L. The patient is in distress but alert and able to cooperate and follow instructions.

1. What is this patient's $P(A-a)O_2$?
2. What type of respiratory failure is this?
3. What is the appropriate initial therapy?

Discussion: This patient does not have hypercapnic respiratory failure, as is confirmed by $PaCO_2$ of 30 mm Hg. The patient does have a serious oxygenation defect, as confirmed by $P(A-a)O_2$.

$$PAO_2 = 0.50\,(713) - 30/0.8 = 318 \text{ mm Hg}$$
$$P(A-a)O_2 = 318 - 50 = 268 \text{ mm Hg}$$

The elevated $P(A-a)O_2$ indicates the presence of severe intrapulmonary shunt. Shunts this severe can occur only when significant airway closure and atelectasis are present. The mode of therapy should be aimed at reinflating collapsed alveoli and keeping the alveoli open throughout the breathing cycle. In this patient, alveolar ventilation is not impaired ($PaCO_2$ = 30 mm Hg). CPAP alone may be effective in reducing shunt. (CPAP does not ventilate the patient; all breaths are patient-initiated and spontaneous.) CPAP may be applied noninvasively via face mask, as would be indicated in this alert, cooperative patient. If hypercapnia and acidemia develop, mechanical ventilation with PEEP would be indicated.

MINI CLINI

Acute Hypercapnic Respiratory Failure

PROBLEM: A patient with COPD presents to the emergency department in moderate respiratory distress. He is alert and cooperative. Respiratory rate is 26 breaths/min. Lung examination shows poor air entry with expiratory wheezing. Room air ABGs show pH 7.24, $PaCO_2$ 60 mm Hg, and PaO_2 60 mm Hg.

1. What type of respiratory failure is this?
2. How should the patient be managed?

Discussion: ABGs show an acute respiratory acidosis with normal $PAO_2 - PaO_2$ gradient.

$$PAO_2 = 0.21\,(713) - 60/0.8 = 74$$
$$P(A-a)O_2 = 74 - 60 = 14 \text{ mm Hg}$$

This patient has hypercapnic respiratory failure related to obstructive lung disease, also known as *ventilatory failure*. In addition to bronchodilators and corticosteroids, the RT should aim to improve ventilation to reverse the respiratory acidosis. In this patient, who is alert and cooperative, NIV via face mask may be tried. Initial mask ventilation can start in the pressure support ventilation mode with a level of support of 10 cm H_2O and 5 cm H_2O PEEP. Tidal volume should be maintained at approximately 6 to 8 ml/kg. If this patient deteriorates despite therapy, he will need to be intubated and mechanically ventilated.

types of respiratory failure can be managed effectively by invasive mechanical ventilation.

There are several ventilator variables, some independently set by the operators and others that are dependent on the set variables. Independent and dependent variables vary with the mode of ventilation. FiO_2 and **PEEP** are independently set variables regardless of mode of ventilation used to manage hypoxemia. In volume-controlled or flow-controlled ventilation, tidal volume, flow, and respiratory rate are independently set variables. In **pressure control ventilation**, driving pressure, inspiratory time, and respiratory rate are independently set variables. Other modes and strategies include inverse ratio ventilation, liquid ventilation, prone positioning, and airway pressure release ventilation. Considerations in selected cases of respiratory failure requiring invasive ventilatory support are briefly reviewed.

Acute Respiratory Distress Syndrome

Profound hypoxemic respiratory failure is often due to severe pneumonia and ARDS. Patients with these conditions have very noncompliant lungs. Volume-cycled ventilation in patients with ARDS frequently leads to high peak airway and plateau pressures. Ventilating these patients with small tidal volumes (about 6 ml/kg) reduces complications associated with mechanical ventilation and improves survival.[64]

Increased Intracranial Pressure

Hyperventilation applied acutely and for short periods may be used to reduce ICP. The goal is to lower $PaCO_2$ to between 25 mm Hg and 30 mm Hg, which causes alkalosis, which in combination with hypocapnia helps reduce cerebral blood flow until ICP can be controlled by other measures. Ongoing ventilatory support should maintain PCO_2 in the range of 30 to 40 mm Hg. By maintaining PCO_2 in this range, sudden increases in ICP can be quickly controlled by short-term hyperventilation. Although reducing blood flow can reduce brain swelling and ICP, cerebral ischemia can also result. Another concern in ventilating patients with elevated ICP is using PEEP to manage hypoxemia. There is a concern that increased intrathoracic pressure secondary to PEEP would cause decreased cerebral venous return leading to increased ICP and that PEEP can decrease cerebral perfusion by limiting cardiac output. The use of PEEP in patients with elevated ICP may require invasive monitoring of ICP because the combination of decreased cerebral perfusion and elevated ICP can narrow cerebral perfusion pressure.[65] Elevation of the head of the bed can offset the increased ICP associated with the application of PEEP.

Obstructive Lung Disease

Patients with obstructive lung disease have markedly increased airway resistance that leads to a decrease in the rate of expiratory flow with resulting hyperinflation. These patients frequently have problems with elevated airway pressure or dynamic hyperinflation (auto-PEEP), which can cause barotrauma and increased dyssynchrony, especially ineffective triggering of the ventilator.[66]

The management goal for patients with obstructive lung disease and respiratory failure is to oxygenate and ventilate the patient successfully, while avoiding dyssynchrony and dynamic hyperinflation. In these patients, lower tidal volumes (6 to 8 ml/kg), moderate respiratory rates, and high sustained (square wave) inspiratory flow rates (70 to 100 L/min) are recommended to avoid dynamic hyperinflation.[67] These maneuvers reduce inspiratory time and prolong expiratory time, which allows a patient with obstructive lung disease to have a longer time to exhale.

Another consideration in patients with obstructive lung disease is the inspiratory threshold load imposed by auto-PEEP resulting in increased patient inspiratory work.[41] In this case, applied (or extrinsic) PEEP can compensate for this threshold load and reduce the work of breathing for patient-triggered breaths in any assisted ventilatory mode.[41]

Ventilatory Support in Chronic Hypercapnic Respiratory Failure

The goal of therapy in hypercapnic respiratory failure (acute ventilatory failure) is to guarantee a set minute ventilation. In treating patients with chronic ventilatory failure, the goal is to normalize the pH but not the $PaCO_2$. Correction of $PaCO_2$ in a patient with chronic hypoventilation from diverse causes can lead to a posthypercapnic metabolic alkalosis, which can produce hypokalemia, seizures, and arrhythmias.

SUMMARY CHECKLIST

- Acute respiratory failure is identified by PaO_2 less than 60 mm Hg or $PaCO_2$ greater than 50 mm Hg, or both, in otherwise healthy individuals at sea level.
- Hypoxemic respiratory failure is most commonly due to $\dot{V}/\dot{Q}$ mismatch, shunt, or hypoventilation.
- Hypercapnic respiratory failure, also known as *ventilatory failure*, results from decreased ventilatory drive, neurologic disease, or increased work of breathing.
- Chronic respiratory failure may manifest with hypercapnia and evidence of a compensatory metabolic alkalosis (chronic ventilatory failure) or with polycythemia reflecting chronic hypoxemia.
- The clinical status of the patient is the most important factor determining the need for ventilatory support.
- Excessive work of breathing is the most common cause of respiratory muscle fatigue.
- The beneficial role of NIV in the acute setting has been best established in acute exacerbations of COPD and in cardiogenic edema.
- Increased FiO_2 and PEEP are the main therapies for severe hypoxemia.
- The goal of therapy in hypercapnic respiratory failure (acute ventilatory failure) is to normalize the pH.

CHAPTER 45

Mechanical Ventilators

ROBERT L. CHATBURN AND TERESA A. VOLSKO

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Define a mechanical ventilator.
- Differentiate between automatic resuscitators and mechanical ventilators.
- Describe the key design features of mechanical ventilators.
- Describe the 10 maxims used to develop a standardized ventilator taxonomy.
- Describe the operating characteristics of mechanical ventilators used along the continuum of care.
- List the basic ways to present monitored data.
- List the three main goals of mechanical ventilator support.

CHAPTER OUTLINE

KEY TERMS

assisted breath
continuous mandatory ventilation (CMV)
continuous spontaneous ventilation (CSV)
control system
cycle
elastance
intermittent mandatory ventilation (IMV)
loaded breathing
mandatory
mode
pressure-control ventilation
resistance
spontaneous breath
time constant
trigger
trigger variable
volume-control ventilation

To safely and effectively initiate and manage a mechanical ventilator, the respiratory therapist must thoroughly understand (1) ventilator design, classification, and operation; (2) appropriate clinical application of ventilatory modes (i.e., the proper matching of ventilator capability with physiologic need); and (3) the physiologic effects of mechanical ventilation, including gas exchange and pulmonary mechanics. This chapter focuses on the first of these. It explains classification terminology and outlines a framework for understanding current and future ventilatory support devices.[1-3]

HOW VENTILATORS WORK

To understand how ventilators work, one must have some knowledge of basic mechanics. A ventilator is a machine, which is a system designed to alter, transmit, and direct applied energy in a predetermined manner to perform useful work.[4] These complex machines deliver an array of medical gas mixtures such as nitric oxide, helium, and oxygen. Sophisticated software and advanced monitoring systems make it possible to deliver mechanical breaths from conventional or normal physiologic to high frequency rates.

Ventilators used along the continuum of care, from intensive care units to patient transport to long-term and home care, require energy in the form of either electricity or compressed gas to function. The energy is transmitted or transformed (by the ventilator's drive mechanism) in a predetermined manner (by the control circuit) to augment or replace the patient's muscles in performing the work of breathing (the desired output). Thus, to understand mechanical ventilators, their four basic functions must be understood:

- Input power
- Power transmission and conversion
- Control system
- Output (pressure, volume, and flow waveforms)

This simple outline format can be expanded to add as much detail about a given ventilator as desired.

Input Power

The power source for a ventilator comes from either electrical energy (energy = volts × amperes × time) or compressed gas (energy = pressure × volume).

Electrical Energy

An electrically powered ventilator uses voltage from an electrical line outlet. In the United States, this line voltage is normally 110 to 115 volts alternating current (AC) (60 Hz). In addition to powering the ventilator, this AC voltage may be reduced and converted to direct current (DC). This DC source can then be used to power delicate electronic control circuits.

Some ventilators, notably portable ventilators used for transport or to provide mechanical ventilation in the home, have rechargeable batteries to be used as a source of power if AC is not available. The length of time power is provided from an internal or external battery depends on the ventilator's drive mechanism, the ventilator settings, the load of the respiratory system, and the type of battery used to provide power. Lithium ion and nickel metal hydride batteries are more compact, weigh less, and have higher power with shorter recharging times compared with similar-sized lead/acid batteries. Battery power becomes essential when providing mechanical ventilation out of the acute care setting. Although portable ventilators have an internal battery that provides power on a limited basis, the availability of an external battery can be an essential lifesaving feature in the event of an extended power outage.

Pneumatic Energy

A pneumatically powered ventilator uses compressed gas as its power source. Most modern intensive care unit (ICU) ventilators are pneumatically powered. Ventilators powered by compressed gas usually have internal pressure-reducing valves so that the normal operating pressure is lower than the source pressure. This allows uninterrupted operation from hospital-piped gas sources, which are usually regulated to 50 psi (pounds per square inch) but are subject to periodic fluctuations.

Most pneumatically powered ICU ventilators still require electrical power to support their control functions (see the following section on control mechanisms). However, a few pneumatically powered ventilators can function without electrical power, using compressed gas to power lung inflation and the ventilator's control circuitry. Pneumatically powered ventilators are ideal in situations where electrical power may be unavailable (e.g., during patient transport), in a mass casualty situation where the influx of patient are triaged and stabilized in an area where electrical power is scarce (e.g., parking lot located adjacent to an emergency department), or as a back-up to electrically powered ventilators in case of extended power failures. They are also particularly useful where electrical power is undesirable, such as near magnetic resonance imaging (MRI) equipment. It is essential to understand how the ventilator consumes compressed gas, especially in settings where the compressed gas source may be limited, such as air or ground transport. Weight restrictions, especially on air transport, affect the number and size of the gas cylinders used. Therefore, it is essential for the respiratory therapist to anticipate the total amount of compressed gas needed (air, oxygen, and specialty gas). Since the compressed gas source is limited during interhospital transport, the respiratory therapist must ensure the compressed gas supply will not deplete and cause the ventilator to fail on the way to the transport team's final destination.

RULE OF THUMB

For patient transport, you must use either a pneumatically powered ventilator or one that can run solely on batteries. Always take along a manually powered bag-valve mask resuscitator, and for long transports be sure to have back-up power available (extra cylinders or batteries).

Power Transmission and Conversion

The power transmission and conversion system consists of the drive and output control mechanisms. The drive mechanism generates the actual force needed to deliver gas under pressure. The output control consists of one or more valves that regulate gas flow to the patient.

Drive Mechanism

The ventilator's drive mechanism converts the input power to useful work. The characteristic flow and pressure patterns the

ventilator produces are determined, in part, by the type of drive mechanism it contains. Drive mechanisms can be either (1) a direct application of compressed gas through a pressure-reducing valve or (2) an indirect application by an electrical motor or compressor. Descriptions of these devices are given in textbooks devoted to respiratory care equipment.[5]

Output Control Valve

The output control valve regulates the flow of gas to the patient. Early ventilators had simple on/off exhalation valves. For most modern ventilators, the output control valve can shape the output waveform, as in the Maquet SERVO-i (Maquet, Bridgewater, NJ). Commonly used output control valves include the pneumatic diaphragm, electromagnetic poppet/plunger valve, and proportional valve.[6]

Control System

To manipulate pressure, volume, and flow, a ventilator must have a **control system**. A control system measures and directs the output of the ventilator and operates the exhalation manifold. A ventilator control circuit may include mechanical, pneumatic, electrical, electronic, or fluidic components. Most modern ventilators combine two or more of these subsystems to provide user control.

Mechanical control circuits use devices such as levers, pulleys, and cams. These types of circuits were used in the early manually operated ventilators illustrated in history books.[7] Pneumatic control is provided using gas-powered pressure regulators, needle valves, jet entrainment devices, and balloon-valves. Some transport ventilators use pneumatic control systems.

Electrical control circuits use only simple switches, rheostats (or potentiometers), and magnets to control ventilator operation. Electronic control circuits use devices such as resistors, capacitors, diodes, and transistors as well as combinations of these components in the form of integrated circuits. The most sophisticated electronic systems, incorporated into ventilators used in critical care, use microprocessors and complex software algorithms to manage monitoring and control ventilator function.

Fluidic logic-controlled ventilators, such as the Bio-Med MVP-10 (Bio-Med Devices, Stanford, CT) also use pressurized gas to regulate the parameters of ventilation. However, instead of simple pressurized valves and timers, these ventilators use fluidic logic circuits that function much like electrical circuit boards.[8] Fluidic control mechanisms have no moving parts and low gas consumption, which make them useful for patient transport. Additionally, fluidic circuits are immune to failure from surrounding electromagnetic interference, as can occur around MRI equipment. It is important to note that the MVP-10 does not have an alarm system to alert the clinician of a patient disconnect, or changes in the patient's lung mechanics that will affect minute ventilation. It is essential for the clinician to rely on information from noninvasive (e.g., pulse oximetry and end-tidal carbon dioxide monitoring) and cardiopulmonary monitoring (e.g., heart rate, respiratory rate, blood pressure) to evaluate and optimize the patient–ventilator interaction.

The Operator Interface

The ventilator's operator interface has undergone extensive evolution over the last 35 years. Originally, the displays on ventilators were analog. Operator inputs, or settings, were accomplished with hard-wired knobs, buttons, and dials. The ventilator outputs, such as alarm conditions and ventilating pressure, were displayed with bulbs, light emitting diodes (LEDs), and meters. Some simple transport ventilators still use analog displays (Figure 45-1). The development of inexpensive microprocessors has led manufacturers to use digital displays almost exclusively on all types of ventilators. Digital interfaces use LED or LCD screens for visual display of ventilator data along with some multipurpose hard-wired buttons. More advanced displays use dedicated special-purpose buttons and dials (Figure 45-2). The most advanced interfaces use the concept of the "virtual" instrument, meaning that knobs, buttons, dials, and meters are simulated on a computer screen (sometimes a touch screen) and often incorporate a single mechanical dial that is used to set multiple parameters (Figure 45-3). Computer screens allow graphic displays of alarm settings as, for example, bar graphs along with pressure, volume, and flow waveforms as scalars or loops.

Ventilator Displays

The output displays of monitored data have also evolved significantly over the last 30 years. Ventilator and patient data are available as alphanumeric values, waveforms, trend lines, and even picture graphics.

Alphanumeric Values. Measured or calculated data in the form of alphanumeric values are presented in numbers or text. Typically F_IO_2, pressures (mean, baseline, peak, and plateau), volumes (inhaled/exhaled tidal volume, minute ventilation), and frequency are represented as numeric values. A variety of calculated parameters including I:E ratio, peak inspiratory and expiratory flow, percent leak, resistance, and compliance may also be displayed.

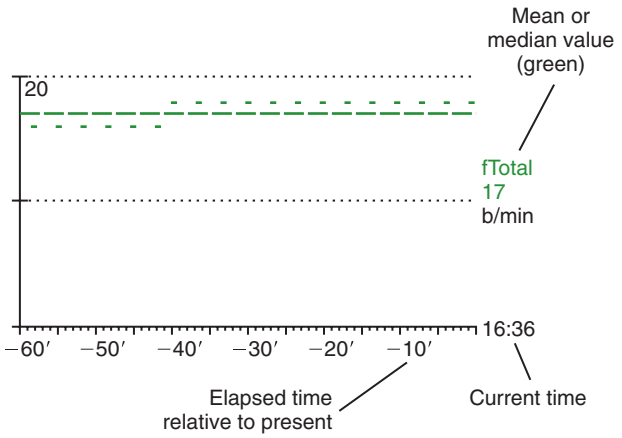

FIGURE 45-4 Trend screen display from the Hamilton G5 ventilator. (Courtesy Hamilton Medical.)

Trends. Trends provide clinicians with measured or calculated data related to ventilatory support over time (Figure 45-4). Gradual or sudden changes in the patient's ventilatory status can be identified by evaluating trends. Alarm logs can also be accessed and provide an additional layer of detail important for adjusting alarm limits to minimize nuisance alarms and enhance safety. Alarm logs can be invaluable in the event of a suspected ventilator failure and may be used as evidence in a legal investigation if significant patient harm has occurred.

Waveforms and Loops. Graphic displays of pressure, volume, and flow convey a wealth of information. Not only is it possible to determine the mode of ventilation by examining these graphics but one can also determine the causes of patient–ventilator asynchrony, including flow asynchrony, delayed or premature cycling, and missed triggers. Graphic representations of respiratory mechanics are helpful for identifying the ventilator parameters to be adjusted to improve the ventilator-patient interaction.[9,10] When pressure, volume, or flow is graphed on the vertical axis with time on the horizontal axis, a waveform or "scalar" display (Figure 45-5) is the result. Loop displays plot one variable against another as *x-y* graphs (Figure 45-6). Pressure-volume (PV) loops can be used to set optimal PEEP and tidal volume levels (Figure 45-7).[11] PV loops are created by using a "super syringe" to inject discrete volumes of gas and then measuring static pressures (static pressure–volume curve) or by using a ventilator at very low constant inspiratory flows (less than 10 L/min) or slow pressure ramps to minimize the pressure due to flow resistance and create what are called *quasi-static* loops. It is usually necessary to heavily sedate and/or paralyze the patient to avoid errors due to the patient's inspiratory efforts or minimize patient anxiety and discomfort during the maneuver. For volume control modes, pressure-volume loops are useful in displaying overdistention. Flow-volume loops are helpful in identifying the need for suctioning and/or response to bronchodilator therapy. An example of a composite display showing numeric values, waveforms, and loops is shown in Figure 45-8.

Picture Graphics. An interesting development in ventilator displays involves the use of picture graphics to represent useful

MINI CLINI

The Use of Trending Data to Optimize the Application of Mechanical Ventilation

PROBLEM: A patient with respiratory distress is ventilated with the following settings:

Mode: PC-CMV
Set frequency: 12/minute
Inspiratory pressure: 28 cm H_2O
PEEP: 8 cm H_2O
F_IO_2: 0.60
Inspiratory time: 1 second
The following trends are available:

Date	8/8	8/8	8/8	8/8	8/8	8/8
Time	0000	0200	0400	0600	0800	1000
V_T (mL)	420	415	390	385	373	362
Total frequency (Breaths/minute)	12	12	12	12	12	12
Minute ventilation (L/minute)	5.04	4.98	4.68	4.62	4.48	4.34

What value does the trend monitoring provide for the clinician? What additional data are needed for the clinician to optimize ventilation?

Answer: The data shows that the patient has had no respiratory effort over the recorded time period monitored. This can be seen by comparing the set frequency to the total frequency. The trends also show that the tidal volume has decreased over time. This can be attributed to an increase in airway resistance or a reduction in lung compliance (or both) because the mode was a form of pressure ventilation. Accessing the trends for airways resistance will enable the clinician to differentiate between airways resistance and lung compliance problems. If the airways resistance has remained relatively stable, the pulmonary compliance has decreased. Additional testing, such as chest radiography and arterial blood gas monitoring, may be required to determine pathologic changes such as atelectasis as well as aberrancies in acid-base balance.

information about the patient–ventilator system. Obstructed endotracheal tubes and auto-PEEP problems are detected more quickly and treated sooner with graphic rather than conventional displays.[12] Clinicians also perceive lower subjective workloads when using picture graphics.

Hamilton Medical was the first to make use of innovative picture graphics on their G5 ventilator. They created a graphic representation of the lungs, called a *dynamic lung panel,* that visually displays information about resistance and compliance by the shape and color of the lungs and airways (Figure 45-9). In addition, they have created a unique graphic representation called the *vent status panel* which displays key parameters (e.g., oxygenation, ventilation, and spontaneous breathing activity) and shows when each item is in or out of an acceptable zone and for how long. This makes weaning status, for example, easy to identify. Dräger Medical followed with a similar graphic display called the *Smart Pulmonary View,* which is a graphic display of respiratory system compliance and resistance as well as of the spontaneous and mandatory minute volume (Figure 45-10).

Alarm Settings

The purpose of ventilator alarms is to bring events to the attention of the clinician. *Events* are conditions or occurrences that require clinician awareness or intervention. Events can be classified according to four levels of priority.[13] Level 1 events are immediately life threatening. These include things such as insufficient or excessive gas delivery to the patient, exhalation valve failure, control circuit failure, or loss of power. Alarm indicators in this category should be mandatory (cannot be turned off by the operator), redundant, and noncanceling. Level 2 events range from mild irregularities in machine function to dangerous situations that could threaten patient safety if left unattended. These include failure of the air-oxygen blending system, inadequate or excessive PEEP, auto-triggering, circuit leak, circuit occlusion, inappropriate I:E ratio, and failure of the humidification system. Alarms in this category are not necessarily redundant and may be self-canceling (i.e., automatically turned off if the event ceases). Level 3 events reflect changes in the level of ventilatory support. Examples include changes in the patient's ventilatory drive or respiratory system mechanics and the presence of auto-PEEP. Level 3 events often trigger the same alarms as Levels 1 and 2. Level 4 events are focused entirely on the patient. These include changes in gas exchange, dead space, oxygenation, and cardiovascular functions. Many ventilators do not warn of these events, and external monitors are thus required for surveillance.

Ventilators do not display alarm settings in terms of levels of priority. Instead, they tend to lump them all together on the screen (Figures 45-11 and 45-12). The actual setting of alarm thresholds is a complicated topic that has been studied but for which little information is available regarding mechanical ventilation. The basic goal is to maximize true alarms and minimize false alarms. A high false alarm rate leads to clinicians ignoring warnings. False alarms can also lead to inappropriate responses. On average, ICU alarms occur 6 times per hour with only a small percentage indicating an actual urgent clinical situation (23%) and a high percentage being false positive alarms (44%).[14,15] Although studies have not addressed mechanical ventilator alarms specifically, it is not hard to imagine similar

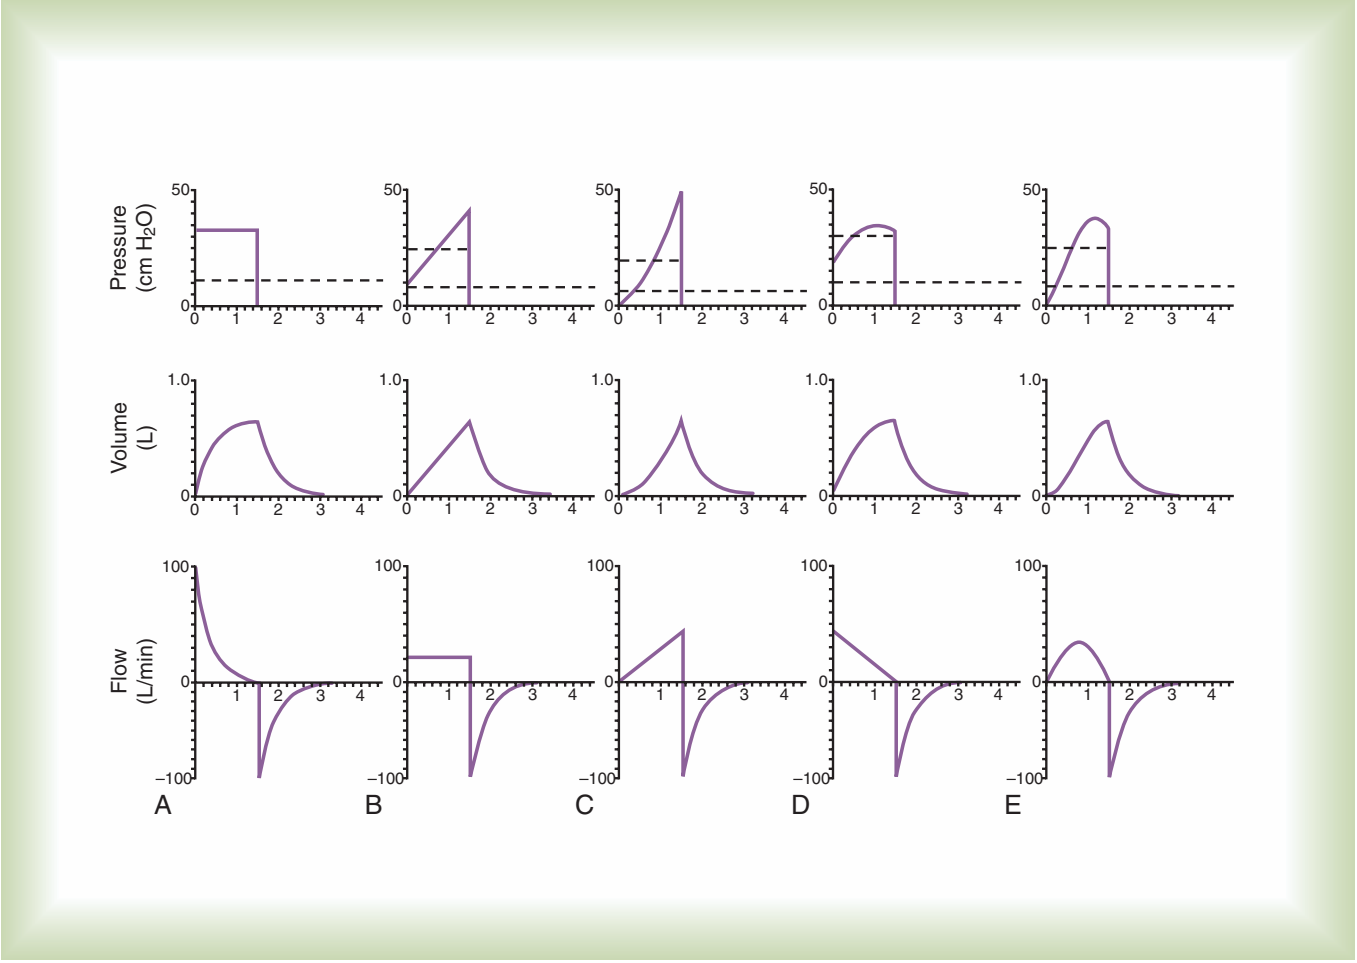

FIGURE 45-5 Model pressure, volume, and flow waveforms generated with a computer using the equation of motion. **A,** Pressure-controlled inspiration with a rectangular pressure waveform (identical to flow-controlled inspiration with an exponential decay flow waveform). **B,** Flow-controlled inspiration with a rectangular flow waveform (identical to volume-controlled inspiration with an ascending ramp volume waveform). **C,** Flow-controlled inspiration with an ascending ramp flow waveform. **D,** Flow-controlled inspiration with a descending ramp flow waveform. **E,** Flow-controlled inspiration with a sinusoidal flow waveform. The short dotted lines represent mean inspiratory pressure, while the long dotted lines represent mean airway pressure (assuming zero PEEP). Note that for the rectangular pressure waveform in **A,** the mean inspiratory pressure is the same as the PIP. For all waveforms, V_T = 644 ml, compliance = 20 ml/cm H_2O, and resistance = 20 cm H_2O/L/sec.

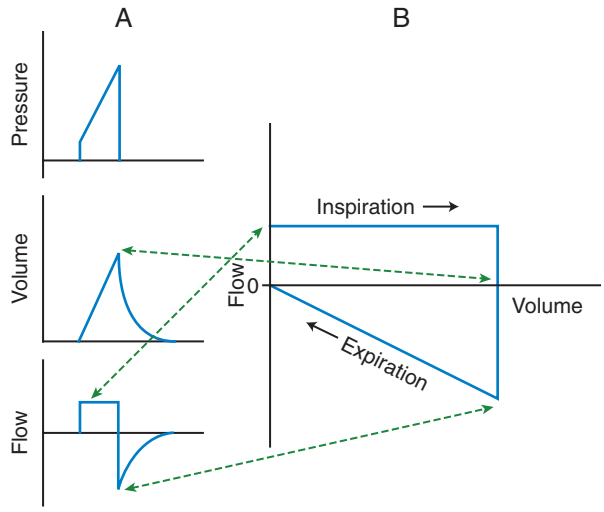

FIGURE 45-6 Idealized waveforms (**A**) for volume control ventilation with corresponding idealized dynamic (not static or quasi-static) pressure-volume loop (**B**). results for such a study. Ventilator alarms are usually set by the operator (or as default values by the ventilator) as either a set value or a set percentage of the current value. Examples would be low and peak airway pressure alarms set at the current value plus or minus 5 cm H_2O or low and high tidal volume/minute ventilation set at plus or minus 25% of the current value. The problem is that the parameters for which clinicians want to set alarms, and these three in particular, are highly variable, with significant portions of readings at extreme values. Therefore limits set as absolute values or percentages may reduce safety for some extreme values while increasing nuisance events for other values. An alternative approach might be to reference the alarm limits to the current value of the parameter such that extreme values have tighter limits. Further research is needed to identify optimization algorithms (i.e., minimize both harmful and nuisance events) for intelligent targeting schemes to automatically set alarms during mechanical ventilation.

The Patient Interface

The patient interface is the connection between the ventilator and the patient—typically a system of plastic hoses, and often called the *patient circuit*. From the perspective of understanding how ventilators work, the important thing to know about the patient circuit is that it contributes to discrepancies between the desired and actual ventilator output values. This is because the patient circuit has its own compliance and resistance. Thus, the pressure measured on the inspiratory side of a ventilator will always be higher than the pressure at the airway opening due to patient circuit resistance. In addition, the volume and flow coming out of the ventilator will exceed that delivered to the patient because of the compliance of the patient circuit.

Using an analogy to electrical circuits, compliance of the delivery circuit can be shown to be connected in series with the compliance of the respiratory system (that is, both elements sharing the same driving pressure). Consequently, the total compliance of the ventilator-patient system is simply the sum

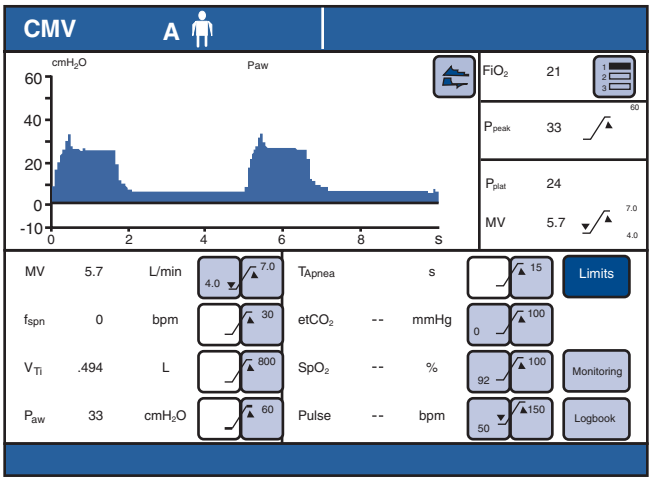

FIGURE 45-12 Alarm panel of Dräger Evita XL ventilator. (Courtesy Dräger Medical.)

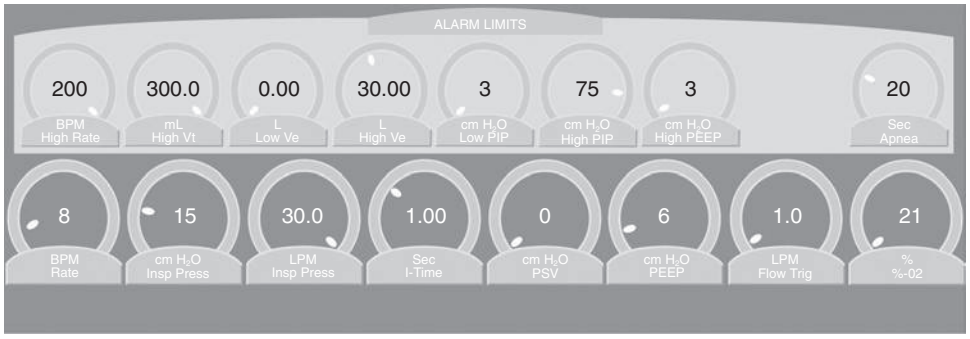

FIGURE 45-11 Alarm panel of CareFusionAvea ventilator. (Courtesy CareFusion.)

of the two compliances. Similarly, the resistance of the delivery circuit is connected in series with the respiratory system resistance (that is, both elements sharing the same flow) so that the total resistance is the sum of the two. Based on these assumptions, the relationship between the volume input to the patient (at the point of connection to the patient's airway opening) and the volume output from the ventilator (at the point of connection to the patient circuit) can be described by the following equation:

$$\text{Volume input to patient} = \frac{\text{Volume output from ventilator}}{1 + C_{pc}/C_{rs}} \qquad \textbf{Equation 45-1}$$

where C_{pc} is the compliance of the patient circuit, and C_{rs} is the total compliance of the patient's respiratory system. The equation shows that the larger the patient circuit compliance compared with the patient's respiratory system, the larger the denominator on the right-hand side of the equation. Hence, the smaller the delivered tidal volume is compared with the volume coming from the ventilator's drive mechanism.

Assuming that the volume exiting the ventilator is the set tidal volume, the patient circuit compliance (C_{pc}) is calculated as follows:

$$C_{pc} = \frac{\text{Set tidal volume}}{P_{plat} - \text{PEEP}} \qquad \textbf{Equation 45-2}$$

where P_{plat} is the pressure measured during an inspiratory hold maneuver with the Y-piece of the patient circuit occluded (patient not connected), and PEEP is end-expiratory pressure (that is, baseline pressure). Most authors recommend the use of PIP for P_{plat} in this equation, which is acceptable but may lead to a slight underestimation of patient circuit compliance. P_{plat} is slightly lower than PIP because of the flow-resistive pressure drop of the patient circuit if pressure is not measured at the Y-piece. This difference is greatest in small-bore, corrugated patient circuit tubing but is probably insignificant.

The effects of patient circuit compliance are most troublesome during volume-controlled ventilation. For example, in neonatal ventilation the patient circuit compliance can be as much as three times that of the respiratory system, even with small-bore tubing and a small-volume humidifier. Thus in an attempt to deliver a preset tidal volume, the volume delivered to the patient may be as little as 25% of that exiting the ventilator, whereas 75% is compressed in the patient circuit.

During pressure-control ventilation the compliance of the patient circuit has the effect of rounding the leading edge of a rectangular pressure waveform, which reduces the peak flow and could reduce the volume delivered to the patient. This effect is prevented if the pressure limit is maintained for at least 5 time constants of the respiratory system.

For both pressure- and volume-control ventilation the patient circuit compliance and resistance, along with the resistance of the exhalation valve (in series with the patient circuit and respiratory system resistance) increase the expiratory time constant. Thus a large circuit compliance coupled with a short expiratory time can lead to inadvertent or auto-PEEP.

In summary, the set values for pressure, volume, and flow may be different from the output (from ventilator) values due to calibration errors and the effects of the patient circuit. Thus two general sources of error cause discrepancies between the desired and actual patient values.

IDENTIFYING MODES OF MECHANICAL VENTILATION

Ventilator manufacturers coin unique names for modes available on their respective devices, primarily as marketing tools. As a result, there have been no industry standards for naming modes of ventilation. This makes it difficult for clinicians to understand how the various modes of ventilation function. In some cases, ventilator modes function in the same way but have very different names. For example, Pressure-Control Ventilation Plus Adaptive Pressure Ventilation on the Hamilton Galileo is the same as Pressure Regulated Volume Control on the Siemens Servo 300. Volume control continuous mandatory ventilation (VC-CMV) on the Maquet SERVO-i ventilator and the PB 840 have identical names, and function very differently.[16]

The 10 Maxims for Understanding Modes

A formal taxonomy for classifying modes of ventilation is now available.[17,18] This portion of the chapter will explain the derivation of this taxonomy in the form of 10 fundamental maxims (concise statements of scientific principles). These fundamental constructs of ventilator design and function are a culmination of data from an international survey[19] and more than 30 years of mechanical ventilation teaching experience.

1. A Breath is One Cycle of Positive Flow (Inspiration) and Negative Flow (Expiration) Defined in Terms of the Flow-Time Curve.

Breath delivery is one of the most basic functions a mechanical ventilator performs. A breath can simply be defined as one cycle of inspiratory flow followed by a matching expiratory flow (Figure 45-13). These flows are paired by size, meaning approximately equal inspiratory and expiratory volumes. However, there are some modes of ventilation in which inspiration is not followed immediately by the matching expiration. Airway pressure release ventilation provides an example of this. During this mode of ventilation the transition from low pressure to high pressure results in a large mandatory breath during inspiration, followed by a few small spontaneous inspirations and expirations during the low-pressure phase, which contribute to a smaller exhaled volume. The transition from high pressure to low pressure results in the matching mandatory exhalation. It is also possible to have many small mandatory breaths superimposed on larger spontaneous breaths, as seen during high-frequency oscillatory ventilation.

Inspiratory time and expiratory time are the two most basic definitions in reference to a breath. Inspiratory time is defined as the period from the start of inspiratory flow to the start of expiratory flow. Inspiratory time is equal to inspiratory flow

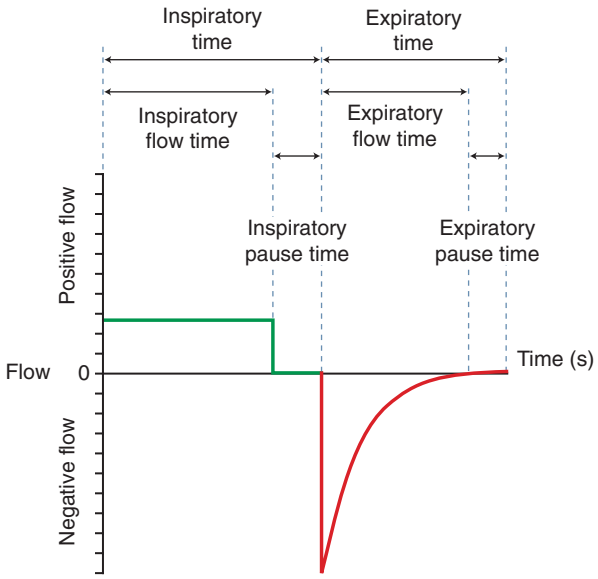

FIGURE 45-13 A breath is defined in terms of the flow-time waveform. (Courtesy Mandu Press Ltd.)

time plus inspiratory hold time. Inspiratory hold or pause time is the period from the cessation of inspiratory flow (into the airway opening) to the start of expiratory flow during mechanical ventilation. On some ventilators, the operator can directly set inspiratory hold time. On others, hold time is the difference between the preset inspiratory time and the inspiratory flow time due to the preset tidal volume at the preset inspiratory flow (i.e., inspiratory flow time = tidal volume/inspiratory flow). An inspiratory pause is often used to improve oxygenation by increasing mean airway pressure. It may also be used to create a static airway pressure also known as *plateau pressure*. During an inspiratory pause, the flow of gas to and from the patient ceases. Therefore, the pressure displayed during the inspiratory pause, or plateau pressure, can be used to calculate respiratory system resistance and compliance. The period from the start of expiratory flow to the start of inspiratory flow is known as *expiratory time*.

2. A Breath is Assisted If the Ventilator Provides Some or All of the Work of Breathing.

Ventilators are designed to assist with the patient's work of breathing. Work is defined in terms of the pressure necessary to deliver the tidal volume to the respiratory system. In the simplest case, work is the pressure change during inspiration times the volume change (i.e., tidal volume).[20] An **assisted breath**, therefore, is one for which the ventilator does some work on the respiratory system. Pressure is generated either by the patient's inspiratory muscles (P_{mus}) or the ventilator (P_{vent}), which causes an increase in the pressure difference across the respiratory system, called *inspiratory pressure* on some ventilators.[21]

On a ventilator graphic display, an assisted breath is identified as one in which airway pressure rises above baseline during inspiration (from Maxim 1, inspiration is identified by flow above zero). A drop in airway pressure below baseline during inspiration indicates that the patient is doing work against the ventilator. We say the breath is "loaded" rather than assisted. Some loading is unavoidable if the patient must signal to the ventilator when to start inspiratory flow by a drop in airway pressure, called *triggering* (see below).[22] Optimization of ventilator settings minimizes **loaded breathing** by maximizing the synchrony between the ventilator output and the patient's demand.

3. A Ventilator Assists Breathing Using Either Pressure Control or Volume Control Based on the Equation of Motion for the Respiratory System.

To understand how a ventilator assists breathing, we make use of a very important model of patient–ventilator interaction called the *equation of motion for the respiratory system*.[23] This equation is a mathematical model describing a physical model composed of a single flow conducting tube (representing the airways) and a single elastic compartment (representing the lungs and chest wall) as shown in Figure 45-14. There are many versions of this equation, but the simplest version, as it relates to ventilator mode classification, is as follows:

$$P_{vent}(t) + = EV(t) + R\dot{V}(t) \qquad \textbf{Equation 45-3}$$

Where $P_{vent}(t)$ is inspiratory pressure generated by the ventilator as a function of time, E is the **elastance** of the respiratory system ($\Delta P/\Delta V$), V(t) is volume as a function of time, R is respiratory-system **resistance** ($\Delta P/\Delta \dot{V}$), and $\dot{V}(t)$ is flow as a function of time. *Note that all these variables are measured relative to their end expiratory values.* Under normal circumstances these values are P_{vent} = set PEEP, V = end expiratory lung volume (functional residual capacity if PEEP = 0), and $\dot{V} = 0$. Sometimes the equation is written with compliance ($C = \Delta V/\Delta P$) instead of elastance, in which case the term EV(t) becomes V(t)/C. If the patient is spontaneously triggering the ventilator, the left side of Equation 45-3 becomes $P_{muscles} + P_{vent}$, indicating that the work of breathing is shared in some way between the patient and the ventilator. However, if the patient is breathing independent of the ventilator, the left side of Equation 45-3 is simply $P_{muscles}$.

A plot of $P_{vent}(t)$, V(t), and $\dot{V}(t)$ versus time yields the waveforms seen on ventilator displays (Figure 45-15). If the shape of the pressure waveform is predetermined by the ventilator settings, independent of changes in respiratory system mechanics, the ventilator is providing *pressure control* (PC). One way to think about this is that the ventilator controls the left-hand side of Equation 45-1. That means for a given pressure waveform [i.e., graph of $P_{vent}(t)$], volume and flow are dependent on E and R. In more practical terms, if the operator sets inspiratory pressure, or inspiratory pressure is controlled by the ventilator to be proportional to some measure of the patient's inspiratory effort, then we say the mode of ventilation is a form of pressure control.

One very confusing issue with **pressure-control ventilation** is that sometimes the operator sets the magnitude of the

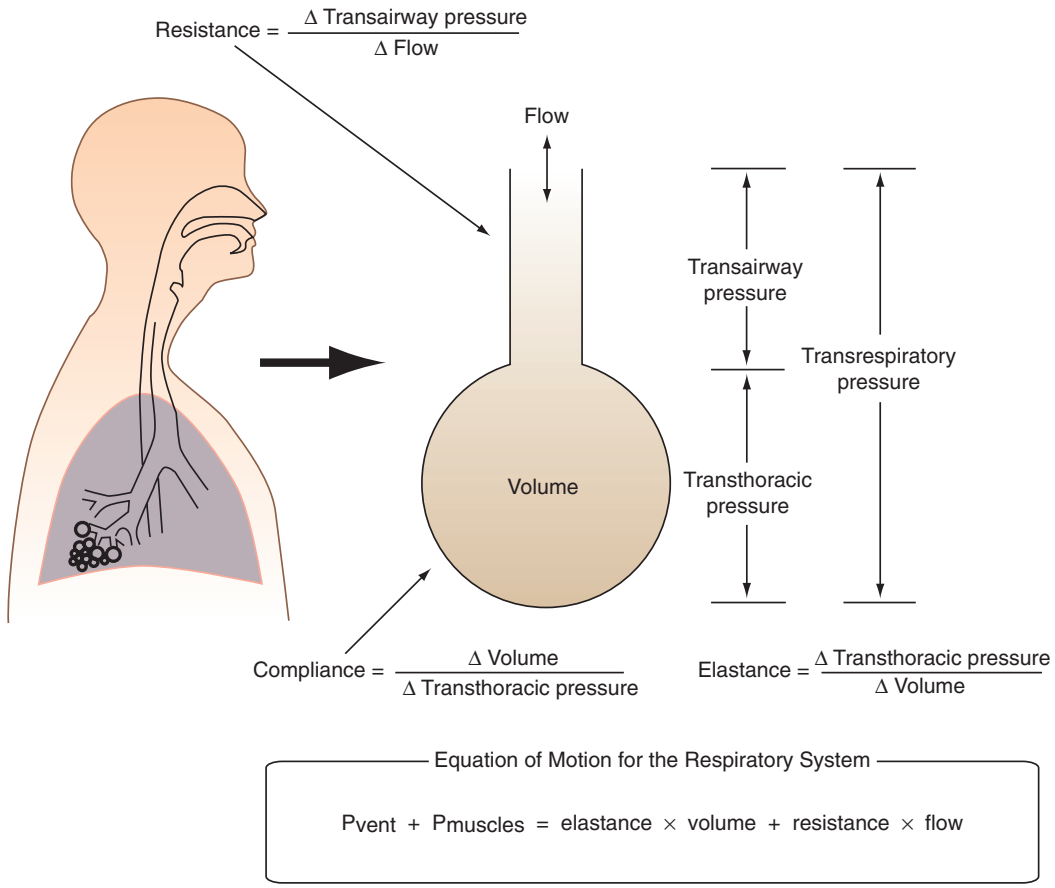

FIGURE 45-14 The respiratory system can be modeled as a single-flow conducting tube connected to a single elastic compartment. This physical model can be described by a mathematical model called the *equation of motion* for the respiratory system. In this model, pressure, volume, and flow are variables (i.e., functions of time), whereas resistance and elastance (or compliance) are constants.

pressure waveform relative to atmospheric pressure (called *peak inspiratory pressure*) and other times the magnitude is set relative to positive end expiratory pressure (PEEP), in this case simply termed inspiratory pressure.[24]

Refer again to Figure 45-15. If the shapes of the volume and flow waveforms are predetermined by the ventilator settings, and are unaffected by respiratory system mechanics, the ventilator is providing *volume control* (VC). In other words, the ventilator controls the right-hand side of Equation 45-1. That means for a given flow waveform [i.e., the graph of $\dot{V}(t)$], the volume waveform [i.e., the graph of $V(t)$] will be predetermined (because volume is simply a function of flow and time). Furthermore, the pressure waveform [i.e., the graph of $P_{vent}(t)$], will be dependent on E and R. In more practical terms, if the tidal volume *and* inspiratory flow are preset, then we say the mode of ventilation is a form of volume control. The term *volume control* is used rather than *flow control* merely for historical reasons. Note that during **volume-control ventilation**, *both* volume and flow are preset prior to inspiration. We emphasize this because there are some *pressure control modes* that allow the operator to set a target tidal volume but allow the ventilator to determine the flow. There are also pressure-control modes that allow the operator to set the maximum inspiratory flow, but not the tidal volume. In this case, tidal volume delivery depends on the operator-set inspiratory pressure target and the patient's respiratory system mechanics.

In some rare cases of nonconventional ventilation, inspiratory flow, inspiratory volume, and inspiratory pressure are all dependent on respiratory system mechanics. As no parameters of the pressure, volume, or flow waveforms are preset, the only control of the breath is the timing (i.e., inspiratory and expiratory times). When this happens the mode is called a form of *time control*. Examples of this are high-frequency oscillatory ventilation (3100ventilator, CareFusion, San Diego, Calif.) and volumetric diffusive respiration (Percussionaire, Sagle, Idaho).

One way to compare volume-control and pressure-control modes of ventilation is to first recognize that the aim is to control the patient's minute ventilation (because minute ventilation determines the $PaCO_2$ for a given rate of metabolic CO_2 production). Next, we can relate the operator-set variables that control minute ventilation for VC versus PC. A convenient way to do this is with influence diagrams, which are graphic illustrations that show how things are interrelated by using circles to represent (in this case) ventilator settings and lines to represent relationships. Figure 45-16 shows the influence diagram for volume-control ventilation and Figure 45-17 shows the influence diagram for pressure-control ventilation. The equations that relate the ventilator settings are given in Table 45-1.

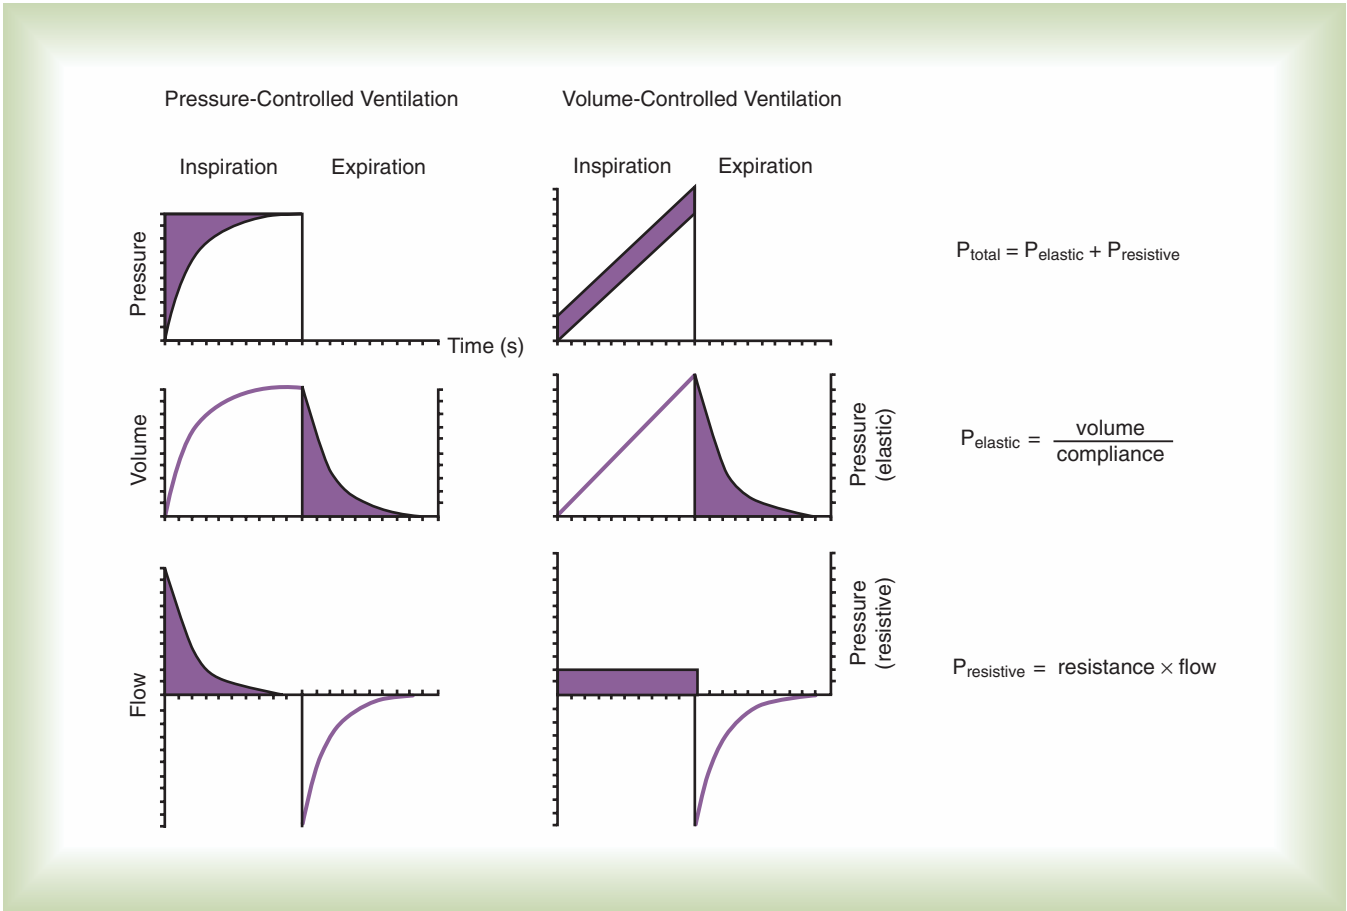

FIGURE 45-15 Idealized waveforms for volume-control ventilation and pressure-control ventilation. Note that the volume waveform has the same shape as the transthoracic or lung pressure waveform (i.e., pressure due to elastic recoil). The flow waveform has the same shape as the transairway pressure waveform (i.e., pressure due to airway resistance). The shaded areas represent pressures due to resistance; the open areas represent pressure due to elastic recoil. The dotted lines represent mean airway pressure. Note that the mean pressure at the airway is the same as that in the lung and that mean pressure for volume-control ventilation is less than that for pressure-control ventilation.

In summary:

Volume control means that *both* volume and flow are preset prior to inspiration.

Pressure control means that inspiratory pressure is preset to some constant value (e.g., Pressure Support mode) or is proportional to inspiratory effort (e.g., Proportional Assist Ventilation and Neurally Adjusted Ventilatory Assist modes).

Time control means that pressure, volume, and flow are all dependent on changing respiratory system mechanics and nothing is predetermined except inspiratory and expiratory times (e.g., high-frequency oscillatory ventilation).

4. Breaths Are Classified According to the Criteria That Trigger (Start) and Cycle (Stop) Inspiration.

The definition of a breath (Maxim 1) implies that the ventilator knows when to start (**trigger**) and when to stop (**cycle**) inspiratory flow. There are several signals that can be used to trigger inspiration, including time, and changes in airway pressure, volume, or flow. An electrical signal from the diaphragm can also be used to trigger inspiration. Common cycle signals are the same as those for triggering. *Sensitivity* is a term used to describe the amount that the trigger or cycle signal must change before inspiration starts or stops.

Trigger and cycle events are key definitions in the development of a classification system for **modes** of ventilation. They are used to define **mandatory** and spontaneous breaths (see Maxim 6). Mandatory and spontaneous breaths are used to describe ventilatory patterns (Maxim 7), and they form the basis for the mode taxonomy (see Maxim 10). Figure 45-18 shows an algorithm that can be used to identify trigger and cycle variables.

5. Trigger Variable and Cycle Events Can Be Either Patient or Machine Initiated.

There are instances when disease processes weaken the diaphragm or medications, such as sedation or paralytic agents, interfere with the patient's ability to generate trigger and cycle signals. Hence it is important to have a backup machine trigger system. However, when a patient's ability to generate trigger and

cycle signals is intact, it is important to deliver inspiratory flow in synchrony with the patient's breathing efforts. Trigger and cycle capabilities are built into the mode of ventilation. The trigger variable can be either time, pressure, flow, or volume.

Inspiration may be triggered after a preset time interval (e.g., because of a preset breathing frequency). In this instance, inspiration has started regardless of any inspiratory efforts made by the patient. During such a breath, therefore, we say that inspiration is machine triggered. Minute ventilation threshold is another signal a ventilator can use to machine-trigger inspiration. Minute ventilation is calculated by dividing the tidal volume by the time for one breath cycle (equivalent to

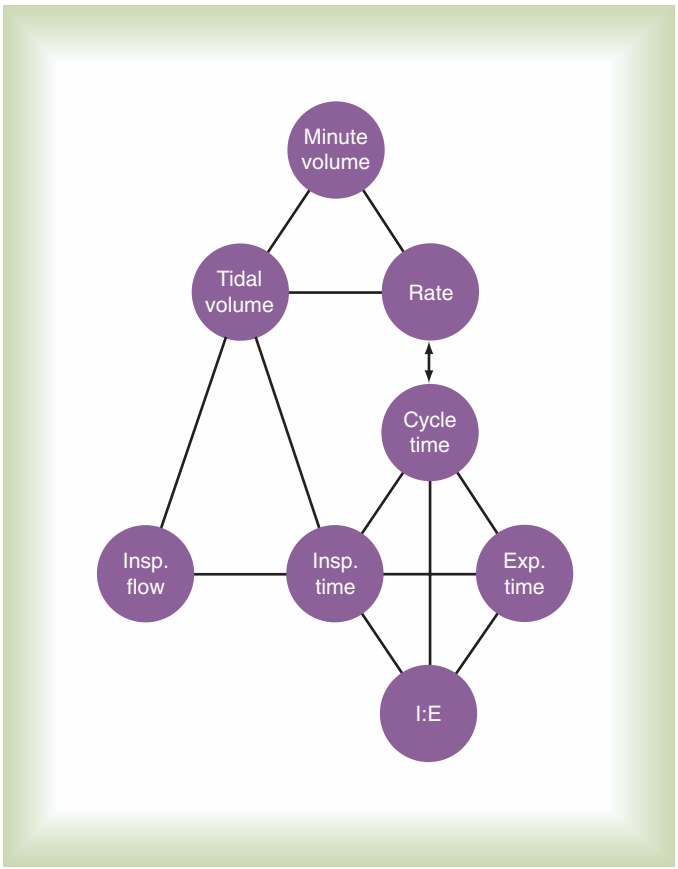

FIGURE 45-16 Influence diagram for volume-control ventilation. Variables are connected by straight lines such that if any two are known, the third can be calculated (see Table 45-1).

TABLE 45-1

Equations Relating the Important Parameters for Volume-Controlled and Pressure-Controlled Ventilation

Mode	Parameter	Symbol	Equation
Volume-controlled	Tidal volume (L)	V_T	$V_T = \dot{V}_E \div f$ $V_T = \dot{V}_I \times T_I$
	Mean inspiratory flow (L/min)	$\bar{\dot{V}}_I$	$\bar{\dot{V}}_I = 60 \times V_T \div T_I$ $\bar{\dot{V}}_I = \frac{\dot{V}_E \times TCT}{T_I}$
Pressure-controlled	Tidal volume (L)	V_T	$V_T = \Delta P \times C \times (1 - e^{-t/\tau})$
	Instantaneous inspiratory flow (L/min)	$\dot{V}_I$	$\dot{V}_I = \left(\frac{\Delta P}{R}\right) e^{-t/\tau}$
	Pressure gradient (cm H_2O)	ΔP	$\Delta P = PIP - PEEP$
Both modes	Exhaled minute ventilation (L/min)	$\dot{V}_E$	$\dot{V}_E = V_T \times f$
	Total cycle time or ventilatory period (seconds)	TCT	$TCT = T_I + T_E = 60 \div f$
	I:E ratio	I:E	$I:E = T_I : T_E = \frac{T_I}{T_E}$
	Time constant (seconds)	τ	$\tau = R \times C$
	Resistance (cm H_2O/L/sec)	R	$R = \frac{\Delta P}{\Delta \dot{V}}$
	Compliance (L/cm H_2O)	C	$C = \frac{\Delta V}{\Delta P}$
	Elastance	E	$E = \frac{1}{C}$
	Mean airway pressure (cm H_2O)	$\bar{P}_{aw}$	$\bar{P}_{aw} = \left(\frac{1}{TCT}\right) \int_{t=0}^{t=TCT} P_{aw} dt$
Primary variables	Pressure (cm H_2O)	P	
	Volume (L)	V	
	Flow (cm H_2O/L/sec)	$\dot{V}$	
	Time (sec)	τ	
	Inspiratory time (sec)	T_I	
	Expiratory time (sec)	T_E	
	Frequency (breaths/min)	f	
	Base of natural logarithm (≈2.72)	e	

multiplying tidal volume by frequency). Depending on the brand of ventilator used, the clinician may be able to set a minimum threshold for minute ventilation. In this case, inspiration is triggered when minute ventilation drops below a preset threshold.

A variety of signals may be used to machine cycle inspiration. Volume cycling refers to inspiration that ends due to a preset tidal volume. Cycling due to a preset inspiratory time (or inspiratory pause time) is referred to as time cycling.

Patient triggering or cycling implies that inspiration starts or stops independent of any preset trigger or cycle signals generated by the ventilator. In the equation of motion, P_{mus}, elastance, and resistance are all patient determined. Inspiration is patient triggered or cycled if it starts or stops because of one or more of these patient-determined variables. When the patient makes an inspiratory effort, the ventilator commonly detects this by a change in airway pressure, volume, or flow. Inspiratory effort may also be detected by electrical signals derived from the movement of the diaphragm (e.g., neurally adjusted ventilatory assist [NAVA]) or expansion of the chest wall (e.g, electrical impedance tomography). Similarly, if the patient makes an expiratory effort, then inspiration may be cycled off.

Respiratory system mechanics play a critical role in triggering and cycling. These factors are easiest to understand in the passive patient ($P_{mus} = 0$). Let us first consider the cycling of inspiration. If the ventilator delivers a constant inspiratory flow, then peak airway pressure is determined by the preset flow and the elastance and resistance of the patient's respiratory system. Suppose the ventilator is set to cycle inspiration off when a preset pressure threshold is met; for a given preset inspiratory flow, the elastance and resistance of the patient's respiratory system determines the time for this threshold. If these patient-determined factors change, inspiratory time will change. Cycling thus occurs independently of any preset machine-generated signal and inspiration is patient cycled. Thus, pressure cycling is a form of patient cycling. This can also be observed when a patient makes an expiratory effort, such as a cough in response to airway irritation by the device interface or secretions. Pressure cycling most often occurs as an alarm condition (high pressure alarm), but it is also a routine cycling mechanism used in automatic resuscitators.[25]

Another example of patient cycling occurs with a mode of ventilation called *Pressure Support*. Pressure Support delivers pressure-controlled breaths to spontaneously breathing

patients. During Pressure Support, inspiration is triggered by patient effort and cycled when the decaying flow signal meets a preset threshold (usually expressed as a percentage of the peak inspiratory flow), which in turn determines the inspiratory time. If P(t) in the equation of motion is set to be constant (i.e., preset constant inspiratory pressure), inspiratory flow can be calculated as a function of time. The solution is:

$$\dot{V}(t) = \frac{\Delta P}{R}(e^{-t/RC}) \qquad \textbf{Equation 45-4}$$

The term RC in above equation is known as the respiratory **time constant**, or the time at which an exponential function attains 63% of its steady state value in response to a step input (ΔP). In other words, in this case, it is the time necessary for inspiratory flow to drop to 63% of its peak value (Figure 45-19). The time constant, for a passive patient, determines how long it will take to reach the cycle threshold. The time constant thus determines the inspiratory time independent of any cycle signal generated by the ventilator, and we say the inspiration is patient cycled. Interestingly, a passive patient can trigger inspiration by the same mechanism, except in this case the trigger threshold is based on the decay of expiratory pressure (an exponential flow through a constant expiratory resistance gives an exponential pressure waveform). This is the mechanism used in some automatic resuscitators.[25]

As a further refinement, patient triggering can be defined as starting inspiration based on a patient signal (i.e., a measurement indicating the patient's breathing motion) occurring in a *trigger window*, independent of a machine trigger signal. A trigger window comprises the entire expiratory time minus a short refractory period required to reduce the risk of triggering a breath before exhalation is complete. If a signal from the patient (i.e., some measured variable indicating an inspiratory effort) occurs within this trigger window, inspiration starts and is defined as a patient-triggered event.

A *synchronization window* is a short period during which a patient signal may be used to synchronize the beginning or ending of inspiration to the patient's actions. The synchronization window occurs at the end of a preset expiratory time or at the end of a preset inspiratory time. If a patient signal occurs during an expiratory time synchronization window, inspiration starts and is defined as a machine-triggered event initiating a mandatory breath. The breath is defined in this manner because the mandatory breath would have been time triggered regardless of whether the patient signal had appeared or not. This distinction is necessary to avoid logical inconsistencies in defining mandatory and spontaneous breaths, which are the foundation of the mode taxonomy. A synchronization window may be used at the end of the inspiratory time of a pressure-controlled, time-cycled breath. An example of this would be when a patient signal occurs during the inspiratory time synchronization window and expiration starts, which is defined as a machine-cycled event, ending a mandatory breath.

Some ventilators offer the mode called *airway pressure release ventilation* (APRV). In this mode of ventilation both expiratory and inspiratory synchronization windows can be used. This mode provides us with an example of the importance of distinguishing between trigger/cycle windows (allowing

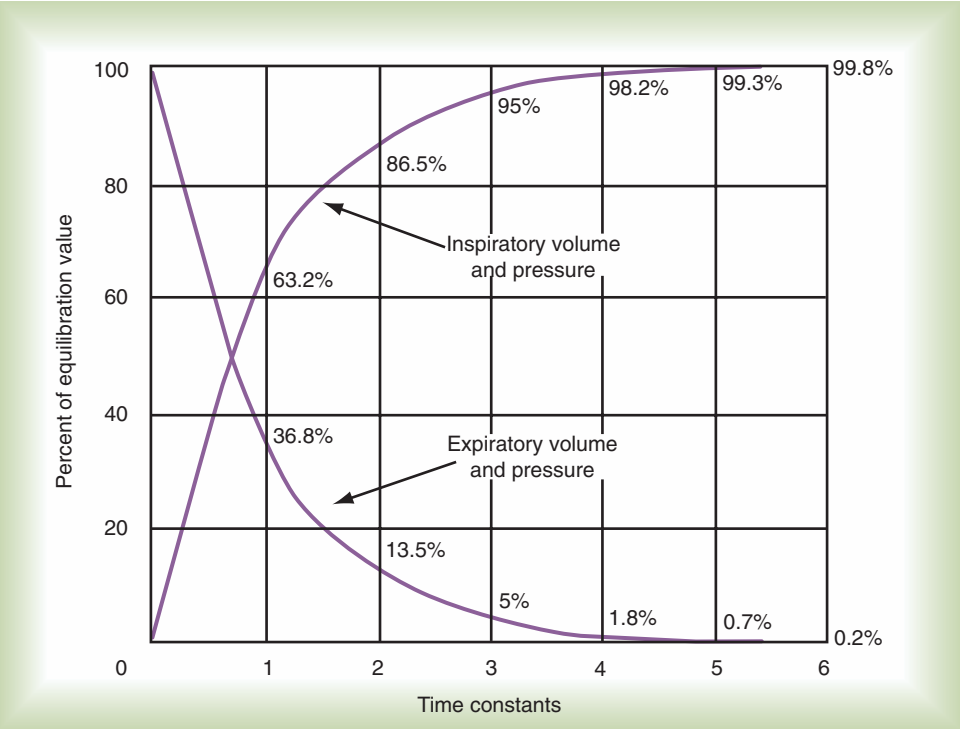

FIGURE 45-19 The time constant is a measure of how long the respiratory system takes to passively inflate or deflate in response to a sudden change in transrespiratory system pressure. The time constant is calculated as the product of resistance times compliance and is expressed in units of time, usually seconds.

for patient-triggered breaths) and synchronization windows (allowing for patient-synchronized, machine-triggered breaths). APRV is intended to provide a set number of releases or drops from a high-pressure level to a low-pressure level. Spontaneous breaths can occur at the high and low-pressure levels (although there may not be enough time to accomplish this if the duration of the low pressure is too short). Using the standardized vocabulary, these releases (paired with their respective rises) are actually mandatory breaths because, as originally described, they were time triggered and time cycled. There are ventilators that have synchronization windows added to both the expiratory time (to synchronize the transition to the high pressure with a patient inspiratory effort) and inspiratory time (to synchronize cycling with the expiratory phase of a spontaneous breath taken during the high-pressure level). If both triggering and cycling occurred with patient signals in the synchronization window, and if these events were called *patient-triggered* and *patient-cycled,* the result would be the ambiguous possibility of having spontaneous breaths (i.e., synchronized) occurring during spontaneous breaths (unsynchronized breaths during the high-pressure level).

On modes that are classified as forms of IMV (such as APRV), the operator must distinguish between the mandatory minute ventilation and the spontaneous minute ventilation (to gauge the level of mechanical support); this cannot be done if the definition of mandatory and spontaneous breaths are in any way ambiguous.

In summary:

Patient triggering means starting inspiration based on a signal from the patient independent of a machine trigger signal.

Machine triggering means starting inspiratory flow based on a signal (usually time) from the ventilator, independent of a patient trigger signal.

Patient cycling means ending inspiratory time based on signals representing the patient-determined components of the equation of motion (i.e., elastance or resistance) and including effects due to inspiratory effort. Flow cycling is a form of patient cycling because the rate of flow decay to the cycle threshold, and hence the inspiratory time, is determined by patient mechanics.

Machine cycling means ending inspiratory time independent of signals representing the patient-determined components of the equation of motion.

An algorithm for distinguishing between machine and patient trigger/cycle events is shown in Figure 45-20.

RULE OF THUMB

When initiating mechanical ventilatory support it is important to ensure that trigger sensitivity is set appropriately for the patient. High or low sensitivity thresholds may cause a delay in flow delivery or auto-triggering, respectively, which can ultimately increase a patient's work of breathing.

6. Breaths are Classified as Spontaneous or Mandatory Based on Both the Trigger and Cycle Events.

The terms *spontaneous* and *mandatory* as types of breaths are fundamental concepts for the classification of modes. The dictionary definition of *spontaneous* is "without premeditation or external stimulus." If we apply this definition to breathing, it implies that the patient retains substantial control over timing. Therefore, **spontaneous breaths** are those for which the patient determines the start and end of inspiration, independent of any machine settings for inspiratory time and expiratory time. In terms of the previous two maxims then, a spontaneous breath is one for which inspiration is both triggered and cycled by the patient. A spontaneous breath may occur during a mandatory breath (e.g., airway pressure release ventilation).

Some authors use the term spontaneous breath to refer only to unassisted breaths. But that is an unnecessary limitation that prevents the word from being used as a key term in the mode taxonomy. The definition given here applies for assisted and unassisted breathing. For unassisted breathing, the brain provides the trigger and cycle signals. For assisted breathing, the signals may come from the brain or the ventilator.

A mandatory breath is a breath for which the patient has lost control over timing (i.e., frequency or inspiratory time). During a mandatory breath, the start and/or end of inspiration is determined by the ventilator, independent of the patient. Again, in terms of the previous two maxims, a mandatory breath is one for which the machine triggers or cycles inspiration (or both). A mandatory breath can occur during a spontaneous breath (e.g., high-frequency jet ventilation). A mandatory breath is, by definition, assisted.

Summary:

A *spontaneous breath* is one for which inspiration is both triggered and cycled by the patient.

A *mandatory breath* is anything else (machine triggered and patient cycled; patient triggered and machine cycled; machine triggered and machine cycled).

7. There Are Three Basic Breath Sequences: Continuous Mandatory Ventilation, Intermittent Mandatory Ventilation, and Continuous Spontaneous Ventilation.

Spontaneous and mandatory breaths come out of a ventilator like dots and dashes come out of a telegraph machine. Because there are only two types of breaths, it follows that there are only three possible breath sequences: all breaths are mandatory, called **continuous mandatory ventilation (CMV)**; there are both mandatory and spontaneous breaths, called **intermittent mandatory ventilation (IMV)**; and all breaths are spontaneous, called **continuous spontaneous ventilation (CSV)**.

More specifically, continuous mandatory ventilation is a breath sequence for which spontaneous breaths are not possible between mandatory breaths because every patient trigger signal in the trigger window produces a machine-cycled inspiration (i.e., a mandatory breath). Continuous mandatory ventilation

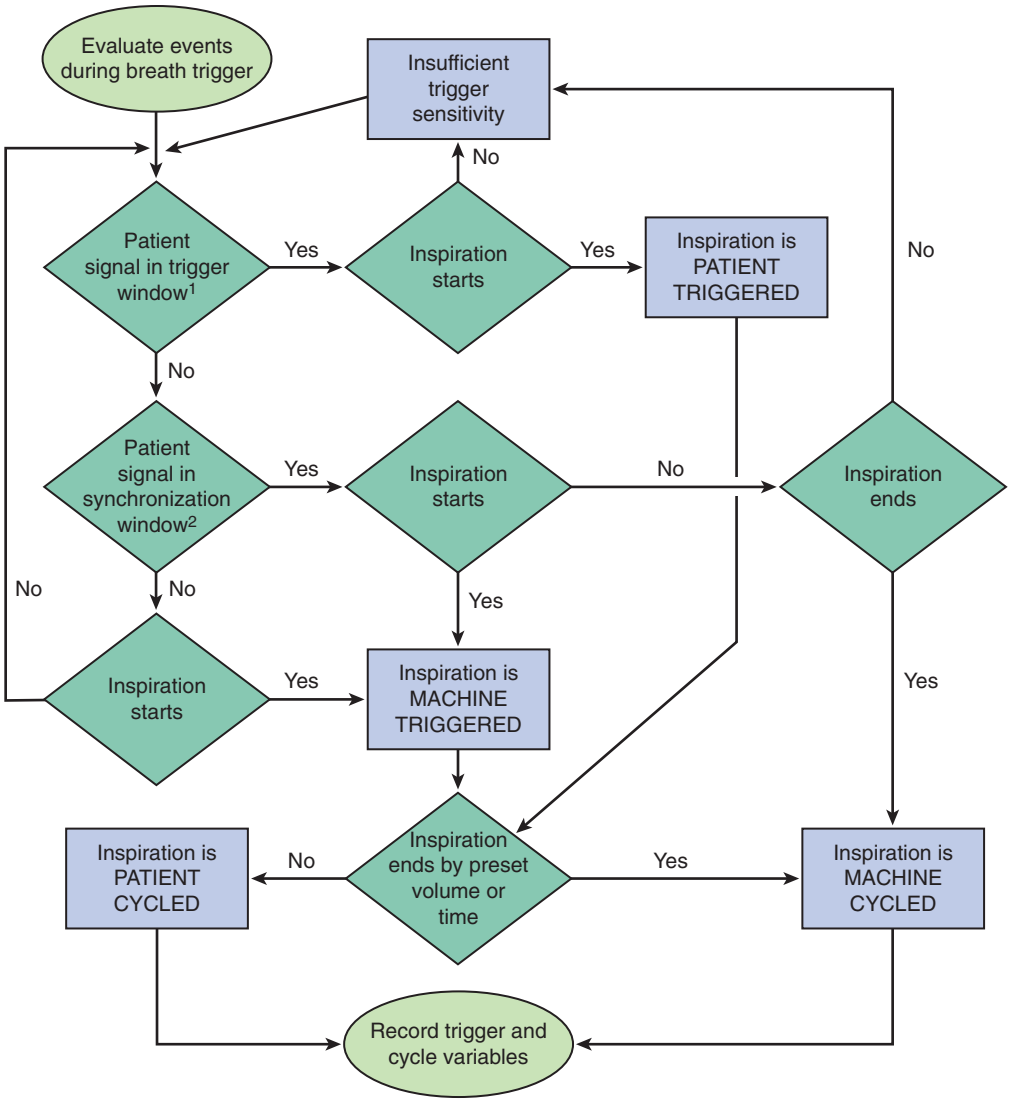

FIGURE 45-20 An algorithm for distinguishing between machine vs. patient events for triggering and cycling. (Courtesy Mandu Press Ltd.)

is commonly referred to as Assist/Control. Machine-triggered mandatory breaths may be delivered at a preset frequency with this breath sequence. The mandatory breath frequency for CMV is the set *minimum* value for the frequency. The total frequency may be higher than the set frequency but never below it. In some pressure controlled modes on ventilators with an active exhalation valve, spontaneous breaths may occur during mandatory breaths, but the defining characteristic of CMV is that spontaneous breaths are not permitted between mandatory breaths. Note that trigger windows are used to create CMV whereas synchronization windows are used for IMV.

Intermittent mandatory ventilation has three variations.

1. Mandatory breaths are always delivered at the set frequency (e.g., SIMV Volume Control mode on the Covidien PB 840 ventilator). When a synchronization window is used, the actual ventilatory period for a mandatory breath may be shorter than the set period. Some ventilators, such as the Dräger Evita XL, will add the difference to the next mandatory period to maintain the set mandatory breath frequency.
2. Mandatory breaths are delivered only when the spontaneous breath frequency falls below the set frequency. One example is the S/T mode on the Philips Respironic BiPAP noninvasive ventilator.
3. Mandatory breaths are delivered only when the measured minute ventilation (i.e., product of breath frequency and tidal volume) drops below a preset threshold. Examples of this variation include Dräger's Mandatory Minute Volume Ventilation mode and Hamilton's Adaptive Support Ventilation mode.

In contrast to CMV, in IMV the mandatory breath frequency can never be higher than the set rate, but it may be lower (i.e., the set frequency is a *maximum* value).

Note that use of the definitions for mandatory and spontaneous breaths for determining the breath sequence (i.e., CMV, IMV, CSV) assumes normal ventilator operation. For example, coughing during VC-CMV may result in patient cycling for a patient-triggered breath due to the pressure alarm limit. Although inspiration for that breath is both patient triggered and patient cycled, this is not normal operation and the sequence does not turn into IMV.

Continuous spontaneous ventilation means that all breaths are spontaneous. Alternatively, you could think of it as the opposite of CMV, meaning that mandatory breaths are not permitted between spontaneous breaths.

Note that the definition of a breath sequence depends on the definition of spontaneous and mandatory breaths (Maxim 6) and those definitions rely on the definitions of machine versus patient triggering and cycling (Maxims 4 and 5). The distinctions between CMV, IMC, and CSV are illustrated in Figure 45-21.

8. There Are Five Basic Ventilatory Patterns: VC-CMV, VC-IMV, PC-CMV, PC-IMV, and PC-CSV.

A ventilatory pattern is a sequence of breaths (CMV, IMV, or CSV) with a designated control variable (volume or pressure) for the mandatory breaths (or the spontaneous breaths for CSV). Thus, with two control variables and three breath sequences, there are five possible ventilatory patterns: VC-CMV, VC-IMV, PC-CMV, PC-IMV, and PC-CSV. The VC-CSV combination is not possible because volume control implies that inspiration ends when the preset tidal volume is delivered, which implies ventilator cycling, and ventilator cycling makes every breath mandatory, not spontaneous (Maxim 6).

For completeness, we include the possibility of a time control (TC) ventilatory pattern such as TC-IMV. Although this is uncommon and nonconventional, it is possible, as demonstrated by modes such as high-frequency oscillatory ventilation and intrapulmonary percussive ventilation. Because any mode of ventilation can be associated with one and only one ventilatory pattern, the ventilatory pattern serves as a simple mode classification system.

Ventilatory patterns are a simple mode classification system that offers practical advantages in clinical situations. We can use it to describe different modes a patient may experience without using the names for modes that vary depending on the ventilator manufacturer. For example, during surgery there may be no need to worry about patient–ventilatory synchrony and thus we might say VC-CMV was used (instead of saying Volume Assist/Control or CMV, names that relate to specific ventilators). Postoperatively, we could say we switched to PC-CMV to allow unrestricted inspiratory flow when the patient begins to make some breathing effort (instead of saying Pressure Assist/Control or Pressure Control; again names of modes on specific ventilators). When the patient is evaluated for extubation, a "spontaneous breathing trial" may be attempted using PC-CSV (instead of saying Pressure Support or Volume Support). Referring to modes in terms of breathing patterns instead of specific names on particular ventilators simplifies both verbal communication, and perhaps more important, documentation in the patient's record.

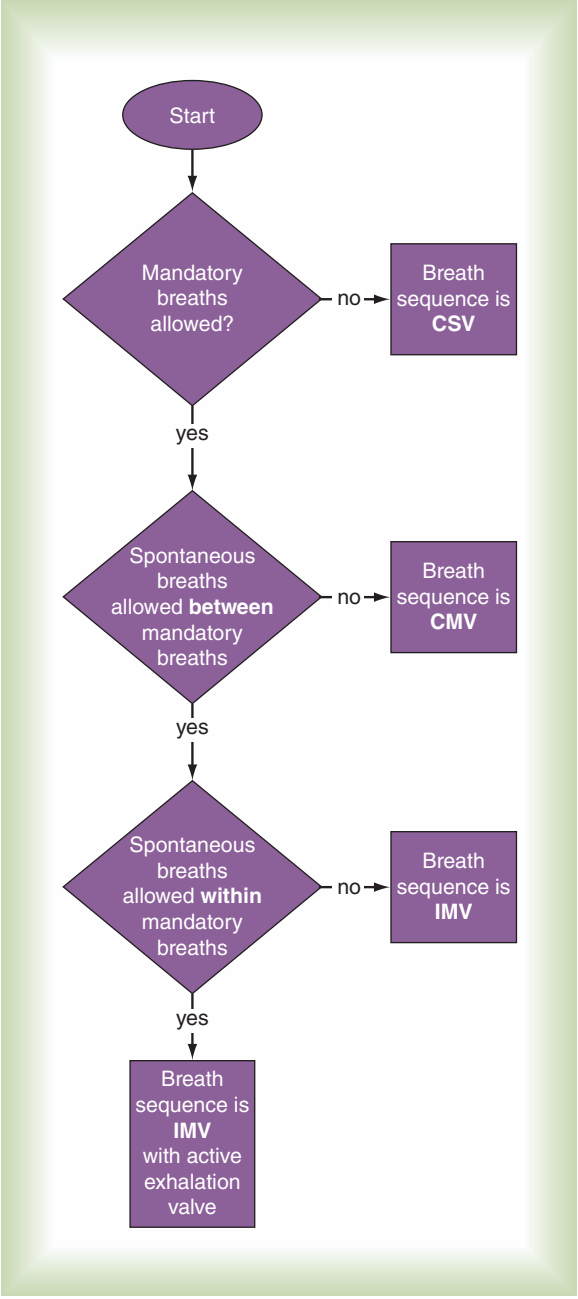

FIGURE 45-21 Algorithm distinguishing among CSV, CMV, and IMV.

9. Within Each Ventilatory Pattern There Are Several Types That Can Be Distinguished by Their Targeting Schemes (Set-Point, Dual, Bio-Variable, Servo, Adaptive, Optimal, and Intelligent).

Although the concept of ventilatory patterns may serve as a simple classification system in some cases, a better way to

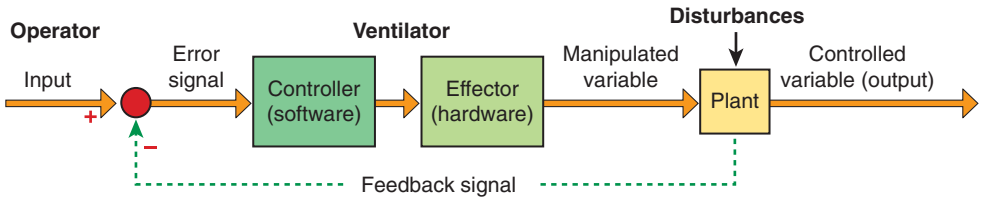

FIGURE 45-22 Schematic of a closed loop feedback control scheme for a ventilator. (Courtesy Mandu Press Ltd.)

identify the differences among modes is necessary. To do this, we need a deeper understanding of the feedback control schemes used by engineers who design modes. We refer to these as *targeting schemes*.

Targeting Schemes. Figure 45-22 illustrates a basic schematic of a closed-loop or feedback control scheme. The operator sets a desired *input*, for example, inspiratory pressure. The software sends control signals to the flow control and exhalation valves. The manipulated variable (typically flow) is delivered to the patient. The resulting inspiratory pressure (the *output*) is measured as a feedback signal and compared to the input setting. A variety of disturbances, such as patient circuit characteristics, leaks, patient ventilatory efforts, and respiratory system mechanics, to name a few, can affect the output. Any difference between the input and output generates an error signal that is passed on to the control valves to bring the output closer to the input. This system is referred to as a targeting scheme in this chapter as it relates to modes of ventilation.

The targeting scheme is a key component of a mode description. A target is basically a predetermined goal of ventilator output. Pressure, volume, and flow waveforms are called *within-breath* targets. Inspiratory pressure, rise time, inspiratory flow and tidal volume (set-point and dual targeting), and constant of proportionality between inspiratory pressure and patient effort (servo targeting) are examples of within-breath targets. Preset values within a breath that end inspiration, such as tidal volume, inspiratory time, or percent of peak flow, may also be considered cycle variables.

There may also be *between-breath targets*. These serve to modify the within-breath targets or the overall ventilatory pattern. Between-breath targets are used with more advanced targeting schemes, where targets act over multiple breaths. A simple example of a between-breath target is comparing actual exhaled volume to a preset between-breath tidal volume to automatically adjust the within-breath constant pressure or flow target for the next breath. Average tidal volume (for adaptive targeting), percent minute ventilation (for optimal targeting), and combined PCO_2, volume, and frequency values describing a zone of comfort (for intelligent targeting) are examples of between-breath targets and targeting schemes.

There are at least seven targeting schemes used on commercially available ventilators:[26]

1. *Set-point:* The operator sets all parameters of the pressure waveform (pressure control modes) or volume and flow waveforms (volume control modes) and the ventilator makes no automatic adjustments to targets. The advantage is simplicity. The disadvantage is that changing patient condition may make the settings inappropriate, so that frequent manual adjustments are necessary. An example mode name is Volume Assist/Control.
2. *Dual:* The ventilator can automatically switch between volume control and pressure control during a single inspiration. The advantage is the ability to adjust to changing patient condition and assure either a preset tidal volume or peak inspiratory pressure, whichever is deemed most important. The disadvantage is that some forms are complicated, difficult to set, and need constant readjustment. The original mode using dual targeting was called *Volume Assured Pressure Support*. In this mode, inspiration started off in pressure control but changed to volume control if flow decayed to the preset value before the tidal volume was delivered.[27] An example of the opposite approach, such as switching from volume control to pressure control, is Flow Adaptive Volume Control on the Maquet SERVO-i ventilator. If the patient makes little or no inspiratory efforts the mode looks like VC-CMV (e.g., Assist/Control). But if the patient makes strong enough efforts, the mode looks like PC-CSV (e.g., Pressure Support).[16]
3. *Bio-variable:* Studies have shown that varying tidal volume breath-by-breath to mimic normal breathing improves gas exchange.[28,29] Currently this biologically variable targeting scheme is available in only one mode, Variable Pressure Support on the Dräger V500 ventilator. The operator sets a target inspiratory pressure and a percent variability from 0% to 100%. A setting of 0% means the preset inspiratory pressure will be delivered for every breath. A 100% variability setting means that the actual inspiratory pressure varies randomly from PEEP/CPAP level to double the preset pressure support level.
4. *Servo:* The output of the ventilator (pressure/volume/flow) automatically follows a varying input. In current modes, this means that the inspiratory pressure is proportional to the patient's inspiratory effort; the more assistance the patient demands, the more the ventilator delivers. No other targeting scheme does this. The disadvantage is that it requires estimates of artificial airway and/or respiratory system mechanical properties or special equipment to monitor the respiratory effort signal. Example mode names include Automatic Tube Compensation (ATC), Proportional Assist Ventilation (PAV), and Neurally Adjusted Ventilatory Assist (NAVA).

5. *Adaptive:* The ventilator automatically sets target(s) between breaths in response to varying patient conditions. The advantage is that it can adjust to changing patient lung mechanics (including inspiratory effort). The disadvantage is that the automatic adjustment may be inappropriate if the algorithm assumptions are violated or they do not match the patient's actual physiology.[30] The first mode to use this was called *Pressure Regulated Volume Control.*
6. *Optimal:* The ventilator automatically adjusts the targets of the ventilatory pattern to either minimize or maximize some overall performance characteristic. The advantage is that it can adjust to changing patient condition. The disadvantage is that the automatic adjustment may be inappropriate if the algorithm assumptions are violated or they do not match the patient's actual physiology. The only mode currently using this is Adaptive Support Ventilation (ASV).
7. *Intelligent:* A targeting scheme that uses artificial intelligence programs such as fuzzy logic, rule-based expert systems, and artificial neural networks. The advantage is that it can adjust to changing patient condition. The disadvantage is that the automatic adjustment may be inappropriate if the algorithm assumptions are violated or they do not match the patient's actual physiology. The only modes currently using this scheme are SmartCare/PS and IntelliVent (not available in the United States).

These targeting schemes along with example modes that use them are summarized in Table 45-2.

TABLE 45-2

Specifications for Some Modes Found on the Draeger Evita XL Ventilator

Name (Abbreviation)	Description	Advantage	Disadvantage	Example Mode Name	Ventilator (Manufacturer)
Set-point (s)	The operator sets all parameters of the pressure waveform (pressure control modes) or volume and flow waveforms (volume control modes)	Simplicity	Changing patient conditions may make settings inappropriate	Volume control CMV	Evita Infinity V500 (Drager)
Dual (d)	The ventilator can automatically switch between volume control and pressure control during a single inspiration	It can adjust to changing patient conditions and ensure either a pre-set VT or peak inspiratory pressure, whichever is deemed most important	It may be complicated to set correctly and may need constant readjustment if not automatically controlled by the ventilator	Volume control	Servo-I (Maquet)
Servo (r)	The output of the ventilator (pressure/volume/flow) automatically follows a varying input	Support by the ventilator is proportional to inspiratory effort	It requires estimates of artificial airway and/or respiratory system mechanical properties	Proportional assist ventilation	PB840 (Covidien)
Adaptive (a)	The ventilator automatically sets target(s) between breaths in response to varying patient conditions	It can maintain stable VT delivery with pressure control for changing lung mechanics or patient inspiratory effort	Automatic adjustment may be inappropriate if algorithm assumptions are violated or if they do not match physiology	Pressure-regulated volume control	Servo-I
Bio-variable (b)	The ventilator automatically adjusts the inspiratory pressure or VT randomly	It simulates the inspiratory time or V_T observed during normal breathing and may improve oxygenation or mechanics	Manually set range of variability may be inappropriate to achieve goals	Variable pressure support	Evita Infinity V500
Optimal (o)	The ventilator automatically adjusts the targets of the ventilator pattern to either minimize or maximize some overall performance characteristic (e.g., work or rate of breathing)	It can adjust to changing lung mechanics or patient inspiratory effort	Automatic adjustment may be inappropriate if algorithm assumptions are violated or if they do not match physiology	ASV	GS (Hamilton Medical)
Intelligent (i)	This is a targeting scheme that uses artificial intelligence programs such as fuzzy logic, rule-based expert systems, and artificial neural networks	It can adjust to changing lung mechanics or patient inspiratory effort	Automatic adjustment may be inappropriate if algorithm assumptions are violated or if they do not match physiology	SmartCare/PS IrdelliVent-ASV	Evita Infinity V500 S1 (Hamilton Medical)

Limitations of Automatic Targeting Schemes. As targeting schemes have evolved, they have become more automated and, as a result, more complicated. Automation relies on various assumptions—for example, that compliance and resistance are linear or that a patient's carbon dioxide production is a particular number of mL per minute. If the underlying assumptions of a targeting scheme are violated, unexpected and possibly unwanted results may result. Set-point targeting provides an example. This targeting scheme assumes constant respiratory system mechanics. If respiratory system mechanics change rapidly, either peak airway pressure (during volume control ventilation) or tidal volume (during pressure control ventilation) may become unstable and drift out of acceptable ranges.

Dual targeting assumes that mechanics may change but may be useless without careful setting of the criteria for switching between volume- and pressure-control breaths. Servo control requires accurate data for respiratory system mechanical properties, such as resistance and elastance; if the data are unavailable, the mode cannot be used. Some forms of adaptive targeting assume that changes in respiratory system mechanics are related only to compliance. The ventilator is unable to distinguish between patient inspiratory effort and an increase in compliance. The targeting scheme is fooled into decreasing support when the patient needs it most.[30]

Optimal targeting is based on mathematical models (e.g., the relations among power of breathing, lung mechanics, frequency, and tidal volume). When the models do not match the actual physiology of the patient, they may instruct the ventilator to do inappropriate things (e.g., hyper/hypoventilate the patient or increase risk of ventilator-induced lung damage).

Intelligent targeting systems may rely on rules in the form of "if…then" statements; "if the patient does this, then the ventilator should do that." Ventilator algorithms or operational rules are derived from the consensus of clinical experts. These rules currently cover a very small set of actual clinical scenarios. Assumptions upon which the artificially intelligence system are based may be easily violated by actual patient conditions. For example, the targeting scheme might assume that the patient can be aggressively weaned when in fact the patient is not ready. Awareness of these drawbacks of ventilator technology should prompt the clinician to fully understand both the capabilities and limitations of the modes used.

10. A Mode of Ventilation is Classified According to Its Control Variable, Breath Sequence, and Targeting Scheme(s).

In general terms, a mode of ventilation is a predefined pattern of interaction between the ventilator and the patient. Historically, modes have been referred to by the names coined by ventilator manufacturers, who use them as marketing devices. As a consequence, there are now so many different names that understanding and comparing all modes has become nearly impossible. The solution is to use a *taxonomy* or formal classification system. The use of a taxonomy may make it easier (1) to compare research reports and facilitate the development of evidence-based clinical practice; (2) for clinicians to select the most appropriate modes, making optimal ventilator management more likely; and (3) for manufacturers to communicate with clients, thus improving the effectiveness of both sales and training.

The taxonomy of modes is based on the concepts of the control variable, the breath sequence, and the targeting scheme, as described in the previous nine maxims.

The Taxonomy for Mechanical Ventilation

A taxonomy is a hierarchy (outline) of concepts starting with the most general and progressing to more specific with each successive level of the outline. The ventilator mode taxonomy has four hierarchical levels (analogous to the order, class, genus, and species used in biology)[17,18]

1. Control variable (pressure or volume)
   A. Breath sequence (CMV, IMV, or CSV)
      i. Primary breath targeting scheme (for CMV or CSV)
         a. Secondary breath targeting scheme (for IMV)

The "primary breath" is either the only breath there is (mandatory for CMV and spontaneous for CSV) or it is the mandatory breath in IMV. The targeting schemes can be represented by single, lower case letters: set-point = s, dual = d, servo = r, bio-variable = b, adaptive = a, optimal = o, intelligent = i. For example, on the Covidien PB 840 ventilator there is a mode called *A/C Volume Control*. This mode is classified as volume control, continuous mandatory ventilation with set-point targeting, represented by VC-CMVs. A mode with the same functionality on the Dräger Evita XL ventilator is called *Continuous Mandatory Ventilation*. On that ventilator, you can alter the targeting scheme by activating a feature called *AutoFlow*. This changes the mode to pressure control continuous mandatory ventilation with adaptive targeting, PC-CMVa. Finally, some modes represent compound targeting schemes. For example, some ventilators offer Tube Compensation, a feature that increases inspiratory pressure in proportion to flow to support the resistive load of breathing through an artificial airway. This is a form of servo targeting. On the Dräger Evita XL, you can add Tube Compensation to CMV with AutoFlow to get a mode classified as PC-CMVar (*ar* represents the compound targeting scheme composed of servo added to set-point). A mode classified as pressure control intermittent mandatory ventilation with set-point control for both primary (mandatory) and secondary (spontaneous) breaths would have a tag that looks like this: PC-IMVs,s. If you added Tube Compensation to the spontaneous breaths (e.g., Covidien PB 840) the tag would change to PC-IMVs,sr. If you added it to both mandatory and spontaneous breaths (e.g., Dräger Evita XL), the tag would change to PC-IMVsr,sr.

The structure of this mode classification system is reminiscent of the taxonomy of biological organisms comprised of order (control variable), family (breath sequence), genus (primary targeting scheme), and species (secondary targeting scheme). Modes in the same "species" can be further differentiated by describing their "species variety" in term of their phase variables (i.e., trigger and cycle variables plus the within- and

between-breath targets and control algorithms). An example of the use of a "species variety" description is to distinguish between Proportional Assist Ventilation and Neurally Adjusted Ventilatory Assist, both of which are forms of PC-CSVr. They can be distinguished simply by noting that PAV breaths are triggered and cycled with flow signals whereas NAVA is triggered and cycled with an electrical signal representing diaphragm activation. Of course there are a great many other distinguishing features (e.g., targeting algorithms) but these are better described in the operator's manuals than, for example, in a general classification table.

How to Classify Modes

Translating the name of a mode into a mode classification using the taxonomy we have described is a simple three-step procedure:

Step 1: Identify the control variable. Simply put, if you set inspiratory pressure, or if pressure is proportional to inspiratory effort, then the control variable is pressure. On the contrary, if you set tidal volume and inspiratory flow, then the control variable is volume. Figure 45-23 shows the decision algorithm with a few refinements to accommodate dual targeting.

Step 2: Identify the breath sequence. Figure 45-24 shows the decision rubric.

Step 3: Identify the targeting schemes for the primary and (if applicable) secondary breaths (see Table 45-2).

Examples

To demonstrate these steps, we will classify some of the most commonly used modes in intensive care units, starting with A/C Volume Control (Covidien PB 840). For this mode, both

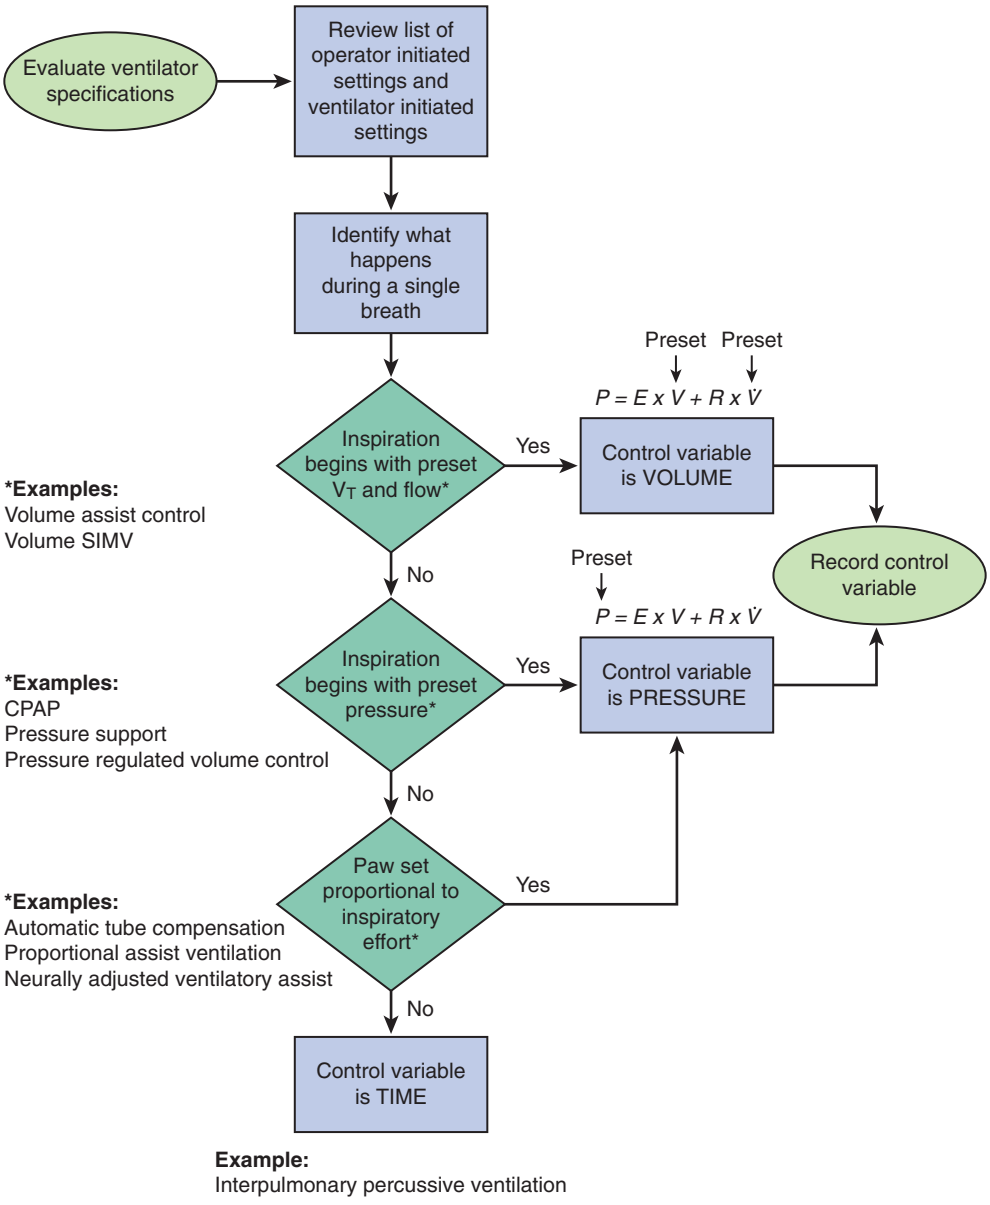

FIGURE 45-23 Algorithm for determining the control variable of a mode. (Courtesy Mandu Press Ltd.)

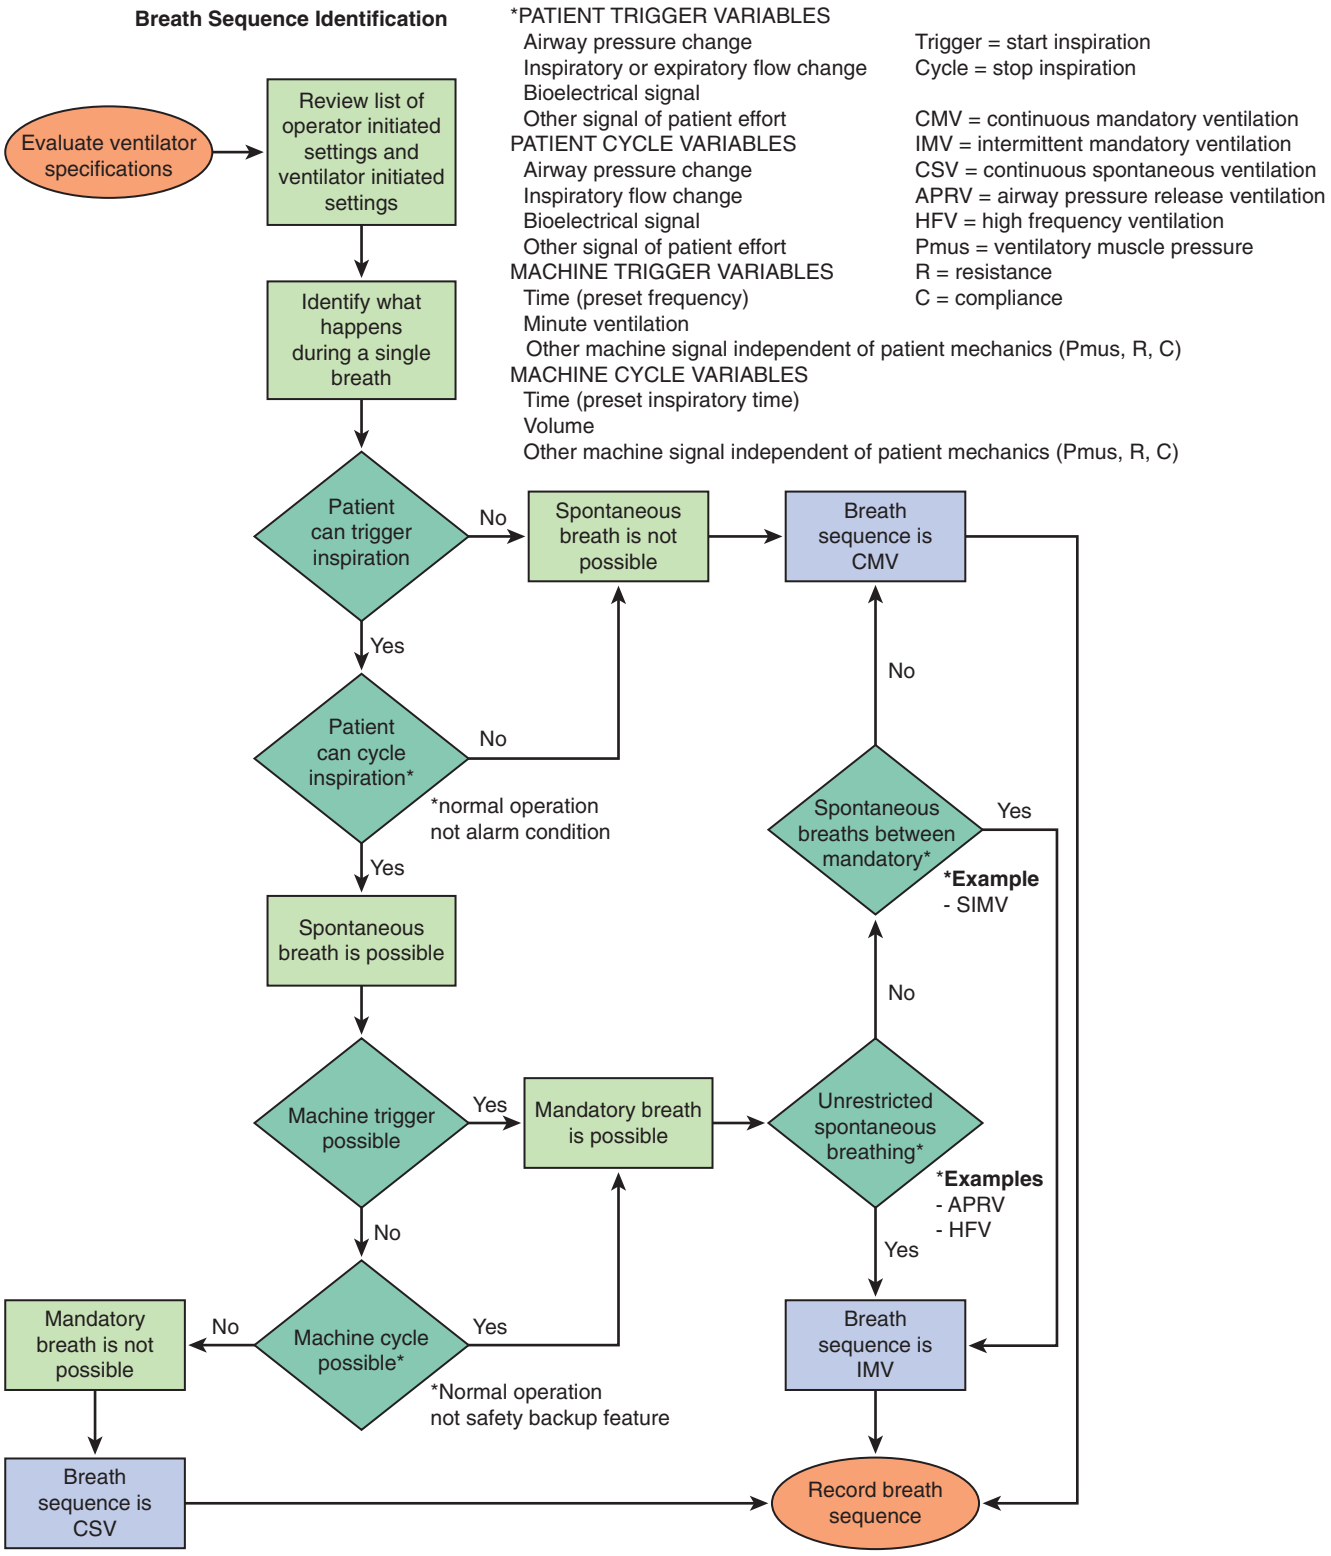

FIGURE 45-24 Algorithm for determining the breath sequence of a mode. (Courtesy Mandu Press Ltd.)

inspiratory volume and flow are preset, so the control variable is volume. Every breath is volume cycled, which is a form of machine cycling. Any breath for which inspiration is machine cycled is classified as a mandatory breath. Hence, the breath sequence is continuous mandatory ventilation. Finally, the operator sets all the parameters of the volume and flow waveforms, so the targeting scheme is set-point. Thus, the mode is classified as volume control continuous mandatory ventilation with set-point targeting (the tag or abbreviation is thus VC-CMVs).

Another common mode is Volume Control Plus (Covidien PB 840). For this mode, the operator sets the tidal volume but not the inspiratory flow. Because setting volume alone (like setting flow alone) is a necessary but not sufficient criterion for volume control, the control variable is pressure. Spontaneous breaths are allowed between mandatory breaths, which means the breath sequence is IMV. The ventilator adjusts the inspiratory pressure of mandatory breaths to achieve an average preset tidal volume, making the primary targeting scheme adaptive. Spontaneous breaths between mandatory breaths are either CPAP or Pressure Support, so the targeting scheme is set-point. The mode tag is thus PC-IMVa,s.

A very common mode for spontaneous breathing trials (or for assistance of spontaneous breaths in IMV modes) is Pressure Support. For this mode, the operator sets an inspiratory pressure, so the control variable is pressure. All breaths are patient triggered and patient cycled (note what was said about flow cycling above), so the breath sequence is CSV. Because the ventilator does not adjust any of the parameters of the breath, the targeting scheme is set-point and the tag is PC-CSVs.

If carefully applied, the taxonomy has the power to clarify and unmask hidden complexity in a mode that has a cryptic name. Take for example the mode called *CMV+AutoFlow* on the Dräger Evita XL ventilator. While "CMV" on this ventilator is the same as "Volume Assist/Control" described above, adding the "AutoFlow" feature changes it to a completely different mode. For CMV+AutoFlow, the operator sets a target tidal volume but not inspiratory flow. Indeed, inspiratory flow is highly variable because the ventilator actually sets the inspiratory pressure within a breath. Thus, the control variable, according to the equation of motion, is pressure. Every inspiration is time cycled and hence every breath is mandatory and the breath sequence is continuous mandatory ventilation (CMV). The ventilator adjusts the inspiratory pressure between breaths to achieve an average tidal volume equal to the preset value using an adaptive targeting scheme. Thus, the mode is classified as pressure control continuous mandatory ventilation with adaptive targeting (PC-CMVa).

On the other hand, the taxonomy also can unmask the complexity in an apparently simple mode. The mode called *Volume Control* (Maquet SERVO-i) allows setting of tidal volume and inspiratory time. Setting both volume and inspiratory time is equivalent to setting mean inspiratory flow (flow = volume/time), hence the control variable is volume. Every breath is normally time cycled and hence mandatory, so our initial thought is that the breath sequence is CMV. The tricky part is the targeting scheme. The operator's manual states that "if a pressure drop of 3 cm H_2O is detected during inspiration, the ventilator (switches) to Pressure Support with a resulting increase in inspiratory flow." This indicates dual targeting as described in maxim 9. Noting that the breath may switch to Pressure Support alerts us that the breath sequence is not what it first seemed to be. A breath may be patient triggered with a patient inspiratory effort, and if the effort is large enough and long enough, inspiration is flow cycled, not time cycled. Flow cycling (at a certain percentage of peak inspiratory pressure) is a form of patient cycling because the time constant of the patient's respiratory system determines when the cycle threshold is met for passive exhalation. Alternatively, the patient may make an expiratory effort that cycles inspiration off. Either way, a patient-triggered and patient-cycled breath is a spontaneous breath. Thus, spontaneous breaths may occur between mandatory breaths and the breaths sequence is actually IMV. Finally, the tag for this mode is VC-IMVd,d. Note that with dual targeting modes we need to identify which control variable is in effect at the start of inspiration (Figure 45-23) and in this case it is volume. In contrast, the mode called *Pressure A/C with Machine Volume* (CareFusionAvea) incorporates dual targeting, it starts out in pressure control and may switch to volume control.

Finally, some modes are comprised of compound targeting schemes. For example, some ventilators offer Tube Compensation, a feature that increases inspiratory pressure in proportion to flow to support the resistive load of breathing through an artificial airway. This is a form of servo targeting. On the Dräger Evita XL, Tube Compensation can be added to CMV with AutoFlow to get a mode classified as PC-CMVar (*ar* represents the compound targeting scheme composed of servo added to set-point, with no comma because there are only primary breaths). A mode classified as pressure control intermittent mandatory ventilation with set-point control for both primary (mandatory) and secondary (spontaneous) breaths would have a tag that looks like this: PC-IMVs,s (with a comma to denote primary and secondary breaths). If you added Tube Compensation to the spontaneous breaths (e.g., Covidien PB 840) the tag would change to PC-IMVs,sr. If you added it to both mandatory and spontaneous breaths (e.g., Dräger Evita XL) the tag would change to PC-IMVsr,sr. Another example is IntelliVent mode (Hamilton G5 ventilator), which uses optimal targeting to minimize the work rate and intelligent targeting to establish lung protective limits and adjust PEEP and FiO_2. The tag for this mode is PC-CMVoi,oi.

The utility of this taxonomy becomes evident when comparing modes on different ventilators (e.g., for making a purchase decision). For example, suppose your hospital has standardized on two common ICU ventilators, the Covidien PB 840 and the Maquet SERVO-i. You could construct a simple pocket card to show how the different names of modes are actually the same by classification (Table 45-3); the mode called *Assist/Control Volume Control Plus* on the PB 840 is the same as the mode called *Pressure Regulated Volume Control* on the SERVO-i, as indicated by the fact that they have the same tag: PC-CMVa.

COMPARING MODES OF MECHANICAL VENTILATION

The use of the ventilator mode taxonomy allows clinicians to appropriately match the technology to the patients' needs. Clinicians must not only know what tool to use but how to use it. Knowing how to use a mode involves understanding the technological capabilities of the mode and how they serve the goals of mechanical ventilation. These goals are safety, comfort, and liberation. *Safety* means maintaining adequate gas exchange

TABLE 45-3

Example of Pocket Card Comparing Mode Names from Two Common ICU Ventilators

Covidien PB 840	Mode Tag
A/C Volume Control	VC-CMVs
SIMV Volume Control with Pressure Support	VC-IMVs, s

MINI CLINI

Calculate the Expiratory Time Setting from the Frequency and Inspiratory Time

PROBLEM: You are assigned to the neonatal intensive care unit (NICU) and have successfully intubated a newborn term infant diagnosed with respiratory distress syndrome. You are manually ventilating the infant with a flow-inflating bag at a frequency of 25 breaths per minute. An inline manometer indicates the PIP is approximately 24 cm H_2O and the PEEP is 4 cm H_2O. The infant's vital signs (heart rate, respiratory rate, and blood pressure) are within normal limits and Spo_2 is 95%. The pressure and frequency you are using manually will serve as the initial ventilator settings on an infant ventilator. With this particular ventilator, however, setting the inspiratory and expiratory times determines the frequency. The attending physician has requested an inspiratory time (T_I) of 0.3 seconds. Calculate the expiratory time (T_E) necessary to give the desired frequency.

Discussion: *Step 1:* Compute the total cycle time (TCT) using the frequency (f):

$$TCT = \frac{1}{f} = T_I + T_E$$

$$f = \frac{25\ \text{breaths}}{\text{minute}} \times \frac{1\ \text{minute}}{60\ \text{seconds}} = \frac{25\ \text{breaths}}{60\ \text{seconds}}$$

$$TCT = \frac{1}{25\ \text{breaths}/60\ \text{seconds}} = \frac{60\ \text{seconds}}{25\ \text{breaths}} = \frac{2.4\ \text{seconds}}{\text{breath}}$$

Step 2: Compute the expiratory time:

$$T_E = TCT - T_I = 2.4 - 0.3 = 2.1\ \text{seconds}$$

Step 3: Check the digital display to verify the set frequency remains at 25/minute.

and hemodynamics while avoiding harm in the form of atelectrauma and volutrauma. *Comfort* means optimizing synchrony between the patient and the ventilator. *Liberation* means getting the patient off the ventilator in the shortest time with the fewest adverse events.

These goals can be further refined into specific objectives and clinical aims that may then be applied to individual patients. Goals, objectives, and aims are the product of a clinical assessment. After identifying the patient's need, the clinician simply matches those needs to the technological capabilities of the available modes of ventilation.[31]

TYPES OF VENTILATORS

Conventional Versus High-Frequency Ventilators

Ventilators may be divided into categories according to type and the setting in which the ventilator will be used. The two categories ventilators may be divided into are conventional and nonconventional. Conventional ventilators produce breathing patterns that are at or near physiologic normal values for the intended population (e.g., adult, pediatric, and infant). There are also manufacturing limits on the maximum breath rate a conventional ventilator may deliver. The Food and Drug Administration places a maximum breath rate limit of 150 breaths per minute for conventional ventilators. Tidal volumes that are either operator set or delivered to the patient as a result of a preset pressure through a conventional ventilator are sufficient or large enough to clear anatomic dead space. Conversely, high-frequency ventilators typically produce respiratory frequencies or breathing rates that are much higher than physiologically possible and tidal volumes that are less than anatomic dead space.

Conventional Ventilators

Conventional ventilators may be used with a variety of interfaces in the critical care setting. Options are available on this type of ventilator for use with an artificial airway (endotracheal or tracheostomy tube) or noninvasively with a variety of

MINI CLINI

Calculate Inspiratory Hold Time Given Set Inspiratory Time, Tidal Volume, and Flow

PROBLEM: You are performing a ventilator check on an ICU patient with a blunt chest trauma. The ventilator is set to deliver volume control SIMV. The physician wants the minimum mean airway pressure for the given level of ventilation to preserve the patient's already low cardiac output. She asks you to make sure the night shift therapist removed the inspiratory hold. Determine from the ventilator settings alone whether there is an inspiratory hold, and if so, make the appropriate changes to eliminate it.

Ventilator settings are:
Tidal volume: 500 ml = 0.5 L
Inspiratory flow: 60 L/min = 1 L/sec
Inspiratory time: 0.8 second
Frequency: 10 breaths per minute

Discussion: *Step 1:* Calculate the inspiratory flow time (TIF) using appropriate unit conversions:

$$T_{IF} = \frac{\text{tidal volume}}{\text{inspiratory flow}}$$

$$= \frac{500\ \text{mL}}{60\ \text{L/minute}} \times \frac{1\ \text{L}}{1{,}000\ \text{mL}} \times \frac{60\ \text{seconds}}{1\ \text{minute}} = 0.5\ \text{seconds}$$

Step 2: Compare the set inspiratory time (0.8 second) with the flow time resulting from the tidal volume and flow settings (0.5 second). Inspiratory time lasts longer than inspiratory flow. Because inspiration is time cycled, this means that there is an inspiratory hold of duration equal to 0.8 − 0.5 = 0.3 second.

Step 3: You could eliminate the inspiratory hold either by decreasing the inspiratory flow or decreasing the inspiratory time. Your goal is to minimize the mean inspiratory pressure. You choose to decrease inspiratory time for two reasons: (1) it decreases the I:E ratio and may allow more time for spontaneous breaths to occur, thus lowering mean intrathoracic pressure; (2) decreasing inspiratory flow may make tidal volume delivery slower than the patient demands, thus decreasing patient–ventilator synchrony.

interfaces (e.g., nasal, oronasal, or full face masks). The availability of the noninvasive option eliminates the need for a standalone noninvasive ventilator. However, standalone noninvasive ventilators do have applications and are also used in the critical care setting. Detail will be given to this type of ventilator in the latter portion of this chapter. Ventilators used in the critical care environment have the capability to assess and monitor complex ventilator–patient interactions. Work of breathing and the intricacies of breath delivery may be examined by evaluating numerically or graphically displayed data. Many ventilators also apportion automatic adjustments to breath delivery in response to changes in lung mechanics and parameters preset by the operator. In addition to universal patient population applications, some critical care ventilators are manufactured with an internal battery. The SERVO-i, for example has a plug-in battery module. This ventilator can provide at least 3 hours of uninterrupted power supply when six rechargeable 12-volt batteries are used in the module. Uninterrupted ventilatory assistance may then be provided not only in the critical care setting, but during interhospital transport. Minimizing circuit disconnections can enhance safety by reducing the risks for derecruitment, hemodynamic instability, and factors contributing to nosocomial infections. The aforementioned features provide a platform through which clinicians may optimize the patient–ventilator interaction.

High-Frequency Ventilators

The availability of sophisticated devices such as jet ventilators and high-frequency oscillators facilitates ventilatory management of infants, children, and adults in the PC-IMV mode who fail to maintain adequate oxygenation and acid-base balance with conventional ventilatory support. High-frequency jet ventilators, such as the Bunnell Life Pulse (Bunnell Inc., Salt Lake City, UT), deliver short bursts, or jet pulses, of mixed gas through a special adaptor for endotracheal tubes or a specially designed endotracheal tube. High-frequency jet ventilators require a high pressure source (20 to 50 psig) to function. This type of ventilator consists of a system for regulating inlet pressure (psig), a cycling mechanism, and a device such as an air-oxygen blender for controlling F_IO_2. The small volumes of gas are delivered at rapid rates (4 to 250 times the normal respiratory rate). The benefits of rescue and elective use of high-frequency jet ventilation (HFJV) as a treatment for acute lung disease and adult respiratory distress syndrome are unclear. However, the literature supports its effectiveness in maintaining alveolar ventilation and reducing morbidity during surgical repair of tracheal and airway anomalies.

High-frequency oscillation (HFO) also allows very small tidal volumes to be delivered at rapid frequencies (180 to 1200 cycles per second). High-frequency oscillators utilize a piston or diaphragm to produce the airflow oscillations. Tidal volume is dependent on the force and distance the piston moves from baseline. A special endotracheal tube is not required to implement this form of PC-IMV. The SensorMedics 3100A and 3100 B high-frequency oscillators (CareFusion, San Diego, CA) are approved and commercially available for use in neonatal/pediatric (<35 kg) and pediatric/adult populations (>35 kg), respectively.

Classification of Ventilators by Use

Ventilators may also be categorized by the setting in which they are used, specifically critical care, subacute, home care and long-term care, and transport. Their designs match the needs of the population as well as the unique characteristics of the setting in which they are used. Ventilator manufacturers have paid particular attention to economic constraints health care facilities are facing. Innovations in ventilator design have broadened their use across settings. An example of this is the use of ventilators for different patient ages. Although ventilators will not be subcategorized as adult or pediatric in this chapter, is it crucial

for the practitioner to be aware of the factors such as minimal tidal volume limits, trigger sensitivity, response time, and availability of leak compensation when selecting a ventilator for use with the pediatric population.

Critical Care Ventilators

Critical care ventilators provide clinicians with sophisticated methods for breath delivery. This class of ventilators also provides advanced monitoring capabilities and tools that enable clinicians to readily assess the patient–ventilator interaction. Calculations of lung mechanics parameters including auto-PEEP, static and dynamic compliance, inspiratory/expiratory resistance, rapid shallow breathing index, time constant, and work of breathing are integrated into ventilators used in this environment. Integrated physiologic noninvasive and invasive assessment tools, such as esophageal pressure monitoring and end-tidal CO_2 monitoring are also commercially available. The availability of these features equips bedside caregivers with the tools needed to assess patient–ventilator interaction and match ventilator capability with physiologic need.

Subacute Care Ventilators

Generally, mechanically ventilated patients in this setting have a stable cardiopulmonary status. Their condition is such that the care provided in this setting does not depend heavily on high-technology monitoring or complex diagnostic procedures. Rather, the focus is on coordinated services aimed at managing complex medical conditions, liberation from ventilatory support, and rehabilitation services. Ventilators used in this care venue have less sophisticated monitoring systems and mode options. Subacute care may be rendered in freestanding facilities or within a specialized unit within a hospital. As a result, the design of ventilators used in this environment bridge the gap between those designed specifically for critical care and those designed for home care and extended skilled care. As one example of this category of ventilators, The Savina (Dräger Medical, Telford, PA) offers some features of critical care ventilators, such as graphic display of pressure, volume, and flow waveforms, and the availability of a noninvasive ventilation mode of operation. The availability of a low-pressure oxygen option enables oxygen delivery independent of a central gas supply. An oxygen concentrator can be used to supply oxygen to the patient breathing circuit. This is analogous to oxygen delivery methods used by ventilators in the home care and long-term care environment.

Home Care Ventilators

Patients with chronic respiratory failure from primary pulmonary disease, trauma, or neuromuscular disease may require ventilatory assistance to augment or replace spontaneous breathing and maintain life. Ventilators designed for use in the home or at long-term care institutions facilitate the transition of patients from the acute and subacute care environment to one focusing on enhancing the individual's quality of life, and provision of services to sustain or improve physical and physiologic function in a cost-efficient manner. Ventilators must be able to support the ventilatory needs of the patient and provide supplemental oxygen in a venue where compressed gas resources are limited, power supply interruptions may occur, and patient mobility needs must be met. The interface on this type of ventilator is much simpler than those found on ventilators used in critical or subacute care. The availability of a low-pressure input port is an essential feature that allows supplemental oxygen to be delivered by stationary and portable devices commonly used in the home, such as oxygen concentrators, small high-pressure tanks, and portable liquid oxygen reservoirs. Machine dimensions are also an important consideration, and this type of ventilator is generally compact in nature. The option to lock operator-set parameters minimizes the occurrence of inadvertent setting changes and concomitant alterations in alveolar ventilation and acid-base balance.

Ventilators used in home care and extended care facilities require not only an internal battery for brief power interruptions, but connections for an external battery when the power supply is interrupted for extended periods of time due to natural disasters, man-made occurrences, and participation in academic, employment, or recreational activities. The Carina home ventilator (Dräger Medical) is an example of a home ventilator that can provide invasive or noninvasive ventilation. Although the ventilator's primary power source is 100-V or 240-V AC, the internal battery provides patients with approximately 2 hours of power. There is also an external battery pack that offers an additional 10-hour power supply when fully charged.

Transport Ventilators

Transport ventilators share attributes common to ventilators used in the home and critical care environments. It is necessary for this ventilator type to be lightweight, compact, durable, maintained on a reliable power supply, and have low compressed gas consumption. The ventilator interface should be easy to navigate, allowing the clinician to set or change parameters prior to or during movement to and from a prescribed destination. Operator-set and monitored data should be visible under optimal conditions or conditions of low ambient light. These characteristics enhance patient safety and minimize the potential for complications or adverse effects to occur during air or ground transport. Monitoring is also an important consideration. Clinical practice guidelines recommend the level of monitoring during patient transport be analogous with that provided to the patient during stationary care. Modern transport ventilators provide the ability to display scalar waveforms and numerical data. The BioMed Crossvent 4+ (BioMed Devices, Inc. Guilford, Conn.) is an example of a ventilator that can be used to transport critically ill patients of any age, from infant to adult. This particular ventilator may be configured with a blender, to allow for the delivery of a range of oxygen concentrations from 21% to 100% or with an air-entrainment unit that delivers either 50% or 100% oxygen without the need for an external air supply source. Pressure-controlled and volume-controlled ventilation may be provided in the CMV, IMV, or CSV mode. Tidal volumes may be adjusted from 5 to

2500 mL and flow delivered at rates up to 120 L/minute. The internal battery offers 6 hours of uninterrupted power when fully charged. This unit is small (28 cm × 25.4 cm × 14 cm) and weighs less than 5 kg. The unit's main display screen is color and backlit for enhanced visibility.

Noninvasive Ventilators

Noninvasive ventilation is used across the continuum of care—from critical care to home care—with individuals of any age. As previously mentioned, a noninvasive ventilation feature may be incorporated in critical care ventilators (e.g., SERVO-i and Puritan Bennett 840), subacute ventilators (Savina), and home care ventilators (Carina). However, standalone noninvasive ventilators exist and are extensively used in a variety of settings from the hospital to home. In the acute and critical care setting, noninvasive ventilators have been used to reduce complications associated with diagnostic procedures, such as bronchoscopy, as well as in the treatment of acute respiratory insufficiency, respiratory failure and prevention of postextubation failure. This technology has also been associated with positive outcomes in the outpatient setting. The literature reports the use of noninvasive ventilation to restore and maintain adequate alveolar ventilation with individuals compromised by neuromuscular disorders, congestive heart failure, chronic obstructive lung disease, and sleep-disordered breathing.

There are features common to home and hospital-grade units that enhance patient comfort and promote adherence to therapy. Ramp time allows the clinician to program a delay in the initiation of a delivered inspiratory pressure. Ramp time is usually adjustable (e.g., 0 to 45 minutes), during which the patient breathes at a preset or operator-set expiratory pressure (e.g., 4 cm H_2O). Likewise, rise time can be altered to reduce pressure overshoot and enhance breath delivery. The ability to detect and quantify interface leak, estimated tidal volume, and minute ventilation delivery are additional helpful tools. Hospital-grade units have the capability to display patient data in graphic and numeric form. Clinicians are able to view pressure, flow, and scalar waveforms, for example, on the BiPAP Vision (Respironics Inc., Murrysville, PA). As with critical care ventilators, careful analysis of waveforms may assist clinicians in the identification and correction of patient–ventilator synchrony.

SUMMARY CHECKLIST

- Ventilators can be described in terms of their input power requirements (e.g., electrical or pneumatic) and how the input power is transformed into desired outputs of pressure, volume, and flow.
- A key feature of a ventilator is the variety of modes of ventilation it offers.
- A mode of ventilation is a predetermined pattern of interaction with the patient. Modes are given many confusing names but they can be understood using a simple classification system.
- Mode classification is based on identifying 3 main components: the primary control variable, the breath sequence, and the targeting schemes used for mandatory and spontaneous breaths.
- Pressure control means that pressure delivery is predetermined by a targeting scheme such that inspiratory pressure is either proportional to patient effort or has a particular waveform regardless of respiratory system mechanics. Volume control means that inspiratory flow and volume delivery are predetermined by a targeting scheme to have particular waveforms independent of respiratory system mechanics.
- A spontaneous breath is one for which the timing and size of the breath is determined by the patient (i.e., inspiration is patient triggered and patient cycled). A mandatory breath is one for which the patient cannot determine the timing and/or size of the breath (i.e., inspiration is machine triggered and/or machine cycled).
- Spontaneous breaths may be assisted (meaning that the ventilator provides some portion of the work of breathing) or unassisted. Mandatory breaths are generally assisted.
- The breath sequence of a mode is the pattern of mandatory versus spontaneous breaths. Continuous spontaneous ventilation (CSV) means that all breaths delivered by the ventilator are spontaneous. Intermittent mandatory ventilation (IMV) means that spontaneous breaths can occur between mandatory breaths. Continuous mandatory ventilation means that spontaneous breaths cannot occur between mandatory breaths.
- The targeting scheme is a description of the relation between operator settings and ventilator outputs for a mode. Currently, all modes can be classified as having one of six targeting schemes (set-point, dual, servo, adaptive, optimal, and intelligent).
- Ventilators can also be categorized by the settings in which they are used. Examples include: critical care, subacute care, home care, transport, and noninvasive ventilators.

CHAPTER 46

Physiology of Ventilatory Support

ROBERT M. KACMAREK

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the pressures and pressure gradients that affect gas delivery during spontaneous breathing, negative pressure ventilation (NPV), and positive pressure ventilation (PPV).
- Identify the effects of mechanical ventilation on oxygenation, ventilation, and lung mechanics.
- Describe the currently available modes of mechanical ventilation.
- Discuss the indications and physiologic effect of positive end expiratory pressure (PEEP).
- Describe the cardiovascular effects of PPV and NPV.
- Describe the effects of PPV on intracranial pressure, renal function, liver and splanchnic perfusion, gastrointestinal function, and central nervous system.
- Identify and list the complications and hazards of providing mechanical ventilatory support.
- Discuss how to minimize adverse effects of mechanical ventilation.

CHAPTER OUTLINE

KEY TERMS

aerophagia
autoregulation
atelectrauma
barotrauma
biotrauma
mean airway pressure

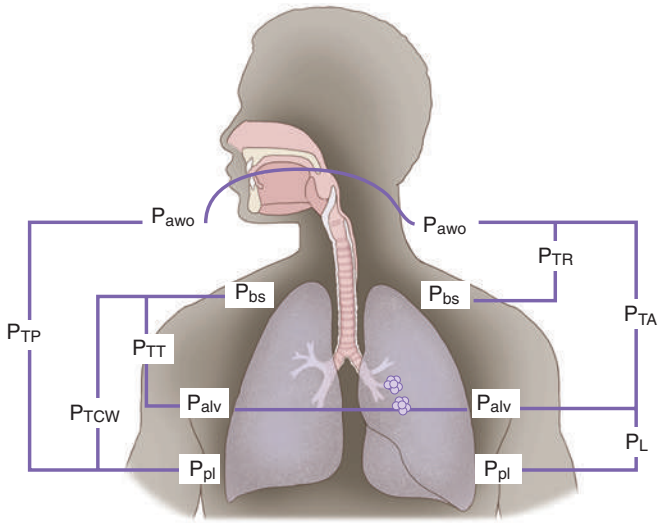
patient-ventilator asynchrony
time constant
transairway pressure
transalveolar pressure
trans–chest wall pressure
transdiaphragmatic pressure
transpulmonary pressure
transrespiratory pressure
transthoracic pressure
volutrauma

Mechanical ventilation can be beneficial or detrimental depending on how it is applied and modified as the patient's condition changes. Respiratory therapists (RTs) must be able to anticipate the physiologic effects of mechanical ventilation and respond appropriately when complications arise. This chapter familiarizes the reader with (1) the physiologic effects of mechanical ventilation on lung and cardiovascular function and other body systems, (2) the basic approaches to providing mechanical ventilation, and (3) the complications and hazards of mechanical ventilation. A solid understanding of the normal physiology of breathing is essential for all RTs, especially when working with patients receiving mechanical ventilation. RTs must understand intrathoracic pressure changes associated with spontaneous, negative pressure, and positive pressure breathing. Intrathoracic pressure changes are necessary for ventilation to occur; however, large changes in these pressures may also induce physiologic changes in other systems.

PRESSURE AND PRESSURE GRADIENTS

For gas to flow through the airway, a pressure gradient must exist. The airways begin at the mouth and end at the alveoli, so mouth pressure (*pressure at the airway opening* [P_{awo}]) and *alveolar pressure* (P_{alv}) are important in describing gas flow, as are *intrapleural pressure* (P_{pl}) and *body surface pressure* or atmospheric pressure (P_{bs}). In addition, *intraabdominal pressure* (P_{ab}) affects the impact of P_{pl} change on diaphragm movement. P_{pl} is the pressure in the pleural space, the virtual space between the visceral and parietal pleurae, and is usually negative in relation to P_{alv}. Figure 46-1 shows a graphic model of the respiratory system with these pressures identified as points in space. The respiratory system is everything that exists between the airway opening and the body surface. The associated pressure difference is **transrespiratory pressure** (P_{TR}), defined as $P_{awo} - P_{bs}$. The components of transrespiratory pressure correspond to the



P_{awo} - Mouth or airway opening pressure
P_{bs} - Body surface pressure
P_{alv} - Alveolar pressure
P_{pl} - Pleural pressure

Transrespiratory pressure -	P_{TR}	=	$P_{awo} - P_{bs}$
Transairway pressure -	P_{TA}	=	$P_{awo} - P_{alv}$
Transpulmonary pressure -	P_{TP}	=	$P_{awo} - P_{pl}$
Transalveolar pressure -	P_L	=	$P_{alv} - P_{pl}$
Trans-chest wall pressure -	P_{TCW}	=	$P_{pl} - P_{bs}$
Transthoracic pressure -	P_{TT}	=	$P_{alv} - P_{bs}$

FIGURE 46-1 Pressures and pressure gradients in the lung. Airflow is a function of the transairway pressure (P_{ta}), which is the pressure gradient between the airway (P_{awo}) and the alveoli (P_{alv}). Transalveolar pressure (P_L) maintains alveolar inflation, and transpulmonary pressure (P_{tp}) is the pressure needed to expand the lungs and chest wall.

TABLE 46-1

Changes in Airway Pressure Gradients during Spontaneous, Negative, and Positive Pressure Ventilation

Pressure (cm H_2O) Ventilation Type	Transpulmonary Pressure	Transthoracic Pressure	Transairway Pressure	Transrespiratory Pressure
Spontaneous				
Inspiration	Small increase (+)	Increase (+)	Increase (+)	Constant (–)
Expiration	Small increase (–)	Increase (–)	Increase (–)	Constant (+)
Negative (NPV)				
Inspiration	Small increase (+)	Increase (+)	Increase (+)	Constant (–)
Expiration	Small increase (–)	Increase (–)	Increase (–)	Constant (+)
Positive (PPV)				
Inspiration	Small increase (+)	Increase (+)	Increase (+)	Increase (+)
Expiration	Decrease (–)	Decrease (–)	Decrease (–)	Decrease (–)

components of the graphic model. The airways are represented by **transairway pressure** (P_{TA}), defined as $P_{awo} - P_{alv}$. The lungs are represented by the **transalveolar pressure**: ($P_L = P_{alv} - P_{pl}$). However, clinically what can be measured is **transpulmonary pressure**: ($P_{TP} = P_{awo} - P_{pl}$). The chest wall is represented by **trans–chest wall pressure**: ($P_{TCW} = P_{pl} - P_{bs}$). If the lungs and chest wall are lumped together, they can be represented by **transthoracic pressure**: ($P_{TT} = P_{alv} - P_{bs}$).

Another pressure gradient not defined in Figure 46-1 that also affects gas movement is the **transdiaphragmatic pressure** (P_{di}). This pressure gradient is the difference between intraabdominal pressure and pleural pressure and affects diaphragmatic movement: ($P_{pl} - P_{ab}$).

Airway, Alveolar, and Intrathoracic Pressure, Volume, and Flow During Spontaneous Ventilation

Spontaneous breathing is normally an autonomic phenomenon. In other words, we do not think about breathing; it is controlled by the autonomic nervous system. Not until our breathing is stressed do we consider the effort to breathe or the energy expended. At end-exhalation, intrapleural pressure is slightly negative. Alveolar, mouth, and body surface pressures are zero. The diaphragm contracts in response to stimulation of the phrenic nerve via the respiratory center in the medulla of the brain. When the diaphragm contracts, it descends into the abdominal cavity, decreasing intrapleural pressure. When intrapleural pressure becomes more negative, alveolar pressure becomes negative as well. The effects of spontaneous breathing on the pressure gradients are shown in Table 46-1. Under normal circumstances, a decrease in intrapleural pressure results in decreased alveolar pressure, increased transairway pressure, and inspiration of the tidal volume (V_T) (Figure 46-2).

At end-inspiration, alveolar pressure returns to zero when the muscles of inspiration stop contracting. Lung recoil causes a sudden increase in alveolar pressure in relation to pressure at the mouth, reversing the transairway pressure gradient, and air

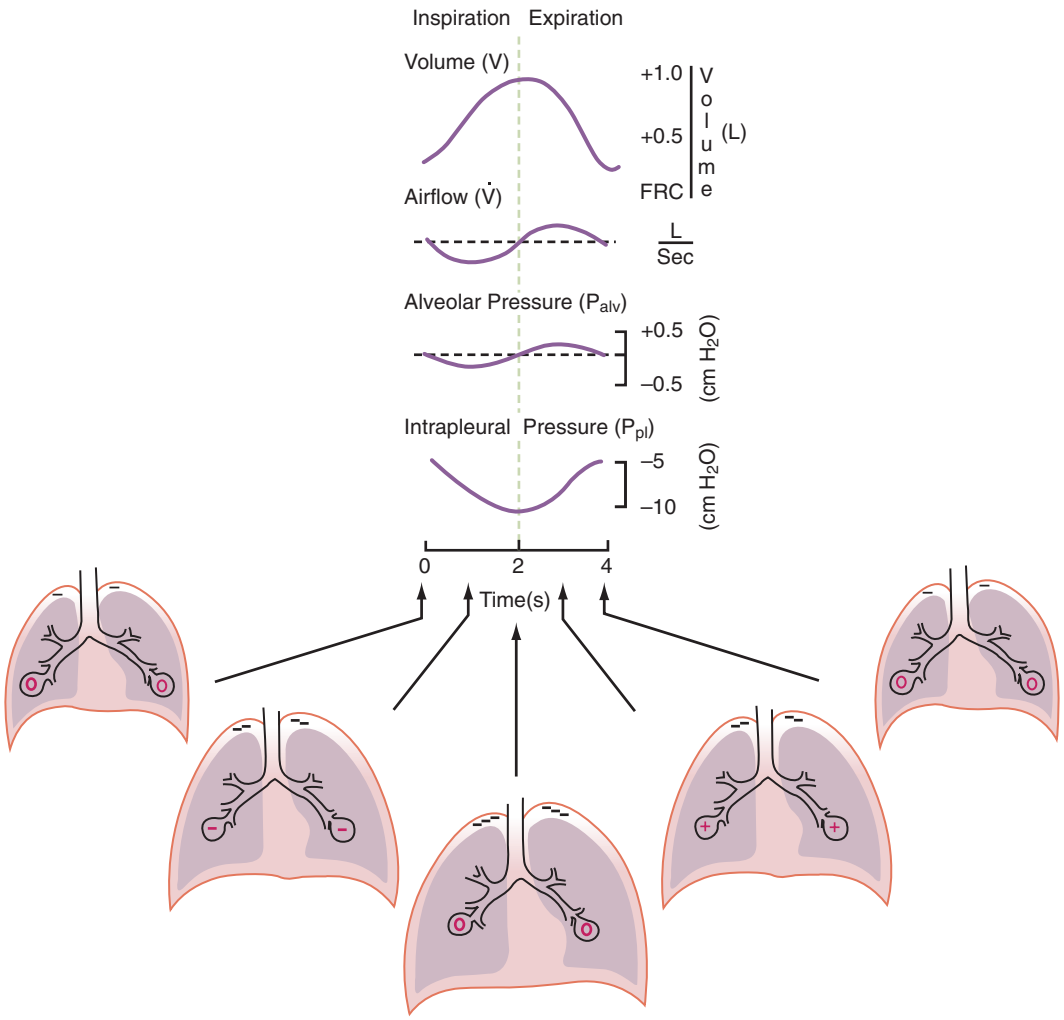


FIGURE 46-2 Changes in pressure, volume, and flow during a single spontaneous breath. (Modified from Martin L: Pulmonary physiology in clinical practice: the essentials for patient care and evaluation, St Louis, 1987, Mosby.)

flows out of the lungs. Normally, there is a short end expiratory pause before the next inspiration.

V_T and flow during spontaneous ventilation may be described by the equation of motion.[1,2] The equation of motion describes the relationship between muscle pressure (analogous to pleural pressure in spontaneous breathing), compliance, resistance, flow, and volume as follows:

$$P_{musc} = \text{Volume}/\text{Compliance} + (\text{Resistance} \times \text{Flow})$$

where P_{musc} is muscle pressure (P_{tp}), volume is tidal volume, compliance is lung-thorax compliance, resistance is airway resistance, and flow is gas flow through the airway. When the equation is rearranged, volume inhaled during spontaneous ventilation is proportional to muscle pressure and lung-thorax compliance and inversely related to the product of airway resistance and flow:

$$\text{Volume} = [P_{musc}/(\text{Resistance} \times \text{Flow})] + \text{Compliance}$$

Ventilation (owing to transpulmonary pressure) is the sum of the pressure needed to move gas through the airways (transairway pressure) and the pressure needed to inflate the alveoli (transalveolar pressure):

$$\text{Transpulmonary pressure} = P_{ta} + P_{alv}$$

Airway, Alveolar, and Intrathoracic Pressure, Volume, and Flow During Negative Pressure Mechanical Ventilation (NPV)

Mechanical NPV is similar to spontaneous breathing. NPV decreases pleural pressure (P_{pl}) during inspiration by exposing the chest to subatmospheric pressure. Negative pressure at the body surface (P_{bs}) is transmitted first to the pleural space and then to the alveoli (P_{alv}). Because the airway opening remains exposed to atmospheric pressure during NPV, a transairway pressure gradient is created. Gas flows from the relatively high pressure at the airway opening (zero) to the relatively low pressure in the alveoli (negative). As with spontaneous breathing, alveolar expansion during NPV is determined by the magnitude of the transpulmonary pressure gradient. During expiration in

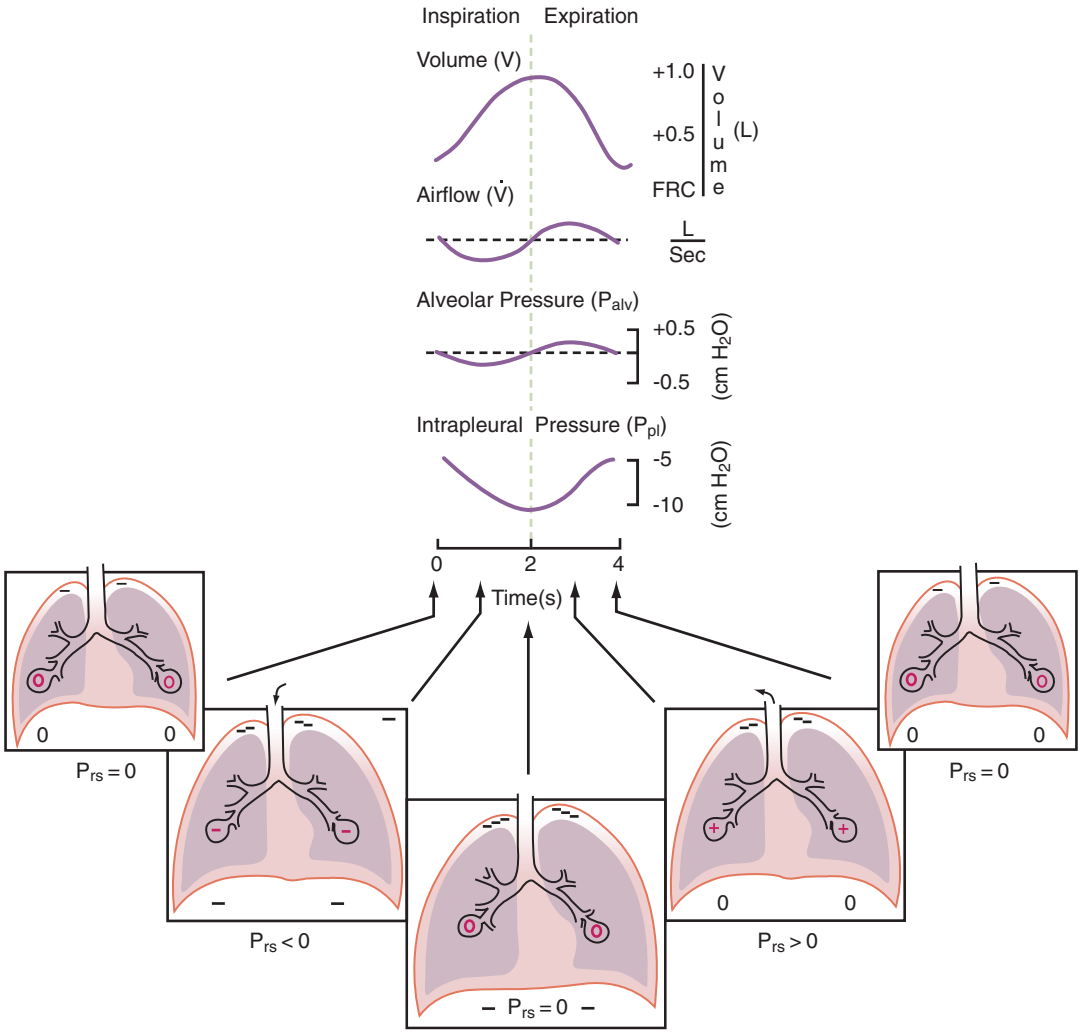

FIGURE 46-3 Changes in pressure, volume, and flow during a single mechanical negative pressure breath. The box surrounding the lungs represents the enclosure formed by the negative pressure ventilator. *Prs,* Pressure of the respiratory system. (Modified from Martin L: Pulmonary physiology in clinical practice: the essentials for patient care and evaluation, St Louis, 1987, Mosby.)

both spontaneous breathing and NPV, the lungs and chest wall passively recoil to their resting end expiratory levels. As this recoil occurs, pleural pressure becomes less negative, and alveolar pressure increases above atmospheric pressure (Figure 46-3). This increase in alveolar pressure reverses the transairway pressure gradient. As P_{alv} becomes greater than P_{awo}, gas flows from the alveoli to the airway opening. The effects of NPV on the pressure gradients are shown in Table 46-1.

Volume and flow during NPV also are described by the equation of motion except transairway pressure developed by the ventilator fully or partially replaces the patient's respiratory muscle pressure as follows:

$$P_{musc} + P_{vent} = \text{Volume/Compliance} + (\text{Resistance} \times \text{Flow})$$

In this equation, P_{vent} is the pressure the ventilator develops to overcome the patient's lung-thorax compliance and airway resistance to deliver the V_T. In this case, P_{vent} is negative but is the driving force behind decreasing the intrapleural pressure and increasing the transairway and transpulmonary pressures.

Physiologic complications associated with NPV are uncommon because NPV simulates normal spontaneous breathing. The most common problems with NPV are related to interference with caring for the patient caused by the device surrounding the chest (the iron lung or chest cuirass). Supplemental oxygen (O_2) cannot be provided to the patient through the negative pressure ventilator. Depending on patient need, low-flow or high-flow O_2 delivery devices must be used to provide O_2 therapy. Immediate access to patients requiring routine or emergent medical care may be difficult in systems that enclose the entire thorax and lower body, such as the iron lung and Porta-Lung (Respironics Inc, Murrysville, PA) (see Chapter 49). These systems may impede venous return by creating a negative pressure in the abdomen and lower half of the body, which may lead to hypotension, a phenomenon known as "tank shock." The risk of glottis closure and the development of obstructive sleep apnea have been reported in association with NPV of patients with chronic obstructive pulmonary disease (COPD) and neuromuscular dysfunction.

Airway, Alveolar, and Intrathoracic Pressure, Volume, and Flow During Positive Pressure Mechanical Ventilation (PPV)

PPV causes air to flow into the lungs because of an increase in airway pressure, not a decrease in pleural pressure as occurs during spontaneous breathing and NPV (Figure 46-4). However, similar to spontaneous breathing and NPV, PPV causes an increase in P_{tp}, which allows gas to flow into the lungs. Gas flows into the lungs because pressure at the airway opening (P_{awo}) is positive, and alveolar pressure (P_{alv}) is initially zero or less positive. Alveolar pressure rapidly increases during the inspiratory phase of PPV. The increased alveolar pressure expands the airways and alveoli. Because alveolar pressure is greater than pleural pressure (P_{pl}) during PPV, positive pressure is transmitted from the alveoli to the pleural space, causing pleural pressure to increase during inspiration. Depending on the compliance and resistance of the lungs, pleural pressure may markedly exceed atmospheric pressure during a portion of inspiration. These changes in pleural pressure during PPV can lead to significant physiologic changes (see later section). Pressure gradients during PPV are similar to pressure gradients during spontaneous breathing and NPV except that they are created by a positive pressure at the airway opening instead of a negative pressure in the pleural space (see Table 46-1). All pressure gradients change in the same direction as during NPV and spontaneous breathing except the transrespiratory pressure, which changes in the opposite direction.

Similar to spontaneous breathing, the recoil force of the lungs and chest wall, stored as potential energy during the positive pressure breath, causes passive exhalation. As gas flows from the alveoli to the airway opening, alveolar pressure decreases to atmospheric level, while pleural pressure is restored to its normal subatmospheric level (see Figure 46-4).

Volume and flow during PPV are also described by the equation of motion. The magnitude of P_{vent} not only depends on the patient's lung mechanics but also on the P_{musc} of the patient. If the patient makes no effort, P_{vent} is responsible for all volume and flow. During volume-controlled ventilation, as muscle

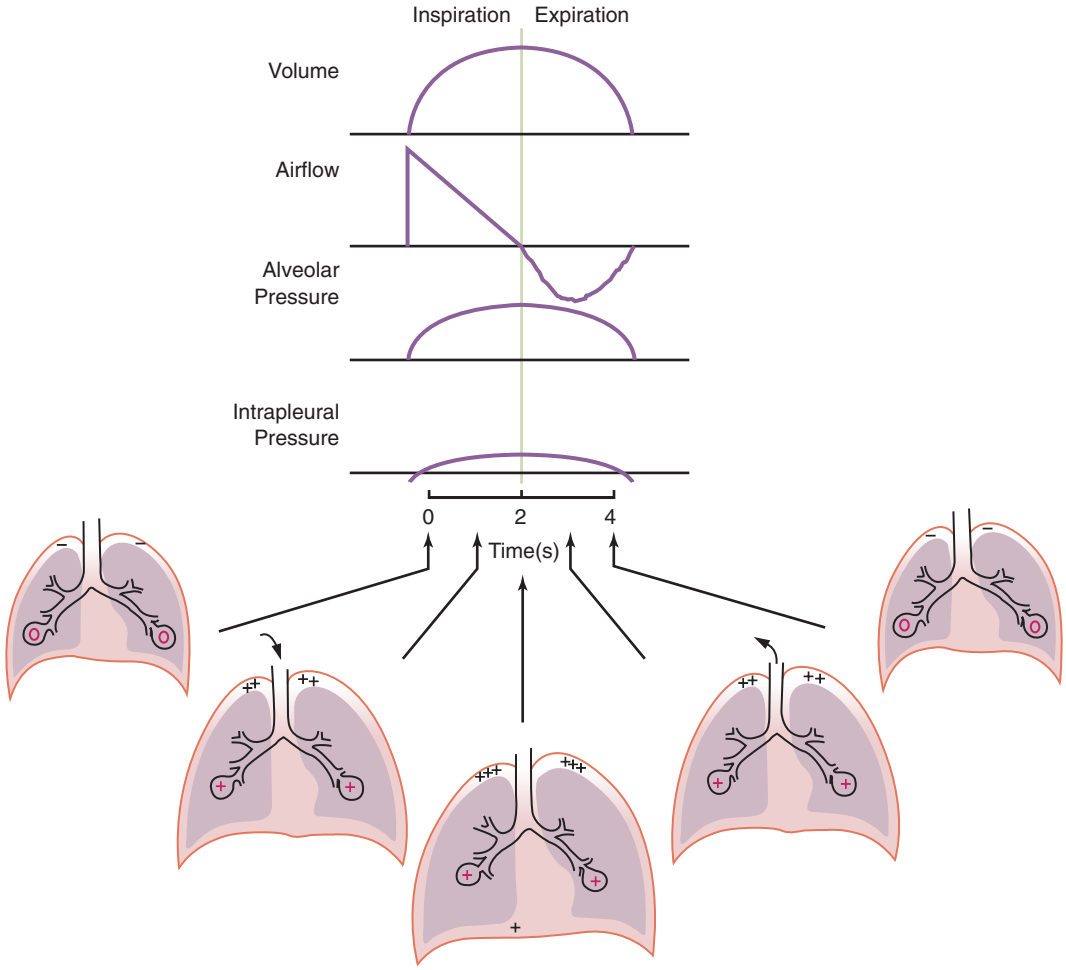

FIGURE 46-4 Changes in pressure, volume, and flow during a single decelerating flow, positive pressure breath. *Arrows* into and out of the trachea represent airflow. (Modified from Martin L: Pulmonary physiology in clinical practice: the essentials for patient care and evaluation, St Louis, 1987, Mosby.)

effort increases, P_{vent} decreases, and V_T remains constant. During pressure-controlled ventilation, as P_{musc} increases, V_T increases, and P_{vent} remains unchanged.

RULE OF THUMB

Ideally, the tranpulmonary pressure should be as low as possible during mechanical ventilation. A transpulmonary pressure less than about 28 cm H_2O minimizes the development of ventilator-induced lung injury. If the plateau pressure is kept less than 28 cm H_2O, the transalveolar pressure can never exceed this level during controlled ventilation.

EFFECTS OF MECHANICAL VENTILATION ON VENTILATION

Minute Ventilation

The primary indication for mechanical ventilation is *hypercapnic respiratory failure,* also known as *ventilatory failure*. For patients with acute ventilatory failure, the goal of mechanical ventilation is improving alveolar ventilation to compensate for the patient's inability to maintain normal $PaCO_2$. $PaCO_2$ is inversely related to alveolar ventilation, which is related to minute ventilation. Minute ventilation ($\dot{V}_E$) is the product of tidal volume (V_T) and ventilatory rate (f):

$$\dot{V} = V_T \times f$$

Use of a mechanical ventilator usually implies a change in V_T, ventilatory rate, or both from preintubation values. A normal spontaneous V_T is approximately 5 to 7 ml/kg. The currently accepted V_T for mechanical ventilation in acute respiratory failure is 4 to 8 ml/kg predicted body weight (PBW). These volumes are based on predicted body weight. The mechanical ventilator rate depends on the patient's status. For postoperative ventilation, a rate of 12 to 20 breaths/min may be adequate. Conditions that necessitate a higher initial rate include acute respiratory distress syndrome (ARDS), pulmonary fibrosis, acutely increased intracranial pressure (ICP) (with caution; see later), and metabolic acidosis. Conditions that may necessitate a lower rate include acute asthma exacerbation, to allow an increased expiratory time to minimize air trapping. When an appropriate V_T is established, the set rate is adjusted to achieve desired $PaCO_2$. Mechanical ventilation increases minute ventilation by increasing V_T, ventilator rate, or both.

Increased Alveolar Ventilation

Alveolar ventilation ($\dot{V}_A$) is inversely related to $PaCO_2$ as defined by the following relationship:

$$\dot{V}_A = (\dot{V}CO_2 \times 0.863)/PaCO_2$$

where $\dot{V}CO_2$ is carbon dioxide (CO_2) production.[2]

As alveolar ventilation decreases, $PaCO_2$ increases. As CO_2 production increases, alveolar ventilation must increase to maintain the same $PaCO_2$. Mechanical ventilation may be needed in either case. It is more useful to look at this equation solved for $PaCO_2$ because changes in $PaCO_2$ usually correlate with the need for mechanical ventilation:

$$PaCO_2 = (\dot{V}CO_2 \times 0.863)/\dot{V}_A$$

If $\dot{V}_A$ decreases or $\dot{V}CO_2$ increases, $PaCO_2$ increases, and hypercapnic respiratory failure follows; mechanical ventilation may be indicated in this setting. Because mechanical ventilation increases ventilation, $PaCO_2$ can be decreased to the desired level depending on the total ventilatory rate.

MINI CLINI

Alveolar, Transpulmonary, and Transalveolar Pressures

PROBLEM: Mr. Jones is 58 years old, 5 feet 8 inches tall, and weighs 410 lb and is being ventilated because of ARDS. His current ventilator settings are pressure control mode, peak pressure 35 cm H_2O, PEEP 20 cm H_2O, FiO_2 0.50, respiratory rate 30 breaths/min, and V_T 400 ml. At the end of expiration gas flow returns to zero about 100 msec before the end of the breath. What are the alveolar, transpulmonary, and transalveolar pressures for Mr. Jones?

Solution: Because there is a short end inspiratory pause, it is reasonable to assume that the peak airway pressure in pressure control is equal to the average peak alveolar pressure. The average is used because alveolar units have different time constants and as a result different peak pressure, but when there is end inspiratory equilibration of pressure, the resulting value is the average pressure across all lung units. To be more confident of this value, an additional end inspiratory pause can be added for a single breath to determine better the end inspiratory pause pressure or plateau pressure.

To determine the transpulmonary pressure ($P_{awo} - P_{pl}$) and transalveolar pressure ($P_{alv} - P_{pl}$), an estimate of pleural pressure must be made. The ideal method is to measure the esophageal pressure. Although not exactly equal to the pleural pressure, it accurately reflects changes in pleural pressure. Some authors have also recommended evaluation of bladder pressure, which changes in the same manner as esophageal pressure. The reading from the esophageal catheter at the time an end inspiratory pause was applied was 10 cm H_2O. The transpulmonary pressure and transalveolar pressure are the same: 35 − 10 cm H_2O or 25 cm H_2O. This is because Mr. Jones was ventilated in pressure control, and there was a short end inspiratory pause, so both peak and plateau pressures were equal. However, if he was ventilated in volume ventilation and the peak airway pressure was 45 cm H_2O, while the plateau pressure remained 35 cm H_2O when an end inspiratory pause was added, the transalveolar pressure and transpulmonary pressure would still be the same: 35 − 10 cm H_2O or 25 cm H_2O.

Mr. Jones is receiving lung protective ventilation because his transalveolar pressure is only 25 cm H_2O. The high airway pressures are needed because of his stiff chest wall, which minimizes the transmission of pressure across the lung, reducing lung stretch.

Ventilation/ Perfusion Ratio

Spontaneous ventilation results in gas distribution mainly to the dependent and peripheral zones of the lungs. Controlled PPV tends to reverse this normal pattern of gas distribution, and most of the delivered volume is directed to nondependent lung zones (Figure 46-5). This phenomenon is caused partly by the inactivity of the diaphragm and chest wall during controlled PPV. Although these structures actively facilitate gas movement during spontaneous breathing, inactivity of these structures during controlled PPV impedes ventilation to dependent lung zones. An increase in ventilation to the nondependent zones of the lung, where there is less perfusion, increases the ventilation/perfusion ($\dot{V}/\dot{Q}$) ratio, effectively increasing physiologic dead space. The increase in $P(A-a)O_2$ often observed with PPV is caused by areas of low $\dot{V}/\dot{Q}$ ratio.

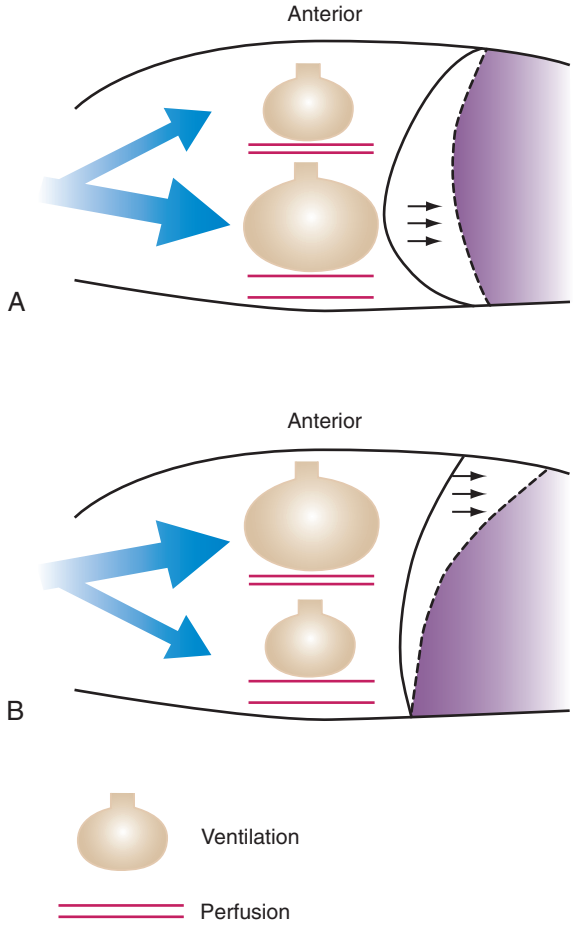

FIGURE 46-5 Effect of spontaneous ventilation and PPV on gas distribution in a supine subject. **A,** During spontaneous ventilation, diaphragmatic action distributes most ventilation to the dependent zones of the lungs, where perfusion is greatest. The result is a nearly normal $\dot{V}/\dot{Q}$ ratio. Partly because of diaphragmatic inactivity, PPV reverses this normal pattern of gas distribution, and most delivered volume is directed to the upper lung zones. **B,** An increase in ventilation to the upper lung zones, where there is less perfusion, increases the $\dot{V}/\dot{Q}$ ratio, effectively increasing physiologic dead space. At the same time, higher alveolar pressure in the better ventilated upper lung zones diverts blood flow away from these areas to the areas receiving the least ventilation. The result is areas of low $\dot{V}/\dot{Q}$ ratio and impaired oxygenation. (Modified from Kirby RR: Clinical application of ventilatory support, New York, 1990, Churchill Livingstone.)

PPV decreases the $\dot{V}/\dot{Q}$ ratio in the bases and dependent lung zones mainly as a result of ventilation being primarily distributed to nondependent lung zones. The $\dot{V}/\dot{Q}$ ratio may also increase in nondependent lung zones because of the effect of PPV on perfusion. PPV can compress the pulmonary capillaries. This compression increases pulmonary vascular resistance and decreases perfusion. Minimal blood flow perfuses the areas with the greatest V_T and contributes to a further increase in dead space. Conversely, blood intended for these areas is diverted to regions with lower vascular resistance—generally more dependent lung regions. Pulmonary blood flow during PPV tends to perfuse the least well-ventilated lung regions. This perfusion decreases the $\dot{V}/\dot{Q}$ ratio in those areas and increases the $P(A-a)O_2$.

Alveolar and Arterial Carbon Dioxide

Normal alveolar carbon dioxide tension ($PACO_2$) is 40 mm Hg, whereas mixed venous blood typically has a $P\bar{v}CO_2$ of 45 mm Hg. Under normal circumstances, CO_2 moves out of the blood at the pulmonary capillary interface; the result is a $PaCO_2$ of 40 mm Hg. In the event of a decrease in alveolar ventilation or an increase in CO_2 production, $PaCO_2$ increases. Mechanical ventilation can increase minute volume and alveolar ventilation and reduce $PACO_2$ and $PaCO_2$. With an increase in V_D/V_T, $PaCO_2$ increases if there is no change in minute volume; this may occur when alveolar blood flow is decreased by acute pulmonary embolism, an excessive level of positive end expiratory pressure (PEEP), or advanced dead space–producing disease such as emphysema or pulmonary embolism.

When excessive PEEP is used, blood flow is diverted from ventilated alveoli to hypoventilated alveoli; the result is an increased $\dot{V}/\dot{Q}$ ratio. In emphysema, formation of bullae is coincident with the destruction of pulmonary capillaries; the result is large areas of poorly perfused but ventilated alveoli. Pulmonary emboli may completely occlude pulmonary vessels; the result is lack of perfusion to alveoli distal to the blockage.

Acid-Base Balance

Respiratory acidemia, defined by a $PaCO_2$ greater than 45 mm Hg and a pH less than 7.35, occurs when minute ventilation and alveolar ventilation per minute ($\dot{V}_A$) are inadequate to meet the needs of the body. Respiratory acidemia can occur when the V_T is low, even though an accompanying mandatory rate is high.

Volume delivery also decreases if high airway pressures develop secondary to volume loss as a result of ventilator circuit tubing compliance (compressible volume loss). Ventilator circuits may have compliance of 1 to 3 ml/cm H_2O, which effectively reduces V_T:

$$\text{Volume lost} = \text{Tubing compliance} \times (\text{Peak pressure} - \text{PEEP})$$

Tubing compliance was a concern with older ventilators; however, most intensive care unit (ICU) ventilators in use at the

present time allow the user to compensate for compressible volume loss as a result of tubing compliance. When activated, the volume set is the volume delivered to the patient. This issue is discussed in more detail later in the chapter.

An increase in V_D/V_T ratio can cause a reduction in alveolar ventilation, even though minute ventilation may be normal or increased. These problems emphasize the importance of proper selection of V_T and mandatory rate. When respiratory acidemia exists, the patient may become restless and anxious, resulting in **patient-ventilator asynchrony** (see Chapter 47). A communicative patient may complain of dyspnea. If these symptoms are observed, especially when $PaCO_2$ is increased, minute ventilation generally should be increased.

Respiratory alkalemia occurs if the minute ventilation is too high. It is recognized when $PaCO_2$ is less than 35 mm Hg and pH is greater than 7.45. A patient who is dyspneic, anxious, or in pain may develop this condition; the usual manifestations are an increased ventilatory rate or patient-ventilator asynchrony or both. The ventilator can cause respiratory alkalemia secondary to an inappropriately high V_T or rate. Regardless, the result is excessive minute and alveolar ventilation. This condition requires that the RT adjust the ventilator appropriately and address the patient's pain or anxiety to avoid the systemic effects of a prolonged alkalosis.

Metabolic acidemia in a patient receiving mechanical ventilation is recognized by a normal $PaCO_2$, with a decreased pH (<7.35), decreased bicarbonate level (<22 mEq/L), and increased base excess (<−2 mEq/L). With metabolic acidemia, the patient tries to compensate by increasing minute ventilation to blow off CO_2 in an effort to increase the pH. The resulting increase in work of breathing (WOB) may lead to ventilatory muscle fatigue and continued respiratory failure. The best therapy for metabolic acidosis is to manage the underlying cause while supporting the patient's ventilation as needed. Many patients cannot be liberated from mechanical ventilation until the underlying acidosis is controlled.

Bicarbonate has been used as therapy for metabolic acidosis. If it is administered, bicarbonate quickly combines with hydrogen ions and dissociates to form CO_2 and water, a reaction that may increase WOB. Generally, bicarbonate administration is not recommended until acidosis is severe (pH <7.2). When necessary, bicarbonate is administered according to the following formula:[2]

$$NaHCO_3^- \text{ required} = [\tfrac{1}{4} \text{ Body weight (kg)} \times \text{Base deficit}]/2$$

A temporary measure to compensate partially for metabolic acidosis is to increase minute ventilation during therapy to control the acidosis with the goal of a pH greater than 7.20.

Metabolic alkalemia is defined as a normal $PaCO_2$ with an elevated pH (>7.45) and an increased bicarbonate level (>26 mEq/L) and base excess (>+2 mEq/L). With metabolic alkalemia, in an effort to compensate for the increased pH, the patient tries to decrease minute ventilation. If weaning is attempted when the patient has a metabolic alkalemia, the patient may continue to hypoventilate, and weaning may fail. As with metabolic acidemia, the underlying cause should be determined and managed. Common causes of metabolic alkalosis include hypochloremia or hypokalemia secondary to gastrointestinal loss, diuretics, or steroid administration. See Chapter 14 for details on acid-base balance.

EFFECTS OF MECHANICAL VENTILATION ON OXYGENATION

Inspired Oxygen

Mechanical ventilators usually deliver an increased fractional inspired oxygen (FiO_2) ranging from room air (0.21) to 100% O_2 (1.0). As a result, the alveolar partial pressure of oxygen (PAO_2) and arterial partial pressure of oxygen (PaO_2) may be restored to normal with appropriate management. The effectiveness of increased FiO_2 in the management of hypoxemia depends on the cause of hypoxemia. Hypoxemia caused by a decrease in the $\dot{V}/\dot{Q}$ ratio or hypoventilation is more responsive to increased FiO_2 than hypoxemia caused by a diffusion defect or shunt. Hypoxemia caused by hypoventilation responds well to an increase in FiO_2, but alveolar ventilation can be restored only by improved ventilation. Hypoxemia caused by diffusion defect and shunt generally respond better to an increase in PEEP than to an increase in FiO_2. The fact that PaO_2 responds well to increased FiO_2 generally indicates that a low $\dot{V}/\dot{Q}$ ratio is the cause of hypoxemia. If the patient is receiving mechanical ventilation and has adequate alveolar ventilation, failure of the PaO_2 to respond to increased FiO_2 likely means that hypoxemia is due to a diffusion defect or shunt.

Alveolar Oxygen and Alveolar Air Equation

Increasing FiO_2 increases PAO_2, according to the alveolar air equation:[2]

$$P_AO_2 = [FiO_2(P_B - 47)] - P_aCO_2 \times [FiO_2 + (1 - FiO_2/R)]$$

where PAO_2 is the partial pressure of oxygen in the alveoli; FiO_2 is the fractional inspired oxygen; P_B is the barometric pressure in mm Hg; 47 is the partial pressure of water vapor in the alveoli in mm Hg at 37° C; $PaCO_2$ is the partial pressure of carbon dioxide in arterial blood in mm Hg; and R is the respiratory exchange ratio ($\dot{V}CO_2/\dot{V}O_2$), normally 0.8.

When FiO_2 is increased, PAO_2 increases as well, if there is no change in $PaCO_2$ or the respiratory exchange ratio. $PaCO_2$ may change with a change in alveolar ventilation or metabolic rate. O_2 consumption and CO_2 production increase with an increase in metabolic rate, such as with fever or overfeeding. If metabolic rate and alveolar ventilation are constant, an increase in FiO_2 results in a proportional increase in PAO_2.

Arterial Oxygenation and Oxygen Content

Mechanical ventilation at FiO_2 of 0.21 may restore arterial oxygenation if the only cause of hypoxemia was hypoventilation. Hypoventilation may be the sole cause with central nervous system depression, apnea, and neuromuscular disease. With

other causes of hypoxemia, an increase in FiO_2 is needed to increase arterial O_2 content.

O_2 content is directly related to arterial oxygenation and hemoglobin concentration, defined by the equation for arterial oxygen content (CaO_2):[2]

$$CaO_2\ (vol\%) = (1.34 \times Hb \times SaO_2) + (PaO_2 \times 0.003\ ml\ O_2/mm\ Hg)$$

where 1.34 is a constant for the amount of O_2 carried by each fully saturated gram of hemoglobin (1.34 ml O_2/1 g hemoglobin), Hb is the hemoglobin concentration in g/dl, SaO_2 is the oxygen saturation of hemoglobin, and 0.003 is the amount of O_2 carried in the plasma in ml/mm Hg PaO_2. Under circumstances of normal diffusion, FiO_2, and hemoglobin concentration, the arterial content is normal at approximately 19.8 ml O_2/100 ml blood. As defined by this equation, CaO_2 decreases if hemoglobin concentration, arterial saturation, or PaO_2 decreases.

Decreased Shunt

Mechanical ventilation alone does not decrease shunt. Otherwise, it would be much easier to restore PaO_2 in patients with ARDS. Administration of PEEP with mechanical ventilation or to a spontaneously breathing patient in the form of continuous positive airway pressure (CPAP) helps to maintain open alveoli and stabilize small, collapsed, or fluid-filled alveoli. The results are an increase in alveolar surface area for diffusion and improvement in $\dot{V}/\dot{Q}$ matching and arterial oxygenation.

PEEP or CPAP should be used judiciously (see later in this chapter and Chapter 48). High pressure can overdistend alveoli and redistribute pulmonary blood flow to capillaries surrounding poorly ventilated alveoli, resulting in increased shunt.

Increased Tissue Oxygen Delivery

When a mechanical ventilator is used to improve arterial oxygenation by increasing FiO_2 or PEEP, CaO_2 increases. However, the increase in CaO_2 represents only part of tissue O_2 delivery because O_2 delivery is defined by CaO_2 and cardiac output, as follows:[2]

$$DO_2\ (\text{tissue oxygen delivery in ml/min}) = CaO_2\ (ml\ O_2/100\ ml\ blood) \times \text{Cardiac output (L/min)} \times 10$$

where 10 is a constant for converting deciliters to milliliters.

Normal tissue O_2 delivery is approximately 990 ml/min because the normal CaO_2 is approximately 20 vol%, and the normal cardiac output is approximately 5 L/min. When PaO_2, CaO_2, and cardiac output are adequate, so is tissue O_2 delivery. When PEEP is needed to improve PaO_2, it must be used cautiously because PEEP increases intrathoracic pressure. When intrathoracic pressure is increased, pleural pressure around the heart also increases, and the increase can affect the mechanical activity of the heart and impede venous return and decrease cardiac output. As discussed in Chapter 48, careful titration of PEEP must include monitoring the cardiovascular status of the patient. *Optimal PEEP* provides adequate arterial oxygenation and tissue O_2 delivery.

MINI CLINI

Oxygen Delivery

PROBLEM: Oxygen delivery (DO_2) depends on PaO_2, hemoglobin concentration, and cardiac output. The formula for DO_2 is:

$$DO_2 = CaO_2 \times \text{Cardiac output (L/min)} \times 10$$

where CaO_2 is the arterial oxygen content, and 10 is the conversion factor between deciliters and milliliters. Normal DO_2 is 990 ml/min. DO_2 is normal when the hemoglobin concentration is 15 g/dl, cardiac output is 5.0 L/min, and PaO_2 is 100 mm Hg:

$$\begin{aligned} DO_2 &= [15\ g\ Hb \times 1.34\ ml\ O_2/g\ Hb \times 0.97\ (SaO_2) + \\ &\quad 0.003 \times 100\ mm\ Hg] \times (5.0\ L/min) \times 10 \\ &= 19.8\ (CaO_2) \times 5\ (L/min) \times 10 = 990\ ml/min \end{aligned}$$

When the practitioner calculates DO_2 and determines it to be low, the component of the formula that is low denotes the problem and the therapeutic target. If CaO_2 is low because of a low hemoglobin concentration, increasing the hemoglobin concentration with blood transfusion is indicated. If CaO_2 is low because of low PaO_2 or SaO_2, increasing PaO_2 and SaO_2 with O_2 or PEEP is indicated. If cardiac output is low, the cause (decreased preload, increased afterload, decreased contractility, or bradycardia) is determined, and appropriate therapy is initiated. Frequently, a decrease in CaO_2 results in an increase in the cardiac output to compensate for decreased DO_2.

Example: Given PaO_2 of 65 mm Hg, hemoglobin concentration of 10 g/dl, SaO_2 of 91%, and cardiac output of 4.8 L/min, what increase in cardiac output is necessary to maintain DO_2 of 900 ml/min?

$$\begin{aligned} &DO_2 \text{ at given values is } [(1.34 \times 10 \times 0.97) + \\ &(0.003 \times 65)] \times 4.8 \times 10 = 633\ ml/min \end{aligned}$$

An increase in cardiac output to 6.8 L/min results in DO_2 that is close to normal: $[(1.34 \times 10 \times 0.97) + (0.003 \times 65)] \times 6.8 \times 10 = 897$ ml/min. However, an increase in cardiac output to 6.8 L/min increases myocardial work. Because the cause of decreased DO_2 in this patient is hypoxemia and anemia, the goal of therapy should be to increase PaO_2. This strategy allows cardiac output and work to return to normal while adequate DO_2 is maintained. Increasing the hemoglobin concentration is normally not performed by transfusion unless the hemoglobin concentration is less than 8 to 10 g/dl because of the adverse effects associated with transfusions.

EFFECTS OF POSITIVE PRESSURE MECHANICAL VENTILATION ON LUNG MECHANICS

Time Constants

The time necessary for **passive** inflation and deflation of the lung or each alveolus is determined by the product of compliance and resistance. This product is the **time constant** of the

lung or alveolar unit. The compliance of a "normal" lung is 0.1 L/cm H_2O, and resistance of a normal lung is 2.5 cm H_2O/L/sec. The time constant for a normal lung is 0.25 second (1.0 L/cm $H_2O \times 0.25$ cm H_2O/L/sec). For patients with normal lungs, 95% of the alveoli are inflated within three time constants (i.e., within 0.25 second). In four time constants (1.0 second), 98% of alveoli are inflated, and in five time constants (1.25 second), 99.3% of alveoli are inflated. The same numbers apply for exhalation.

The two major factors that affect alveolar time constants are changes in compliance and changes in resistance. If compliance or resistance decreases, the time constant for a given lung unit decreases, and the lung fills and empties faster. If compliance or resistance increases, the time constant increases, and it takes more time to fill and empty the lung.

There are clinical implications for patients with disorders consistent with abnormal time constants. A longer inspiratory time may be needed for patients with asthma because airway resistance is increased. Attempting to ventilate these patients with a normal inspiratory time may result in inadequate volume to affected lung units because the airways are obstructed, and volume is likely to travel to airways with the lowest resistance. Inspiratory time in severe asthma needs to be set between about 1.0 second to 1.5 seconds to ensure adequate gas delivery. The primary limiting factor is that the airways are also obstructed during exhalation. The expiratory time must also be longer to allow as complete an exhalation as possible.

Asthma is very different from COPD, in which the inspiratory time constant is normal, but the expiratory time constant is long. In general, asthma requires very slow respiratory rates with longer than normal inspiratory and expiratory times to account for the altered time constants during both inspiration and expiration. Patients with COPD generally tolerate a more rapid rate because only the expiratory time constant is lengthened. In both of these situations, air trapping is very common because of the long time constants. In patients with COPD, inspiratory times are generally short (about 0.7 to 0.9 second). In patients with ARDS or acute lung injury (ALI), time constants are very short, and as a result inspiratory times can also be very short. Most patients with ARDS require an inspiratory time of only 0.5 to 0.8 second. Expiratory time constants are also short—hence the ability to ventilate these patients rapidly with small V_T. Respiratory rates greater than 30 breaths/min are frequently well tolerated by patients with ARDS. The major concern with patients with ARDS and their short time constants is that any disruption of the airway rapidly results in loss of lung volume. Atelectasis occurs with disconnections from the ventilator of only 1 or 2 seconds. As a result, *all* patients with ARDS should be suctioned *only* with inline suction catheters, and any circuit disconnection should be avoided. Ventilator management in the care of patients with COPD, asthma, and ARDS is described in detail in Chapter 48.

Increased Pressure

Peak inspiratory pressure (PIP) is the highest pressure produced during the inspiratory phase. It is the sum of the pressures necessary to overcome airway resistance and lung and chest wall compliance. PIP is also known as *peak pressure* or *peak airway pressure*.

Plateau pressure (P_{plat}) is the pressure observed during a period of inflation hold or end inspiratory pause. To obtain a plateau pressure, the RT initiates an inspiratory pause time of 0.5 to 2.0 seconds. During inspiration, the peak pressure is reached and then immediately followed by the inspiratory pause. During the pause, pressure decreases to a pressure plateau. When a valid plateau pressure value is obtained, the inspiratory pause time is returned to zero. Plateau pressure represents the average peak alveolar pressure (P_{alv}). In volume-controlled ventilation, plateau pressure is always lower than peak pressure because the peak pressure is the sum of the alveolar pressure and the pressure needed to overcome airway resistance. When flow is delivered by a square waveform, the difference between plateau pressure and peak pressure is the pressure necessary to overcome airway resistance. If the V_T is divided by the difference between the plateau pressure and PEEP, the quotient is the quasistatic lung-thorax compliance:[3]

$$C_{static} = V_T/(P_{plat} - PEEP)$$

This value is referred to as the lung-thorax compliance because the compliance of the lungs and the compliance of the rib cage are being calculated as a unit. The lung compliance cannot be determined without the use of an esophageal balloon.[3] Ideally, the volume lost owing to tubing compliance should be subtracted from the V_T if the ventilator has not compensated for it, making the equation:[3]

$$C_{static} = \text{Adjusted } V_T/P_{plat} - \text{total PEEP})$$

In addition, the total PEEP should be subtracted from the P_{plat}. That is the total of applied PEEP plus any auto-PEEP present. The reason for this is that the baseline pressure prior to the start of inspiration is the total PEEP, not the applied PEEP.[3]

It may be more useful to follow trends in lung compliance, rather than making judgments on only one calculation. A downward trend in compliance means that the lungs or chest wall is stiffer, as in ARDS.

Airway resistance (R_{aw}) during volume ventilation is estimated by the difference between PIP and P_{plat} divided by the inspiratory flow ($\dot{V}_I$) in L/sec, provided that the flow is constant (square waveform):[3]

$$R_{aw} = (PIP - P_{plat})/\dot{V}_I$$

During mechanical ventilation, the plateau pressure should be less than 28 cm H_2O.[4,5] At levels greater than 28 cm H_2O, alveolar damage from overdistention is likely. This form of *ventilator-induced lung injury (VILI)* is referred to as **volutrauma** (see later). This trauma can result in air leakage from alveoli, the release of inflammatory mediators, and multisystem organ failure (MSOF). When the plateau pressure approaches 28 cm H_2O during either volume or pressure ventilation, the pressure limit or the V_T should be decreased. This approach to ventilation is referred to as *lung protective ventilation*.[3-5]

RULE OF THUMB

When measuring lung mechanics, airway resistance and compliance always use the same ventilator settings to make comparisons from one point in time to another much easier. In adults, settings are volume ventilation, V_T 500 ml, square wave flow, and peak flow set at 60 L/min.

Mean Airway Pressure

Mean airway pressure is the average pressure across the total cycle time (TCT). The mean airway pressure ($P_{\overline{AW}}$) can be calculated manually if the flow is constant, as follows:[3]

$$P_{\overline{AW}} = \tfrac{1}{2}(PIP - PEEP) \times (\text{Inspiratory time}/TCT) + PEEP$$

Mean airway pressure is computed by the ventilator as the integral of the pressure signal over the total cycle time (as a rolling average), so the RT can record the ventilator computed value, rather than manually calculating it. Because expiratory (baseline) pressure is lower than inspiratory pressure, the mean pressure is between peak and end expiratory pressure. The variables affecting mean pleural and mean airway pressure are summarized in Box 46-1. For a given minute volume, partial ventilatory support modes such as synchronized intermittent mandatory ventilation (SIMV) result in lower mean airway and pleural pressures than continuous mandatory ventilation (CMV) modes. For a specific mandatory breath, as peak pressure increases, so does mean pressure. Likewise, long inspiratory times increase mean pressure. Prolonging expiratory time has the opposite effect on mean airway pressure. Generally, the harmful cardiovascular effects of PPV are more likely to occur when $P_{\overline{AW}}$ or inspiratory-to-expiratory (I : E) ratio increases (e.g., >1 : 1).

The pressure waveform of a mandatory breath affects mean pressure. In Figure 46-6, for a given inspiratory time, the constant pressure pattern (curve *A*) results in the greatest area under the airway pressure curve and the highest mean airway pressure. A constant pressure pattern is normally produced by a pressure targeted breath that provides decreasing (descending ramp) flow. The effect of PEEP on mean airway pressure is simple: Every 1 cm H_2O of applied PEEP increases the mean airway pressure 1 cm H_2O.

Box 46-1 Factors That Increase Mean Airway Pressure

- Absence of spontaneous ventilation
- Increasing positive pressure
- Increasing duration of inspiration
- Decreasing duration of expiration
- Nature of inspiratory waveform
- Increasing level of PEEP
- Decreasing compliance, increasing airways resistance

Effect of Peak Airway Pressure on Lung Recruitment

As peak airway pressure increases, previously collapsed, small, or fluid-filled alveoli are recruited, that is, reopened.[6] This reopening of alveoli increases alveolar surface area and restores functional residual capacity (FRC). At the alveolar level, the surface area available for diffusion is increased. As a result, PaO_2 increases, consistent with Fick's law. The use of extrinsic PEEP maintains the airways and recruited open alveoli. Extrinsic PEEP is controlled directly by the PEEP control on the ventilator, and the RT always knows how much extrinsic PEEP is present. Several factors, including inverse ratio ventilation (IRV), may add intrinsic PEEP or auto-PEEP by starting the next breath before the previous exhalation has ended. The amount of intrinsic PEEP added by IRV can be measured by implementing an end expiratory pause, which stops the next breath from being delivered. During this end expiratory pause, alveolar and mouth pressures equilibrate, and the total PEEP is now presented by the ventilator. The amount of auto-PEEP present is the difference between the total PEEP and the extrinsic PEEP:

$$\text{Intrinsic PEEP (auto-PEEP)} = \text{Total PEEP} - \text{Extrinsic PEEP}$$

Increased Lung Volume: Tidal Volume

The volume delivered during pressure-controlled modes varies with changes in set pressure, patient effort, and lung mechanics. For all pressure-targeted modes, the volume delivered at a given pressure decreases as compliance decreases. An increase in resistance, active exhalation, or muscle tensing by the patient during inspiration also decreases delivered volume in pressure ventilation.

If pressure serves as the limit variable instead of the cycle variable, changes in airway resistance during pressure-limited ventilation may or may not affect delivered volume. In this case, the key factor is the time available for pressure equilibration. Volume can remain constant even if airway resistance increases, as long as there is sufficient time for alveolar and airway

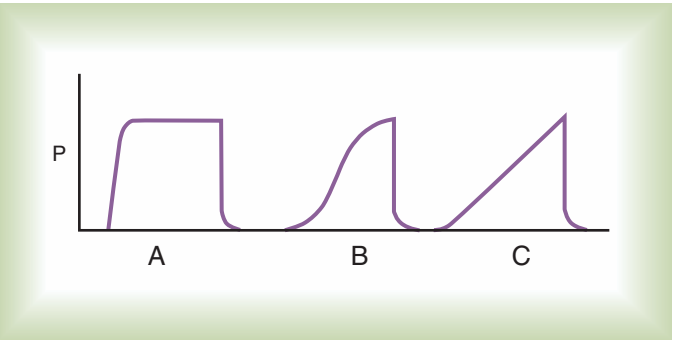

FIGURE 46-6 Pressure patterns resulting from a descending ramp flow waveform *(A)*, a sine wave flow waveform *(B)*, and a constant flow waveform *(C)*. Because waveform *A* has the highest pressure for the longest inspiratory time, it also has the greatest mean airway pressure.

pressures to equilibrate. However, if insufficient time is available for pressure equilibration, delivered volume decreases as airway resistance increases. The length of time needed for pressure equilibration is usually at least three times greater than the time constant for the respiratory system. In pressure modes, ventilator-delivered flow varies with patient effort and lung mechanics; this tends to avoid patient-ventilator asynchrony.[7]

Increased Functional Residual Capacity

FRC is not known to change significantly with the application of PPV alone because passive exhalation allows the end expiratory pressure to return to atmospheric pressure with each breath. If an increase in FRC is to be achieved, end expiratory pressure must be increased. This increase is commonly achieved with PEEP or CPAP. PEEP or CPAP does not recruit collapsed lung units but prevents lung units that have been opened from collapsing at end expiration. Peak airway pressure recruits lung volume. The magnitude of the increase in FRC sustained by PEEP or CPAP is proportional to the lung-thorax compliance. With acute restriction, as PEEP is increased, lung compliance improves. Initially, the FRC gain as PEEP is added is small. However, as FRC and compliance increase, additional increments of PEEP tend to result in larger increases in FRC up to the point at which overdistention occurs. At that point, as PEEP is increased, increases in FRC decline, as does compliance. There is no practical way of measuring FRC in all patients, so other methods of determining an increase in FRC are used, such as improving PaO_2 at a constant FiO_2, increasing PaO_2/FiO_2 ratio, decreasing shunt fraction, or decreasing FiO_2 while maintaining PaO_2. The management of PEEP is described in more detail in Chapter 48.

Pressure-Volume Curve and Lung Recruitment in Acute Respiratory Distress Syndrome

Figure 46-7 depicts the pressure-volume (P-V) relationship of the lung-thorax in an idealized patient with ARDS.[8] On the inflation P-V curve, there are two points of inflection: the lower inflection point referred to as P_{flex} or *lower corner pressure,* and an upper inflection point, also referred to as *upper corner pressure.* These two points represent defined changes in compliance. The lower inflection point represents an abrupt increase in lung-thorax compliance as collapsed or atelectatic lung begins to be recruited.[9] The upper deflection point represent the point where the rate of lung recruitment decreases and overinflation begins.[9] It is most important to realize from this graph that the lung is recruited by pressure and that the higher the peak airway pressure, the greater the potential for lung to be recruited. The maximum pressure needed to recruit a given patient's lung is unknown; however, pressures up to 50 cm H_2O most likely are safe with most patients when applied for short (1 to 3 minutes)

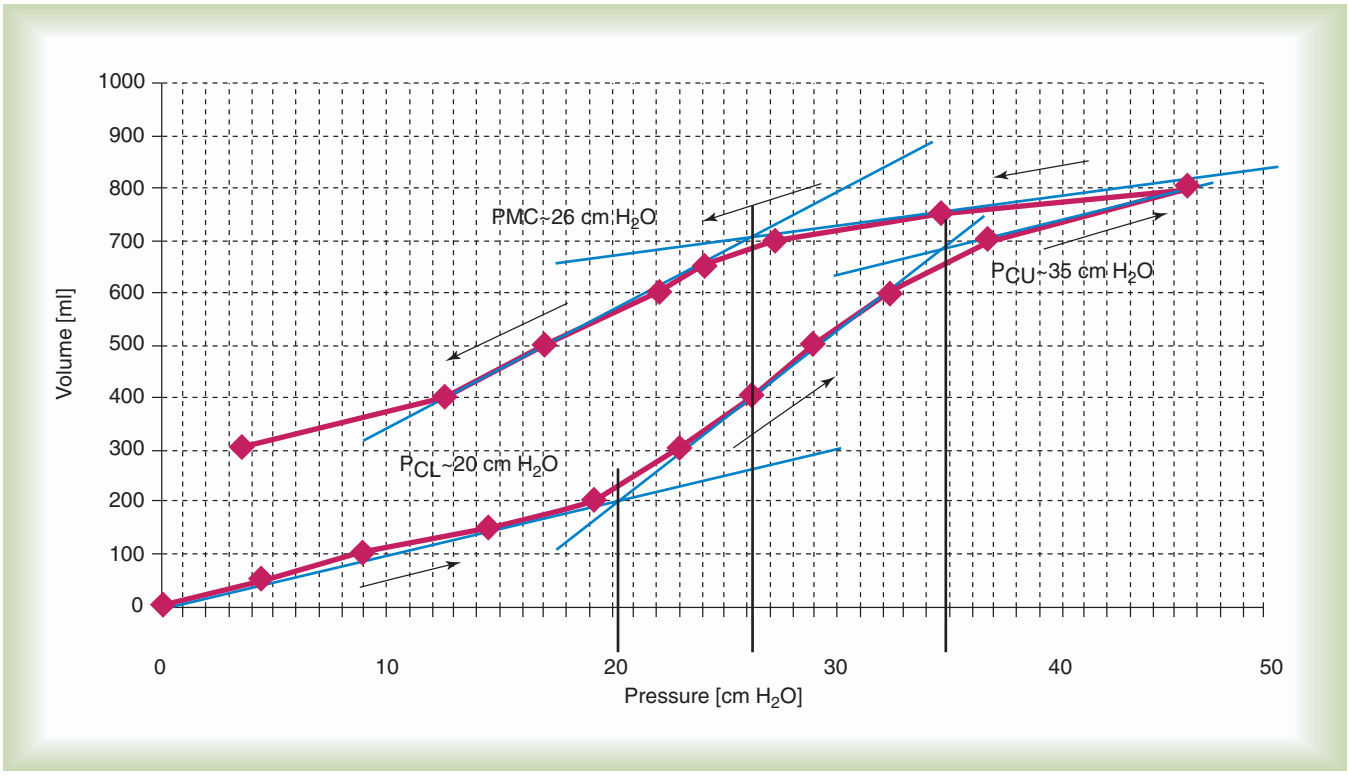

FIGURE 46-7 P-V curve of the lung-thorax indicating the inflation and deflation limbs. *Arrows* indicate direction of flow. P_{CL}, Lower corner pressure or P_{flex} or lower inflection point; P_{CU}, upper corner pressure or upper inflection point; P_{MC}, point of maximum compliance change. (Modified from Godon S, Fujino Y, Hromi JM, et al: Optimal mean airway pressure during high frequency oscillation. Anesthesiology 94:862-868, 2001.)

periods.[10-12] If these pressures were applied for longer periods, lung injury would most likely result.

The deflation limb of the P-V curve is similar in shape to the inflation limb but is separated from the inflation limb. This hysteresis (separation) is a result of surfactant and surface tension interactions. Basically, less pressure is required to keep the lung open on the deflation limb of the P-V curve than on the inflation limb; this is obvious on examination of the volume maintained in the lung at P_{flex}, or 20 cm H_2O. On the inflation limb, lung volume increases about 200 ml at 20 cm H_2O, but on the deflation limb, lung volume increases about 550 ml. The goal of an open lung approach to ventilation that has been proposed by many authors is to open the lung and then to ventilate the patient on the deflation limb of the P-V curve.[10-12]

Figure 46-7 is an idealized P-V curve; actual patient P-V curves in ARDS are not as well defined. In 10% to 20% of patients with ARDS, P_{flex} cannot be identified on the inflation P-V curve. As a result, despite two positive randomized controlled trials using P_{flex} to set PEEP,[13,14] the use of P-V curves clinically has not become common practice; a second reason for this is the difficulty of measuring the P-V curve. However, many newer ICU ventilators are including algorithms that allow P-V curves to be performed by the ventilator with the ventilator identifying P_{flex}. This option may increase the use of the P-V curve for the management of patients with ARDS.

The approach to setting PEEP that assures ventilation on the deflation limb of the P-V curve and the minimal PEEP to sustain the benefit of lung recruitment is a decremental PEEP trial immediately after a lung recruitment maneuver (RM).[12,13,15] Many different approaches to performing lung RMs have been published, but the approach that is considered the safest and most efficacious is the use of pressure-controlled continuous mandatory ventilation (PV-CMV).[12,13,15] To perform a lung RM with PC-CMV, high enough PEEP must be set to avoid derecruitment after each inspiration. Essentially, a minimum of 20 cm H_2O PEEP is required during the RM. Peak pressure is usually started at 35 to 40 cm H_2O, and if the patient tolerates the pressure hemodynamically, it may be increased to 50 cm H_2O, ensuring a driving pressure of no more than 15 cm H_2O (Box 46-2). Inspiratory time is increased to about 1.5 to 2.0 seconds, and respiratory rate is decreased to about 15 to 20 breaths/min. The maneuver is applied for 1 to 3 minutes. During the RM, the patient must be sedated to apnea to avoid fighting the ventilator.

Before any RM, the patient must be hemodynamically stable. RMs should not be performed in patients with existing **barotrauma** or with a high likelihood of developing barotrauma (blebs or bullae) or in patients who are hemodynamically unstable. In addition, RMs are most effective and result in the least adverse reaction if performed early in the course of ARDS. During and after the RM, the patient must be carefully monitored for hemodynamic and oxygenation instability and the development of barotrauma.

After an RM, the best way to identify the minimum effective PEEP level that maintains the lung open is to perform a decremental PEEP trial.[12,13,15] This trial is performed by changing the mode from PC-CMV to volume-controlled continuous mandatory ventilation (VC-CMV), V_T 4 to 6 ml/kg, inspiratory time 1.0 second or less, PEEP 20 to 25 cm H_2O, and rate set at the maximum that does not cause auto-PEEP.[8] After stabilization (3 to 5 minutes), dynamic compliance is measured.[8] PEEP is then decreased 2 cm H_2O, the patient is stabilized (3 to 5 minutes), and measurement of dynamic compliance is repeated; this is continued until the PEEP level at which the compliance decreases is identified. Generally, compliance at 20 to 25 cm H_2O PEEP is low, and it increases as PEEP is decreased; compliance then decreases as PEEP is decreased further. Open lung PEEP is the PEEP associated with the highest compliance. Set PEEP is open lung PEEP plus 2 cm H_2O.

After open lung PEEP is identified, the lung is again recruited because during the decremental PEEP trial derecruitment occurred. After recruitment, PEEP is set at the identified level, ventilation is adjusted using a lung protective V_T (4 to 8 ml/kg), and rate is adjusted to normalize PCO_2. After all is set, FiO_2 is decreased to the level that maintains PaO_2 in the range of 55 to 70 mm Hg. Repeat RMs may be needed if the patient did not respond to the initial RM or if the patient is disconnected from

Box 46-2 Performance of Recruitment Maneuver and Decremental Positive End Expiratory Pressure Trial

Pressure control ventilation settings are:
- PEEP 20-30 cm H_2O
- Peak inspiratory pressure 35-50 cm H_2O
- Driving pressure no greater than 15 cm H2O
- Inspiratory time 1-2 sec
- Rate about 15-20 breaths/min
- Time 1-3 min

After completing RM, set PEEP at 20 or 25 cm H_2O, ventilate with VC, V_T 4 to 6 ml/kg ideal body weight, increase rate, avoid auto-PEEP.
Measure dynamic compliance after 3 to 5 minutes of stabilization.
Decrease PEEP 2 cm H_2O.
Measure dynamic compliance after 3 to 5 minutes of stabilization.
Repeat until maximum compliance is determined.
Optimal PEEP = maximum compliance PEEP + 2 cm H_2O.
Repeat RM and set PEEP at the identified settings; adjust ventilation.
After PEEP and ventilation are set and stabilized, decrease FiO_2 until PO_2 is in target range.
If response is poor and the patient tolerates the procedure well, repeat RM with PEEP 25 cm H_2O and peak pressure 40 cm H_2O after a period of stabilization.
If response is still poor and the patient tolerates the procedure well, repeat RM with PEEP 30 cm H_2O and peak pressure 45 cm H_2O.
If response is still poor and the patient tolerates the procedure well, repeat RM with PEEP 35 cm H_2O and peak pressure 50 cm H_2O.
Do not exceed 50 cm H_2O peak airway pressure during RM.

the ventilator and derecruitment occurs. A successful RM is one that allows the FiO_2 to be reduced to less than 0.5.

The use of RM has been documented in many case series; however, no data have been published indicating that outcome is improved as a result of RMs and decremental PEEP settings. Research is ongoing.

RULE OF THUMB

A lung RM is most likely to be successful if it is performed early in the course of ARDS. Ideally, if indicated, a lung RM should be performed once the patient is fully stabilized after intubation and initiation of mechanical ventilation. The longer the patient is mechanically ventilated, the less likely it is that the RM would be successful.

Increased Dead Space

The dead space fraction is increased with the institution of mechanical ventilation owing to inspiratory mechanical bronchodilation and the preferential ventilation of more apical, nondependent alveoli, the reduction of blood flow away from ventilated alveoli, and the continued perfusion of basilar or dependent alveoli (see Figure 46-5). This increase is concurrent with a decrease in $\dot{V}/\dot{Q}$ ratio.

Decreased Work of Breathing

Although improper ventilator management can increase WOB (poor patient-ventilator interaction, see Chapter 47 for details), one of the primary objectives of mechanical ventilation is to decrease WOB. PPV can significantly reduce WOB in patients with actual or impending respiratory muscle fatigue. RTs frequently see patients relax as the ventilator assumes a major portion of their WOB. To lessen WOB, ventilation must be sufficient to meet the patient's needs. Otherwise, a spontaneously breathing patient tends to resist the ventilator, and an asynchronous breathing pattern develops. Inappropriately applied PPV can result in alveolar hypoventilation and consequently a considerable increase in the patient's WOB.

Mode, trigger setting, and inspiratory flow have an effect on WOB. WOB consists of two components: (1) ventilator work (WOB_{vent}) occurring as the ventilator forces gas into the lungs and (2) patient work (WOB_{pt}) as the inspiratory muscles draw gas into the lungs. The magnitude of WOB_{pt} depends on compliance, resistance, and ventilatory drive and on ventilator variables, such as trigger sensitivity, peak flow, cycling coordination, and V_T.[16,17]

Regardless whether flow or pressure triggering is selected, either should always be set as sensitive as possible without causing autotriggering. The less sensitive the setting, the greater the patient effort. In older generation ventilators, flow triggering was shown to require less effort than pressure triggering.[18] However, with the newest generation of ICU ventilators, both are equally effective.

As described in Chapter 45, a mode of ventilation is a ventilatory pattern that can be described by identifying the control variable, breath sequence, and targeting scheme. The breath sequence may be thought of as being on a continuum from assuming very little to assuming all WOB. As the breath sequence is changed from continuous spontaneous ventilation (CSV) to CMV, the ventilator assumes more WOB. An example of this transition would be from CPAP to pressure support to CMV. In CPAP, a continuous spontaneous mode of ventilation, the patient assumes all WOB. The ventilator merely provides positive pressure throughout the patient's breathing cycle. The ventilator assumes more WOB during CMV. Pressure support is also an example of CSV. During pressure support ventilation (PSV), the patient determines breath timing (length of inspiration and expiration) and frequency. Depending on the set inspiratory pressure, the clinician may program the ventilator to provide a minimal to a maximal amount of WOB. In instances where the patient has no spontaneous efforts, all breaths during CMV are time triggered, and all work performed is WOB_{vent}. Although it may be advantageous for the ventilator to assume all WOB for a while, extended periods of passive ventilation may cause diaphragmatic atrophy, which may unnecessarily prolong the need for mechanical ventilation and delay weaning. At initiation of patient-triggered pressure or volume modes, WOB_{pt} resumes.

During assisted ventilation, pressure-targeted modes are generally more capable of meeting patient ventilatory demands and minimizing WOB_{pt}.[19] As pressure level is increased, ventilatory muscles are unloaded, V_T increases for a given amount of patient effort, and WOB_{pt} decreases. Most clinicians increase pressure level until the breathing pattern approaches normal—that is, until the spontaneous ventilatory rate is 15 to 25 breaths/min and the spontaneous V_T is normal (5 to 8 ml/kg).

Measuring WOB is technically difficult. It is often accomplished by esophageal balloon monitoring, in which a balloon is placed in the distal third of the esophagus, and a pneumotachometer is attached to the airway (see Chapter 51). WOB is the integral of the esophageal pressure and V_T. Normal WOB is 0.6 to 0.9 J/L.[20]

MINIMIZING ADVERSE PULMONARY EFFECTS OF POSITIVE PRESSURE MECHANICAL VENTILATION

Decreasing Pressure

The main objective of mechanical ventilation is to provide a minute ventilation appropriate to achieve adequate alveolar ventilation and supplemental O_2 and PEEP to provide adequate arterial oxygenation.

Peak pressure is the result of the pressure required to overcome system resistance and compliance. Although there is no absolute maximum pressure, most practitioners try to avoid peak pressures greater than 40 cm H_2O. As the peak pressure approaches 40 cm H_2O, it is important to consider the causes. Factors that increase airway resistance include airway edema, bronchospasm, and secretions. The RT can manage or avoid these problems by ensuring adequate humidity, bronchial

MINI CLINI

Overcoming an Increase in the Work of Breathing

PROBLEM: A patient's WOB is minimal during mechanical ventilation with an appropriate V_T and rate. As the ventilator support is gradually discontinued and the patient is expected to take over more of WOB, airway resistance associated with breathing through an endotracheal tube may become clinically important. The RT must be able to recognize this problem readily and know how to correct it.

A patient has received mechanical ventilation in volume-controlled CMV mode for the past week. The patient's condition is now clinically stable, and ventilation is provided by PSV. As the PSV pressure level is reduced to 8 cm H_2O, the patient begins using accessory muscles to breathe, the spontaneous respiratory rate increases to 30 breaths/min, and the patient reports shortness of breath. Blood gas values are acceptable, and no abnormal lung sounds are present. What is the problem, and what should the RT do?

Solution: The patient may be experiencing excessive WOB because of airway resistance associated with the endotracheal tube; a small sized tube or partial obstruction of the tube with secretions may be the problem. Other possibilities that should be considered include deterioration in the patient's cardiopulmonary status, but the normal blood gas values and lung sounds suggest the problem is not the lungs. Passing a suction catheter through the tube may help to identify the problem. If the catheter does not pass easily, the tube may be partially obstructed. Two options exist: change the tube or extubate the patient. Because the tube would need to be removed regardless of the choice, a trial extubation should be considered. Because this patient is at risk immediately after extubation, noninvasive ventilation should be started. If the patient cannot tolerate extubation, an appropriate-sized endotracheal tube can be reinserted.

hygiene (suctioning, airway care), and administration of bronchodilators and antiinflammatory drugs. Factors that increase the pressure needed to inflate the lung and overcome compliance include alveolar and interstitial edema, atelectasis, fibrosis, and chest wall restriction.

Plateau pressure reflects mean maximum alveolar pressure. Plateau pressures of 28 cm H_2O or greater have an increased likelihood of causing lung injury.[3,4,5] If plateau pressure approaches 28 cm H_2O during volume ventilation, the V_T should be decreased so that the plateau pressure is less than 28 cm H_2O, or with pressure ventilation, target pressure should be set less than 28 cm H_2O.[4,21]

Mean airway pressure is decreased by decreasing inspiratory time, V_T, respiratory rate, PEEP, or PIP. Increased mean airway pressure reduces venous return and may reduce cardiac output.

Positive End Expiratory Pressure or Continuous Positive Airway Pressure

PEEP is the application of positive pressure at end-exhalation. PEEP is used primarily to improve oxygenation in patients with refractory hypoxemia. As a rule, refractory hypoxemia exists when PaO_2 cannot be maintained at greater than 50 to 60 mm Hg with FiO_2 0.50 or greater. PEEP improves oxygenation in these patients by maintaining alveoli open, restoring FRC, and decreasing physiologic shunting. The improved alveolar volume provided by PEEP allows a lower FiO_2. Other values such as lung compliance, shunt fraction, and PaO_2/FiO_2 ratio also may improve when PEEP is appropriately applied. PEEP may be indicated in the care of patients with COPD who have dynamic hyperinflation (auto-PEEP).[22,23] (See discussion later in this chapter.)

TABLE 46-2

Physiologic Effects of Positive End Expiratory Pressure

Beneficial Effects of Appropriate PEEP	Detrimental Effects of Inappropriate PEEP
Restored FRC, avoids derecruitment	Increased pulmonary vascular resistance
Decreased shunt fraction	Potential decrease in venous return and cardiac output
Increased lung compliance	Decreased renal and portal blood flow
Decreased WOB	Increased ICP
Increased PaO_2 for a given FiO_2	Increased dead space

Beneficial and harmful effects are associated with the use of PEEP (Table 46-2). Detrimental effects of inappropriately high levels of PEEP include decreased cardiac output, increased pulmonary vascular resistance, and increased dead space. When one or more of these problems occur, PEEP is decreased to the previous level or to a value between the current level and the previous level. If cardiac output decreases and an increase in PEEP is necessary to maintain oxygenation, intravenous fluid, inotropic cardiac drugs, or both are administered to restore cardiac output.

PEEP is contraindicated in the presence of a tension pneumothorax. PEEP should be applied cautiously in patients with severe unilateral lung disease because PEEP would overinflate the lung with higher compliance. The result is lung overdistention and compression of adjacent pulmonary capillaries. Independent lung ventilation can be used to apply separate inspiratory and baseline pressures to the right and the left lung when severe unilateral lung disease is present.[24] PEEP is contraindicated in the care of patients with increased ICP only if the application of PEEP increases ICP further.

RULE OF THUMB

Refractory hypoxemia exists when PaO_2 cannot be maintained at greater than 50 to 60 mm Hg with FiO_2 0.50 or greater. This situation is an indication for PPV with PEEP or CPAP because an increased end expiratory pressure with either of these modalities improves oxygenation by decreasing physiologic shunting.

Effects of Ventilatory Pattern

The most commonly used inspiratory flow patterns are constant or square and descending ramp during volume-controlled ventilation and exponential decay during pressure-controlled ventilation. In mechanical and computer models, a descending ramp (volume-controlled ventilation) flow pattern improves gas distribution to lung units with long-time constants. The literature often refers to the descending ramp as a decelerating flow pattern. Similar findings in humans have been reported. Compared with a square flow waveform, a descending ramp has been shown to reduce peak pressure, inspiratory work, V_D/V_T, and $P(A-a)O_2$ without affecting hemodynamic values.[25] Compared with volume-controlled ventilation with a square flow waveform, pressure-controlled ventilation with an exponential decay flow waveform may result in a higher PaO_2, lower $PaCO_2$, and lower PIPs. However, mean airway pressure is higher with pressure-controlled ventilation compared with volume-controlled ventilation because pressure increases to the set inspiratory pressure and remains constant throughout inspiration. During pressure-controlled ventilation, flow is responsive to patient demand. The ventilator delivers flow to the patient in proportion to patient need. Flow is also greater at the onset of inspiration, resulting in V_T delivery at a time when the lungs are most compliant, the beginning of the breath. As a breath ends, flow is least, and the volume delivered is small. The result is a lower peak airway pressure for any given V_T.

In most spontaneously breathing persons, lower inspiratory flows improve gas distribution. However, during PPV, low inspiratory flow may lead to lengthy inspiratory times and air trapping if expiratory time is too short. High ventilator inspiratory flow allows more time for exhalation and reduces the incidence of air trapping. Avoidance of air trapping improves gas exchange and reduces WOB in patients with high ventilatory demands.[17,26]

An inflation hold also affects gas exchange. By momentarily maintaining lung volume under conditions of no flow, an inflation hold allows additional time for gas redistribution between lung units with different time constants. In both animal and human studies, increasing the length of an inflation hold decreases the V_D/V_T, $PaCO_2$, and inert gas washout time. Adding an inflation hold effectively increases total inspiratory time, shortening the time available for exhalation and predisposes patients with airway obstruction to auto-PEEP. In practice, an inflation hold should be used only to obtain P_{plat} values. Because the technique prevents the onset of exhalation, asynchrony occurs if the patient is actively breathing.

Trigger Site and Work of Breathing

Studies have examined the effects of sensing a patient's inspiratory effort at the tip of the endotracheal tube rather than in the ventilator circuit, as is done with all ventilators. Triggering and managing gas delivery by measurement of pressure at the tip of the endotracheal tube decreases patient effort and improves synchrony; however, no practical system has been designed.[27] In addition, the efficiency of ventilator flow and pressure triggering seems to improve with each new generation of mechanical ventilator.

PHYSIOLOGIC EFFECTS OF VENTILATORY MODES

Volume-Controlled Ventilation Versus Pressure-Controlled Ventilation

Figure 45-5 illustrates the important variables for volume ventilation modes. The figure shows that the primary variable to be controlled is the patient's minute ventilation. A particular ventilator may allow the operator to set minute ventilation directly. More frequently, minute ventilation is adjusted by means of a set V_T and frequency. V_T is a function of the set inspiratory flow and the set inspiratory time. Inspiratory time is affected by the set frequency and, if applicable, the set I : E ratio. The mathematical relationships among all these variables are shown in Table 46-3.

With pressure-controlled ventilation, the goal is also to maintain adequate minute ventilation. However (as the equation of motion shows), when pressure is controlled, V_T and minute ventilation are determined not only by the ventilator's pressure settings but also by the elastance and resistance of the patient's respiratory system. Minute ventilation and hence gas exchange are less stable in pressure-controlled modes than in volume-controlled modes. Figure 45-6 shows the important variables for pressure-controlled ventilation. V_T is not operator set on the ventilator. It is the result of the set inspiratory pressure, the patient's lung mechanics, and the inspiratory time. On most ventilators, the speed with which inspiratory pressure is achieved (i.e., the pressure rise time) is adjustable. That adjustment affects the shape of the pressure waveform and the mean airway pressure.

Continuous Mandatory Ventilation

CMV (also referred to as *assist/control*) is a mode of ventilation in which total ventilatory support is provided by the mechanical ventilator. All breaths are mandatory and delivered by the ventilator at a preset volume or pressure, breath rate, and inspiratory time. If the patient has spontaneous respiratory efforts, the ventilator delivers a patient-triggered breath. If patient efforts are absent, the ventilator delivers time-triggered breaths. The clinician needs to set an appropriate trigger level and flow rate for the patient in this mode of ventilation. There is a potential for the ventilator to autotrigger when the trigger level is set too sensitive. As a result, hyperventilation, air trapping, and patient anxiety often ensue. However, if the trigger level is not sensitive enough, the ventilator does not respond to the patient's inspiratory efforts, which results in increased WOB.

Occasionally, all attempts to optimize patient comfort, reduce WOB, and achieve the goals of this mode of ventilation are futile. In cases in which this mode is poorly tolerated and spontaneous triggering is counterproductive to the goals set for a particular patient, sedation or paralysis or both may be

TABLE 46-3

Equations Relating the Important Parameters for Volume-Controlled and Pressure-Controlled Ventilation

Mode	Parameter	Symbol	Equation
Volume-controlled	Tidal volume (L)	V_T	$V_T = \dot{V}_E \div f$ $V_T = \dot{V}_I \div T_I$
	Mean inspiratory flow (L/min)	$\bar{\dot{V}}_I$	$\bar{\dot{V}}_I = 60 \times V_T \div T_I$ $\bar{\dot{v}}_I = \frac{\dot{v}_E \times TCT}{T_I}$
Pressure-controlled	Tidal volume (L)	V_T	$V_T = \Delta P \times C \times (1 - e^{-t/\tau})$
	Instantaneous inspiratory flow (L/min)	$\dot{v}_I$	$\dot{v}_I = \left(\frac{\Delta P}{R}\right) e^{-t/\tau}$
	Pressure gradient (cm H_2O)	ΔP	$\Delta P = PIP - PEEP$
Both modes	Exhaled minute ventilation (L/min)	$\dot{V}_E$	$\dot{V}_E = V_T \times f$
	Total cycle time or ventilatory period (sec)	TCT	$TCT = T_I + T_E = 60 \div f$
	I : E ratio	I : E	$I:E = T_I : T_E = \frac{T_I}{T_E}$
	Time constant (sec)	τ	$\tau = R \times C$
	Resistance (cm H_2O/L/sec)	R	$R = \frac{\Delta P}{\Delta \dot{V}}$
	Compliance (L/cm H_2O)	C	$C = \frac{\Delta V}{\Delta P}$
	Elastance	E	$E = \frac{1}{C}$

required. These agents may be used to minimize patient effort and normalize WOB.

Volume-Controlled Continuous Mandatory Ventilation

Volume-controlled continuous mandatory ventilation (VC-CMV) is indicated when a precise minute ventilation or blood gas parameter, such as $PaCO_2$, is therapeutically essential to the care of patients.[26] Theoretically, volume control (with a constant inspiratory flow) (Figure 46-8) results in a more even distribution of ventilation (compared with pressure control) among lung units with different time constants where the units have equal resistances but unequal compliances (e.g., ARDS).[27]

During VC-CMV, volume is guaranteed, but airway pressure varies depending on changes in the patient's lung mechanics. A reduction in lung compliance or an increase in resistance causes higher peak airway pressures. Care should also be taken when setting the inspiratory flow. Avoid setting a flow that fails to match patient needs or exceeds patient demand. An insufficient flow rate would result in an imposed increase in the patient's WOB and a concomitant increase in O_2 consumption. The inspiratory phase may be prematurely shortened if the set inspiratory flow exceeds patient demands. Meticulous patient monitoring and use of VC-CMV allow the clinician to achieve precise and predictable physiologic results.

Example. Perhaps the most common application of VC-CMV is its use to ventilate patients in the immediate postoperative period. Patients are often sedated to minimize their response to noxious stimuli and ventilator asynchrony. VC-CMV can achieve fairly precise regulation of gas exchange.

Pressure-Controlled Continuous Mandatory Ventilation

Similar to VC-CMV, pressure-controlled continuous mandatory ventilation (CMV) can be used as a basic mode of ventilatory support. The primary difference between volume-controlled and pressure-controlled ventilation is the control variable with which the clinician is most concerned.[28,29] Theoretically, pressure control (with a constant inspiratory pressure) (Figure 46-9) results in a more even distribution of ventilation (compared with volume control) among lung units with different

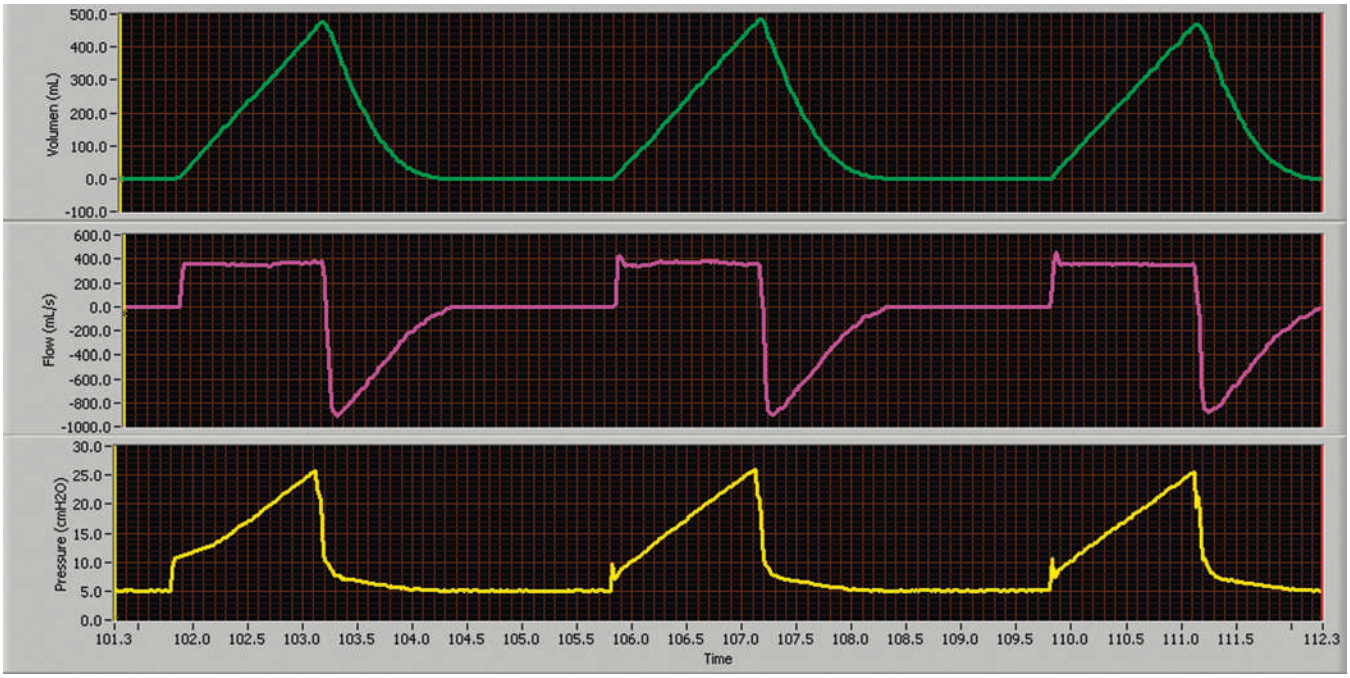

FIGURE 46-8 VC-CMV. *Top,* V_T; *middle,* flow; *bottom,* airway pressure waveform.

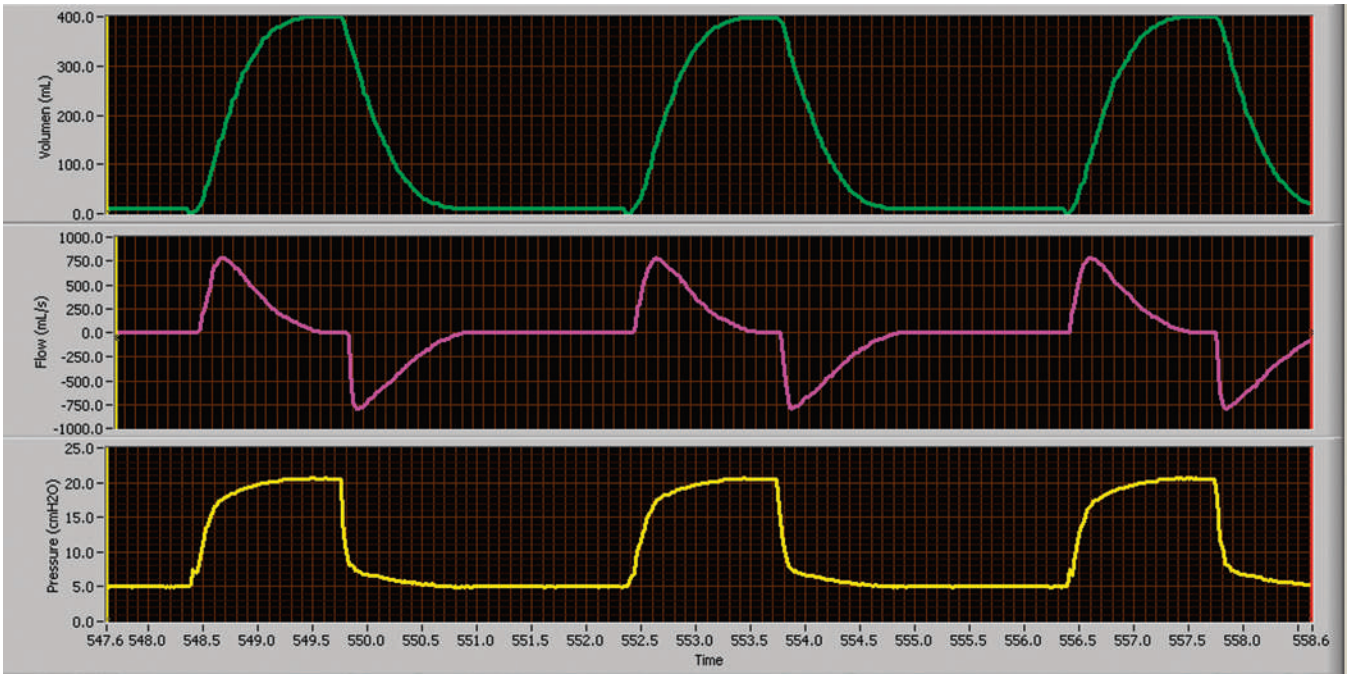

FIGURE 46-9 PC-CMV. *Top,* V_T; *middle,* flow; *bottom,* airway pressure waveform.

time constants when units have equal compliances but unequal resistances (e.g., status asthmaticus).[27] The instability of V_T caused by airway leaks can be minimized by using pressure-controlled rather than volume-controlled ventilation. Increased V_T stability may lead to better gas exchange and lower risk of pulmonary volutrauma.[30]

Use of a rectangular pressure waveform opens alveoli earlier in the inspiratory phase during PC-CMV and results in a higher mean airway pressure than VC-CMV with a rectangular flow waveform, allowing more time for oxygenation to occur.[31] In PC-CMV, however, inspiratory flow is not a parameter set by the clinician. It is variable and dependent on patient effort and lung mechanics, improving patient comfort and patient-ventilator synchrony. However, as lung mechanics or patient effort or both change, volume delivery (V_T and minute ventilation) changes.

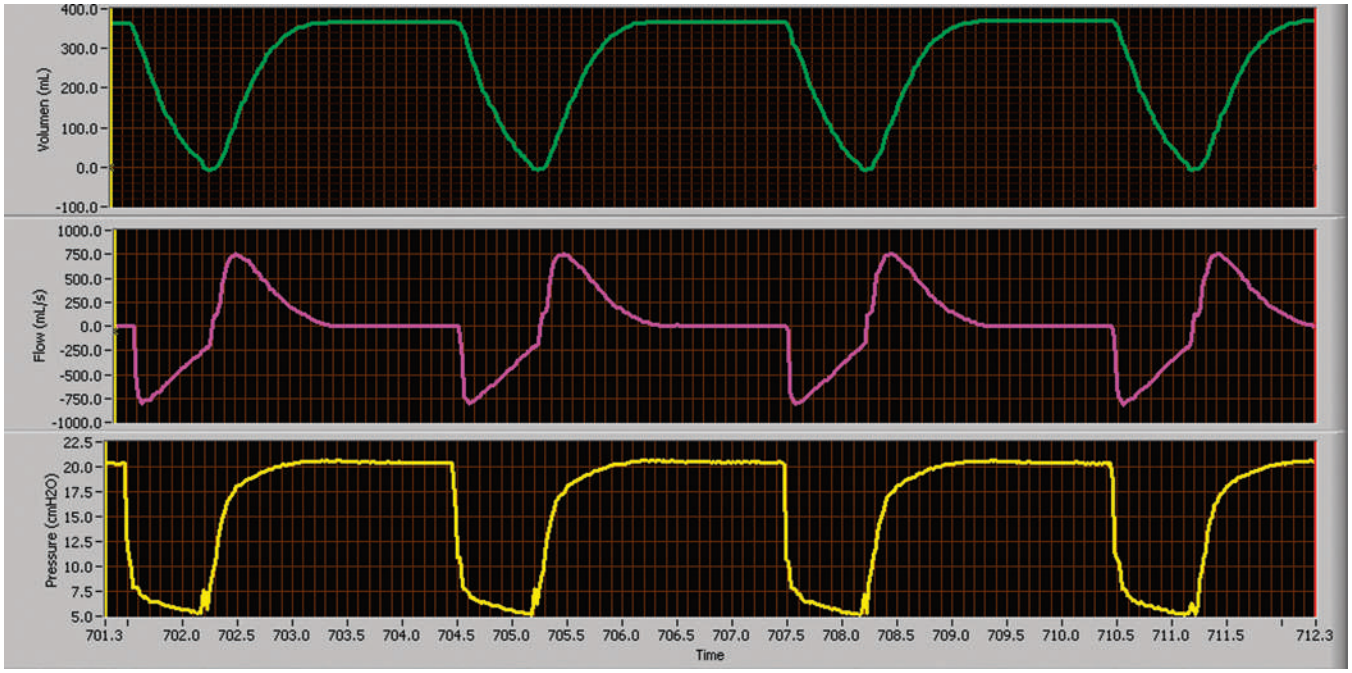

FIGURE 46-10 PC-IRV. The flow waveform for any breath does not return to baseline before the next breath, resulting in auto-PEEP and an increase in mean airway pressure. *Top,* V_T; *middle,* flow; *bottom,* airway pressure waveform.

Because V_T is not directly controlled, the pressure gradient (PIP – PEEP) is the primary parameter used to alter the breath size and CO_2 tensions. Typically, PIP is adjusted to provide the patient with a V_T within the desired range.[32] As with VC-CMV, the mandatory breath rate set by the clinician depends on the presence of ventilatory muscle activity and the severity of lung disease. When higher mandatory breath rates are needed (>30 breaths/min), it is essential for the clinician to provide a sufficient expiratory time and prevent air trapping.

As long as lung mechanics and patient effort remain constant, the volume and peak flow delivered to the patient remain unchanged.[33] When a decrease in patient effort, decrease in compliance, or increase in resistance occurs, less volume is delivered for the preset pressure for each breath. Conversely, improvements in patient effort and mechanics can dramatically increase the volume delivery to the patient in this mode. Close V_T monitoring is required to avoid ventilator-induced hyperventilation or hypoventilation.

The patient's cardiac index and O_2 consumption should be closely monitored as well. Higher mean airway pressures may impair cardiac output. In addition, PC-CMV with IRV can lead to the development of auto-PEEP, which can impair venous return, compromise O_2 delivery to the tissues, and result in marked air trapping.[34]

Pressure-Controlled Inverse Ratio Ventilation

PC-CMV may be used to accomplish pressure-controlled inverse ratio ventilation (PC-IRV), by increasing the inspiratory time directly or by increasing the I : E ratio to the desired value. PC-IRV is defined as pressure-controlled ventilation with an I : E ratio greater than 1 : 1 (Figure 46-10). Although some studies have shown improvement in oxygenation with PC-IRV versus CMV with PEEP, others have shown concurrent decreases in cardiac output.[28,35] Generally, if applied PEEP in normal ratio ventilation is equal to total PEEP (applied and intrinsic PEEP) in PC-IRV, the oxygenation benefits are equivalent without the marked depression in cardiac output.

Intermittent Mandatory Ventilation

As a partial support mode, IMV allows or requires the patient to sustain some WOB. The level of mechanical support needed depends on the specific physiologic process causing the need for mechanical ventilation, presence or degree of ventilatory muscle weakness, and presence and severity of lung disease. In this mode, mandatory breaths are delivered at a set rate. Between the mandatory breaths, the patient can breathe spontaneously at his or her own V_T and rate (Figure 46-11). Breaths can occur separately (e.g., IMV); breaths can be superimposed on each other (e.g., spontaneous breaths superimposed on mandatory breaths, as in bilevel positive airway pressure [bilevel PAP] or airway pressure release ventilation [APRV]); or mandatory breaths can be superimposed on spontaneous breaths, as in high-frequency ventilation administered during spontaneous breathing. Spontaneous breaths may be assisted (e.g., PSV) (Figure 46-12) or unassisted (e.g., PEEP or CPAP).

When the mandatory breath is patient-triggered, modern-day ventilators deliver the mandatory breath in synchrony with the patient's inspiratory effort. If no spontaneous efforts occur, the ventilator delivers a time-triggered breath. Because

MINI CLINI

Using Pressure-Controlled Ventilation

PROBLEM: The RT is caring for a 20-year-old patient with ARDS. The patient has no respiratory effort. Current ventilator settings are as follows:
Mode: VC-CMV
V_T: 400 ml
Frequency: 25 breaths/min
PEEP: 14 cm H_2O
FiO_2: 1
PIPs monitored on the ventilator: 40 to 50 cm H_2O
Mean airway pressure: 22 to 24 cm H_2O
Plateau pressure: 30 cm H_2O

An arterial blood gas is obtained, which reveals pH 7.28, PCO_2 41 mm Hg, and PO_2 50 mm Hg. The physician would like to employ pressure-controlled ventilation. What are the appropriate initial settings in PC-CMV mode to maintain the current minute ventilation?

Solution: Initial ventilator setting would be as follows:
Ventilator frequency, PEEP, and FiO_2: the same
Frequency: 25 breaths/min
PEEP: 14 cm H_2O
FiO_2: 1

To keep the minute ventilation constant, the RT needs to set the PIP high enough to deliver the same V_T as in volume control (400 ml).

1. Calculate the patient's respiratory system compliance:

$$\begin{aligned}\text{Compliance} &= V_T/\text{Plateau pressure} - \text{PEEP}\\ &= 400\text{ ml}/30\text{ cm }H_2O - 14\text{ cm }H_2O\\ &= 25\text{ ml/cm }H_2O\end{aligned}$$

2. Calculate the pressure limit in PC-CMV mode to achieve the target V_T. Because the pressure limit is measured relative to PEEP on this ventilator, the equation is:

$$\begin{aligned}\text{Ventilating pressure} &= V_T/\text{Compliance}\\ &= 400\text{ ml}/25\text{ ml/cm }H_2O\\ &= 16\text{ cm }H_2O\end{aligned}$$

$$\text{PIP} = \text{Ventilating pressure (PC setting 16 cm }H_2O) + \text{PEEP (14 cm }H_2O\text{) or 30 cm }H_2O$$

A shortcut is to realize that the required pressure limit is the plateau pressure on VC-CMV. The PIP (relative to atmospheric pressure) is 30 cm H_2O.

MINI CLINI

Determining Appropriate Ventilator Rate

PROBLEM: A 36-year-old woman with traumatic brain injury was intubated in the emergency department with a 7-mm endotracheal tube and transferred to the RT in the neurointensive care unit. She is paralyzed and sedated. Her current ventilator settings are as follows:
Mode: VC-CMV
V_T: 405 ml
Frequency: 15 breaths/min
FiO_2: 0.5

The pulse oximeter displays 97%, and end-tidal CO_2 monitor is reading 49. The patient's weight is estimated at 45 kg. End-tidal CO_2 is stable and 4 mm Hg higher than $PaCO_2$. The clinical goal is to minimize ICP. Because intracranial blood flow is inversely proportional to $PaCO_2$, ventilation should be increased to maintain $PaCO_2$ at about 35 to 40 mm Hg. The RT needs to make appropriate ventilator changes to achieve the target $PaCO_2$.

Discussion: The current V_T is already large at 8 ml/kg. The increase in ventilation must be achieved by increasing frequency. Because the patient is paralyzed, the ventilation level is controlled by the set frequency, and $PaCO_2$ is predictable. The new frequency required is calculated using the following equation:

$$\text{Required frequency} = \text{Current frequency} \times \text{Current } PaCO_2/\text{Desired } PaCO_2$$

$$\begin{aligned}\text{Required frequency} &= 15\text{ breaths/min} \times 49\text{ mm Hg}/35\text{ mm Hg}\\ &= 21\text{ breaths/min}\end{aligned}$$

spontaneous breaths decrease pleural pressure, ventilatory support with IMV usually results in a lower mean intrathoracic pressure than CMV, which can result in a higher cardiac output.[36]

When used to wean a patient from mechanical ventilation, the intent of IMV is to provide respiratory muscle rest during the mandatory breaths and exercise during spontaneous breaths. However, studies have shown that IMV weaning prolongs the duration of mechanical ventilation compared with PSV and spontaneous breathing trials.[37,38]

Volume-Controlled Intermittent Mandatory Ventilation

Volume-controlled intermittent mandatory ventilation (VC-IMV) has been advocated for patients with relatively normal lung function recovering from sedation or rapidly reversing respiratory failure.[39] However, the use of IMV has greatly decreased over the years in favor of VC-CMV, PC-CMV, and PSV, and there are no specific situations in adults where IMV would be the optimal mode.

Example. VC-IMV has been usually selected for patients with neuromuscular disorders, such as Guillain-Barré syndrome. Typically, normal lung function and an intact ventilatory drive characterize these patients. As the disease progresses, ascending muscle weakness eventually affects the patient's ventilatory muscles. Mechanical ventilation is considered when it is difficult for the patient to sustain V_T and minute ventilation. The degree of support depends on the patient's inherent muscle strength. Large V_T (6 to 8 ml/kg) and high peak flow (>80 L/min) may be needed to alleviate dyspnea and maximize patient comfort.[40] As respiratory muscle function improves, mandatory breath support can be reduced.

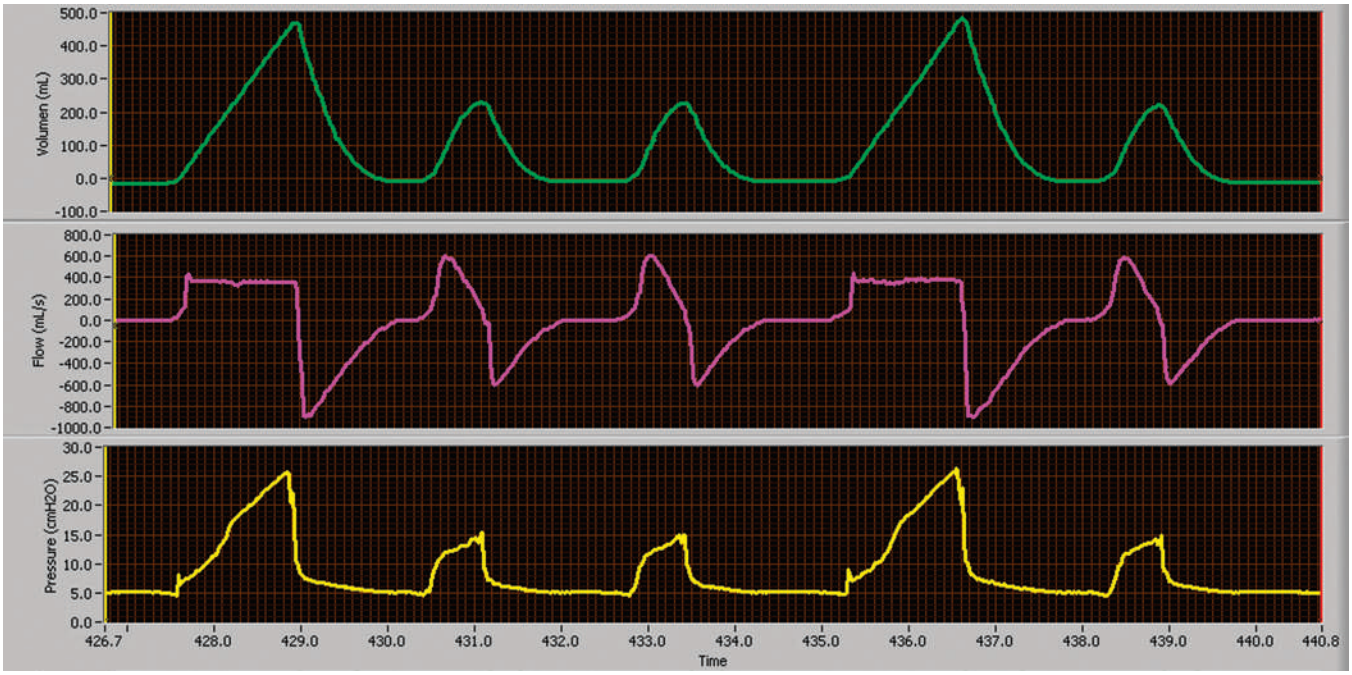

FIGURE 46-12 VC-SIMV + PSV. The addition of PSV to the spontaneous breaths increases spontaneous V_T. *Top,* V_T; *middle,* flow; *bottom,* airway pressure waveform.

Pressure-Controlled Intermittent Mandatory Ventilation

Pressure-controlled intermittent mandatory ventilation (PC-IMV) is indicated when preservation of the patient's spontaneous efforts is important and patient-ventilatory synchrony is a concern.[41] PC-IMV has been traditionally associated with mechanical ventilation of infants not only because of their oxygenation problems but also because traditionally it had been difficult to control V_T at such small values.[42]

Liberation from this mode involves the gradual reduction of the PIP and the mandatory breath rate. As lung compliance improves, adjustments in PIP are necessary to prevent overdistention of the lung. Adjustments in PIP and set mandatory breath rate are critical to prevent hyperventilation.

Example. Perhaps the most familiar scenario is the application of PC-IMV in premature infants with respiratory distress syndrome. Initially, because of a noncompliant lung, compliant chest wall, and poor respiratory effort, the infant may require a relatively high mandatory breath rate to achieve acceptable V_T and acid-base balance. Mandatory breath rates are set to provide adequate minute ventilation.

With PC-IMV, the infant can breathe spontaneously between or during the mandatory breaths, at his or her own rate and V_T. Liberation from this mode of partial support ventilation involves the gradual reduction of the PIP and mandatory breath rate. As the infant's lung compliance improves and spontaneous ventilatory efforts become more effective, lower PIPs and mandatory breath rates are needed to deliver adequate minute ventilation.

Airway Pressure Release Ventilation

A mode related to both PC-IRV and PC-IMV is APRV, in which the patient breathes spontaneously throughout periods of high and low applied CPAP (Figure 46-13).[43] APRV intermittently decreases or "releases" the airway pressure from an upper pressure (P_{high}) or CPAP level to a lower pressure (P_{low}) or CPAP level. The pressure release usually lasts about 0.2 to 1.5 seconds depending on whether or not air trapping is desired. In Figure 46-13, inspiratory time is longer than expiratory time, and spontaneous breaths are superimposed on this mandatory pattern of pressurization and release. Spontaneous breaths are supplemented by PSV. This is a feature of APRV available on some ventilators, where APRV is referred to as *bilevel ventilation.* In APRV, the I : E ratio is usually greater than 1 : 1, which is similar to PC-IRV, but APRV offers the advantage of allowing spontaneous breathing throughout the periods of inspiratory and expiratory positive pressure.[44]

APRV also provides ventilation and oxygenation without adversely affecting hemodynamic values because of the periodic reductions in intrathoracic pressure during the spontaneous breaths. In addition, peak airway pressure during APRV may be less than with VC-IRV for comparable oxygenation and ventilation.[45] APRV compared with conventional volume-controlled or pressure-controlled SIMV showed that with APRV there was a decrease in peak airway pressures, improved hemodynamics, and a decreased need for vasopressor and intropic support.[46] However, the cost of these potential benefits is patient effort; WOB is markedly increased and transpulmonary pressure is excessive, potentially inducing lung injury during APRV.[44] There are no data to indicate a better outcome with APRV than with other approaches to ventilatory support when a similar approach to managing oxygenation is used. Specific indications for APRV are unclear.

Continuous Spontaneous Ventilation

Spontaneous breath modes include modes in which all breaths are initiated and ended by the patient. The level of support these modes of ventilation provide determines the amount of WOB the patient ultimately assumes. CPAP, PSV,[47] automatic tube compensation (ATC), proportional assist ventilation (PAV), and neurally assisted ventilatory assist (NAVA) are continuous spontaneous breath modes.[48]

Continuous Positive Airway Pressure

CPAP is spontaneous breathing at an elevated baseline pressure (Figure 46-14). Breaths are patient-triggered and cycled.[49,50] V_T

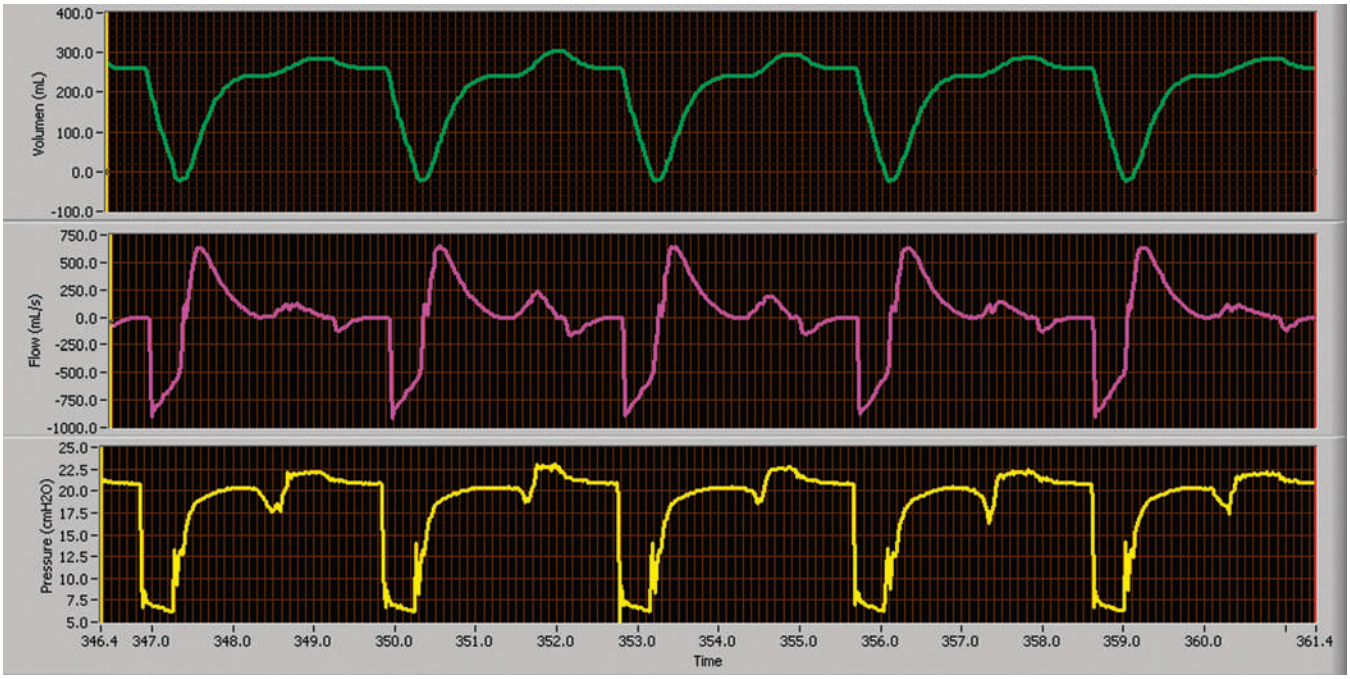

FIGURE 46-13 APRV. In APRV, the patient is able to breathe spontaneously throughout the total cycle time. *Top,* V_T; *middle,* flow; *bottom,* airway pressure waveform.

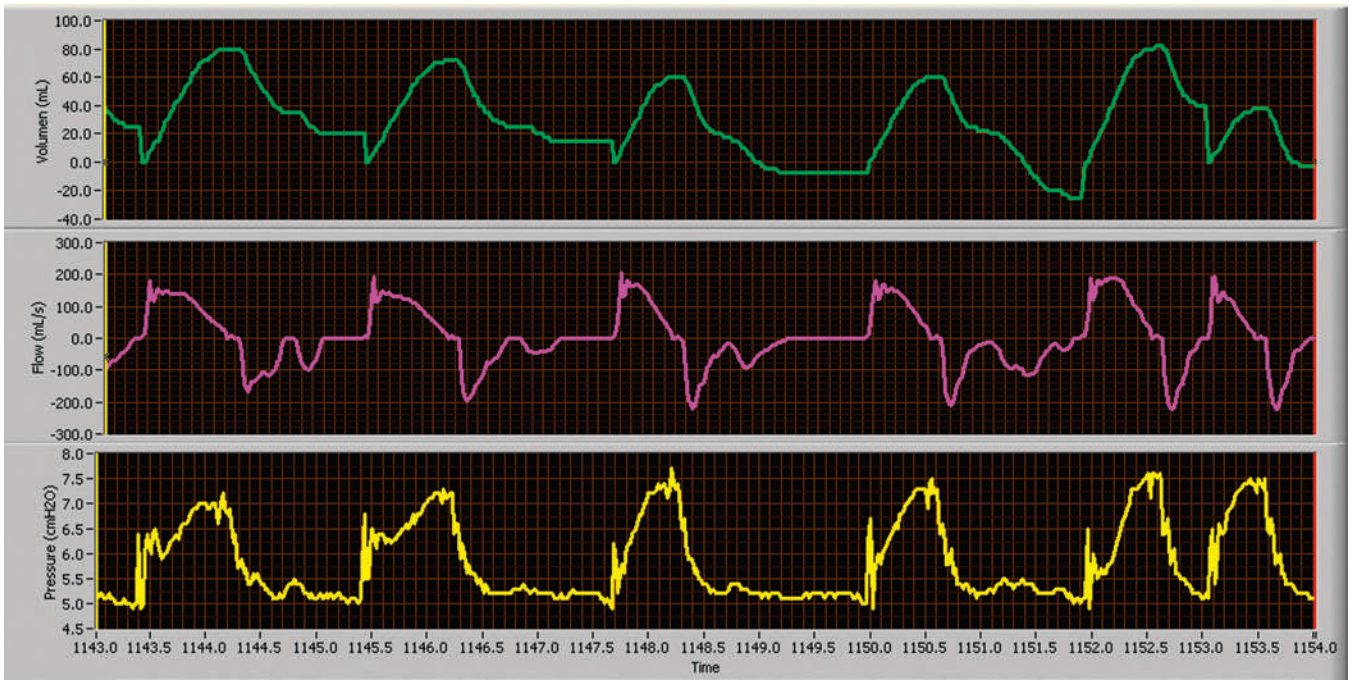

FIGURE 46-14 CPAP. *Top,* V_T scalar; *middle,* flow scalar; *bottom,* airway pressure scalar.

depends on patient effort and lung mechanics. CPAP increases alveolar pressure and maintains alveoli open. In contrast to NPV and PPV, airway pressure with CPAP is theoretically constant (baseline pressure ±2 cm H_2O) throughout the respiratory cycle. Because airway pressure does not change, CPAP does not provide ventilation. For gas to move into the lungs during CPAP, the patient must create a spontaneous transairway pressure gradient. Although NPV and PPV produce the pressure gradients needed for gas flow into the lungs, CPAP maintains alveoli at greater inflation volume, restoring FRC. An important physiologic feature of CPAP is that as alveoli are maintained open, FiO_2 needed to maintain adequate PaO_2 may decrease. Oxygenation becomes more efficient at any given FiO_2, as measured by PaO_2/FiO_2 ratio and shunt fraction. The potential side effects associated with PPV also exist for CPAP but usually to a lesser degree.

Pressure Support Ventilation

PSV is a form of PC-CSV that assists the patient's inspiratory efforts (Figure 46-15). At very low levels of support, this mode unloads WOB the ventilator circuitry imposes on the respiratory muscles.[51] If the level of support is maximized, the ventilator may assume all WOB.[52] The result of high levels of support is a reduction in the respiratory rate, reduction in respiratory muscle activity and fatigue, reduction in O_2 consumption, and improvement or stabilization of spontaneous V_T.[53,54] However, the positive attributes of this mode of ventilation can be negated if ventilator parameters are not properly set. The ventilator must be able to detect spontaneous patient effort. It is critical for the clinician to adjust the trigger sensitivity correctly. Of equal importance is the clinician-set rise time, the time required for the ventilator to reach the inspiratory pressure limit, and termination criteria, the minimal flow resulting in cycling to exhalation (see Chapter 47). Ventilator graphics are often helpful when adjusting these parameters and optimizing patient-ventilator synchrony.

Regardless of the level of support provided, the patient has primary control over the breath rate and inspiratory time and flow rate delivered during this mode of assisted ventilation. The V_T resulting from a PSV breath depends on the preset pressure level, patient effort, and mechanical forces opposing ventilation (lung–chest wall compliance and airway resistance). Of all of the classic modes of ventilation, PSV exerts the least control over the patient's ventilatory pattern and as a result should improve patient-ventilator synchrony. Since the first description of PSV in 1982, it has been used either to overcome the imposed resistance associated with the artificial airway or to provide ventilatory support with minimal control.[55] PSV is useful in any patient with an intact ventilatory drive and a stable ventilatory demand.

Bilevel PAP (BiPAP; Respironics, Inc, Murrysville, PA) is simply PSV with PEEP applied noninvasively.[56] With bilevel PAP, inspiratory positive airway pressure (or PSV) and expiratory positive airway pressure (PEEP) are set. The duration of inspiratory positive airway pressure and expiratory positive airway pressure can be independently adjusted to set the I : E ratio. Although it was originally developed to enhance the capabilities of home CPAP systems used for management of obstructive sleep apnea, bilevel PAP has been successfully used in the home and the hospital for noninvasive ventilatory support of patients with acute and chronic respiratory failure.[57]

Example. An example of the use of PC-CSV is noninvasive PSV and PEEP in the management of a patient with COPD in an acute exacerbation. As described in detail in Chapter 49, PSV

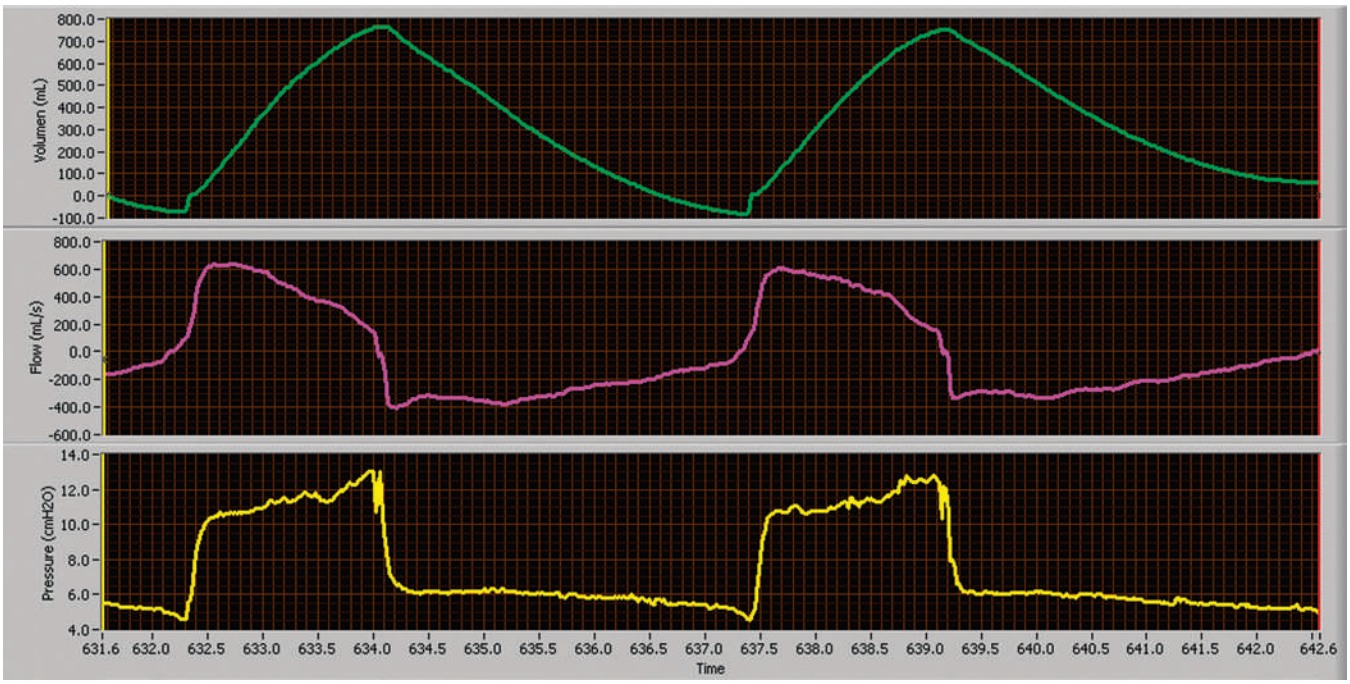

FIGURE 46-15 PSV. *Top,* V_T; *middle,* flow; *bottom,* airway pressure waveform.

has been shown in this setting to decrease the frequency of intubation, length of mechanical ventilation, development of ventilator-associated pneumonia, and patient mortality.

Proportional Assist Ventilation

PAV is based on both the mechanics of the total respiratory system and the resistive properties of the artificial airway; that is, the ventilator delivers a pressure assist in proportion to the patient's desired V_T (volume assist) and to the patient's instantaneous inspired flow (flow assist). The response of these two aspects of ventilatory assistance is automatically adjusted to meet changes in the patient's ongoing ventilatory demand. This algorithm is based on the law of motion as it applies to the respiratory system:

$$P_{musc} + P_{appl} = (Volume \times E) + (Flow \times R)$$

where P_{musc} is pressure generated by the respiratory muscles, P_{appl} is pressure applied by the ventilator, and E and R are elastic and resistance properties of the respiratory system. Assuming that E and R are linear during inspiration, the instantaneous flow and volume to be delivered are proportional to the resistive and elastic WOB. The ventilator continuously measures the instantaneous flow and volume and periodically measures the E and R. Using this information, the ventilator software adjusts gas delivery by estimating P_{musc} and assisting P_{musc} in a proportional manner, the percent set by the clinician. The patient is the determinant of the ventilatory pattern. Patients are given the freedom to select a ventilatory pattern that is rapid and shallow or slow and deep. If the patient desires a small V_T, a low level of pressure is applied, and if a large V_T is desired, a high pressure is applied. The ventilator does not force any control variable except the unloading of E and R in a proportional manner. See Chapter 45 for details on operation of PAV.

Numerous studies have evaluated the effect of PAV during noninvasive PPV.[58-62] Most of these comparisons were between PAV and PSV,[58,62] and in almost all of these comparisons the patients evaluated had chronic respiratory failure and were in an acute exacerbation. Patients managed with PAV had a lower refusal rate, had a more rapid reduction in respiratory rate, and developed fewer complications.[60,61] In these studies, gas exchange and respiratory pattern did not differ between PSV and PAV, but the patients ventilated with PAV were more comfortable. PAV has also been shown to be essentially equivalent to PSV in stable patients with chronic ventilatory failure[59] and in patients with acute cardiogenic pulmonary edema.[62]

PAV has been most widely studied during invasive mechanical ventilation.[63-65] As with the evaluation of PAV in other settings, most of the comparisons focused on the physiologic response observed when PSV is changed to PAV. Generally, during invasive ventilation, the change from PSV to PAV results in lower V_T, more rapid respiratory rate, lower peak airway pressure, and lower mean airway pressure without significant changes in gas exchange or hemodynamics.[66-68] In a randomized comparison of PAV versus PSV each for a 48-hour period in a series of critically ill patients,[65] the percentage of patients' failing the transition to PAV or PSV differed, 11% failing PAV versus 22% failing PSV. In addition, the proportion of patients developing asynchrony was greater with PSV versus PAV. The current data on PAV indicates it can sustain the same patients as PSV—patients who can breathe spontaneously and manage their ventilator drive normally.

Neurally Adjusted Ventilatory Assist

From a conceptual perspective, NAVA is essentially the same as PAV except that PAV responds to changes in airway pressure and flow, whereas NAVA responds to changes in diaphragmatic EMG activity. However, for NAVA to function properly, a specially designed nasogastric catheter with a 10-cm length of EMG electrodes must be in place. Both PAV and NAVA respond to patient effort providing ventilatory support in a proportional manner. The clinician does not set pressure, volume, flow, or time in either mode. The only parameter set is the proportion of effort unloaded by the ventilator; in NAVA, this is set as the number of cm H_2O applied per microvolt of diaphragmatic EMG activity.

NAVA responds similarly to PAV, when compared to pressure support—NAVA results in low airway pressures, smaller tidal volumes, more rapid rates, and increased patient-ventilator synchrony.[69,70] PEEP titration also affects baseline diaphragmatic EMG activity. As PEEP is increased EMG activity decreases. Minimal EMG activity seems to correspond to optimal PEEP level.[71]

NAVA application in neonates results in similar outcomes as observed in adults.[72,73] After the change to NAVA, V_T tends to decrease, respiratory rate to increase, and peak diaphragmatic EMG activity to decrease. In addition, despite the open ventilating system (uncuffed artificial airway), triggering and cycling were still primarily neurally activated.[72,73]

The most important advantage of PAV and NAVA over traditional modes of ventilation is improved synchrony. The specific indications for PAV and NAVA are not fully established; however, both can be reasonably used in any patient with an intact ventilatory drive. The primary indication would be a patient with a significant level of asynchrony.

Automatic Tube Compensation

ATC is similar to the flow assist aspect of PAV but considers only the resistance of the endotracheal tube.[74] ATC is an adjunct that automatically adjusts the airway pressure to compensate for endotracheal tube resistance to gas flow by maintaining tracheal pressure constant at the baseline level.[74] The goal is to eliminate WOB imposed by the endotracheal tube. In ATC, the RT inputs into the ventilator the type and size of artificial airway (endotracheal tube or tracheostomy tube) and the percent compensation desired (10% to 100%). The ventilator continuously measures flow and calculates the amount of pressure needed to overcome the resistance of the airway (pressure = resistance × flow). As a result, the greater the inspiratory demand, the greater the pressure applied. Pressure varies throughout the breath.

ATC may be applied during inspiration (positive airway pressure) or during both inspiration and expiration (negative airway pressure). However, expiratory ATC may result in early airway closure and increased air trapping. ATC has been referred to as *electronic extubation,* meaning that if the airway pressure is low during inspiration (5 to 7 cm H_2O), it is simply overcoming the resistance of the endotracheal tube with a normal inspiratory effort.[75] Consequently, many clinicians consider this an indication that spontaneous ventilation can be maintained without ventilatory support and the patient should be considered for extubation. Although in theory the use of ATC to wean patients appears ideal, no data to date have indicated that ATC weans patients faster than spontaneous breathing trials.

Adaptive Modes and Dual Control

The first adaptive control/dual control mode was described by Amato and colleagues.[76] Their major finding was that the ventilatory workload imposed on the inspiratory muscles during volume-assured PSV was significantly reduced by the use of dual control. In this mode, pressure support is combined with volume control. However, this benefit was due to the fact that inspiration started out in pressure support and stayed there unless the V_T target was not met. The improvement was mostly a result of the improved synchrony between the patient and the machine. These investigators did not show a specific benefit of the actual dual nature of the mode (i.e., switching from pressure support to volume control), and no evidence has been published in the literature since then supporting this mode. Anecdotal reports indicate that it is difficult to adjust pressure, volume, and flow settings to make the mode work properly, in particular, if the mechanical properties of the patient's respiratory system are changing rapidly.

Pressure-regulated volume control (PRVC), or PC-CMV, and *volume support (VS)*, or PC-CSV, are examples of adaptive control/dual control modes. PRVC is based on pressure-controlled ventilation, and VS is based on PSV. In both modes, the ventilator attempts to maintain a target V_T by adjusting the pressure level based on the previous breath. When a clinician places a patient in PRVC, a target V_T, breath rate, and maximum (i.e., alarm) pressure limit are clinician set, whereas for a patient placed in VS, a target V_T and maximum (i.e., alarm) pressure limit are clinician set. In both modes, once the patient is connected to the ventilator, the patient-ventilator interaction that occurs in the first few breaths is critical. Initially, the ventilator calculates total system compliance. On the succeeding three or four breaths, the ventilator monitors the peak airway pressures and expiratory V_T. The ventilator determines the pressure level necessary to deliver the clinician-set "target" V_T, for the given total system compliance. ("Target" is used because the ventilator aims to deliver it, over the course of several breaths, but may not hit the mark if the maximum pressure limit is set too low.)

The patient-ventilator interaction is monitored on a breath-by-breath basis. If the patient's lung compliance improves (or patient effort increases), the ventilator delivers subsequent mandatory breaths at a lower pressure level to maintain the target V_T. This adjustment by the ventilator reduces the risk of alveolar overdistention and volutrauma. Conversely, the ventilator responds to worsening pulmonary compliance (or decreasing patient effort) by increasing the pressure limit until the V_T is achieved. The ventilator makes pressure level changes in small increments, 1 to 3 cm H_2O per breath, and does not exceed the maximum pressure limit set by the clinician. These automatic ventilator responses to changes in a patient's lung mechanics

minimize the risk of ventilator-induced hyperventilation or hypoventilation. The desired outcome is a stable or consistent minute ventilation and enhanced patient comfort. However, the major problem with these modes is that the ventilator cannot distinguish between the patient improving and heightened levels of ventilator demand. If patient demand results in a larger V_T, the ventilator ventilates less.[77]

In most ventilators, pressure can be decreased all the way to the PEEP level. This situation can lead to ventilatory failure.[77] Both RPVC and VS should be used very cautiously in all patients with a normal or increased ventilatory demand. Randomized comparison between these modes and other, more traditional, modes failed to show any outcome benefit.[78,79]

Example. PRVC or VS has been used in infants with respiratory distress syndrome.[80] Rapidly changing pulmonary mechanics from surfactant administration are associated with complications such as pulmonary air leaks, intraventricular hemorrhage, and bronchopulmonary dysplasia. These adaptive modes respond to changes in a patient's lung mechanics and may reduce the incidence of these common complications.

Adaptive support ventilation (ASV), or PC-IMV, is an example of optimal control in adaptive ventilation. Adaptive support ventilation is a pressure-targeted mode that optimizes the relationship between V_T and respiratory frequency based on lung mechanics as predicted by Otis.[81] ASV uses a pressure ventilation format establishing a ventilatory pattern that minimizes WOB and auto-PEEP, while limiting peak airway pressure. In this regard, ASV is similar to PC-CMV and PRVC in its gas delivery format. It differs from PC-CMV and PRVC by its additional algorithmic control of the ventilatory pattern.[82] ASV automatically determines the V_T and respiratory rate that best maintains the peak pressure below the target level.[83] The clinician inputs the patient's ideal body weight, high pressure limit, PEEP, FiO_2, inspiratory rise time, flow cycle percentage, and percentage of predicted minute volume desired. The ventilator periodically measures dynamic compliance and the respiratory time constant and determines the desired mandatory rate. Ideal body weight is used by the ventilator to calculate the minute volume, which is divided by the rate for determination of V_T.[84] The newest adaption to ASV is referred to as Intellivent. With this adaption the ventilator operates the same as with ASV but in addition has the ARDSnet PEEP/FIO_2 tables programmed into the ventilator algorithm. Thus, as the patient's SpO_2 changes PEEP and FIO_2 are adjusted as dictated by the ARDSnet protocols.

When ASV is compared to VC-IMV, ASV decreases inspiratory load and improves patient-ventilator synchrony.[85] Others have shown that ASV resulted in a shorter duration of intubation than VC-IMV in postoperative cardiac patients with no complications.[86] More recently, Belliato and colleagues[87] comparing PC-IMV (optimal) to ASV showed that the ventilator was able to differentiate between patient types and select appropriate settings.[88] Using a lung model, Sulemanji and coworkers[89] determined that ASV could provide better lung protection than a fixed V_T of 6 ml/kg ideal body weight. ASV control has been adapted to respond to end-tidal CO_2 levels.[89] This new adaptation allows specific algorithms to be selected based on patient diagnosis: ARDS, COPD, brain injury, or healthy lung. This mode is the most sophisticated of the closed loop control modes available on ICU ventilators at the present time. However, additional study is needed to determine fully the type of patient in whom ASV is most useful. Current data would indicate ASV works very well in patients under controlled approaches to ventilatory support, but additional data in spontaneously ventilated patients are needed before it can be recommended in these patients.

RULE OF THUMB

Most patients requiring ventilatory support can be effectively ventilated with volume assist/control, pressure assist/control, and PSV modes.

Patient Positioning to Optimize Oxygenation and Ventilation

Patients receiving mechanical ventilation are turned frequently, usually at least every 2 hours, unless turning is contraindicated. Kinetic beds continually rotate patients and are designed to help prevent atelectasis, hypoxemia, secretion retention, and pressure sores. When patients are kept immobile, pooling of secretions in dependent lung zones can promote nosocomial pneumonia, and shrinking of dependent alveoli leads to decreases in ventilation and hypoxemia. However, the use of rotating kinetic beds is controversial in the prevention of nosocomial pneumonia.[90] No data are available to indicate that these very expensive beds improve patient outcome.

Patients with unilateral lung disease benefit from being placed in positions that promote matching of ventilation and perfusion. In unilateral lung disease, only one lung is affected by atelectasis, consolidation, or pneumonia. If the affected lung is placed in the dependent position, blood flow follows. The resultant poor $\dot{V}/\dot{Q}$ ratio in the affected lung contributes to venous admixture and hypoxemia. However, if the patient is rotated so that the good lung is in the dependent position, these relationships are reversed. With the good lung down, blood flows to well-ventilated alveoli, and $\dot{V}/\dot{Q}$ matching and arterial blood gas values improve. An added benefit of this maneuver is that the affected lung is placed in a postural drainage position, which promotes gravity drainage of retained secretions so that they can be removed.

A similar phenomenon has been described in ARDS. In a supine patient with ARDS, alveoli in the bases and posterior segments become atelectatic. Shunt increases, and the patient requires a high FiO_2 and PEEP for adequate oxygenation. If the patient is rotated into the prone position, several mechanisms have been proposed to improve oxygenation.[91] Blood flow is redistributed to areas that are better ventilated. This redistribution improves $\dot{V}/\dot{Q}$ relationships. Prone positioning removes the weight of the heart from its position over the lungs while

the patient is supine. Pleural pressure in the now nondependent collapsed lung becomes more negative, improving alveolar recruitment. In addition, the stomach no longer lies over the dependent basilar posterior segments of the lower lobes.

A number of studies have demonstrated some benefit of prone positioning.[92-95] However, several persons are needed to "flip" the patient while ensuring monitoring lines and catheters are not disrupted and the patient is not inadvertently extubated. Wound dehiscence, facial or upper chest wall necrosis despite extensive padding, cardiac arrest immediately after movement to the prone position, dependent edema of the face, and corneal abrasion have been reported.[93] A recent meta-analysis of existing randomized controlled trials indicated no outcome benefit from prone positioning in patients with ARDS.[94] However, this meta-analysis also found that patients with PaO_2/FiO_2 less than 100 mm Hg were the group most likely to benefit from prone positioning. A recent randomized controlled trail showed the same results.[95] Considering the complications associated with prone positioning, only patients with very severe hypoxemia (PaO_2/FiO_2 <100 mm Hg) should be placed prone.

RULE OF THUMB

Patients who have unilateral or dependent consolidation or atelectasis and severe hypoxemia may benefit from positioning with the affected lung or segments in the nondependent position to promote improvement in $\dot{V}/\dot{Q}$ relationships. Prone positioning is indicated only if the PaO_2/FiO_2 is less than 100 mm Hg. When positioning the patient, great care should be taken to avoid the hazards associated with prone positioning.

CARDIOVASCULAR EFFECTS OF POSITIVE PRESSURE MECHANICAL VENTILATION

Thoracic Pump and Venous Return During Spontaneous and Mechanical Ventilation

The lungs and heart have a close functional relationship, and impaired performance of one affects the other. For this reason, the RT must fully understand what happens to cardiovascular function when a patient receives ventilatory support.

Early studies of the effect of PPV on the cardiovascular system showed an early, small, and transient increase in cardiac output that was followed almost immediately by a marked reduction in left ventricular outflow. Generally, the reduced cardiac output in these cases was directly related to the amount of pressure applied. More specifically, the decrease in left ventricular output corresponded to the increase in pleural pressure that occurred with PPV. Figure 46-16 compares the effects of spontaneous inspiration with the effect observed during PPV. Negative pleural pressure during spontaneous inspiration normally enhances venous return, increases right atrial filling, and improves pulmonary blood flow (see Figure 46-16, *A*). In combination, these factors increase left atrial and left ventricular filling and left ventricular stroke volume.

However, during PPV, pleural pressure can become positive (see Figure 43-16, *B*). Positive pleural pressure compresses the intrathoracic veins and increases central venous and right atrial filling pressures. As these pressures increase, venous return to the heart is impeded, and right ventricular preload and stroke volume decrease, as does pulmonary blood flow. Blood already

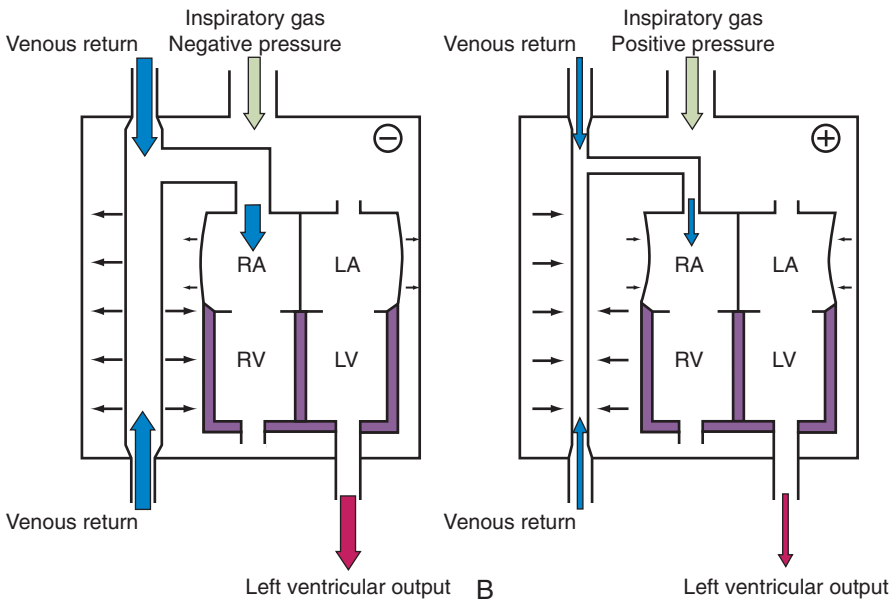

FIGURE 46-16 Relationship between pleural pressure and cardiac output in spontaneous **(A)** and positive pressure **(B)** breathing. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

in the pulmonary circulation is initially displaced into the left side of the heart and causes a transient increase in filling pressure and output. This initial effect lasts for only a few heartbeats. If positive pressure is continued, flow both to and from the left side of the heart decreases.

The high impedance encountered by blood returning to the right heart causes venous pooling, mainly in the capacitance vessels of abdominal viscera. This process effectively removes a large volume of blood from the circulation, which can further impair left ventricular output. These interactions are magnified when pleural pressure is increased further or circulating blood volume is low.[96] The venous impedance caused by PPV is not limited to blood flow coming from the abdomen. An increase in central venous pressure can restrict return flow from the brain. Impedance to venous return from the brain can increase ICP and reduce cerebral perfusion pressure (CPP). In combination with a decrease in left ventricular output, an increase in ICP during PPV can significantly impair cerebral perfusion and possibly result in cerebral ischemia and cerebral hypoxia.

In healthy individuals, the effects of PPV on cerebral blood flow (CBF) are minimized by autoregulatory mechanisms that maintain cranial perfusion pressures within a narrow range. However, patients with preexisting cerebrovascular problems and patients who already have an elevation in ICP may be at risk of decreased cerebral perfusion with PPV. Examples include neurosurgical patients and patients with head injuries, intracranial tumors, or cerebral edema from any cause. ICP monitoring may be necessary in the care of these patients.

Compensation in Healthy Persons

A decrease in cardiac output or blood pressure is rare among individuals with a normal cardiopulmonary system who are receiving mechanical ventilation. Compensatory mechanisms used to counter the decrease in stroke volume include increased heart rate, increase in systemic vascular and peripheral venous resistance, and shunting of blood away from the kidneys and lower extremities, which results in a consistent blood pressure. Because these compensatory mechanisms function by reflexes, the reflexes must be intact. Factors that block or blunt these vascular reflexes include sympathetic blockade, spinal anesthesia, spinal cord transection, and polyneuritis.

Pulmonary Vascular Pressure, Blood Flow, and Pulmonary Vascular Resistance

In patients with a normal cardiopulmonary system who are receiving mechanical ventilation, there is no significant increase in pulmonary vascular pressure or pulmonary vascular resistance and no decrease in pulmonary blood flow. However, when alveoli are distended by increased V_T or high PEEP, pulmonary blood flow is impeded because the alveoli press against the pulmonary capillaries. The pressure increases right ventricular afterload and volume and decreases right ventricular output. The ventricular septum may be shifted to the left, but this effect is more consistent with a high PEEP. This condition decreases left ventricular filling and output. The magnitude of these changes is proportional to lung compliance. As lung compliance decreases, the stiffer lungs can retain the increased pressure imposed by PEEP. In other words, the increased pressure in the lung is not transmitted to the vasculature to impede right ventricular output. An increase in intrapleural pressure secondary to an increase in lung pressure impedes venous return and decreases cardiac output further.

Right and Left Ventricular Function

Under conditions of a normal cardiovascular system with normal ventilation values, there are no significant changes in right or left ventricular function. Otherwise, mechanical ventilation would be difficult to manage, and the mortality and morbidity among patients receiving ventilation would be much higher. Right or left ventricular dysfunction appears to occur if the patient is hypovolemic, is receiving an excessive V_T, or is receiving more than optimum PEEP. The common factor is excessive alveolar pressure, enough to overcome or impede pulmonary blood flow or venous return.

Effect on Left Ventricular Dysfunction

PPV can improve cardiac output in some patients. In patients with left ventricular failure, application of PPV can increase both the left ventricular ejection fraction and the cardiac output. These improvements occur because PPV decreases left ventricular afterload in these patients. Afterload is an important factor in determining cardiac output, as is the resistance of the systemic vasculature. When afterload increases, cardiac output decreases (heart failure). When afterload is decreased by PPV or pharmacologic therapy, cardiac output may increase. This phenomenon explains why the cardiovascular status of some patients deteriorates when PPV is discontinued or treatment is changed from full to partial ventilatory support.

Endocardial Blood Flow

Blood flow in the coronary arteries depends on the gradient between the systemic diastolic pressure and the left ventricular end-diastolic pressure (represented by the pulmonary capillary wedge pressure). Any factor that decreases systemic diastolic pressure or increases wedge pressure decreases endocardial perfusion pressure. The factors of PPV that may decrease the systemic diastolic pressure are high mean airway pressure owing to a high PEEP, large V_T, or long inspiratory time. Factors that may increase the wedge pressure include excessive PEEP and left ventricular failure.

Cardiac Output, Cardiac Index, and Systemic Blood Pressure

When the cardiovascular system is normal with normal ventilation values, there are no significant changes in cardiac output, cardiac index, or systemic blood pressure. Cardiac output can be affected by a decrease in stroke volume with PPV, but this decrease is compensated by an increase in heart rate. Because the cardiac index is the quotient of cardiac output and body surface area (cardiac index = cardiac output in liters per minute/body surface area in square meters), a change in cardiac output

would be reflected in the cardiac index. Systemic arterial pressure remains stable because of reflex compensation, which increases systemic vascular resistance. Cardiac output, cardiac index, and arterial pressure decrease only when mean airway pressure is high and intrapleural pressure increases precipitously. Hypotension owing to PPV alone is rare because clinicians do all that is necessary to prevent it, including adequate fluid administration, proper management of mean airway pressure and PEEP, and use of vasoconstricting drugs. Most cases of hypotension during mechanical ventilation are caused by sepsis and the accompanying vascular collapse.

RULE OF THUMB

Patients most likely to experience hemodynamic effects of mechanical ventilation are patients with a normal or increased lung compliance associated with decreased chest wall compliance. In this setting, there is little lung stretch but maximum transmission of ventilating pressure to the intrathoracic space.

MINIMIZING CARDIOVASCULAR EFFECTS OF POSITIVE PRESSURE MECHANICAL VENTILATION

The effect of PPV on the circulatory system depends primarily on two major factors: mean pleural pressure and cardiovascular status.

Mean Pleural Pressure

Pleural pressure is the pressure in the virtual pleural space. At the bedside, pleural pressure usually is measured indirectly as the esophageal pressure through an esophageal balloon connected to a pressure transducer. Because the esophagus is close to the pleurae, separated by only the flexible esophageal wall, change in esophageal pressure reflects change in pleural pressure but may not equal actual pleural pressure. An alternative to measuring pleural pressure is measuring mean airway pressure. Mean airway pressure is linearly related to mean pleural pressure and can be used clinically for monitoring of pressure changes.[97]

The effect of PEEP on pleural pressure is complex and depends on the patient's lungs and thoracic mechanics. Some of the pressure generated by a ventilator reaches the alveoli, where it is transmitted across the alveolar walls to the pleural space. How much of this alveolar pressure is transmitted to the pleural space depends on lung and thoracic mechanics.

Generally, for a given alveolar pressure, the more compliant the lung, the greater is the increase in pleural pressure. A patient with a disease causing a loss of elastic tissue, such as emphysema, is more subject to the cardiovascular effects of positive pressure than a person with normal lungs. In contrast, a lung with low compliance transmits less pressure to the pleural space; this explains, in part, why high levels of PEEP often are used with minimal cardiovascular effects on patients with low lung compliance (e.g., ARDS).

When the compliance of the chest wall is reduced, expansion of the thorax is limited, and more alveolar pressure is transmitted to the pleural space. Patients who have normal lungs but have thoracic restriction, as caused by kyphoscoliosis and spondylitis, are more subject to the cardiovascular effects of positive pressure than individuals with normal chest wall compliance. A similar effect can occur in patients with normal thoracic compliance who actively oppose a mandatory breath by contracting the expiratory muscles (as might occur in patient-ventilator asynchrony). Contraction of the expiratory muscles effectively decreases thoracic compliance and causes more alveolar pressure to be transmitted to the pleural space.

If resistance to airflow is high, less of the pressure generated at the airway reaches the alveoli. The high peak airway pressure common in patients with obstructive disorders is not reflected in high pleural pressure.

The effects of moderate increases in pleural pressure on cardiac output in healthy persons are minimal. In healthy persons, as left ventricular stroke volume decreases, compensatory responses increase both the cardiac rate and the tone of the venous capacitance vessels. These normal responses ensure adequate blood flow and perfusion pressure. However, if the patient already is hypovolemic or has lost peripheral venomotor tone, cardiovascular compensation may be impossible. In these cases, even a small increase in pleural pressure may result in a marked decrease in cardiac output.

Decreasing Mean Airway Pressure

Mean airway pressure is affected by respiratory rate, V_T, inspiratory time, inspiratory pause, expiratory time, I : E ratio, peak pressure, baseline pressure (PEEP or CPAP), and inspiratory flow waveform. If a decrease in mean airway pressure is necessary, altering any factor that contributes to mean airway pressure has an effect. If the PaO_2 is high, one of the most effective changes is a decrease in PEEP because it has a 1 : 1 relationship with mean airway pressure. If a decrease in PEEP is indicated, the RT must ensure that desaturation does not occur when the decrease has been accomplished. If the patient is being hyperventilated, a decrease in mandatory rate or V_T also decreases mean airway pressure.

The best way to determine the magnitude of the change is to use the mean airway pressure monitor on the ventilator. The peak pressure usually decreases with a decrease in VT. In pressure-controlled modes, the peak pressure may be decreased directly. The plateau pressure is a reflection of mean peak alveolar pressure. In volume-controlled ventilation, a decrease in V_T decreases plateau pressure. In pressure-controlled ventilation, the pressure setting may be reduced to limit plateau pressure. Efforts that increase lung compliance, such as PEEP or administration of diuretics to decrease interstitial edema, also may affect plateau pressure. Inspiratory time, expiratory time, and I : E ratio affect mean airway pressure. As inspiratory time lengthens or expiratory time decreases, mean airway pressure increases.

Fluid Management and Cardiac Output

The relationship between cardiac output and preload (end-diastolic volume) is described by the Frank-Starling phenomenon, which states, "in the normal heart, the diastolic volume (preload) is the principal force that governs the strength of ventricular contraction."[98] As preload (stretch) increases, so does force and presumably stroke volume. Stroke volume continues to increase with preload until the heart is distended by excess preload, after which stroke volume decreases. Another cause of a decrease in stroke volume is the decrease in ventricular contractility that occurs when afterload increases as the result of hypertension. With hypertension comes dilation and distention of the ventricles, which make the heart structurally abnormal. In an abnormal heart, it takes much less preload to put the heart into failure. Failure in this case is defined as decreased stroke volume despite increased preload (Figure 46-17).

When a patient receives PPV, there is risk of a decrease in venous return (preload) because of the increase in intrapleural pressure. Stroke volume may decrease, but the decrease is compensated for by a reflex increase in heart rate and vasomotor tone. Because of these compensatory mechanisms, most patients with a normal cardiopulmonary status who receive mechanical ventilation do not need additional fluid to maintain cardiac output. However, certain conditions can increase the risk of relative or actual hypovolemia, and the increase can decrease stroke volume, even if normal reflex compensation is present. These conditions include hypovolemic shock (owing to trauma and blood loss), sepsis (in which the normal reflex compensation is not present), and high PEEP and high mean airway pressure. In these conditions, fluid or blood administration may be necessary to maintain cardiac output and end-organ perfusion. In some patients who receive PPV with PEEP, an increase in PEEP can decrease cardiac output as discussed earlier. In this case, the outcome of PEEP in terms of improved tissue oxygenation ($DO_2 = CaO_2 \times$ cardiac output) should be determined. If tissue O_2 delivery decreases because of a decrease in cardiac output, but CaO_2 increases, fluid administration may be indicated to restore cardiac output by increasing preload.

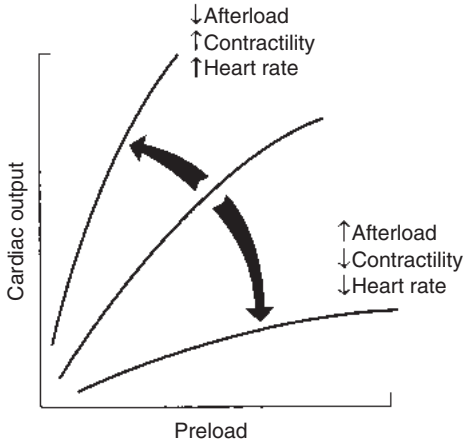

FIGURE 46-17 Effects of preload, afterload, contractility, and heart rate on cardiac output function curve. (Modified from Green JF: Fundamental cardiovascular and pulmonary physiology, ed 2, Philadelphia, 1987, Lea & Febiger.)

Pharmacologic Maintenance of Cardiac Output and Blood Pressure

First-line therapy for decreased cardiac output and blood pressure is fluid administration, unless the patient has congestive heart failure. In heart failure, inotropic therapy is indicated for decreased myocardial contractility, and vasodilators and diuretics are used to control hypertension, which decreases afterload. Diuretics are used to control fluid overload and to decrease preload to the distended heart. These factors in combination may return the heart to a more optimal portion of the Frank-Starling curve and improve stroke volume.

EFFECTS OF POSITIVE PRESSURE MECHANICAL VENTILATION ON OTHER BODY SYSTEMS

Increased Intracranial Pressure (ICP)

Perfusion of the brain is quantified by the cerebral perfusion pressure (CPP). The CPP is the difference between mean arterial pressure (MAP) and ICP. CPP may decrease in any case in which MAP decreases or ICP increases. If CPP decreases, cerebral blood flow (CBF) decreases. The result is cerebral ischemia and a decrease in cerebral O_2 metabolism. The cerebral circulation has the ability to maintain CBF even when CPP changes, a process called *cerebral autoregulation*. Cerebral **autoregulation** is a function of cerebral vascular resistance. If CPP decreases, cerebral vascular resistance decreases to maintain CPP. Cerebral autoregulation functions as long as CPP is in the range of 60 to 150 mm Hg and is limited by the ability of the cerebral arterioles to constrict and dilate. Under normal conditions, cerebral O_2 delivery and CPP exceed the metabolic needs of the brain for O_2 and glucose.

Normal MAP is 93 mm Hg if arterial pressure is 120/80 mm Hg. Normal ICP is less than 10 mm Hg, so normal CPP is about 80 to 85 mm Hg. CPP decreases when MAP decreases or ICP increases. Conditions leading to a decrease in MAP are shock, high PEEP, and high mean airway pressure. Increases in ICP are caused by traumatic brain injury (TBI), cerebral hemorrhage, cerebrovascular accident (stroke), and tumors. A CPP greater than 60 mm Hg maintains CBF and cerebral O_2 metabolism.

CO_2 is a potent cerebral vasodilator and an important regulator of the cerebral arteriolar diameter. As $PaCO_2$ decreases from 40 mm Hg, systemic pH increases. CO_2 concurrently diffuses across the blood-brain barrier. The result is an increased cerebrospinal fluid (CSF) pH. Although $PaCO_2$ is monitored in patients with TBI, the CSF pH modulates cerebral vascular resistance in an effort to decrease the ICP. When mechanical hyperventilation is used, cerebral vascular resistance increases, and the result is decreased ICP; this is why hyperventilation has

been used in the management of TBI and acute increased ICP. However, in the presence of an already decreased CPP, CBF may decrease to the point at which cerebral ischemia is likely; this is the problem with immediate hyperventilation of a patient with TBI. In addition, prolonged hyperventilation allows renal excretion of bicarbonate, which allows the CSF pH to return to normal and negates any positive effect of hyperventilation on ICP. The effect of hyperventilation on the reduction of ICP lasts 1 hour. If hyperventilation is withdrawn and arterial pH and $PaCO_2$ return to normal values, the CSF pH decreases. Subsequent CSF acidosis leads to cerebral vasodilation and a rebound increase in CBF and ICP that exceeds the values before hyperventilation. For these reasons, hyperventilation must be used cautiously in the treatment of patients with TBI.[99]

Treatment of a Patient With a Closed Head Injury

Guidelines for the management of severe TBI were developed by neurosurgeons in the Joint Section on Neurotrauma and Critical Care.[100] The recommendation is as follows: "The use of prophylactic hyperventilation ($PaCO_2 < 35$ mm Hg) during the first 24 hours after TBI should be avoided because it can compromise cerebral perfusion during a time when CBF is reduced. Hyperventilation therapy may be necessary for brief periods when there is acute neurologic deterioration or for longer periods if there is intracranial hypertension refractory to sedation, paralysis, CSF drainage, and osmotic diuretics." The Joint Section further noted that "in the absence of increased ICP, chronic, prolonged hyperventilation therapy ($PaCO_2 <$ 35 mm Hg) should be avoided after TBI." These findings have resulted in several recommendations regarding the care of patients with TBI, as follows:

1. Patients with TBI may have transient, short periods of increased ICP, called *plateau waves*. Plateau waves may be caused by suctioning, repositioning, or other noxious stimuli. During a plateau wave, acute hyperventilation can control ICP until the pressure returns to baseline, at which time ventilation is resumed at the previous rate.
2. Hyperventilation should be avoided after TBI other methods can be employed to decrease elevated ICP. These methods include ventriculostomy for drainage of CSF, craniotomy for removal of mass lesions, osmotic diuretics, sedation, placing the patient in the semi-Fowler position, and paralysis. CPP should be maintained at greater than 70 mm Hg.
3. Intubation should be attempted only after the patient has been sedated, to prevent the associated increase in ICP. Exhaled partial pressure of end-tidal carbon dioxide ($PETCO_2$) should be monitored to maintain a constant $PaCO_2$ after arterial blood gas values are determined to find the correlation between $PaCO_2$ and $PETCO_2$.
4. ICP should be maintained at <20 mm Hg.[100]

Effect on Renal Function

Some patients receiving long-term PPV retain salt and water. In critically ill patients, water retention usually is evident when rapid weight gain occurs. In addition, such patients may have a reduced hematocrit, which is also consistent with hypervolemia secondary to water retention. These early observations are attributed to the direct and indirect effects of PPV on renal function.

In terms of direct effect, PPV can reduce urinary output 30% to 50%. This reduced urinary output during PPV is associated with a simultaneous reduction in renal blood flow, glomerular filtration rate, and sodium and potassium excretion.

Decreases in MAP to less than 75 mm Hg reduce renal blood flow, glomerular filtration rate, and urinary output. However, MAP this low seldom is caused by PPV alone, and kidney autoregulatory mechanisms generally can keep renal perfusion pressure within normal limits over a wide range of arterial pressures. Because restoring cardiac output to normal does not entirely restore urinary output compromised by PPV, other mechanisms must be involved. Impaired renal function during PPV is better associated with a decrease in intravascular volume.

The indirect effect of PPV on renal function may be most important. PPV has a marked effect on the water-retaining and sodium-retaining hormonal systems. Specifically, long-term PPV increases plasma renin activity, plasma aldosterone level, and level of vasopressin (urinary antidiuretic hormone). In addition, PPV decreases atrial natriuretic hormone levels (Figure 46-18).

Decreased right atrial transmural pressure is primarily responsible for the decrease in atrial natriuretic hormone, which leads to sodium retention. Similarly, vasopressin secretion may be enhanced by stimulation of the left atrial stretch receptors, which innervate the posterior pituitary gland. Increased secretion of vasopressin (antidiuretic hormone) and activation of the renin-angiotensin-aldosterone system lead to a decrease in urine output.

Decreased Liver and Splanchnic Perfusion

The effects of PPV on the liver and intestine are related to its effects on the cardiovascular system. Hepatic dysfunction with PPV can occur in patients with otherwise normal livers and manifests as an increase in serum bilirubin level. These effects appear to be directly related to the reduction in hepatic blood flow that occurs with PPV. Regardless of cause, these effects are aggravated by PEEP but can be reversed when cardiac output is returned to pre-PEEP levels with intravascular volume infusions.

Decreased Gastrointestinal Function

An increase in splanchnic resistance can contribute to gastric mucosal ischemia and helps explain the high incidence of gastrointestinal bleeding and stress ulceration in patients receiving long-term PPV. Stress ulcers (erosions of the gastric mucosa) are common among patients with life-threatening illness. Impaired blood flow inhibits the ability of the gastric mucosa to replace itself normally every 2 or 3 days. Stress ulcers are caused by impaired blood flow, not gastric acidity. Gastroduodenal motility also is severely impaired in mechanically ventilated patients.[101] These factors may result in translocation of

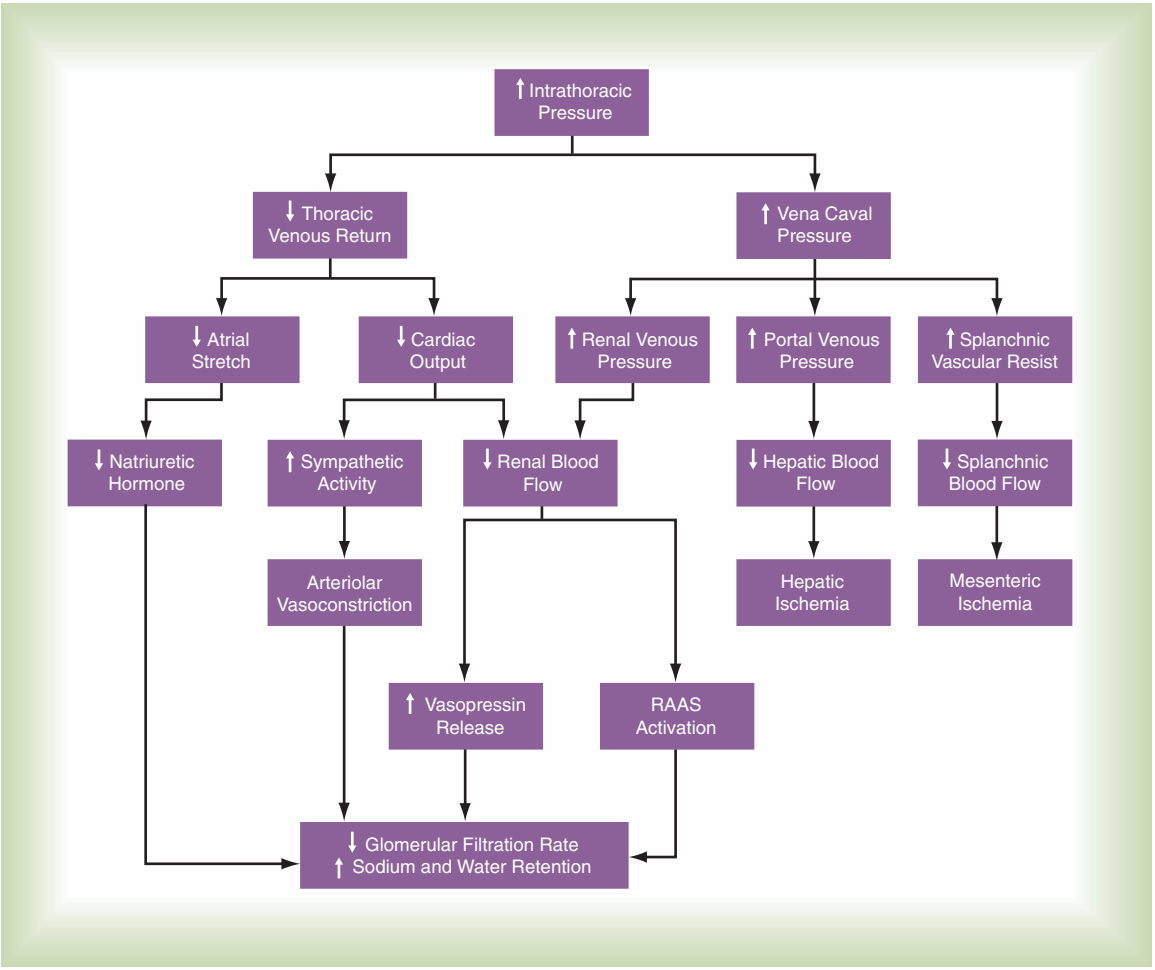

FIGURE 46-18 Cardiac, renal, hepatic, and splanchnic effects associated with increased intrathoracic pressure caused by PPV. *RAAS,* Renin-angiotensin-aldosterone system; ↑, increased; ↓, decreased. (Modified from Florete OG, Gammage GW: Complications of ventilatory support. In Kirby RR, Banner MI, Downs JB, editors: Clinical applications of ventilatory support, New York, 1990, Churchill Livingstone.)

bacteria from the intestine to the blood and nosocomial septicemia. Mechanical ventilation for more than 48 hours and most other conditions necessitating ICU admission are considered indications for stress ulcer prophylaxis. Optimal prophylaxis for stress ulcers is restoration of mesenteric blood flow. Pharmacologic approaches include administration of a cytoprotective agent (sucralfate) and an acid suppression agent (cimetidine or ranitidine).[98]

Gastric distention can be caused by **aerophagia** secondary to an artificial airway cuff leak or by the use of mask ventilation (pressure >20 to 25 cm H_2O). The RT can prevent this complication by taking great care to ensure that the cuff is properly inflated. If patients being ventilated noninvasively are swallowing air, an artificial airway may be considered. In the case of aerophagia and gastric distention, a nasogastric tube may be inserted to evacuate the air.

Bleeding from erosion through the surface vessels of the gastric mucosa is one consequence of stress ulceration. The incidence of bleeding from stress ulcers is almost 100%, but only approximately 5% of bleeding is clinically apparent hemorrhage, and less than 1% to 2% necessitates blood transfusion.

Because patients receiving mechanical ventilation often have an artificial airway or are obtunded, a nutritional deficit may exist. Even in a normal metabolic state, intravenous solutions of saline and dextrose provide only a fraction of the required calories and micronutrients. Patients in the ICU often are hypermetabolic and need two to three times the normal calories. See Chapter 23 for details on nutritional support.

Effect on Central Nervous System

Patients in the ICU are placed into an artificial environment over which they have little control. From the start, the patient loses autonomy. When mechanical ventilation is introduced, the patient is sedated and possibly paralyzed and may not return to a normal, awake level of consciousness until discharged from the ICU. Instead, the patient is kept somnolent (easily aroused and aware) or is stuporous (arousable with difficulty and impaired awareness) or comatose (arousable but unaware).[98] The presence of an artificial airway makes communication

Box 46-3 Modified Ramsay Sedation Scale

1. Agitated, anxious, restless
2. Calm, cooperative, oriented, tranquil
3. Responds to verbal commands
4. Brisk response to light touch
5. Unable to be assessed (paralyzed)

difficult. Caregivers should make a paper tablet and pen, communication board, or communication cards available to patients who are aware enough to write or use them.

Sedatives, Hypnotics, and Neuromuscular Blocking Agents

Sedation is necessary for the management of the nearly inevitable agitation, fear, and anxiety associated with the ICU environment, pain, invasive and noninvasive procedures, and loss of normal sleep pattern. The Society of Critical Care Medicine has published guidelines for sedation and analgesia in the care of critically ill patients.[102]

The level of sedation is monitored with the Modified Ramsay Sedation Scale (Box 46-3). Sedation is titrated to achieve a level of 2 to 3 on the Ramsay scale. This way the patient is responsive, yet not restless or agitated and not paralyzed or comatose.

According to the Society of Critical Care Medicine, facilitation of mechanical ventilation in severe ARDS is the most common reason for prolonged neuromuscular blockade. Neuromuscular blocking agents are used with mechanical ventilation to improve gas exchange, to avoid ICP spikes, to avoid hemodynamic instability, and to prevent bodily injury. Because they paralyze but do not sedate, neuromuscular blocking agents always are used in conjunction with appropriate sedative or analgesic agents (see earlier). In the absence of a sedative, a patient under the influence of a neuromuscular blocking agent is paralyzed and fully aware of the surroundings. During neuromuscular blockade, patients should be assessed for the degree of blockade that is being sustained.[102] The patient is observed for ventilatory effort, and train-of-four stimulation is performed. Neuromuscular blockade should be allowed to dissipate daily so that clinical evaluation, assessment of concomitant sedation and analgesia, and evaluation of the need for continued paralysis can be conducted.

COMPLICATIONS OF MECHANICAL VENTILATION

Negative Pressure Ventilation

Pulmonary

Hypoventilation during NPV can be caused by a decrease in the transairway pressure owing to inadequate negative pressure or leaks in the ventilator or patient-ventilator interface. Iron lung negative pressure ventilators rely on a tight seal at the patient's neck and at all access ports in the tank. Chest cuirass ventilators rely on a tight seal between the cuirass and thorax. Poncho-type ventilators must remain free of leaks or tears. When there is a leak at any of these points, transairway pressure decreases, and the result is a decrease in minute ventilation.

Hyperventilation can occur if the pressure is more negative than is necessary. The results are increased transairway pressure, increased V_T, and increased minute ventilation.

Cardiovascular

Abdominal blood pooling can occur in patients receiving NPV in an iron lung. The negative pressure exerted on the thorax also is exerted on the more compliant abdominal wall. When the pressure in the iron lung becomes negative, the abdominal wall is pulled outward and with it the viscera and associated blood supply. Venous return to the heart, cardiac output, and systemic blood pressure decrease; the result is a condition called "tank shock."

Positive Pressure Ventilation: Artificial Airway Complications

Chapter 36 describes complications related to artificial airways.

Complications Related to Pressure

Ventilator-associated lung injury is the term used to define lung injury in humans owing to mechanical ventilation. These are complications resulting from high pressure, infection, and patient-ventilator asynchrony. High ventilation pressure has long been associated with barotrauma. Barotrauma is categorized as pneumothorax, pneumomediastinum, pneumopericardium, and subcutaneous emphysema (Figure 46-19). All of these complications are descriptions of extraalveolar air. High ventilatory pressure can cause gas to escape through ruptured alveoli. The eventual location of the escaping gas defines the type of barotrauma. If gas escapes through ruptured alveoli into the pleural space, pneumothorax occurs. Gas escaping along perivascular sheaths to the mediastinum produces pneumomediastinum. Further dissection from the mediastinum to tissue planes in the neck and chest wall results in subcutaneous emphysema and potentially pneumomediastinum and pneumoperitoneum.

Pneumothorax is identified by observation of a decrease in chest movement, hyperresonance on percussion, possible deviation of the trachea away from the affected side, and decreased or absent breath sounds over the affected side. In nonintubated patients, there may also be a decrease in vocal fremitus over the affected side. A line separating lung tissue from air is observed on the chest radiograph, although the line sometimes is difficult to see in a small (<20%) pneumothorax. Respiratory distress increases with increasing pneumothorax, as does hypoxemia. Normally, in spontaneously breathing patients, intrapulmonary and pleural pressures are equal in pneumothorax. PPV can cause intrapleural pressures to increase (tension pneumothorax).

Tension pneumothorax is life-threatening, because it tends to develop very rapidly in patients who are mechanically ventilated and shifts the mediastinum, heart, and great

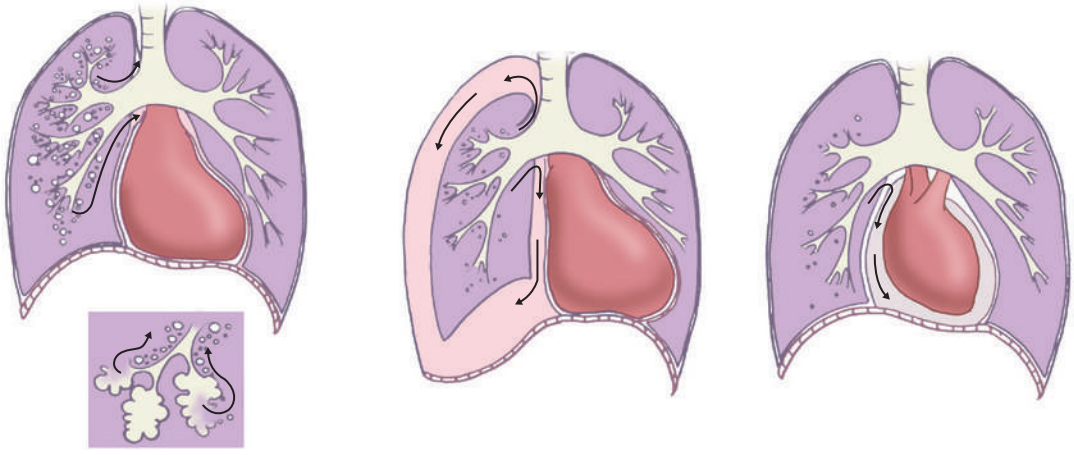

FIGURE 46-19 Pulmonary barotrauma. **A,** Ruptured alveoli are indicated in framed alveoli at bottom. Air dissects from alveoli along vascular sheaths to the hilum and then to the pleural space. **B,** Pneumothorax. Origin of air in lung tissue and its pathway to inflate the pleural space are indicated. The heart shifts to the left because of high pressure in the right side of the chest. **C,** Course of air from the lung to pericardial space. The distended pericardial space causes cardiac tamponade. (Modified from Korones SB: High-risk newborn infants, ed 4, St Louis, 1986, Mosby.)

vessels; the results are a decrease in cardiac output and hypotension. Tension pneumothorax is a medical emergency; it is relieved by insertion of a large-bore needle into the pleural space through the anterior second or third interspace above the rib. This maneuver is followed by chest tube insertion. While waiting for needle decompression, the patient may be ventilated with 100% O_2 at a low V_T and airway pressure. Pneumomediastinum and pneumoperitoneum are identified on a chest radiograph by the presence of air in these locations.

Complications Related to Volume

Ventilator-induced lung injury (VILI) has been defined as the application of pressure, positive or negative, to the lungs causing damage. The damage has been described as an increase in permeability of the alveolar-capillary membrane, pulmonary edema, cell wounding and necrosis, and diffuse alveolar damage as the result of using an inappropriate ventilation strategy. Several more recent reviews summarize understanding of the mechanisms, effects, and means to prevent VILI.[103-105]

It has been shown that overdistention, as opposed to volume or pressure per se, is an important determinant of lung damage. Animals ventilated with large V_T (>30 ml/kg) develop severe injury—hence the term **volutrauma**. The degree of alveolar distention is determined by the transpulmonary pressure (plateau pressure minus the pleural pressure), which must be approximated by the esophageal pressure. As plateau pressure increases, so does transpulmonary pressure, increasing the likelihood of lung damage. Lung damage may also occur when ventilating at low V_T, if alveoli are allowed to deflate and reinflate repeatedly with each breath. This injury is called **atelectrauma**. These two factors have led to the recommendation that lungs should be opened ("recruited") and kept open by an appropriate PEEP level and ventilated to a plateau pressure of no more than 28 cm H_2O by decreasing V_T. This technique is called the *open lung technique* and is described in detail in Chapter 48.

Factors that predispose a patient to VILI include underlying lung disease (injured lungs are more susceptible to VILI), systemic inflammation, surfactant dysfunction, aspiration, pulmonary edema, extremes of age, and heterogeneous lung ventilation. An important factor is the uneven distribution of ventilation, especially in ARDS. Because ARDS is a heterogeneous disorder, there are areas of both low and normal compliance. A given pressure in an area of low compliance may allow lung units to open and close with each breath, causing atelectrauma. The same pressure in an area of normal compliance may cause overdistention and stretch injury. Pulmonary edema is a prominent feature of VILI, owing to an increase in alveolar-capillary membrane permeability. Microvascular damage is characterized by separation of capillary endothelial cells, disruption of alveolar epithelium, and destruction of alveolar type I cells.

VILI occurs via two mechanisms, as shown in Figure 46-20.[106] One mechanism is the physical disruption of tissues and cells *(biophysical injury)*. Physical disruption of the tissues occurs as air ruptures across the alveolar epithelial surface and tracks along the bronchovascular sheath. Air tracks into the interstitium causing pulmonary interstitial emphysema, into the pleural space causing pneumothorax, and into the pericardium causing pneumopericardium. The pulmonary capillary epithelium also fails in response to high-volume ventilation, resulting in hemorrhage and edema. Another factor in biophysical injury is the interdependence of adjacent alveoli and terminal bronchi. When the lung is unevenly expanded, alveolar collapse increases the traction forces between alveoli. This recruitment-derecruitment develops pressures up to 140 cm H_2O across lung units, resulting in air-filled cavities and pseudocysts. Finally, injurious ventilation causes surfactant to become dysfunctional or deficient or both.

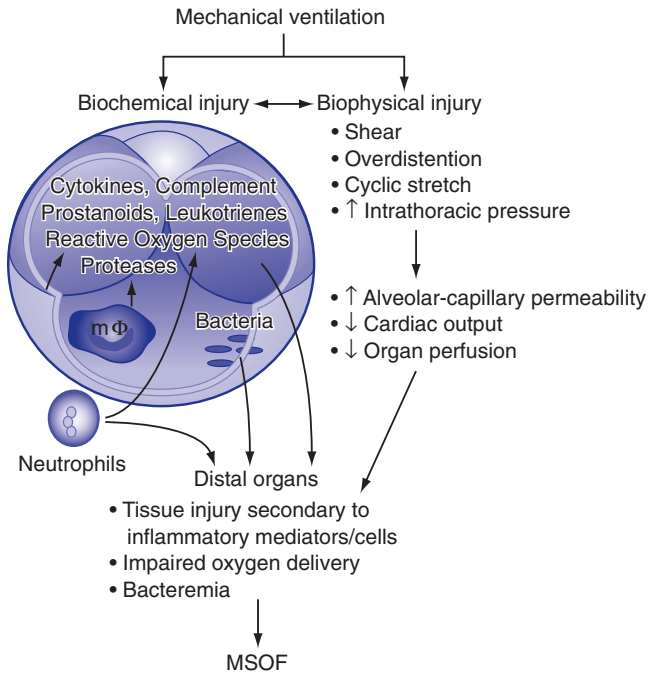

FIGURE 46-20 Mechanisms by which mechanical ventilation might contribute to MSOF. (From Mason RJ, Broaddus VC, Murray JF, et al: Murray and Nadel's textbook of respiratory medicine, ed 4, Philadelphia, 2005, Saunders.)

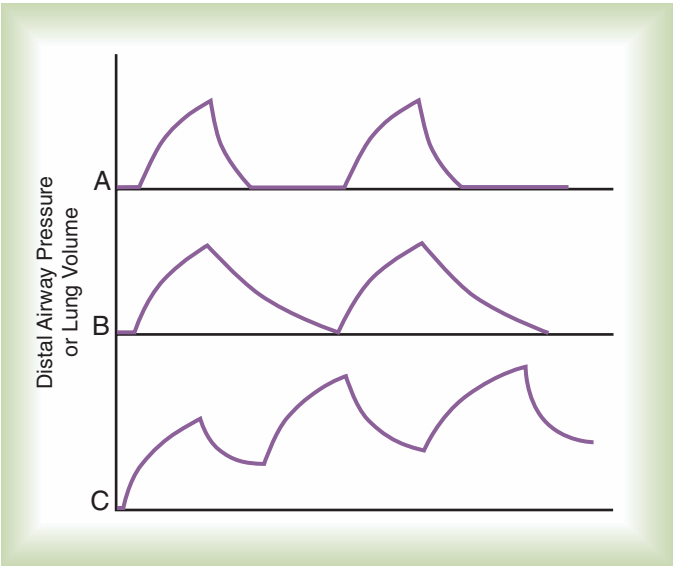

FIGURE 46-21 Causes of auto-PEEP. **A,** When airway resistance is normal and expiratory time is long enough, distal airway pressure and lung volume return to normal after a positive pressure breath. **B,** High expiratory resistance prolongs exhalation to the point at which air-trapping begins and causes auto-PEEP. **C,** Shortening the expiratory time aggravates the problem and worsens auto-PEEP. (Modified from Benson MS, Pierson DJ: Auto-PEEP during mechanical ventilation of adults. Respir Care 33:557, 1988.)

The second mechanism is the release of inflammatory mediators *(biochemical injury)*. When the lungs are abnormally stretched, this is detected by cells and converted into biochemical signals, a process called *mechanotransduction*. These biochemical signals cause the release of cytokines, complement, prostanoids, leukotrienes, reactive O_2 species, and proteases. The release of these substances has been called **biotrauma**. These mediators go on to the terminal organs and cause tissue inflammation, impairment of O_2 delivery, and bacteremia (see 29), leading to multisystem organ failure (MSOF). As mentioned earlier in the chapter, hyperinflation during mechanical ventilation causes bacteria to "spill over" from the gut into the bloodstream, a process called *translocation*. In this manner, translocation contributes to MSOF, as bacteria migrate into the blood and then to terminal organs. Other factors contributing to MSOF are an increase in circulating cell death (apoptotic) factors, suppression of the peripheral immune response, and individual genetic variability.

Alveolar distention occurs when the lungs are stiff and the chest wall is normal or when one or both lungs are ventilated with a high plateau pressure. Plateau pressure ideally should be maintained at less than 28 cm H_2O in all patients. However, in patients with a stiff chest wall (marked obesity, fluid overload, increased abdominal pressure), higher plateau pressure can be tolerated without injury because of the reduction in transpulmonary pressure caused by the stiff chest wall.

Human studies have compared high and low V_T ventilation, using ICU mortality, ventilator-free days, and overall mortality as outcome variables. The consensus is that a low V_T strategy, with PEEP adequate to keep lungs open to avoid atelectrauma, results in a significantly better outcome. In studies in which inflammatory mediators were also measured, high V_T groups had a higher level of inflammatory mediators.[107,108] VILI is related to both mechanical and chemical factors. On one hand, overstretch directly injures the alveolar epithelium and capillary endothelium. On the other hand, through mechanotransduction, cells release many inflammatory mediators into the blood, leading to MSOF.

Auto–Positive End Expiratory Pressure

Air trapping occurs with incomplete emptying of lung units. Lung units prone to air trapping are units with long-time constants (i.e., with high resistance or high compliance). Air trapping during PPV is often referred to as *dynamic hyperinflation, auto-PEEP, occult PEEP,* or *intrinsic PEEP*. This problem associated with air trapping cannot be determined by simple observation of airway pressure. Auto-PEEP often goes unrecognized.

Figure 46-21, *A*, shows the generation of auto-PEEP. As long as airway resistance is normal and expiratory time is sufficiently long, distal airway pressure and lung volume return to baseline during PPV breaths. Alone or in combination, three factors account for the development of auto-PEEP. First, by effectively increasing the time constant of the lung, high expiratory resistance prolongs exhalation to the point at which air trapping begins (see Figure 46-21, *B*). Second, any increase in the minute ventilation increases the likelihood of auto-PEEP. Third, any

shortening of the expiratory time (see Figure 46-21, *C*) aggravates the problem and increases both distal airway pressure and lung volume (auto-PEEP). By increasing FRC and alveolar pressure, auto-PEEP increases WOB and impedes venous return, the result being a decrease in cardiac output. Auto-PEEP also can increase pulmonary vascular resistance.

Patients at greatest risk for auto-PEEP are patients with high airway resistance who are being supported by modes that limit expiratory time. High-risk patient groups include patients with obstructive disease, any disease producing increased secretions, and any disease that increases lung compliance. High-risk ventilatory support techniques include any method that increases the I : E ratio, especially CMV at a high rate or in the assist-control mode, and approaches that purposefully shorten expiratory time, such as IRV or the use of low inspiratory flow. In addition, auto-PEEP can develop in patients with normal lung mechanics if minute volume is high and expiratory time short.

Auto-PEEP increases WOB. This increase in WOB is due to two factors. First, hyperinflation caused by auto-PEEP stretches the lung, and the stretching impairs the contractile action of the diaphragm. Second, the high alveolar pressure caused by auto-PEEP must be overcome before any airway pressure change can occur. This situation effectively reduces machine sensitivity and increases response time. Increased effort is required by the patient before the ventilator recognizes the flow or pressure change and triggers to inspiration. The effect of auto-PEEP on WOB can be minimized by applied PEEP. However, applied PEEP is effective only if auto-PEEP is a result of dynamic airway obstruction. Essentially, PEEP should be applied in increments of 1 to 2 cm H_2O until every patient inspiratory effort is capable of triggering the ventilator.

Oxygen Toxicity

O_2 toxicity causes lung tissue damage and an increase in the permeability of the alveolar-capillary membrane. As suggested in Chapter 41, factors associated with the development of O_2 toxicity include elevated FiO_2, long duration of exposure, and patient susceptibility. FiO_2 of 0.6 or more for longer than 24 to 48 hours is associated with the development of O_2 toxicity. In the presence of a high concentration of O_2, O_2 free radicals are produced. These radicals are the hydroxyl (OH^-), perhydroxyl (HO_2), and superoxide (O_2^-) radicals. Free radicals normally are rapidly detoxified by the enzyme superoxide dismutase, which is produced by alveolar type II cells. With higher FiO_2, the presence of free radicals is greater, and type II cells are less likely to produce superoxide dismutase. The presence of free radicals increases the permeability of the alveolar-capillary membrane. The combination of direct injury by free radicals and decreased surfactant production leads to exudation of fluid into the alveoli and a subsequent decrease in compliance. Every effort should be made to decrease FiO_2 whenever it exceeds 0.6. The decrease usually is accomplished with application of PEEP or CPAP. However, the evidence supporting the development of O_2 toxicity in critically ill patients is poor, and oxygenation should never be sacrificed for the purpose of avoiding O_2 toxicity.

Ventilator-Associated (Nosocomial) Pneumonia

Pneumonia is the second most common nosocomial infection, primarily affecting infants and young children, adults older than 65 years, patients with severe underlying disease, immunosuppressed patients, patients who have depressed sensorium, patients with cardiopulmonary disease, and patients who have had thoracoabdominal surgery. RTs should be prepared to prevent this threat to respiratory patients, who are 6 to 21 times more susceptible to the development of nosocomial pneumonia than the general population. A review by Craven[109] stated that health care costs related to each case of nosocomial pneumonia are about $40,000. Most of these cases of pneumonia are caused by aspiration of bacteria that have colonized the upper gastrointestinal tract or oropharynx. Intubation greatly increases the risk of nosocomial pneumonia because the lower airway is left exposed, and normal protective mechanisms are bypassed. This type of pneumonia has been known for years as *ventilator-associated pneumonia*. This name has been challenged because it is not the ventilator, but rather the microaspiration of microorganisms in oral or gastrointestinal secretions, that causes the infection. Secretions that sit on the top of the endotracheal or tracheostomy tube cuff are aspirated via the small folds in the cuff. Most cases of pneumonia are polymicrobial, consisting of gram-negative organisms. However, methicillin-resistant *Staphylococcus aureus* has been common in the past 10 years. The endotracheal or tracheostomy tube is a site of bacterial growth, and these bacteria become encased in what is referred to as a *biofilm*. The use of a silver-coated endotracheal tube,[110] use of endotracheal tubes with alternative cuff designs,[111] use of subglottic suction airways,[112] proper cuff care,[113] the use of devices to remove biofilm from the inside of the ETT,[114] and avoidance of lavaging when suctioning all reduce the risk of aspiration. See Chapter 36 for details. Another source of infection is the endotracheal tube lumen.

Prevention of Ventilator-Associated Pneumonia

In addition to standard precautions, specific infection control procedures apply to the use of endotracheal tubes and ventilators. These ventilator bundles for prevention of ventilator-associated pneumonia include the following:[113]

- Perform appropriate hand hygiene. Hands should be disinfected with a sanitizer (e.g., Cal-Stat hand sanitizer) before entering any patient's room regardless of the reason and when leaving the patient's room regardless of the activities that occurred in the room.
- Perform gentle suctioning (presumably to help prevent coughing, aspiration, and sloughing of biofilm).
- Place the patient in a semirecumbent position (30- to 45-degree head elevation).
- Do not routinely change ventilator circuits.
- Drain and discard inspiratory tube condensate away from the patient, or prevent its formation by using heated wire circuits or heat and moisture exchangers.

- Use a metered dose inhaler rather than a nebulizer for medication administration. If a small volume nebulizer is used, it should be replaced after each treatment (i.e., one nebulizer = one treatment). However, the new vibrating disc nebulizers are as protective as meter dose inhalers.
- Interrupt sedatives daily to evaluate patient readiness to wean from the ventilator—this is effective in decreasing the length of intubation and mechanical ventilation.
- Assess daily the ability of the patient to perform a spontaneous breathing trial.
- Use noninvasive ventilation whenever possible to avoid intubation.
- Perform regular oral hygiene at least every 4 hours.

Early tracheostomy has been evaluated as a possible preventive measure, but several studies and meta-analyses showed no advantage of tracheostomy in preventing ventilator-associated pneumonia.[109] Other measures that may decrease the likelihood of nosocomial infection include the use of closed suction systems (although the benefit remains unproved); use of disposable resuscitation bags; and high-level disinfection of ventilators, O_2 analyzers, and other equipment between patients.

Ventilator Malfunction

Ventilator malfunction can be categorized as a failure in the patient circuit or a failure in the ventilator. Failures in the patient circuit include failures related to the endotracheal tube: cuff rupture, main stem intubation, laryngeal intubation, esophageal intubation, soft tissue erosion because the cuff pressure is too high, and disconnection from the circuit (Figure 46-22). Failures in the tubing circuit include leaks anywhere there is a tubing connection; a leak at the site of a nebulizer or metered dose inhaler; humidifier malfunctions that include failure to fill the reservoir, overheating, or mechanical failure; and exhalation valve failure. These failures are recognized by the ventilator as changes in respiratory rate, airway pressure, or V_T outside the limits set on the alarms.

Airway and ventilator malfunctions can be avoided with proper care of the endotracheal tube (taping the tube snugly), ensuring equal breath sounds, checking to ensure the tubing is patent and free of leaks, and ensuring that all connections are firmly made. If patient activity is the cause of ventilator disconnection, patient teaching to refrain from attempting to disconnect the ventilator or pulling on or biting the tube or sedation or restraint may be necessary. Failures related to the ventilator include electrical failure, microprocessor failure, exhalation valve failure, internal volume leakage, gas supply failure, and any failure that could result in an increase or decrease in minute ventilation or FiO_2. Ventilators have alarms that alert the RT to these dysfunctions.

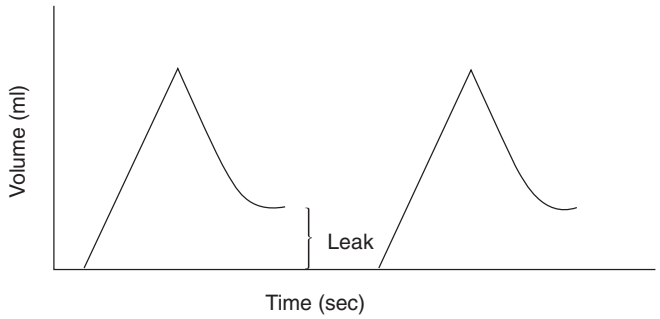

FIGURE 46-22 Volume-time waveform illustrating a leak in the ventilator circuit. Note the abrupt end of expiration before the tracing reaches the baseline.

Patient safety is always the primary concern when a malfunction is detected. For this reason, a manual resuscitator always should be placed near the bedside. If the reason for the patient's distress is clear, such as disconnection at the endotracheal tube, the connection is reestablished, and patient comfort and ventilation are ensured. If the reason is not obvious, the patient is ventilated with a manual ventilator while the cause of the malfunction is investigated. The steps for managing sudden distress in a patient receiving ventilatory support are listed in Table 46-4.

RULE OF THUMB

Always have a manual ventilator (bag-valve-mask device [Ambu bag]) at the bedside of a patient receiving mechanical ventilation. Ensure that the manual ventilator is connected to an O_2 source. If the patient is receiving PEEP, ensure that the manual ventilator is equipped with a PEEP valve that provides PEEP equivalent of that being administered to the patient with the ventilator. Keep the patient connection of the manual ventilator clean and covered and the valve free of secretions.

Operator Error

The provision of mechanical ventilation is highly complex, the equipment used is very sophisticated, and the potential options to be applied to a given patient increase each year. As a result, clinician error is an ongoing concern. To minimize the possibility of error, a clinician should never make an adjustment to a mechanical ventilator unless he or she has been properly trained to operate the ventilator and the clinician's skills at using the machine have been assessed by an independent evaluator. It is essential for the operator to document ventilator settings in a consistent manner and to understand the terminology used when documenting the ventilator-patient interaction in a paper chart or electronic medical record. Appropriate operation of the mechanical ventilator should be assessed on a regular basis based on the severity and criticality of the patient's clinical presentation. To minimize errors, any adjustment should be checked to ensure that the appropriate change was actually made and that the patient responded as expected. A clinician should never leave the bedside of a patient until the clinician is assured that the patient is being ventilated as ordered and that the ventilator is responding as expected. Patient safety should always be the primary concern of all RTs.

TABLE 46-4

Causes of Sudden Respiratory Distress and Remedies in a Patient Receiving Ventilatory Support

Cause	Remedy
Patient Related	
Artificial airway problems	Assessment of cuff, airway position (see Chapter 36)
Pneumothorax	Chest tube insertion
Bronchospasm	Bronchodilator therapy
Secretions	Suctioning, tracheobronchial hygiene
Pulmonary edema	Therapy directed at cause of pulmonary edema
Auto-PEEP	Decreased minute volume, tracheobronchial hygiene, decrease in I : E
Abnormal respiratory drive	Therapy directed at cause, possible sedation or paralysis
Alteration in body posture	Repositioning of patient
Abdominal distention	Therapy directed at cause, insertion of nasogastric tube
Anxiety	Reassurance, anxiolytics, assessment of minute ventilation
Patient-ventilator asynchrony	Assessment of flow and sensitivity, auto-PEEP, change of mode to accommodate patient's pattern of ventilation
Ventilator Related	
System leak	Assessment of connections in the ventilator circuit
Circuit malfunction	Assessment of circuit with test lung, replace if necessary
Inadequate FiO_2	Assessment of SpO_2, assessment of FiO_2 with analyzer, increase in FiO_2, or replacement of blender or ventilator if malfunction is found
Inadequate ventilatory support	Review of therapeutic strategy for the patient (see Chapter 48)
Improper flow-trigger setting	Adjust trigger and flow to patient demand

SUMMARY CHECKLIST

- Response to an increase in FiO_2 helps determine the cause of hypoxemia.
- Hypoxemia responsive to an increase in FiO_2 is likely caused by a low $\dot{V}/\dot{Q}$ ratio.
- Hypoxemia unresponsive to increased FiO_2 is likely caused by a diffusion defect or shunt.
- Alveolar ventilation and CO_2 production determine $PaCO_2$.
- Mechanical ventilation should increase alveolar ventilation and may decrease CO_2 production when WOB is relieved. These factors decrease $PaCO_2$.
- Mechanical ventilation with positive pressure increases dead space and increases $\dot{V}/\dot{Q}$ ratio.
- Inspiratory or expiratory time can be manipulated to improve oxygenation and alveolar emptying in disorders that affect alveolar time constants.
- Physiologic benefits of PPV include improved oxygenation and ventilation, alveolar expansion, decreased WOB and cardiac work, and improved O_2 delivery.
- No outcome differences have been identified among the various modes of ventilation except that SIMV prolongs the weaning process. However, modes of ventilation that allow the patient control over the process of gas delivery have been shown to improve patient-ventilator synchrony.
- No single flow pattern has been shown to be the most physiologically beneficial. However, research results indicate better oxygenation, ventilation, and patient-ventilator synchrony with the decelerating flow compared with the square wave flow pattern.
- A decelerating flow waveform tends to have a lower peak and a higher mean airway pressure, whereas a square wave tends to have a higher peak and a lower mean airway pressure.
- Flow triggering appears to decrease WOB compared with pressure triggering on older generation ventilators.
- PEEP is used to restore FRC in acute restrictive disease and to splint the airways in obstructive disease.
- WOB is decreased by the appropriate application of mode, trigger variable, and flow.
- PPV is detrimental to the $\dot{V}/\dot{Q}$ ratio primarily by shifting ventilation to areas that are less perfused. PPV can cause hyperventilation, tissue damage, and barotraumas if not carefully managed.
- PPV can decrease venous return and cardiac output, especially when it increases intrapleural and mean airway pressures.
- PPV can cause renal, hepatic, and gastrointestinal malfunction primarily owing to decreased perfusion of the capillary tissue beds.
- Elevation of the head, osmotic diuretics, and CSF drainage are effective means of decreasing ICP in TBI. Acute hyperventilation should be used only temporarily until other, more effective means can be employed.
- Ventilator bundles should always be adhered to during mechanical ventilation to minimize the development of ventilator-associated pneumonia.
- Patient safety and error-free patient care are the first priority when caring for any patient.

CHAPTER 47

Patient-Ventilator Interactions

ROBERT M. KACMAREK

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the reasons why appropriate patient-ventilator interactions are critical to ensuring safe and effective mechanical ventilation.
- Discuss those clinical issues that can result in poor patient-ventilator interaction.
- Discuss and define the different types of asynchronies commonly observed during mechanical ventilation.
- Discuss the control variables that affect appropriate patient-ventilator interaction and identify the modes of ventilation that are most likely to result in asynchrony.
- Discuss the steps that should be taken to determine the cause of asynchrony before sedation is ordered.
- Discuss what should be done to modify or eliminate flow asynchrony.
- Discuss what should be done to modify double triggering.
- Discuss what should be done to modify missed triggering.
- Discuss what should be done to modify delayed triggering.
- Discuss what should done to modify autotriggering.
- Discuss the setting of rise time during pressure-targeted ventilation.
- Discuss the setting of expiratory cycling criteria during pressure support ventilation.
- Discuss the reasons why proportional assist ventilation (PAV) and neurally adjusted ventilatory assist (NAVA) modes are most likely to result in the least asynchrony.

CHAPTER OUTLINE

KEY TERMS

atrophy
autotriggering
cycle asynchrony
diaphragmatic dysfunction
double triggering
fatigue
endobronchial intubation
expiratory cycling criteria
innominate artery rupture
missed triggering
mode asynchrony
neurally adjusted ventilatory assist (NAVA)
patient-ventilator asynchrony
proportional assist ventilation (PAV)
reverse triggering
rise time
tension pneumothorax
tracheal malasia
tracheal stenosis
tracheoesophageal fistula
trigger asynchrony
trigger delay

In general, it is relatively easy to set and adjust controlled mechanical ventilation because the patient does not actively interact with the mechanical ventilator. Controlled mechanical ventilation is entirely a result of the adjustments made by the managing clinician. This is not true during assisted patient-triggered ventilation or partial ventilatory support. In this setting the patient and the ventilator must intimately interact, the ventilator must be set to meet the ventilatory demand of the patient, and the patient must be capable of adjusting to the settings of the ventilator. In most modes of mechanical ventilation the patient must follow the lead of the ventilator—that is, adjust to the way the ventilator is set and breathe with a ventilatory pattern that is consistent with the parameters defined by the mode of ventilation applied and the specific settings.[1] When this interaction is not good, **patient-ventilator asynchrony** occurs or the patient is characterized as "fighting the ventilator." However, it must be noted that there are many other clinical/technical issues that can result in poor patient-ventilator interaction. In this chapter all aspects of patient-ventilator interaction will be discussed with a focus on what should be done to improve the interaction. It is important to remember that sedation of the patient is **ALWAYS** the last intervention to be used to improve patient-ventilator interaction. Careful assessment of the patient, the airway, and the ventilator should be made and necessary adjustments carried out before the decision that sedation is necessary to improve the patient-ventilator interaction.[2]

RULE OF THUMB

Appropriate patient-ventilator interaction during patient-triggered assisted ventilation requires intimate coordination between the demands of the patient's respiratory center and the settings of the mechanical ventilator.

Patient-ventilator interaction refers to patient comfort, work of breathing (WOB), and synchrony during ventilator-assisted breaths. Generally, ventilatory support should be initially adjusted to minimize the WOB and to allow the ventilatory muscles to rest.[3,4] **Diaphragmatic dysfunction** often accompanies ventilatory failure, and a sustained increase in workload can lead to structural injury to the ventilatory muscles.[5] When the ventilatory muscles become fatigued, at least 24 hours is required for recovery.[6] Complete rest of the diaphragm, as in controlled ventilation, may lead to diaphragmatic deconditioning, weakness, and atrophy in 48 hours.[6] In the presence of spontaneous breathing, inappropriate ventilator settings may increase patient work and **fatigue** further.[2] However, careful selection of ventilator settings can reduce the workload to a normal range without resulting in deconditioning and **atrophy** of the respiratory muscles.[2]

EFFECTS OF POOR PATIENT-VENTILATOR INTERACTION ON OUTCOME

Regardless of the cause of the poor patient interaction, the result is negative for the patient. At minimum, hemodynamics, ventilatory pattern, and gas exchange are adversely affected. Patients may become hypotensive, hypertensive, tachycardic, or bradycardic. Their ventilatory pattern may markedly change to a rapid shallow pattern or they may attempt to inhale large tidal volumes at a slow rate when their ventilatory drive is affected by pharmacologic agents. Normally, poor patient-ventilator interaction results in hypoxemia as a result of poor matching of ventilation and perfusion or increased true shunt. Both hypercarbia and hypocarbia may result, based on the stimulus. Those who experience hypoxemia will frequently respond with hyperventilation. However, if hemodynamic compromise is present hypocarbia is normally the result.[2]

Most causes of poor patient-ventilator interaction are of rather short duration because the continuation of the cause frequently has significant negative short-term effects. For example, a tension pneumothorax during mechanical ventilation must be corrected quickly or the result is cardiac arrest. Obstruction of the airway, even if partial, normally results in marked changes in airway pressure or tidal volumes that rapidly alert clinicians of a problem. Bronchospasm or pulmonary edema are usually rapidly recognized by the changes in clinical presentation and alterations in patient response to the ventilator. Patient-ventilatory asynchrony is a more subtle problem that can be difficult to identify and can persist for the entire time that the patient is mechanically ventilated. Identification of asynchrony requires careful patient and ventilator waveform assessment and sometimes requires a lengthy observation of waveforms. Although asynchrony is more subtle than other causes of poor patient-ventilator interaction its effects in the long term can be very serious. Recent data indicate that asynchrony occurs in all patients receiving assisted patient-triggered ventilation, is most significant during the morning when clinician-patient interaction is greatest, is present even during periods of sedation, and varies from mild to very severe.[7] What is most important to remember is that asynchrony has been associated with increased length of mechanical ventilation, ICU and hospital length of stay, the need for trachestomy, and ICU and hospital mortality.[7,8,9] At this time it cannot be said that asynchrony causes an increase in mortality but that patients who have high levels of asynchrony have greater ICU and hospital mortality than patients who have a low level of asynchrony. As a result, careful review of ventilator settings should occur during every patient-ventilator assessment and adjustments should be made to minimize the level of asynchrony.

RULE OF THUMB

Asynchrony has been associated with increased length of mechanical ventilation, ICU and hospital length of stay, the need for trachestomy, and ICU and hospital mortality.

MINI CLINI

Management of Emergency Airway Issues

PROBLEM: Mr. Smith is a 36-year-old motor vehicle accident victim presenting with massive head and chest trauma. He is immediately intubated in the emergency department and mechanically ventilated in the volume control mode. He has received sedation and paralysis and is ventilated with the following settings. Tidal volume 500 ml (6 ml/kg PBW), rate 22/min, peak flow 40 liters/min, inspiratory time 0.66 sec. He has 10 cm H_2O PEEP and an F_IO_2 of 60%. At these settings his SpO_2 is 95%, pulse is 78/min, and arterial blood pressure is 110/70. His peak airway pressure is 24 cm H_2O and his plateau pressure is 18 cm H_2O. He has received a total of 4 liters of fluid.

As you are standing at the bedside you observe a breath-by-breath increase in his peak airway pressure and the high-pressure alarm sounds at 50 cm H_2O. His SpO_2 has decreased to 88% and appears to be decreasing breath by breath. His pulse is 140/min and blood pressure is 80/50. You observe that his trachea is deviated to the left, and on auscultation note an absence of breath sounds on the left. His percussion note is hyperresonant on the left side and on palpitation you note a rise only of the right chest. What should you do?

Solution: Clearly some dramatic change in your ability to ventilate the patient has rapidly occurred. This presentation is most likely the result of an airway obstruction, a mainstem intubation, or a tension pneumothorax. Immediately disconnect the patient from the ventilator and suction the endotracheal tube. This will eliminate obstruction of the airway and the ventilator as the problem. It is most likely not a mainstem intubation because most mainstem intubations are into the right mainstem bronchus and the fact that breath sounds are absent on the right eliminates this. In addition, his presentation is more consistent with a tension pneumothorax; rapid deterioration, hyperresonant on the affected side, deviated trachea way from the affected side, and an increase in peak airway pressure with each breath.

Immediate decompression of the chest with a 19-gauge needle is indicated, followed by insertion of a chest tube. Decompression is done by sliding the needle over the third rib at the mid-nipple line. Blood vessels and nerves run along the lower border of the ribs, not the upper border. During these procedures very gentle ventilation with a manual ventilator should occur with 100% oxygen and a rapid shallow pattern minimizing pressure to avoid extending the pneumothorax.

CAUSES OF POOR PATIENT-VENTILATOR INTERACTIONS

The primary causes of poor patient-ventilator interaction are listed in Table 47-1. It is important to note that most of these issues also result in sudden respiratory distress. Except for asynchrony, the causes listed in Table 47-1 can occur in patients under both controlled and assisted ventilated.

TABLE 47-1

Causes of Poor Patient-Ventilation Interaction

Patient-related Causes
Abnormal respiratory drive
Abdominal distension
Alteration in body posture
Artificial airway problems
Agitation
Bronchospasm
Drug-induced problems
Dynamic hyperinflation
Fever
Hemodynamic compromise
Hypoxemia
Pneumothorax
Pulmonary edema
Pulmonary embolism
Secretions
Ventilator-related Causes
Circuit malfunction
Inadequate F_IO_2
Inadequate ventilator support
System leak
Patient-ventilator asynchrony

Change in Clinical Status

One of the primary causes of poor patient interaction with the mechanical ventilator is a change in the patient's clinical status.[2] Excessive secretions, bronchospasm, and agitation are the most common and regularly seen causes of poor patient-ventilator interaction, and these issues should be assessed at every patient-ventilator assessment. In addition, fever, hypoxemia, and hemodynamic compromise are also regular causes of poor patient-ventilator interaction (Table 47-1). When these issues are present the cause should be identified and rapidly corrected. In addition, artificial airway problems, pneumothorax, pulmonary edema, pulmonary embolism, dynamic hyperinflation, alterations of body position, drug administration, and abdominal distension can all cause poor patient-ventilator interaction.[2]

Artificial Airways

Artificial airway problems are a common cause of sudden respiratory distress. As outlined in Chapter 36, a number of problems can suddenly occur with artificial airways. Of primary concern is the development of biofilm on the internal surface of the endotracheal tube, as illustrated in Figure 47-1. Biofilm develops on all endotracheal tubes but the extent of the development is based on the clinical presentation of the patient.[10] Patients who are aspirating oral secretions around the endotracheal tube or who have excessive lower airway secretion production can easily develop obstructions that occupy more than 50% of the lumen of the endotracheal tube, which can rapidly progress to complete occlusion if proper humidification is not provided.[11] If the lumen of the endotracheal tube is nearly totally obstructed, airway resistance markedly increases, resulting in an

FIGURE 47-1 Picture of an endotracheal tube with biofilm/secretions partially occluding greater than ½ of the airway. (From: Mietto C, Foley K, Salerno L, et al: Removal of endotracheal tube obstruction with a secretion clearance device. Respir Care 59: e122–e126, 2014.)

increase in peak airway pressure during volume ventilation and a decrease in tidal volume in pressure ventilation. This is an airway emergency requiring immediate action. Either the endotracheal tube needs to be changed or the secretion must be removed. A number of devices are currently on the market designed to remove secretions form the lumen of the artificial airway (Figure 47-2). These mucus shaver devices can prevent the need to change the airway and dramatically improve ventilation.[12,13]

Another common problem with endotracheal tubes is movement of the airway into the oral pharynx or movement into the right mainstem bronchus. Both of these can be life threatening, although movement into the oral pharynx, essentially extubation, is the most life threatening. In some situations the airway can be moved back into the trachea, but in others reintubation is necessary. If movement of the airway occurs, adequate ventilation is generally impossible. Airway pressures and tidal volumes rapidly decrease and there is frequently gas leakage from the mouth and nose. Thus it is important to determine the location of the endotracheal tube at each patient-ventilator assessment. The tube should be positioned about 23 cm from the teeth (incisors) in men and 21 cm in women. In addition, following intubation the location of the tip of the tube in relation to the carina must be evaluated. In adults the tip of the tube should be 3 to 5 cm above the carina and its length at the teeth should be noted and regularly reassessed to ensure proper placement. A right mainstem intubation presents with sudden increases in airway pressure and absent breath sound on the right side of the chest. Depending on the patient's status, hypoxemia, hypercarbia, and hemodynamic compromise may be present. Careful movement of the tube to the proper position at the teeth corrects this problem but following adjustment a chest x-ray should always be performed to assure proper position. Flexion and extension of the head and neck always results in movement of the tip of the endotracheal tube. Extension of the head and neck moves the tip closer to the carina and flexion moves the tip closer to the pharynx. This movement on average is 1 to 3 cm in either direction.

Other potential problems with artificial airways include cuff herniation, the unequal expansion of the cuff causing part of

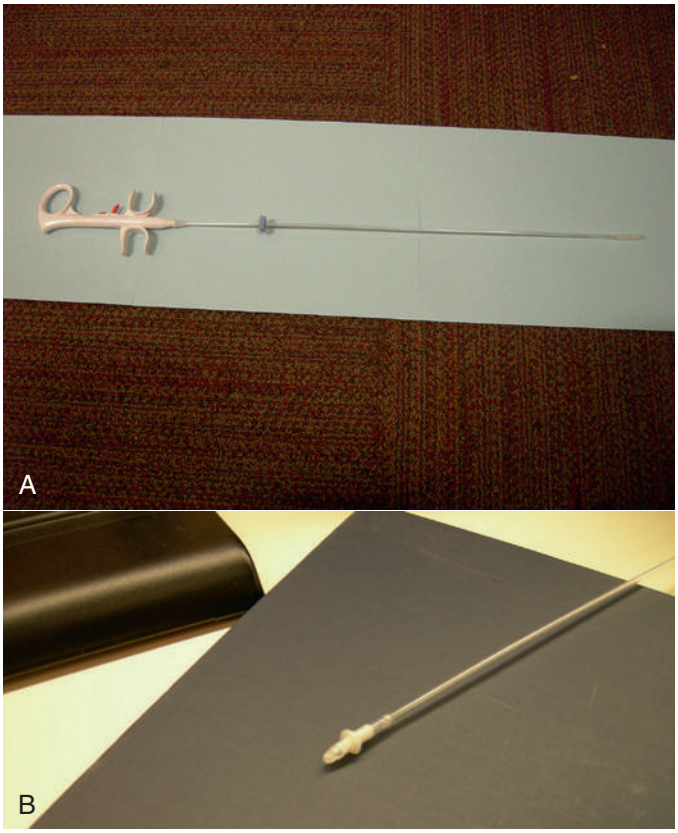

FIGURE 47-2 **A,** Picture of a mucus shaver device. This device is designed to remove biofilm/secretions from the inside of an artificial airway. **B,** Shows the dilated tip of the mucus shaver inflated to remove secretion.

the cuff to partially occlude the tip of the artificial airway. This can occur with both endotracheal and tracheostomy tubes. It is usually identified based on difficulty passing a suction catheter past the tip of the airway, which is resolved by deflating the cuff. If cuff herniation is present, the airway requires replacement. Cuffs can rupture, resulting in an inability to effectively ventilate with large oral/nasal leaks and the inability of the cuff to hold pressure. Again, the airway requires replacement.

Kinking of the endotracheal tube is also a potential problem. This usually occurs in a patient with a well-secured endotracheal tube that the patient is actively trying to move out of their airway by biting and "tonguing" the tube. This causes the tube to move toward the oral pharynx, but because it is well secured it kinks. The result is increased airway resistance. Inability to pass a suction catheter more than a short distance into the airway and visualization of the tube in the mouth and pharynx identifies this problem. Repositioning of the tube is indicated. Differentiation of tube kinking from tube obstruction can be difficult but biofilm and secretion obstruction usually occur in the lower third of the airway and kinking the middle to the first third of the airway.

Long-term artificial airway placement can also result in the development of **tracheal stenosis**, **tracheal malasia**, **tracheoesophageal fistula**, and **innominate artery rupture**. Of these,

innominate artery rupture is the most devastating. It requires surgical intervention and can be fatal. It is difficult to identify the problem until the rupture actually occurs. However, in some patients the tracheostomy tube will start to pulsate with eroding of the tracheal wall toward the innominate artery, allowing the pulse to be counted from the pulsation.

Pneumothorax

Another life-threatening situation during mechanical ventilation is the development of a pneumothorax, which in most circumstances is a tension pneumothorax. That is, with every positive pressure breath more gas moves into the pleural space but is unable to exit the space. As a result the pressure in the pleural space continues to increase, causing lung collapse and eventually causing complete cardiovascular collapse and cardiac arrest. Treatment is decompression of the pleural space and the placement of a chest tube. Initially, a 19-gauge needle can be inserted to relieve the pressure. The needle is inserted at the mid-nipple line, sliding over the top of the third rib or the highest point of the thoracic cage, allowing the gas to exit and relieving the tension.

A tension pneumothorax typically develops very rapidly. Airway pressure increases with each breath in volume ventilation, whereas tidal volume decreases with each breath in pressure ventilation. The change is more dramatic in volume ventilation than in pressure ventilation because the pressure in the pleural space can increase only to the peak pressure set by the clinician in pressure ventilation, whereas in volume ventilation pressure can increase to the pressure limit setting, which may be set very high. As pressure increases, the affected side's lung collapses and begins to compress the unaffected side. In severe cases the mediastium and trachea are shifted away from the side with the pneumothorax. Patients rapidly become hemodynamically unstable. Breath sounds are absent on the side of the pneumothorax, the percussion note is hyperresonnent on the affected side, and palpitation of the chest generally shows a rise and fall only of the side of the chest opposite the pneumothorax.

RULE OF THUMB

A tension pneumothorax causes increasing airway pressure with each breath in volume ventilation and decreasing tidal volume with each breath in pressure ventilation. As pressure in the pleural space increases, lung collapse occurs.

Airway Emergencies

A rapid deterioration in the patient's clinical status associated with increased airway pressure and decreased tidal volume associated with progressive hemodynamic compromise and deteriorating gas exchange should always alert clinicians to the possibility of three problems: tension pneumothorax, airway obstruction, and right mainstem intubation. Box 47-1 lists the steps that should be taken to identify the cause of the problem. Removing the patient from the ventilator and manually ventilating (ambuing) with rapid shallow breaths will eliminate the ventilator as the cause of the concern. Rapid suctioning of the airway will determine if airway obstruction is the problem. If obstruction is not the problem, then **endobronchial intubation** or a **tension pneumothorax** is the cause. If assessment of the patient is consistent with a tension pneumothorax and the tube is at the correct length at the teeth, the problem is almost always a tension pneumothorax. Severe hemodynamic compromise and continued increasing of airway pressure are not normally seen in a right mainstem intubation.

Box 47-1 Management of Sudden Respiratory Distress

1. Remove the patient from the ventilator.
2. Initiate manual ventilation using a self-inflating bag delivering 100% oxygen.
3. Perform a rapid physical examination and assess monitored indices.
4. Check patency of the airway (pass a suction catheter).
5. If death is imminent, consider and treat the most likely causes (e.g., pneumothorax, airway obstruction).
6. After the patient is stabilized, undertake more detailed assessment and management.

The Mechanical Ventilator

A potential but infrequent cause of poor patient-ventilator interaction is malfunction of the mechanical ventilator. Poor responsiveness and ventilator circuit issues can be a problem, but with the newest generation of mechanical ventilators these technical malfunctions are rarely the cause of poor patient-ventilator interaction. However, the ventilator settings should be checked to ensure that an appropriate tidal volume, respiratory rate, and F_IO_2 are being delivered.

RULE OF THUMB

The percentage of breaths on average that are asynchrous is about 3% but at some period of time in many patients over 50% of the breaths may be asynchronous!

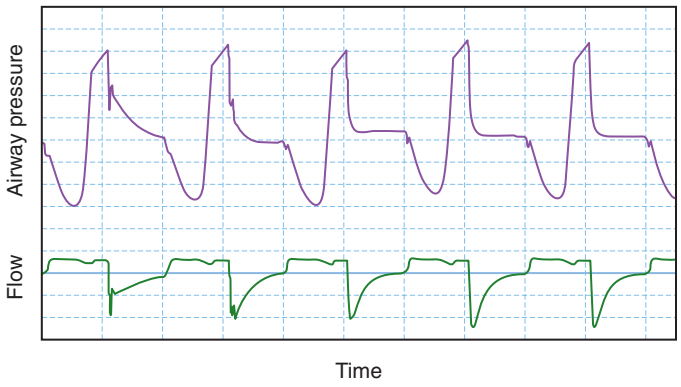
VARIABLES CONTROLLED DURING MECHANICAL VENTILATION

During spontaneous ventilation the individual has complete control over the process of gas movement into and out of the lungs. In health, normal breathing is a process that generally goes unnoticed; we breathe without conscious thought of breathing and without any effort. As we know from the equation of motion (discussed in detail in Chapter 46), all of the

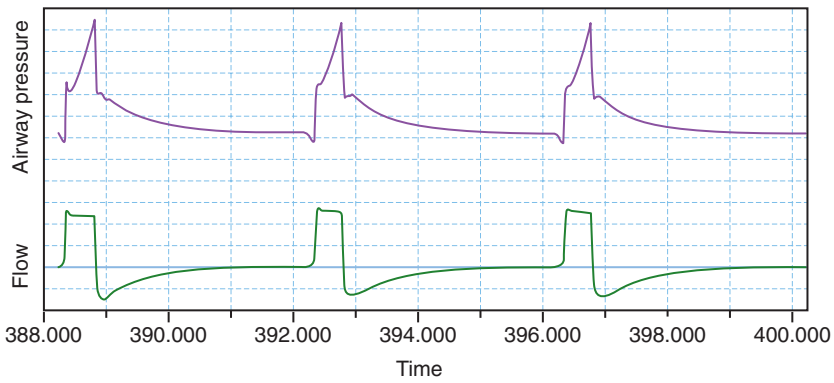
MINI CLINI

Assist/Control Volume Ventilation Square Wave

PROBLEM: Mrs. Jones, a 68-year-old with COPD, presented in the emergency department in an acute exacerbation. She was initially managed with noninvasive pressure support at 8 cm H_2O and 8 of PEEP. However, after 24 hrs she was intubated and mechanically ventilated in volume assist/control (A/C). She was started at a tidal volume of 300 ml (5 ml/kg PBW) with an inspiratory time of about 1.0 sec and a peak square wave flow of 20 L/min. Her PEEP level is set at 8 cm H_2O and F_IO_2 at 50%. Her SpO_2 is 90%, pulse 120/min, blood pressure 150/100, and respiratory rate 30/min. You study her airway pressure and flow waveforms and observe the following:



Solution: The shape of the airway pressure versus time curve would indicate that there is marked flow asynchrony. The airway pressure during triggering is below baseline for a considerable period of time and the rise in the airway pressure curve is concave and does not reach peak pressure until more than halfway through the inspiratory time. To try to correct this, peak flow should be increased to 50 l/min and the inspiratory time decreased to 0.6 sec. When this is done the following airway pressure and flow waveforms are obtained. These much more closely resemble the ideal waveforms during controlled ventilation.



work of breathing is provided by the individual in spontaneous breathing. During controlled ventilation the patient has absolutely no control over the process of ventilation. The ventilator moves gas into and out of the lungs based on how the clinician decides to set the mechanical ventilator. Thus, from the patient's perspective no active work is performed and no concern exists for coordination between what the respiratory center desires versus how the clinician sets the ventilator. Of course to achieve controlled ventilation the patient must be pharmacologically medicated to apnea. Assisted mechanical ventilation is very different from either spontaneous breathing or controlled ventilation. In this case the patient and the ventilator must intimately interact. Ideally the ventilator is set to meet the neurologic output from the respiratory center and there is no competition between the respiratory center and the ventilator. However, this is rarely achieved in critically ill patients. The percentage of breaths on average that are asynchrous is about 3% but at some time in many patients over 50% of the breaths are asynchronous.[7]

Generally, the more control exerted by the ventilator the greater the likelihood that the patient will be asynchronous. Remember that with the classic modes of ventilation the

TABLE 47-2

Variables Controlled During Mechanical Ventilation
Possible Variables Controlled: Pressure, Flow, Volume, and Time

Volume A/C	Volume Flow Time
Pressure A/C	Pressure Time
Pressure Support	Pressure
PAV and NAVA	None

ventilator leads and the patient must follow. Specifically, if the clinician sets the inspiratory time at 1.0 sec or the tidal volume at 400 ml this is what the patient must accommodate to. This accommodation is difficult and as a result asynchrony occurs. Depending on the mode of ventilation, the ventilator can control one or more of the following gas delivery variables: pressure, flow, volume or time (Table 47-2). The more variables controlled the greater the likelihood of asynchrony. Volume ventilation is the most controlling mode of ventilation because the ventilator in some way controls volume, flow, and time. The only variable the patient can control is pressure. As a result, the likelihood of asynchrony is greater with volume A/C than any other mode of ventilation. With pressure A/C the ventilator only controls pressure and time; less control means less likelihood of asynchrony. In pressure support only the pressure is controlled; thus, of all the classic modes of ventilation the mode that is least likely (if set properly) to cause asynchrony is pressure support. However, as is well documented in the literature,[14-17] **proportional assist ventilation (PAV)** and **neurally adjusted ventilatory assist (NAVA)** are the modes of ventilation that are least likely to cause asynchrony because they do not exert any control over the patient. These modes do not control pressure, flow, volume or time. What they do is provide a proportional assist based on patient demand (see Chapters 45 and 46). They do not require the patient to conform to the settings of the clinician, but instead they require the ventilator to follow the output of the respiratory center, and as a result the patient's respiratory center controls the ventilatory pattern—thus, less asynchrony.

Figure 47-3, modified from the original figure of Magdy Younes, depicts the response of different modes of ventilation to patient demand.[18] As noted, when patient demand (effort) increases in volume ventilation the ventilator provides less support, and an inverse relationship between patient effort and ventilator pressure is established. In pressure ventilation, when patient demand increases the ventilator support remains unchanged. However, in PAV and NAVA as patient effort increases ventilatory support increases, and as patient effort decreases ventilatory support decreases. Control is by the patient's respiratory center, creating greater synchrony than any other approaches to ventilatory support.

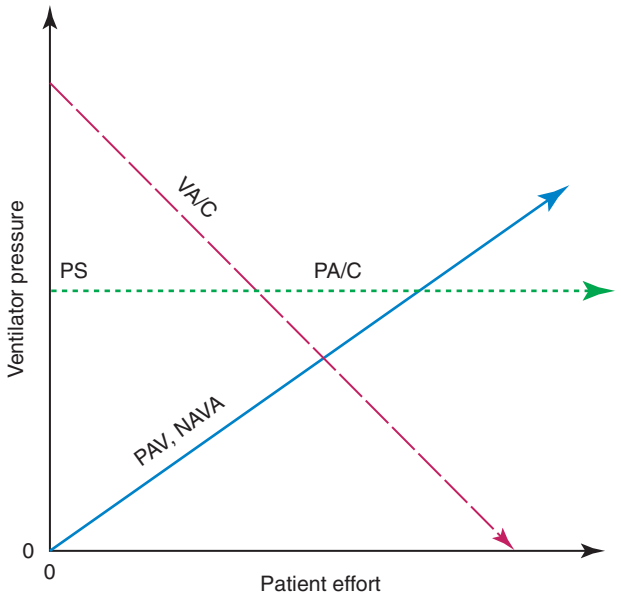


FIGURE 47-3 Relationship between ventilator pressure and patient effort during various forms of ventilatory support. During volume ventilation, there is always an indirect relationship between ventilator pressure and patient effort; the greater the patient effort, the less the ventilator pressure, and the greater the potential asynchrony. With pressure ventilation, airway pressure theoretically does not change as patient effort increases; there is equal ventilator work regardless of patient effort. During PAV and NAVA, ventilator pressure and patient effort are directly related. That is, as patient effort increases, ventilatory pressure increases. With PAV and NAVA, all the clinician sets is the distribution of effort between ventilator and patient. (Modified from Younes M: Proportional assist ventilation, a new approach to ventilatory support. Theory. Am Rev Respir Dis 145:114–117, 1992.)

RULE OF THUMB

The ventilator can control one or more of the following gas delivery variables: pressure, flow, volume, or time. The more of these variables controlled by the ventilator, the greater the likelihood of asynchrony.

TYPES OF ASYNCHRONY

Table 47-3 lists the types of asynchrony and the subcategories of **trigger asynchrony**. **Flow asynchrony** occurs when the flow from the ventilator does not match the flow demand of the patient.[19-21] This can occur in any mode of ventilation but most commonly occurs in volume ventilation because the clinician sets the tidal volume, peak flow, flow waveform, and inspiratory time. Thus, the patient's respiratory center must demand exactly the same gas delivery each and every breath or there will be flow asynchrony.

There are several forms of trigger asynchrony and each can occur in any mode of ventilation. The most common form of trigger asynchrony is **trigger delay**, in which the length of time between the beginning of neuro-inspiration and activation of

TABLE 47-3
Types of Asynchrony

Flow asynchrony	Inadequate flow at onset and during inspiration to meet patient demand	
Trigger asynchrony	Poor coordination of patient's initiation of inspiration and ventilator response	Trigger delay Double trigger Missed trigger Auto trigger Reverse triggering
Cycling asynchrony	Poor coordination of patient's desire to exhale and ventilator response	Inappropriately short inspiratory time Inappropriately long inspiratory time
Mode Asynchrony	Inappropriate mode

Inappropriate Mode of Ventilation	

the ventilator is excessive.[22] Under normal circumstances, trigger delay should not exceed 100 milliseconds to avoid patient perception of the delay and an increase in ventilatory drive.[23-25] Another common form of trigger asynchrony is **missed triggering**, in which the patient is unable to trigger the ventilator with each inspiratory effort. Frequently a pattern of missed triggering and triggering is established.[26] That is, for every 2 or 3 inspiratory efforts the ventilator is only triggered once.[27] **Double triggering** is usually a result of the patient's ventilatory center desiring a larger breath or a longer inspiratory time than is set on the ventilator.[28] This causes the patient to continue inspiration when the ventilator transitions into the expiratory phase, resulting in the ventilator triggering a second time. The biggest problem with double triggering is that there is no exhalation after the first breath, so that the actual delivered tidal volume may be up to double what is set on the ventilator. Double triggering is most common with volume A/C because of the precise setting of the tidal volume. **Autotriggering** is a much less frequent form of trigger asynchrony. It is the seemingly automatic triggering of the ventilator without any patient inspiratory effort.[29]

The most recently described from of trigger asynchrony is **reverse triggering**. With reverse triggering a controlled mechanical breath results in stimulation of the respiratory center, which then triggers the subsequent breath.[30,31] This form of asynchrony occurs only during controlled ventilation. Most of the other forms of asynchrony occur only during assisted ventilation.

Cycle asynchrony occurs when the ventilator ends the breath at a time different from when the patient's respiratory center wants to end the breath.[32,33,34] It is more common in pressure-targeted than in volume-targeted ventilation, but it can occur in all modes of ventilation. Cycle asynchrony is described in two forms: asynchrony that results in an inappropriately long inspiratory time and asynchrony that results in an inappropriately short inspiratory time.

Mode asynchrony is the selection of a mode of ventilation that simply is highly unlikely to meet a patient's inspiratory demand. As should be obvious from Table 47-2, during assisted ventilation it is most likely that mode asynchrony occurs with volume A/C, followed by pressure A/C, and then pressure support. It is least likely to occur with PAV and NAVA.

CAUSES OF ASYNCHRONY

Table 47-4 summarizes the major causes of asynchrony. Across all modes of ventilation, inappropriately set sensitivity, inappropriate selection of PEEP, and the presence of auto-PEEP result in asynchrony. The one exception to this is NAVA; because NAVA is controlled by the diaphragmatic EMG signal the presence of auto-PEEP does not affect the function of this mode.[35] All other modes are triggered by airway pressure, flow or volume and are dramatically affected by auto-PEEP. In volume ventilation, poor matching of the ventilator settings to the patient's ventilatory drive results in asynchrony. Specifically, inadequate peak flow and inadequate or excessive inspiratory time result in asynchrony. In pressure A/C or pressure support ventilation asynchrony is caused by inappropriately set rise time, inappropriately set inspiratory time (pressure A/C) or termination criteria (pressure support), and inadequate or excessive tidal volume. Finally, selection of an inappropriate mode can cause asynchrony (see Chapters 46 and 48).

RULE OF THUMB

Asynchrony is a result of inappropriate matching of the ventilator's settings and the patient's ventilatory demand or the presence of auto-PEEP.

FLOW ASYNCHRONY

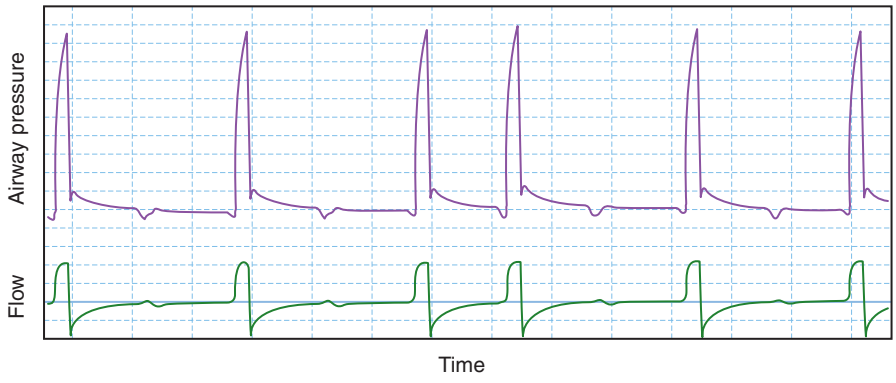
Volume Ventilation

Flow asynchrony can occur in any mode of ventilation but is more common in volume A/C because a precise flow pattern and peak flow is set, resulting in the selected tidal volume being delivered in a precise inspiratory time. This is not physiologic; with normal spontaneous breathing there is a large variability in the ventilatory pattern from breath to breath.

MINI CLINI

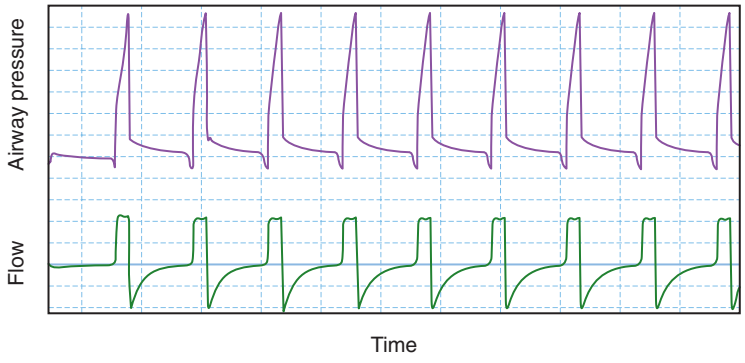
Assist/Control Pressure Targeted Ventilation

PROBLEM: Mr. Garcia is a 72-year-old patient with severe COPD who has been intubated and mechanically ventilated for the last 3 days. The ventilator is set with a PEEP of 5 cm H_2O, F_IO_2 of 0.4, and volume A/C tidal volume of 480 ml (6.5 ml/kg PBW). The ventilator respiratory rate is 18/min. The patient's pulse is 105/min, blood pressure 130/90, and SpO_2 92%. When you look at the ventilator you notice the following airway pressure and flow waveforms:



In addition, when you palpate the patient's diaphragm you note that the diaphragm is contracting at a rate of 36 times per minute with the ventilator only responding at a rate of 18 times per minute.

Solution: The expiratory flow does not return to baseline before the patient attempts to inspire. As a result, Mr. Garcia has auto-PEEP. The level must be fairly high since he is mistriggering at a ratio of two breaths to one ventilator-triggered breath. To correct this, either Mr. Garcia's tidal volume should be decreased or applied PEEP should be increased. Since his tidal volume is at 6.5 Ml/kg PBW it is unlikely that a further change will affect the level of auto-PEEP. Because he has dynamic airway obstruction from his severe COPD, adding PEEP to balance the auto-PEEP across the dynamic airway obstruction should decrease the pressure gradient to trigger the ventilator. PEEP should be increased in 1 to 2 cm H_2O steps until Mr. Garcia can trigger the ventilator with every inspiratory effort. At an applied PEEP level of 12 cm H_2O the mistriggering disappeared.



If a patient is spontaneously triggering the ventilator, peak flow delivery during volume ventilation should match the patient's inspiratory flow demand.[19-21] Most adult patients with moderate to strong ventilatory demands require a peak flow of 60 L/min or greater. As shown by Marini and colleagues,[19,20] if the peak flow does not meet the patient's inspiratory demand, the WOB performed by the patient increases (see Figure 47-4). In this setting, the efficiency of the work may be greater than during spontaneous breathing, but the overall patient work may be similar.[19,20] In volume ventilation, there is always an indirect relationship between the work provided by the ventilator and the patient's WOB (Figure 47-3). The more work the patient does, the less work the ventilator performs for the patient. If the patient is triggering the positive pressure breaths, the WOB is shared between the patient and the ventilator. For this reason, patients initially receiving assisted ventilation show altered gas delivery patterns after they are sedated to apnea. With the transition to controlled ventilation, the peak airway pressure usually increases during volume ventilation.[36] Because the patient no longer performs a portion of the WOB, the work performed by the ventilator must increase. The opposite is also true in volume ventilation when the patient's ventilatory demand is high—the

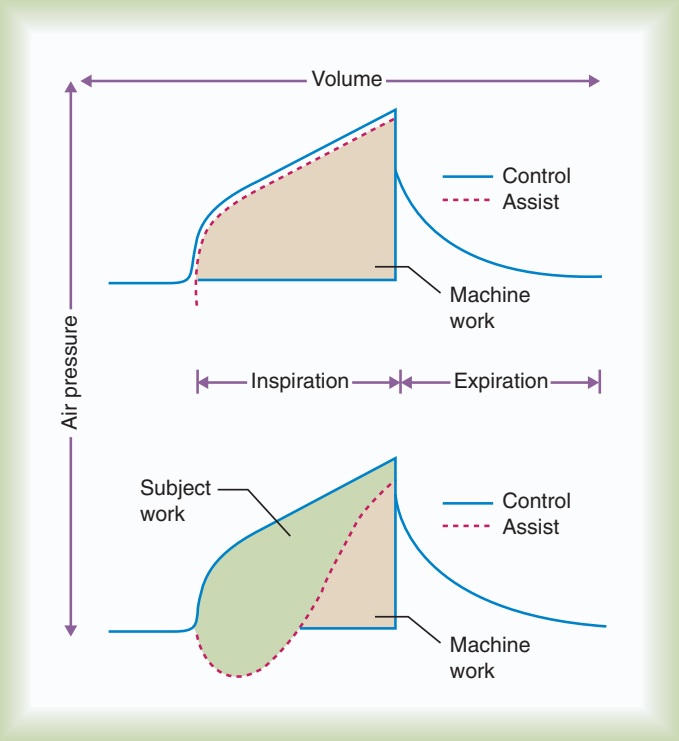


FIGURE 47-4 Plot of an ideal pressure-time waveform during volume-targeted ventilation *(top).* Plot of actual pressure-time curve *(dotted line)* is superimposed on the ideal curve *(bottom).* The scooped-out actual pressure waveform is evident. *Green area* reflects the work performed by the patient during assisted volume-targeted ventilation. This type of actual pressure waveform is indicative of inadequate peak inspiratory flow or too lengthy an inspiratory time. The peak flow should be increased, normally to between 60 L/min and 90 L/min to minimize patient effort during volume-limited ventilation. (Modified from Marini JJ, Rodriguez M, Lamb V: The inspiratory workload of patient-initiated mechanical ventilation. Am Rev Respir Dis 134:902, 1986.)

patient can be doing a disproportionate amount of work if the ventilator is not set to meet the patient's inspiratory demand.

Most ventilators during volume A/C can deliver gas flow in a decelerating or square wave flow pattern. If the patient is triggering inspiration, we recommend a decelerating flow pattern, especially when a small V_T is being delivered.[36,37] A decelerating flow pattern allows a high peak flow to be delivered but also ensures that the inspiratory time can be adequately set. In patients who are sedated and who are not triggering the ventilator, the choice of flow waveform is unimportant, and the setting of peak flow depends on the inspiratory time and V_T desired by the clinician.

If a patient is triggering every breath, the set inspiratory time should equal the patient's neuro-inspiratory time.[38] As illustrated in Figure 47-5, when the ventilator's inspiratory time is decreased to equal the patient's desired inspiratory time and peak flow is increased to match the patient's demand, the patient's WOB and effort correspondingly decrease (Box 47-2). This improvement in asynchrony can be performed without changing the tidal volume, as illustrated in Figure 47-5. A

Box 47-2 Flow Asynchrony: *Volume Ventilation*

To correct flow asynchrony:
- Change to decelerating flow
- Increase peak flow (>60 L/min)
- Match ventilator's inspiratory time to patient's inspiratory time
- Ensure that the airway pressure waveform is as similiar as possible to the ideal airway pressure waveform during controlled volume ventilation

patient with a moderate to high ventilatory demand rarely desires an inspiratory time greater than 1 second.[36] Many adults with moderate or high ventilatory demands desire an inspiratory time between 0.6 second and 0.9 second.[37] Carefully matching the ventilator's inspiratory time with the patient's inspiratory time generally markedly improves patient-ventilator synchrony.

In general, the airway pressure waveform during volume A/C ventilation should be similar to the airway pressure waveform during controlled ventilation (Figure 47-4). The greater the actual waveform differs from the ideal, the greater the patient WOB and the greater the asynchrony.[19,20] If the ventilator cannot be set to meet patient demand and all other potential causes of asynchrony have been ruled out, the patient will require sedation or a change in the mode of ventilation. In general, the mode should be changed before the patient is markedly sedated.

RULE OF THUMB

Flow asynchrony can occur in any mode of ventilation but is more common in volume A/C since a precise flow pattern and peak flow is set, resulting in the selected tidal volume being delivered in a precise inspiratory time.

Pressure Ventilation

Flow asynchrony occurs in pressure ventilation but it is less likely than in volume ventilation if the ventilator is set properly. All newer generation critical care ventilators include an inspiratory pressure **rise time** or pressure slope control. This control functions only with pressure-limited breaths (PSV, PCV, PRVC, volume support, airway pressure release ventilation, pressure SIMV). The purpose of this control is to adjust the rate at which flow increases from baseline to peak[38-40] (Figure 47-6). Generally, rise time should be set at a value that ensures adequate inspiratory gas flow (meeting or exceeding patient demand) without an excessive "overshoot" of the pressure at the beginning of inspiration. A slow or low rise time increases the patient's WOB[38-40] (Figure 47-7). If the rise time is inadequate to meet the patient's demand a concavity during the initial part of inspiration is noted, similar to what occurs in volume A/C with inadequate flow.[41] As in volume ventilation, the rise time should be set to ensure the actual airway pressure waveform matches the ideal airway pressure waveform (Box 47-3).

FIGURE 47-5 Airway pressure (P_{aw}), flow, volume, raw (R_{aw}) electromyographic activity of the diaphragm (E_{di}), integrated E_{di}, and muscular work of the diaphragm (P_{mus}) in volume ventilation during varying inspiratory flow and inspiratory time settings (columns *A, B, C, D, E*). As peak flow is increased and inspiratory time is decreased (left to right), indices of patient effort and work are decreased. Ideal settings of flow and inspiratory time generally can be identified by observing the airway pressure curve during volume ventilation. The closer the airway pressure curve is to the ideal curve (*D* and *E*), the less the patient's work. (From Fernandez R, Mendez M, Younes M: Effect of ventilator flow rate on respiratory timing in normal humans. Am J Respir Crit Care Med 159:710–719, 1999.)

Box 47-3 Flow Asynchrony: *Pressure Ventilation*

To correct flow asynchrony:
- Adjust rise time until the initial airway pressure rises rapidly without any concavity but does not exceed the set pressure at the beginning of inspiration
- If inadequate flow: initial concavity in airway pressure, increase rise time
- If excessive flow: initial airway pressure exceeds the set level, decrease rise time

RULE OF THUMB

Flow asynchrony can be greatly improved in volume ventilation by increasing peak flow and decreasing inspiratory time. In pressure ventilation flow asynchrony can be corrected by adjusting rise time.

TRIGGER ASYNCHRONY

As noted in Table 47-3, there are numerous types of trigger asynchrony and of these missed triggering is a common cause of asynchrony. However, the single most important variable affecting trigger asynchrony is the presence of auto-PEEP.

Auto-PEEP/Missed Triggering

As illustrated in Figure 47-8, auto-PEEP is a result of air trapped in the lung at the end of exhalation.[42] This is most commonly caused by dynamic airway obstruction[43] but it is also caused by the delivery of excessive minute ventilation/tidal volume.[44] In dynamic airway obstruction because of airways disease the structural integrity of the airways is compromised. A loss of smooth muscle causes the airway diameter to change from inspiration to expiration. During expiration the elastic recoil of the lung and thorax causes these damaged airways to at least partially collapse and in some cases totally collapse, trapping gas behind the obstruction or limiting flow to the point that at

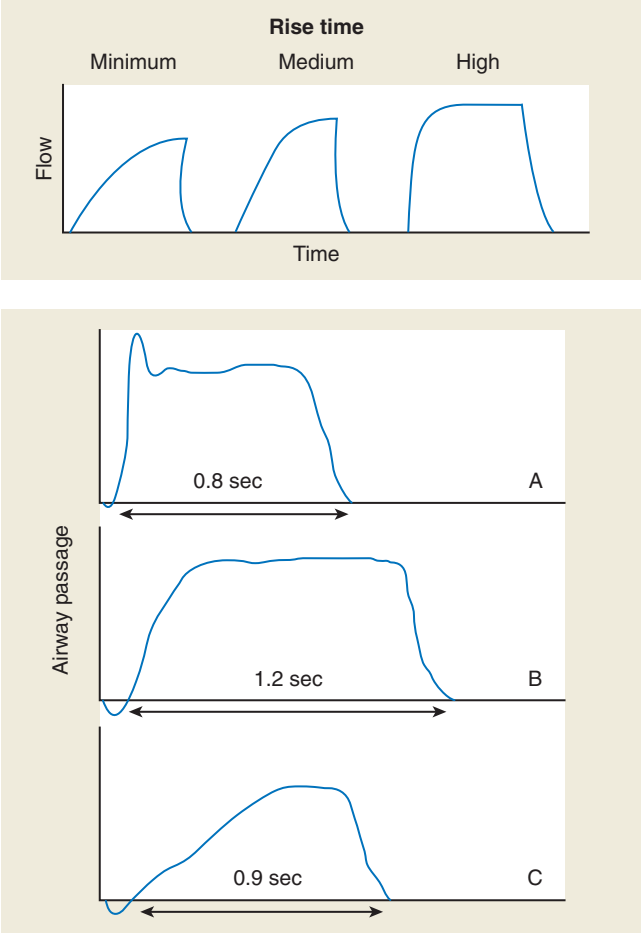

FIGURE 47-6 The effect of different rise time settings is illustrated. When rise time is adjusted the slope of the flow acceleration from zero to peak flow is altered. A slow rise time indicates that peak flow will not be achieved until sometime after the midpoint of the breath. A high rise time indicates that peak flow will be obtained early in the breath. A medium rise time is somewhere in between. The actual setting variation is manufacturer dependent.

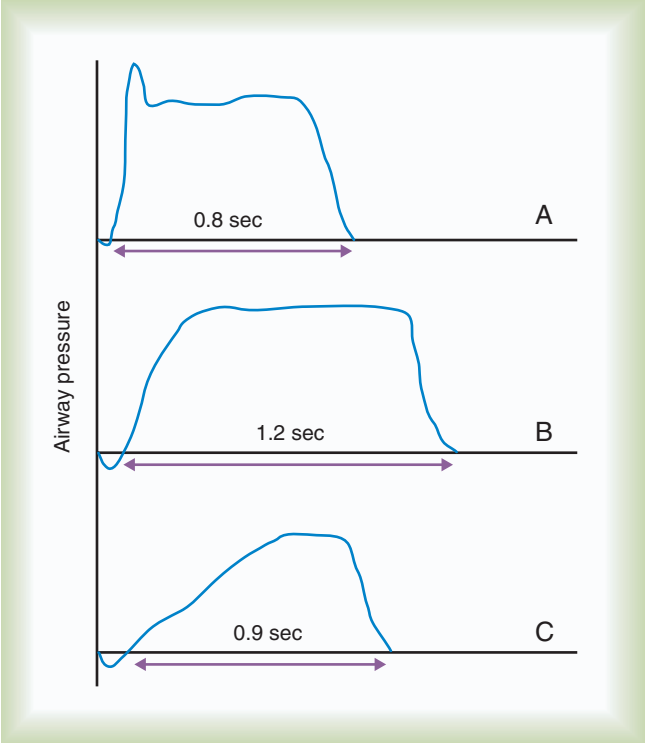

FIGURE 47-7 Effect of changing rise time during pressure-targeted breaths for a patient who prefers a moderate flow. *A,* Flow exceeds patient demand, and a pressure spike and short inspiratory time result. *B,* As flow is decreased, inspiratory time lengthens, and the pressure spike disappears. Machine output matches patient demand. *C,* When flow is reduced further, patient demand exceeds machine flow; the result is deformation of the pressure waveform and a decrease in inspiratory time. (Modified from Branson RD, Campbell RS, Davis K, et al: Altering flow rate during maximum pressure support ventilation [PSV_{max}]: effect on cardiorespiratory function. Respir Care 35:1056–1069, 1990.)

end-exhalation there is gas in the lung periphery under pressure or the presence of auto-PEEP.[42,43] The presence of auto-PEEP is not uniform. In some lung units no auto-PEEP is present, and in others there are varying levels of auto-PEEP. When auto-PEEP is measured it is the average level of auto-PEEP that is determined.

Auto-PEEP can develop in any patient who is mechanically ventilated if the minute ventilation/tidal volume is excessive and cannot be passively exhaled in the expiratory time defined by the respiratory center.[44] Auto-PEEP essentially has the same effect as applied PEEP but only in the lung units where auto-PEEP develops. In reference to asynchrony, auto-PEEP is the primary reason why missed triggering occurs. Essentially the patient cannot decompress the auto-PEEP with every inspiratory effort, and missed triggering occurs. In COPD patients auto-PEEP can be greater than 15 cm H_2O and frequently shows a pattern of 1 triggered breath to 1, 2, or 3 missed triggered breaths[27] (Figure 47-9).

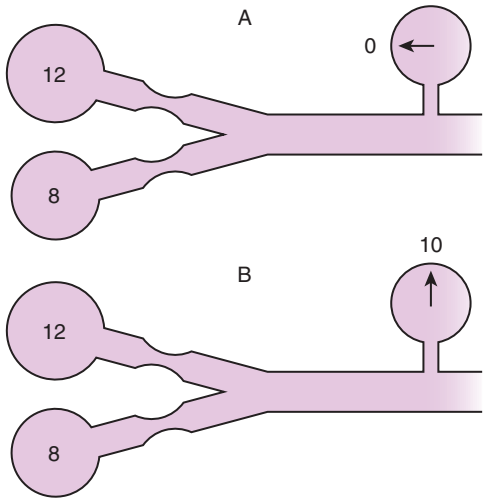

FIGURE 47-8 **A,** Shows two alveoli with different auto-PEEP levels and no end expiratory pause. **B,** Shows the same alveoli with an end expiratory pause. Note that in **A** the end expiratory pressure is zero since the system is open at end exhalation, while in **B** the average auto-PEEP level (10 cm H_2O) is indicated on the manometer because of the end expiratory pause.

RULE OF THUMB

The primary cause of missed triggering is auto-PEEP.

Applied PEEP has been advocated in the presence of auto-PEEP when the cause of the auto-PEEP is dynamic airways obstruction.[34] In this setting applied PEEP in the presence of auto-PEEP is indicated only if the patient has difficulty triggering the ventilator. Because the patient is spontaneously breathing, the measurement of auto-PEEP (end expiratory pause) is very difficult; the patient frequently forces exhalation, negating the measurement. The presence of auto-PEEP is generally indicated by the expiratory flow waveform (Figure 47-10) and the fact that there are missed triggered breaths. That is, the patient inspires but is unable to trigger the ventilator. In this case, PEEP is slowly applied in increments of 1 to 2 cm H_2O, rechecking the patient and ventilator response rate with each adjustment. When the patient is able to trigger the ventilator with each inspiratory effort, the PEEP level is set properly.[29] The exact auto-PEEP level may never be known in these patients; however, this is unimportant. What is important is that each patient effort triggers the ventilator. The literature indicates that if the amount of PEEP applied does not exceed approximately 80% of the measured auto-PEEP, the patient's lung mechanics are not affected by the application of PEEP.[45] Auto-PEEP should be rechecked to ensure intrinsic PEEP does not increase as PEEP is applied. Box 47-4 summarizes methods for minimizing the effects of auto-PEEP. An absolute contraindication to applied PEEP is an uncontrolled tension pneumothorax. However, PEEP should be cautiously applied in any patient with severe intrinsic lung disease, hypotension, and elevated intracranial pressure. During controlled ventilation, increasing PEEP simply because of the presence of auto-PEEP is not indicated.

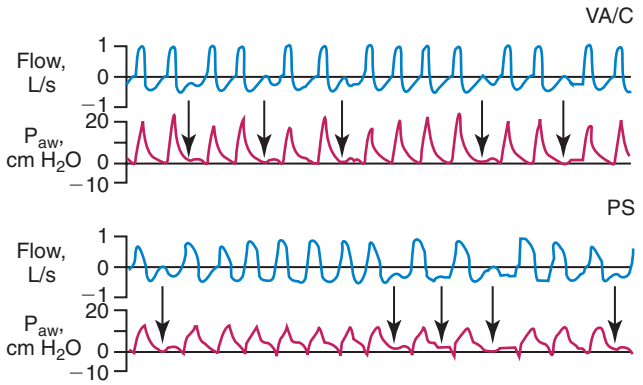

FIGURE 47-9 Airway pressure and flow waveforms during *VA/C* and pressure support *(PS)* ventilation in which frequent missed triggers are observed. (Modified from Leung P, Jubran A, Tobin MJ: Comparison of assisted ventilator modes on triggering, patient effort, and dyspnea. Am J Respir Crit Care Med 155:1387, 1997.)

RULE OF THUMB

In the presence of dynamic airways obstruction the application of PEEP offsets the effect of auto-PEEP on missed triggering.

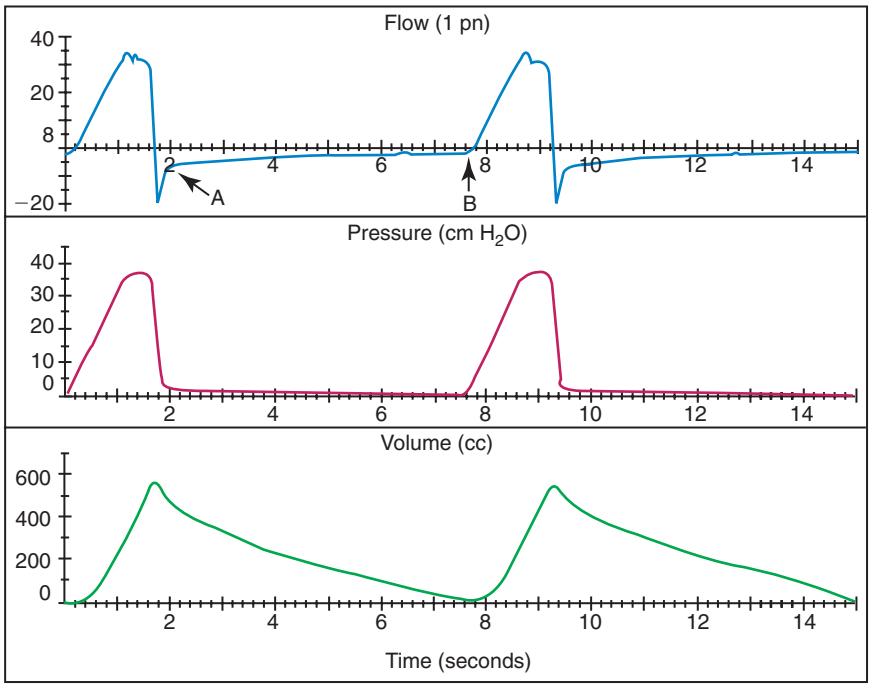

FIGURE 47-10 Airway flow, pressure, and volume in a patient with severe airflow obstruction and auto-PEEP. There is a rapid decrease in expiratory flow at the onset of exhalation because of the obstruction *(arrow A)*, and there is a lack of return of flow to baseline at the end of the breath *(arrow B)*. This type of expiratory flow pattern, regardless of the expiratory time, indicates auto-PEEP. The amount of auto-PEEP cannot be determined from this example, but anytime end expiratory flow is greater than zero, auto-PEEP is present.

In patients without intrinsic lung disease who develop auto-PEEP, dynamic airways obstruction is not present. Auto-PEEP is a result of excessive minute ventilation/tidal volume. Usually returning the tidal volume to the recommended 4 to 8 ml/kg PBW level eliminates the auto-PEEP and as a result the missed triggering.[44]

Box 47-4 Techniques for Minimizing Effects of Auto-PEEP

- Decrease airflow obstruction
- Secretion management
- Aggressive bronchodilation
- Larger sized endotracheal tubes
- Modify ventilatory pattern
- Decrease inspiratory time
- Increase inspiratory flow (on ventilators with inspiratory peak flow control)
- Decrease percentage inspiratory time (on ventilators with $\%T_i$ control)
- Decrease VT
- Increase expiratory time
- Decrease rate
- Use low-compressible volume circuit
- Apply PEEP or CPAP to balance auto-PEEP

Outside of auto-PEEP the only other factor that can result in missed triggering is inappropriately set sensitivity. In general, sensitivity should be set as sensitive as possible without causing autotriggering. Should flow or pressure sensitivity be used? With older generation ICU ventilators pressure sensitivity was less effective than flow sensitivity.[46,47] But in today's generation of ICU ventilators both function equivalently.[25] When both are set appropriately neither should be the cause of missed triggering.

RULE OF THUMB

Excessive minute ventilation/tidal volume in patients without dynamic airways obstruction results in auto-PEEP. Decreasing tidal volume to the 4 to 6 ml/kg PBW range generally eliminates the auto-PEEP.

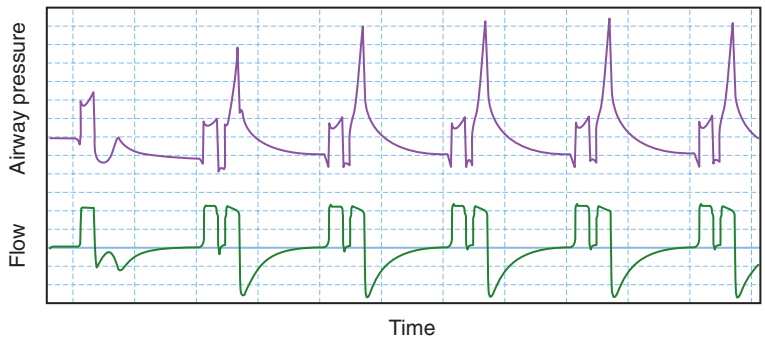
Trigger Delay

Trigger delay is caused by an inappropriately set sensitivity and auto-PEEP insufficient to cause mistriggering.[25,39] Normally the trigger delay should be minimal, less than 100 milliseconds. When it exceeds 150 milliseconds the cause should be determined. Adjusting the sensitivity, setting the tidal volume

MINI CLINI

Volume Targeted A/C Ventilation

PROBLEM: Mr. King is 54-year-old with acute pancreatitis who has developed ARDS. He is currently being ventilated in volume A/C mode with a tidal volume of 6 ml/kg PBW (400 ml). His respiratory rate is 26/min, inspiratory time is 0.5 sec. Gas is being delivered in a square wave flow pattern with a peak flow of 48 liters/min. The patient is tachycardic, pulse rate 118/min, blood pressure 138/98, and SpO_2 92%. Visual assessment of the patient's ventilatory pattern indicates he is using his accessory muscles with every breath. You observe the following waveform on the ventilator:



Solution: Assessment of the pressure and flow waveforms indicate that there is frequent double triggering. You have a number of choices on how to eliminate the double triggering: sedation, increasing the tidal volume to 8 ml/kg PBW, increasing the inspiratory time while changing the waveform to decelerating flow, changing to pressure support, or performing a number these changes. Changing to pressure support at a pressure level that maintains the tidal volume <8 ml/kg PBW may be the best option if the patient can maintain his ventilatory pattern. This would allow the patient to determine his tidal volume needs on a breath-by-breath basis. The tidal volume can simply be increased; this may work in some patients but in others the constant tidal volume may still be a problem. Inspiratory time can be increased with the waveform changed to decelerating flow and the tidal volume increased to 8 ml/kg PBW. This may also be a very viable option. Sedation is always the last choice and may not eliminate the double triggering until the patient is sedated to total apnea.

appropriately, and/or applying PEEP should correct delayed triggering unless there is a true malfunction of the ventilator (Box 47-5).

Autotriggering

Setting the sensitivity control to be overly sensitive will cause autotriggering. In addition, autotriggering can be caused by the movement of water accumulated in the ventilator circuit. The back and forth movement of fluid in the circuit can cause triggering of the ventilator. Leaks in the ventilator circuit are the most likely cause of autotriggering. The most easily missed cause of autotriggering is in the post–cardiac surgical patient who is in a hyperdynamic state.[29] The forceful contraction of the heart can trigger the ventilator. Careful assessment of diaphragmatic contraction and readjustment of the sensitivity setting are indicated (Box 47-6).

Box 47-5 Correcting Trigger Delay

Trigger delay is caused by:
- Auto-PEEP
- Poor sensitivity setting
- Ventilator malfunction

Correct by:
- Minimizing auto-PEEP
  - Apply PEEP
  - Decrease minute volume/tidal volume
  - Appropriately set sensitivity
  - Replace ventilator

Box 47-6 Autotriggering

Caused by:
- Circuit leaks
- Water in circuit
- Inappropriately set sensitivity
- Hyperdynamic cardiac contractions

Corrected by:
- New ventilator circuit
- Removal of water from the circuit
- Appropriate setting of sensitivity

Double Triggering

Double triggering most commonly occurs in volume A/C when the tidal volume delivered is less than the patient demands or the inspiratory time set on the ventilator is less than the neuroinspiratory time.[28] Double triggering is a problem because, as demonstrated in Figure 47-11, in most cases of double triggering there is no exhalation between the two breaths. Thus, the tidal volume during the double triggered breath is twice the set tidal volume. A patient with a lung protective tidal volume of 6 ml/kg PBW would periodically be receiving a tidal volume of 12 ml/kg PBW, which is clearly not a lung protective tidal volume.[48,49] Double triggering can usually be corrected by increasing the tidal volume (but not greater than 8 ml/kg PBW), increasing the inspiratory time, or changing from volume A/C to pressure A/C or pressure support.[48,49] If none of these changes eliminate the double triggering, sedation is indicated (Box 47-7).

RULE OF THUMB

Double triggering is most commonly observed in volume ventilation when the set tidal volume and inspiratory time are less than the patient's demand. Increasing tidal volume or inspiratory time, or changing to pressure-targeted ventilation can correct double triggering.

Reverse Triggering

Reverse triggering is a form of double triggering that occurs during controlled ventilation. It has primarily been described

Box 47-7 Double Triggering

Caused by:
- Inadequate tidal volume
- Short inspiratory time
- Inappropriate mode of ventilation

Corrected by:
- Increased tidal volume (≦8 ml/kg PBW)
- Increased inspiratory time to match patient's inspiratory time
- Mode changed to pressure support

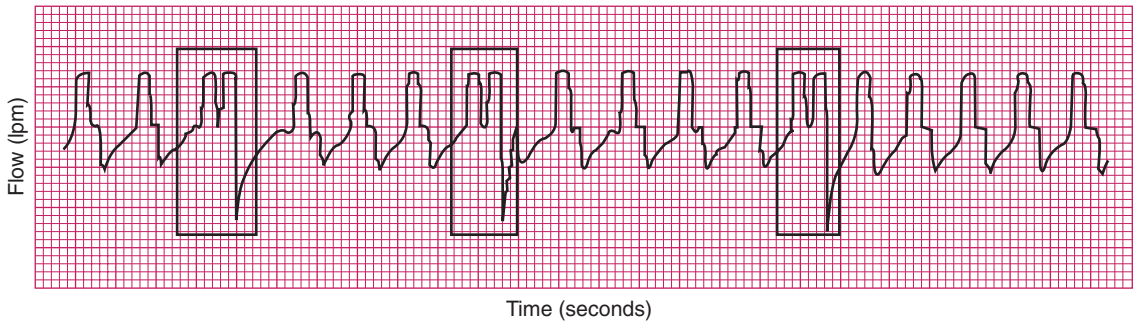


FIGURE 47-11 Double triggering in VA/C ventilation. (Modified from Pohlman MC, McCallister KE, Schweickert WD, et al: Excessive tidal volume from breath stacking during lung-protective ventilation for acute lung injury. Crit Care Med 36:3019–3023, 2008.)

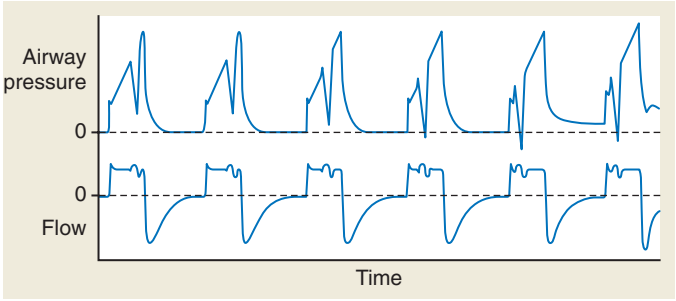

FIGURE 47-12 These waveforms illustrate reverse triggering. Note that the volume targeted breaths are all machine triggered, no patient effort. However, within each machine breath there is a patient inspiratory effort. Reverse triggering is the stimulation of a patient effort following a machine-controlled breath.

in patients with ARDS in which a controlled mechanical breath stimulates the respiratory center via stretch receptors to attempt a spontaneous breath.[30,31] The reverse trigger can occur in any mode of ventilation and can occur within the controlled breath or during the subsequent expiratory phase (Figure 47-12). Little is known about why reverse triggering develops or its effects on the patient, except that it can cause double triggering and the periodic delivery of excessive tidal volumes. If reverse triggering occurs, alteration of tidal volume or inspiratory time should be attempted. Since the patient is already sedated, sedation is not the solution. More research is needed to determine the potential harm of reverse triggering, its causes, and treatment.

CYCLE ASYNCHRONY

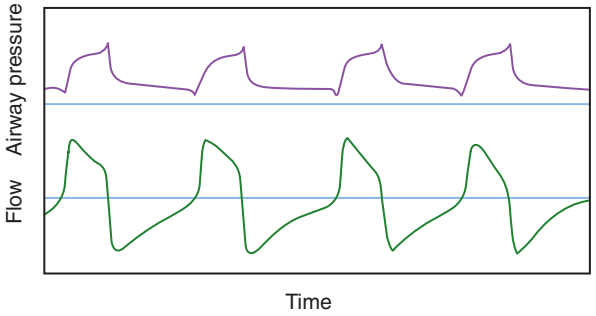
Cycle asynchrony is a result of a difference between the inspiratory time of the patient and the inspiratory time of the ventilator.[34] Thus, cycle asynchrony can result in excessively long inspiratory times (Figure 47-13) or excessively short inspiratory times (Figure 47-14). Theoretically, cycle asynchrony can occur in any mode of ventilation but is by far most commonly seen in pressure ventilation.[33] If the ventilator's inspiratory time is excessive compared to the patient's inspiratory time, a spike in pressure above the set level is commonly observed at the end of the pressure-targeted breath (Figure 47-13). If the ventilator inspiratory time is too short, a double trigger will occur every breath (Figure 47-14).

During pressure support cycle asynchrony can be corrected by adjusting the variable that terminates inspiration or the **expiratory cycling criteria**.[36,37] Normally, pressure support is terminated when the peak flow decreases to a predetermined level. Historically, this level was 25% of peak flow.[39] However, not all patients choose to terminate inspiration at this 25% setting (Figure 47-15). Patients with marked respiratory distress and patients with chronic pulmonary disease choose to end inspiration at high terminal flows.[33] In our experience, these patients require a termination criterion set at 50% or higher. Figure 47-16 depicts the problem encountered by patients if the termination criterion is set at a lower percentage than that at which the patient chooses to end inspiration; specifically, the patient's neuro-inspiratory time is shorter than the ventilator's inspiratory time.[33] When this happens, the patient activates accessory muscles of expiration to force the ventilator into exhalation. In Figure 47-16 abdominal muscles are activated midway through the ventilator inspiratory phase; that is, the patient starts to exhale in the middle of the ventilator's inspiratory phase. The clinician can identify that this is happening by an increase in the set pressure at the end of inspiration. This increase indicates that the breath is terminated by the pressure support secondary termination criterion, an increase in airway pressure above the

MINI CLINI

Pressure Support Ventilation

PROBLEM: Mrs. Gonzalez is a 68-year-old female with COPD presenting with an acute exacerbation. She has failed noninvasive ventilation and has been intubated and invasively ventilated in the pressure support mode. Her pressure support level is 12 cm H_2O with 8 cm H_2O PEEP delivering an average tidal volume of 6.5 ml/kg PBW (350 ml). F_IO_2 is 0.5 and respiratory rate is 28/min. She appears to be working hard to interact with the ventilator; she is using her accessory muscles to breath. Her SpO_2 is 90% and her blood gases are PO_2 59 mmHg, PCO_2 55 mmHg, with a pH of 7.34. You note the following pressure and flow waveforms on the ventilator.



Solution: The patient and the ventilator are not ending inspiration at the same time. The patient is choosing to begin exhalation during the pressure support breath. This is shown on the airway pressure waveform as an increase in the airway pressure at the end of the pressure support breath. In addition, upon palpation of the diaphragm you note that Mrs. Gonzalez is contracting her abdominal muscles during the inspiratory phase of the ventilator, trying to force exhalation. To correct this, the expiratory cycling criterion must be properly set. It is currently set at 25% of peak flow but needs to be set at a much higher percentage. You should slowly increase the expiratory cycling criterion until the airway pressure waveform does not show a spike in airway pressure at the end of the breath. To do this, slowly increase the expiratory cycling criterion in 5% increments, observing the effect on the airway pressure curve. The lowest percentage that eliminates the pressure spike is the correct setting. When set properly, the patient's respiratory rate should decrease and contraction of her abdominal muscles during inspiration should end.

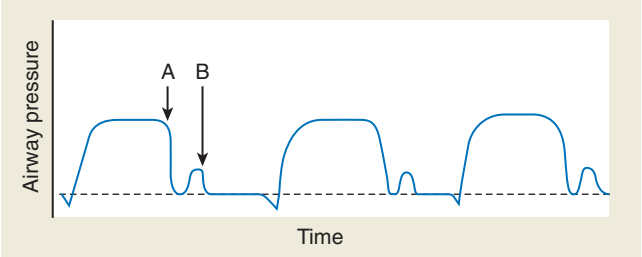


FIGURE 47-13 Cycling asynchrony in pressure ventilation is illustrated. In this figure the patient's inspiratory time is longer than the ventilator's inspiratory time. *A* indicates the end of the ventilator's inspiratory time, and *B* indicates the end of the patient's inspiratory time. To correct this the ventilator's inspiratory time must be increased to equal the patient's inspiratory time. In pressure support this is done by decreasing the percent cycle sensitivity and in pressure control breath by directly increasing the set inspiratory time.

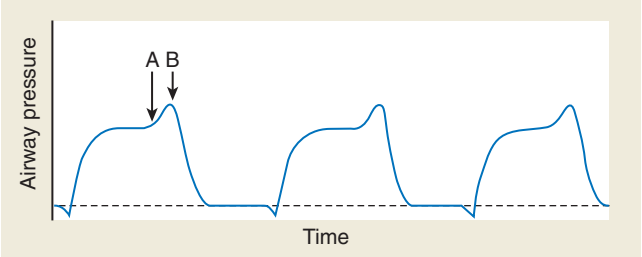

FIGURE 47-14 Cycling asynchrony in pressure ventilation is illustrated. In this figure the patient's inspiratory time is shorter than the ventilator's inspiratory time. *A* indicates the end of the patient's inspiratory time, and *B* indicates the end of the ventilator's inspiratory time. To correct this the ventilator's inspiratory time must be decreased to equal the patient's inspiratory time. In pressure support this is done by increasing the percent cycle sensitivity and in pressure control breath by directly decreasing the set inspiratory time.

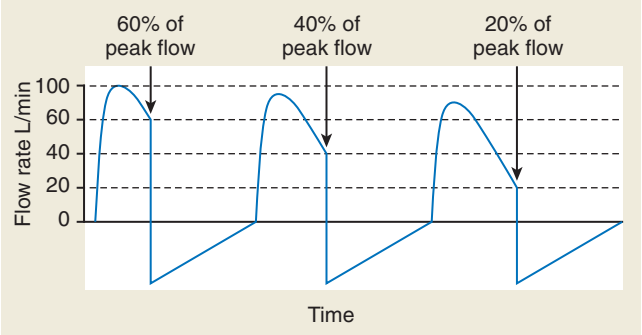

FIGURE 47-15 Function of cycling (termination) sensitivity (criterion). In all three breaths the peak flow is 100 liters/min. However, the first breath has the shortest inspiratory time, cycling criterion 60% (60% of peak flow). The middle breath has a longer inspiratory time, cycling criterion 40% (40% of peak flow). The last breath has the longest inspiratory time, cycling criterion 20% (20% of peak flow).

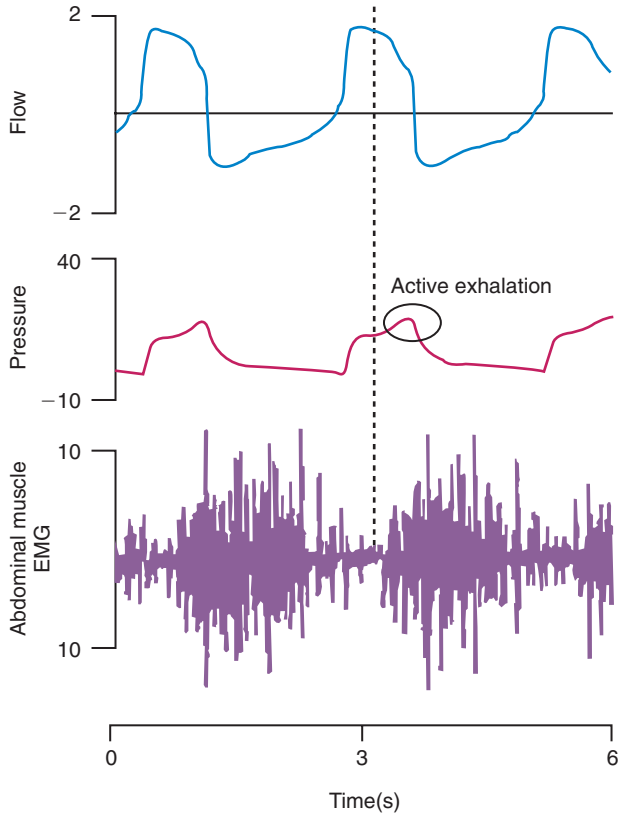

FIGURE 47-16 Airway flow, airway pressure, and abdominal muscle electromyographic (EMG) activity during pressure support ventilation with an inappropriately set termination criterion. *Dotted line* indicates the point where the patient initiates expiration. However, the ventilator does not cycle to exhalation until the spike in airway pressure *(circle)*. In this case, inspiration is cycled to exhalation by the ventilator's secondary cycling mechanism by an increase in airway pressure. Termination criterion should be increased until the spike in airway pressure is eliminated and the time at which the patient terminates the breath is equal to the time the ventilator terminates the breath. (From Parthasarathy S, Jubran A, Tobin MJ: Cycling of inspiratory and expiratory muscle groups with the ventilator in airflow limitation. Am J Respir Crit Care Med 158:1471–1478, 1998.)

set level. This level is ventilator-specific.[39] If the breath is ended by a spike in pressure, the termination criterion needs to be increased slowly until there is a smooth decrease in pressure. If the ventilator does not have the ability to adjust the termination criterion, the problem can be corrected by switching to PA/C. PA/C essentially operates during assisted breaths the same as PSV except that inspiration terminates at a set time.[33] If there is a spike in pressure at the end of a PA/C breath, the inspiratory time setting needs to be decreased until the spike disappears. In all other pressure modes inspiratory time or termination criteria can be adjusted to ensure patient and ventilator end the breath at the same time.

In patients with relatively healthy lungs if the termination criterion is set too high or inspiratory time too short, double triggering can occur every breath.[50,51] These are primarily postoperative patients or overdose patients (Figure 47-14). In these

Box 47-8 Cycle Asynchrony

Caused by:
- Pressure A/C or SIMV
  - Ventilator inspiratory time to short
  - Ventilator inspiratory time to long
- Pressure support
  - Expiratory cycling criteria percentage too high
  - Expiratory time criteria percentage too low

Corrected by:
- If ventilator inspiratory time too long
  - Decrease ventilator inspiratory time in pressure A/C or SIMV to eliminate the pressure spike at the end of the breath
  - Increase expiratory cycling criteria percentage so that the breath ends sooner, eliminating the pressure spike at the end of the breath
- If ventilator inspiratory time too short
  - Increase ventilator inspiratory time in pressure A/C or SIMV to eliminate the double tigger at the end of the breath
  - Decrease expiratory cycling criteria percentage so that the breath ends sooner, eliminating the double tigger at the end of the breath

patients the termination criterion is decreased until the double trigger is eliminated. As opposed to the patient with high ventilatory demand who requires a termination criteria of >50%, these patients frequently require the termination criteria be set at only 10% to 15%. In this setting, termination criterion is slowly decreased followed by careful assessment until the double triggering is gone. In pressure A/C and pressure SIMV where inspiratory time is set, inspiratory time is slowly increased until the double triggering is eliminated (Box 47-8).

RULE OF THUMB

Cycle asynchrony occurs most commonly in pressure ventilation when the patient's neuro-inspiratory time and the ventilator's inspiratory time are not equal.

MODE ASYNCHRONY

Mode asynchrony implies that an inappropriate mode of ventilation has been selected for a given patient. There are many biases regarding mode of ventilation and little data to support any relationship between mode and patient outcome. See Chapters 45, 46, and 48 for detailed discussion regarding modes of ventilation. However, it is increasingly clear that asynchrony is highest in volume ventilation because of its control over the variables associated with ventilation. Of all the classic modes of ventilation, pressure support is the least confining and should result in little asynchrony. PAV and NAVA, however, can be expected to result in the least asynchrony because those modes do not control any gas delivery variable and follow the patient's desires rather than dictating to the patient the required ventilatory pattern.[14-17] However, for clinicians to accept these modes of ventilation they must be willing to accept the resultant ventilatory pattern. Most patient's respiratory centers when experiencing respiratory distress/failure select a ventilatory pattern resulting in rapid shallow breathing, that is, tidal volumes in the 4 to 6 ml/kg PBW and respiratory rate >25/min. In spite of this pattern both PAV and NAVA have been shown to reduce asynchrony.[14-17]

The mode of ventilation that can be the most problematic is SIMV. This is because of the variation in ventilatory load between mechanical and spontaneous breaths (see Chapters 46 and 48 for details). As the percentage of the total spontaneous breaths increase, the work of breathing also increases, not only in the spontaneous breaths increase but also in the mechanical breaths.[52,53] Essentially, the respiratory center cannot distinguish between mechanical and spontaneous breaths once around 50% of the breaths are spontaneous, resulting in the same level of patient work exerted during both spontaneous and mechanical breaths.[52,53] This is a major reason why SIMV has been shown to be the mode least effective in weaning patients from ventilatory support.[54,55]

SUMMARY CHECKLIST

- Patient-ventilator interaction is not a problem during controlled ventilation because the patient is not interacting with the ventilator, but is always a major issue during patient-triggered ventilation.
- Poor patient-ventilator interaction has been associated with increased length of mechanical ventilation, length of ICU stay, need for a tracheotomy, and mortality.
- A change in patient status is commonly the reason for the development of poor patient-ventilator interaction.
- Artificial airway issues can cause marked changes in patient-ventilator interaction.
- The development of a pneumothorax or tension pneumothorax is a major cause of markedly deteriorating patient-ventilator interaction.
- Whenever there is an acute severe change in the ability to provide ventilatory support the three most probable causes are tension pneumothorax, airway obstruction, and right mainstem bronchus intubation.
- Malfunction of the mechanical ventilator can be a cause of poor patient-ventilator interaction but it is a high unlikely cause with today's mechanical ventilators.
- The four variables that can be controlled during classic modes of mechanical ventilation are pressure, flow, volume, and time.
- The less control exerted by the mechanical ventilator on the patient's ventilatory pattern, the less likely it is that the patient will develop patient-ventilator asynchrony.
- The general types of asynchrony are flow asynchrony, trigger asynchrony, cycle asynchrony, and mode asynchrony.
- Asynchrony can be caused by inappropriately set sensitivity, PEEP, flow, tidal volume, and inspiratory time.

- Flow asynchrony is a result of the flow provided by the ventilator being inadequate to match the patient's inspiratory demand.
- Trigger asynchrony can manifest as missed triggering, delayed triggering, autotriggering, double triggering, and reverse triggering.
- Missed triggering and delayed triggering are normally a result of auto-PEEP.
- Autotriggering is normally a result of circuit leaks or fluid moving back and forth in the ventilator circuit, but can also be caused by hyperdynamic contractions of the myocardium.
- Flow asynchrony is a result of the ventilator providing less flow then the patient's respiratory center requires.
- Mode asynchrony occurs when the selected mode of ventilation does not match the patient's ventilatory demands.
- Volume ventilation can be expected to cause the most asynchrony because it controls volume, flow, and time.
- Pressure support should result in the least asynchrony of the commonly used modes of ventilation.
- PAV and NAVA cause the least asynchrony because they do not force a ventilatory pattern but follow the ventilatory pattern selected by the patient.

CHAPTER 48

Initiating and Adjusting Invasive Ventilatory Support

ROBERT M. KACMAREK

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the goals of ventilatory support.
- Describe how to choose an appropriate ventilator to begin ventilatory support.
- Explain how to select an appropriate mode of ventilation given a patient's specific condition and ventilatory requirements.
- Choose appropriate initial ventilator settings, based on patient assessment.
- Describe how to assess a patient after initiation of ventilation.
- Discuss how to adjust ventilatory support based on oxygenation and ventilation status.
- Discuss how to ventilate using the concept of lung protective ventilation.
- Explain how to adjust the ventilator on the basis of the patient's response.

CHAPTER OUTLINE

KEY TERMS

assist/control volume ventilation
controlled ventilation
full ventilatory support
high-frequency oscillatory ventilation (HFOV)
lung protective ventilatory strategy
neurally adjusted ventilatory assist (NAVA)
partial ventilatory support
plateau pressure (P_{plat})
pressure-controlled ventilation (PCV)
pressure-regulated volume control (PRVC)
pressure support ventilation (PSV)
proportional assist ventilation (PAV)
synchronized intermittent mandatory ventilation (SIMV)
transpulmonary pressure
volume-controlled ventilation
volume support

Mechanical ventilation entails the use of sophisticated life-support technology aimed at maintaining tissue oxygenation and removal of carbon dioxide (CO_2). At its most basic level, mechanical ventilation supports or replaces the normal ventilatory pump, moving air into and out of the lungs. The primary function of a mechanical ventilator is simply to ventilate. The main indication for mechanical ventilation is inadequate or absent spontaneous breathing.

Mechanical ventilation is not without risk, and the complications and hazards can be life-threatening. The decision to initiate mechanical ventilatory support is a serious one that requires sound clinical judgment and a clear understanding of the various approaches to ventilatory support. This chapter reviews and describes the initial set-up of the ventilator. After ventilator initiation, adjustments in ventilatory support are made on the basis of the patient's response. Techniques for patient stabilization; methods for optimizing oxygenation, ventilation, and acid-base balance; and methods for minimizing harmful side effects are described.

GOALS OF MECHANICAL VENTILATION

The goals of mechanical ventilatory support are to maintain adequate alveolar ventilation and oxygen (O_2) delivery, restore acid-base balance, and reduce the work of breathing (WOB) with minimum harmful side effects and complications.[1] Mechanical ventilation also may reduce increased myocardial work secondary to hypoxemia and an increased WOB.[1] Other physiologic objectives of mechanical ventilatory support include increasing or maintaining lung volume with positive end expiratory pressure (PEEP) and continuous positive airway pressure (CPAP) for promotion, improvement, or maintenance of lung recruitment.[1]

A **lung protective ventilatory strategy** is an approach to mechanical ventilation that includes the use of small tidal volume (V_T) and appropriate levels of PEEP.[2] This approach was first described in patients with acute lung injury (ALI) or the acute respiratory distress syndrome (ARDS). However, the concept of lung protection should be applied to all patients requiring ventilatory support for acute respiratory failure. Lung injury is primarily caused by an elevated transpulmonary pressure during positive pressure ventilation.[3] **Transpulmonary pressure** is the difference between alveolar pressure and pleural pressure. A safe transpulmonary pressure during mechanical ventilation is not firmly established, but most clinicians would agree that the lower the transpulmonary pressure, the less likely the development of ventilator-induced lung injury.[4] On a theoretical basis, Chiumello et al. arguing from the perspective of stress and strain applied to the lungs during ventilatory support, identify 27 cm H_2O as the maximum transpulmonary pressure without increasing the risk of significant lung injury.[4] Thus, most recommend that plateau pressure should be maintained ≤28 cm H_2O. See Chapter 51 for a discussion of esophageal and transpulmonary pressure measurements. High transpulmonary pressures are associated with alveolar overdistention and lung injury.[3]

Plateau pressure (P_{plat}), the end inspiratory equilibration pressure, measures the mean peak alveolar pressure and is the best bedside clinical reflection of transpulmonary pressure.[2,4,5] Although P_{plat} is not an accurate measurement of transpulmonary pressure, the transpulmonary pressure during controlled ventilation never exceeds the P_{plat}.[4] P_{plat} provides an excellent bedside assessment of the level of potentially dangerous ventilating pressure. Limiting P_{plat} reduces the likelihood of ventilator-induced lung injury. Generally, the lower the P_{plat}, the better the patient outcome.[2,5] Ideally, P_{plat} should be less than 28 cm H_2O.[5] However, a P_{plat} greater than 28 cm H_2O may be applied in patients with a decreased thoracic compliance without resulting in overdistention[5] because a decrease in chest wall compliance (obesity, massive fluid resuscitation, abdominal distention, elevated bladder pressure) increases the pleural

pressure, decreasing the transpulmonary pressure. Generally, the lowest possible P_{plat} is maintained by selecting a V_T of 4 to 8 ml/kg of ideal body weight (IBW). The higher the P_{plat}, the smaller the V_T should be. Generally, V_T greater than 10 ml/kg IBW is never indicated in critically ill patients.

Lung injury can also be caused by repetitive opening and closing of unstable lung units.[6] The application of an appropriate level of PEEP ensures that unstable lung units are maintained in the open position reducing the likelihood of additional lung injury.

Driving pressure, the difference between the peak airway pressure and PEEP has been recently linked to mortality. It has recently been demonstrated that driving pressures greater than 15 cm H_2O increase mortality.[8] Thus, the keys to lung protection are:

1. Transpulmonary pressure ≤27 cm H_2O; this usually corresponds to a plateau pressure of ≤28 cm H_2O unless there is a decrease in chest wall compliance.
2. A driving pressure of <15 cm H_2O.
3. A tidal volume of 4 to 8 ml/kg of IBW.
4. A PEEP set to avoid derecruitment during exhalation.

Specific clinical objectives of mechanical ventilation include reversal of hypoxemia, hypercapnia, and associated respiratory acidosis and prevention or reversal of ventilatory muscle dysfunction. The general trajectory of pH, PCO_2, and PO_2 during the progression of acute respiratory failure is depicted in Figure 48-1. Mechanical ventilation may be used to allow sedation or paralysis for certain procedures, to decrease myocardial and ventilatory muscle O_2 consumption to maximize O_2 delivery to the tissues, to decrease intracranial pressure acutely in the presence of closed head injury or cerebral edema (by reducing $PaCO_2$ to 25 to 30 mm Hg for a short period and promoting cerebral vasoconstriction), to prevent or reverse atelectasis, and to stabilize the chest wall in the case of a massive flail or chest wall resection. Table 48-1 lists the most common causes of acute respiratory failure leading to ventilatory support in the United States and Canada. Hazards of mechanical ventilation include decreased venous return and cardiac output, patient-ventilatory asynchrony, and ventilatory muscle dysfunction owing to inappropriate ventilator settings, ventilator-associated pneumonia, and ventilator-induced lung injury.[1] Box 48-1 lists the goals of ventilatory support, and Box 48-2 lists specific objectives of mechanical ventilation.

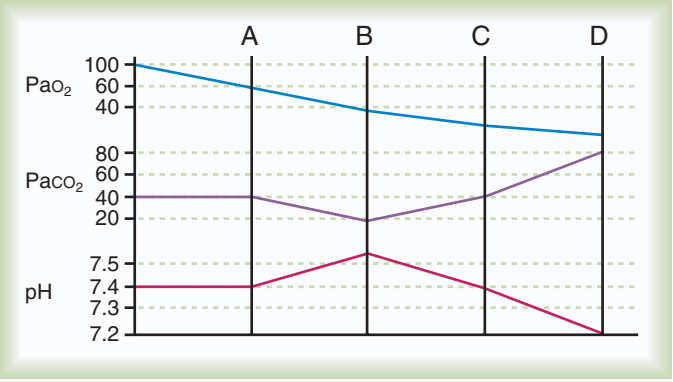

FIGURE 48-1 Typical progression of acute respiratory failure. Initially, there is a decline in arterial O_2 tension and saturation. When PaO_2 decreases to approximately 60 mm Hg *(A)*, the patient begins to breathe more, $PaCO_2$ decreases, and pH increases. Early in the progression, arterial blood gas results show acute alveolar hyperventilation (uncompensated respiratory alkalosis) secondary to hypoxemia. As the patient's condition worsens, increases in ventilatory workload typically lead to the adoption of a rapid, shallow breathing pattern; although minute ventilation may remain high, effective ventilation decreases, $PaCO_2$ begins to increase, and pH begins to decrease *(B)*. At point *C,* arterial blood gas results may show normal $PaCO_2$ and pH with moderate to severe hypoxemia. If mechanical ventilation is not initiated, the patient's condition may progress to acute ventilatory failure, severe hypoxemia, and corresponding severe respiratory acidosis *(D)*.

TABLE 48-1

Most Common Causes of Acute Respiratory Failure Requiring Mechanical Ventilation in the United States and Canada

Condition	Rank	Percentage
Postoperative respiratory failure	1	17
Sepsis	1	17
Other	2	16
Heart failure	3	13
Pneumonia	3	13
Trauma	3	13
ARDS	4	9
Aspiration	5	3

Modified from Esteban A, Anzueto A, Alia I, et al: How is mechanical ventilation employed in the intensive care unit? An international utilization review. Am J Respir Crit Care Med 161:1450, 2000.

Box 48-1 Physiologic Goals of Ventilatory Support

- Support or manipulate gas exchange
- Maintain alveolar ventilation ($PaCO_2$ and pH)
- Maintain arterial oxygenation (PaO_2, SaO_2, SpO_2, CaO_2, and DO_2)
- Increase end expiratory lung volume, functional residual capacity (FRC)
- Reduce or manipulate WOB
- Minimize cardiovascular impairment
- Ensure patient-ventilatory synchrony
- Avoid ventilator-induced lung injury

Box 48-2 Specific Clinical Objectives of Ventilatory Support

- To reverse hypoxemia
- To reverse acute respiratory acidosis
- To prevent or reverse atelectasis
- To reverse ventilatory muscle dysfunction
- To decrease systemic or myocardial O_2 consumption
- To maintain or improve cardiac output
- To reduce intracranial pressure
- To stabilize the chest

VENTILATOR INITIATION

When the decision to begin mechanical ventilatory support is made, one must choose the mode of ventilation, select an appropriate device, and establish the initial ventilator settings. In the selection of initial ventilator settings, the goal is to optimize the patient's oxygenation, ventilation, and acid-base balance, while avoiding harmful side effects. This goal is achieved by choosing an appropriate mode of ventilation, fractional inspired oxygen (FiO_2), V_T (volume ventilation) or pressure level (pressure ventilation), rate, peak flow and flow waveform, inspiratory time, and PEEP level. Appropriate trigger sensitivity, pressure limit, alarms, backup ventilation, and humidification must be selected. After initial ventilator setup, adjustments must be made on the basis of the patient's response and the patient-specific clinical objectives of ventilatory support. Most patients who need mechanical ventilatory support receive invasive positive pressure ventilation; however, an increasing number of patients are being ventilated noninvasively (see Chapter 49). Next, the clinician must choose the mode of ventilation (e.g., volume assist/control [VA/C], pressure assist/control [PA/C], pressure support ventilation [PSV], **pressure-regulated volume control [PRVC]**, **volume support**, adaptive support ventilation, **proportional assist ventilation [PAV]**, or **neurally adjusted ventilatory assist [NAVA]**) and initial ventilator settings (e.g., rate, V_T or pressure level, FiO_2, PEEP). Finally, the clinician must choose appropriate alarm and apnea settings. Box 48-3 summarizes key decisions that must be made as a part of initial ventilator setup.

Box 48-3 Initial Ventilator Setup

Initial ventilator setup includes the following key decisions:
- Noninvasive vs. invasive ventilation
- Type and method of establishment of an airway
- Partial vs. full ventilatory support
- Choice of ventilator
- Mode of ventilation
- Assist/control ventilation (volume vs. pressure) vs. SIMV (with or without pressure support)
- Pressure support
- Other newer modes and adjuncts to ventilation

Next, the clinician must consider key ventilatory values:
- Trigger method (pressure or flow trigger) and sensitivity
- V_T (volume ventilation) or pressure level (pressure support and PA/C)
- Rate
- Inspiratory flow, inspiratory time, expiratory time, or I:E ratio
- Inspiratory flow waveform
- FiO_2
- PEEP

Last, the clinician must choose appropriate alarm and backup values:
- Low-pressure, low PEEP alarms
- High-pressure limit and alarm
- Volume alarms (low V_T/high V_T, high and low minute ventilation)
- High rate and low rate alarms
- Apnea alarm and apnea ventilation values
- High/low O_2 alarm
- High/low temperature alarm
- I:E ratio limit and alarm

Noninvasive Ventilation

Although more than 75% to 80% of all patients receiving ventilatory assistance receive it invasively, the use of noninvasive ventilation should be considered in select patients requiring ventilatory assistance. Noninvasive ventilation is preferred in some patients because the outcomes are better. Chapter 49 provides details on all aspects on noninvasive ventilation.

Establishment of the Airway

Conventional mechanical ventilatory support requires the establishment of an artificial airway. Initially, nearly 100% of patients receiving positive pressure ventilation are intubated, and of these, 99% have oral endotracheal tubes, and only about 1% are intubated nasally.[7] Approximately 5% to 10% of patients receiving mechanical ventilation have a tracheotomy performed at some point.[7] Airway management is described in detail in Chapter 36.

Pressure-Controlled Versus Volume-Controlled Ventilation

The next decision to be made regarding initiation of mechanical ventilation is whether to use a primarily pressure-targeted or volume-targeted mode of ventilation. Volume-targeted ventilation essentially includes VA/C and synchronized intermittent mandatory ventilation (SIMV). Pressure ventilation includes PA/C, SIMV, PRVC, volume support, and airway pressure release ventilation. In addition, the clinician can select the patient-controlled modes PAV or NAVA. However, most patients are initially ventilated with pressure or volume forms of ventilation. The operational capabilities of these modes are described in detail in Chapter 45, and the indications, benefits, and concerns regarding these modes are discussed in Chapter 46.

Full Ventilatory Support Versus Partial Ventilatory Support

Full ventilatory support can be defined as the application of mechanical support such that all or most of the energy necessary for effective alveolar ventilation is provided by the ventilator.[9] When a ventilator is set to deliver full ventilatory support, the patient is either passive or simply triggers the breath to initiate inspiration allowing the ventilator to perform most of the work of breathing. However, it is very difficult to set the ventilator to assume all of the work of breathing without significantly sedating the patient. In most patient-triggered approaches to ventilatory support, patient-ventilatory synchrony is a major issue, and very careful titration of the ventilator settings is necessary to ensure synchrony and minimize patient WOB. See Chapter 47 for details on patient-ventilatory synchrony.

Partial ventilatory support implies that only a percentage of the WOB is provided by the ventilator.[9] Normally, when partial ventilatory support is indicated, SIMV, PSV, volume support, PAV, and NAVA are the modes of choice. However, as

with full ventilatory support, care in setting the ventilator is critical to ensure that patient-ventilator synchrony is maximized. Partial ventilatory support strategies minimize the loss of ventilatory muscle function, require less sedation, assist in recruiting and stabilizing alveolar units, and generally move patients closer to ventilator discontinuance than full ventilatory support approaches.

Choice of a Ventilator

After the decision is made to initiate mechanical ventilator support, the clinician must select an appropriate ventilator. This decision should be guided by considering the features, modes available, pressure and flow capabilities, alarms and monitoring systems included, and reliability. However, the most important feature is the clinician's familiarity with the equipment. Only a ventilator with which the clinician is totally familiar with every feature should ever be used.

INITIAL VENTILATOR SETTINGS

Initial ventilator settings are chosen based on the patient's clinical presentation and the need to provide full or partial ventilator support.

Choice of Mode

Most modern critical care ventilators include VA/C, PA/C, SIMV, and PSV and many of the newer modes of ventilation. However, some modes of ventilation are found only on a specific type of ventilator, such as PAV PB 840 and PB 980 (Covidien-Nellcor, Boulder, Colorado), adaptive support ventilation and Intellivent Hamilton ventilators (Hamilton Medical, Bonaduz, Switzerland), NAVA Servo-i ventilator (Maquet, Inc, Wayne, New Jersey), and SmartCare Draeger ventilators (Draeger Medical, Inc, Telford, Pennsylvania).

Assist/Control Ventilation (Patient-Triggered or Time-Triggered Continuous Mandatory Ventilation)

Assist/control ventilation can be delivered in either pressure-targeted or volume-targeted ventilation. Suggested initial settings for **assist/control volume ventilation** in the care of adults are listed in Box 48-4. Advantages of assist/control volume ventilation include the assurance that a minimum safe level of ventilation is achieved, yet the patient can still set his or her own breathing rate. In the event of sedation or apnea, a minimum safe level of ventilation is guaranteed by the selection of an

MINI CLINI

Selecting Initial Ventilator Settings

PROBLEM: A 52-year-old man, 5 ft 10 in (178 cm) tall and weighing 200 lb (91 kg), is being returned from the operating room after coronary artery bypass surgery. He is being manually (bag-tube) ventilated with supplemental O_2 by the anesthesiologist en route to the ICU. He is apneic at this time. The patient has no history of lung disease and has never smoked cigarettes. Heart rate and blood pressure are stable, and SpO_2 during manual ventilation is 99%. What initial mode, V_T, rate, and FiO_2 should the RT select when starting ventilatory support for this patient?

Solution: The patient is apneic at this time but is likely to resume spontaneous breathing as the anesthetic wears off and sedation is reduced. Because the patient is expected to resume breathing spontaneously, volume ventilation or pressure ventilation in assist/control or SIMV is appropriate.

Initial V_T and rate should be selected to provide full ventilatory support. Generally, initial V_T of approximately 6 to 8 ml/kg IBW or pressure control setting to establish this V_T with a rate of 12 to 20 breaths/min provides an adequate starting minute ventilation for most adult patients. The formulas for estimating IBW are:

$$\text{IBW in kilograms (men)} = [106 + 6(H - 60)]/2.2$$
$$\text{IBW in kilograms (women)} = [105 + 5(H - 60)]/2.2$$

where H is height in inches.

For this patient:

$$\text{IBW} = [106 + 6(70 - 60)]/2.2 = 75.5\ \text{kg}$$

On the basis of IBW of 75.5 kg, initial V_T can be set at about 450 ml. Initial inspiratory flow should be set at 60 L/min with a decreasing ramp flow waveform to achieve an inspiratory time of approximately 0.8 second. Initially, rate can be set at 12/min. Because the patient has a normal respiratory system and it is usual to return from the operating room with a below-normal body temperature, a low initial control rate is indicated. Trigger sensitivity (assist/control or SIMV) should be set so that minimal patient effort triggers the ventilator without autocycling.

Initial FiO_2 should be set at 1.0, but because of the patient's history and the presence of normal lung function, it is expected that it will be reduced rapidly as the patient recovers. Initial PEEP is set at 5 cm H_2O. If the SIMV mode is chosen, PSV should be started at 10 cm H_2O and adjusted as needed when the patient resumes spontaneous breathing.

In summary, appropriate initial ventilator settings for this patient are:

Mode: Assist/control (volume or pressure) or SIMV (volume or pressure) with PSV
V_T: 6 ml/kg, 450 ml
f_{mach}: 12 breaths/min
PSV: 10 cm H_2O (SIMV mode only)
FiO_2: 1.0 followed by immediate assessment and SpO_2 observation with titration downward as indicated
Inspiratory flow and time: 60 L/min, decreasing ramp, inspiratory time approximately 0.8 second
Pressure limit: Adjust to 10 to 15 cm H_2O above PIP after patient connection
Humidification: Heated humidifier to achieve temperature >35° C at the airway or an appropriate HME

Box 48-4 Typical Values for Ventilator Initiation for Adults Receiving Volume or Pressure Assist/Control Ventilation

- Trigger sensitivity: –0.5 to –1.5 cm H_2O or 1 to 2 L/min set to minimize trigger work without autocycling
- V_T: Volume ventilation 6 to 8 ml/kg IBW; pressure ventilation, pressure level to achieve 6 to 8 ml/kg IBW
- Rate: Backup rate of ≥12 to 14 breaths/min if providing assisted ventilation
- Inspiratory flow: Volume ventilation 60 to 80 L/min to achieve inspiratory time of approximately <1 second and I:E ratio of ≤1:2; inspiratory flow ≥80 L/min may be required to meet or exceed the patient's spontaneous inspiratory flow demand
- Flow waveform volume ventilation: Decreasing ramp
- Inspiratory time pressure ventilation: <1.0 second
- PEEP: 5 cm H_2O
- Pressure limit: Start at 30 to 40 cm H_2O depending on approach (volume 40 cm H_2O, pressure 30 cm H_2O) and adjust after patient connection to 10 to 15 cm H_2O above PIP
- Humidification: Begin with heated humidifier to provide temperature 35° C at the airway connection or appropriate HME

Box 48-5 Advantages and Disadvantages of Pressure-Controlled Ventilation

ADVANTAGES

- Variable flow results in square pressure waveform and improves gas distribution
- Ensures that P_{plat} cannot exceed set pressure control level
- All alveoli are placed under the same sustained inspiratory pressure, which decreases hyperinflation of more compliant alveoli compared with volume ventilation square wave flow
- Sustained inspiratory pressure may result in more alveolar recruitment
- Improved gas distribution allows for lower V_T
- Lower PIP is achieved compared with that achieved with volume ventilation with a square flow waveform

DISADVANTAGES

- Higher mean airway pressure can decrease venous return and decrease cardiac output if preload is inadequate
- V_T varies depending on lung compliance, resistance, and patient effort
- If V_T or minute ventilation alarms are not set properly, alveolar hypoventilation and acidosis may not be detected

appropriate backup rate, usually approximately 4 to 6 breaths/min less than the patient's assist rate but not less than the rate necessary to provide a minimum safe level of ventilation (e.g., a backup rate of at least 12 to 14 breaths/min).[9]

Because assist/control ventilation usually provides full ventilatory support, it may result in less WOB than partial support modes. However, less WOB should not be assumed just because the patient is in assist/control ventilation. Trigger work may be significant if inappropriate sensitivity settings are selected. In addition, when a breath is triggered, inspiratory muscle activity persists.[10,11] If the inspiratory flow rate during volume ventilation does not meet or exceed the patient's inspiratory demand, or inspiratory time is too lengthy, the patient's WOB may be greater or equaling the work of a spontaneous unassisted breath.[10,11] In pressure ventilation, lengthy inspiratory times, inadequate rise time, and improperly set pressure levels can also cause asynchrony (see Chapter 47).

If properly applied and tolerated by the patient, assist/control ventilation may provide ventilatory muscle rest that allows the ventilatory muscles to recover from ventilatory muscle dysfunction. Disadvantages of assist/control mode include an increase in WOB if not applied properly.[9,12] Assist control also may be poorly tolerated by awake, nonsedated patients. The patient may fight the ventilator, or asynchronous patient-to-ventilator breathing patterns may develop. Because flow is based on patient demand in pressure-targeted ventilation, synchrony is generally better achieved during PA/C than with VA/C ventilation. Advantages and disadvantages of **pressure-controlled ventilation (PCV)** are described in Box 48-5.

Assist/control volume ventilation is the most common ventilator mode used throughout the world as the primary initial mode of ventilatory support.[7,13] Regardless of the indication for ventilatory support or underlying disease, this mode is able when properly adjusted and the patient is properly managed to provide adequate ventilatory support for all indications for ventilatory support.[6,13]

Controlled Ventilation (Time-Triggered Continuous Mandatory Ventilation)

Controlled ventilation, pressure or volume, is achieved using the assist/control mode when the patient is apneic because of a medical condition, anesthesia, or use of sedative drugs and paralytic agents. Ventilators in use today do not prevent a patient with sufficient effort from triggering the ventilator, a situation always to be avoided. Controlled ventilation can be achieved only with pharmacologic agents. Advantages of controlled ventilation include eliminating WOB and complete control over the patient's ventilatory pattern. In cases in which WOB is high, controlled ventilation may allow for ventilatory muscle rest, reduce O_2 consumption of the ventilatory muscles, and "free up" O_2 for delivery to the tissues.[9]

Controlled ventilation is a common initial approach in situations of severe acute respiratory failure, especially if the primary problem is hypoxemia. Figure 48-2 depicts the effects of inspiratory time on V_T during controlled ventilation. Disadvantages of controlled ventilation include the need for sedatives and perhaps paralytic drugs. All patients given paralytic drugs must be sedated adequately because paralysis does not alter the patients' perception of their surroundings. All patients' senses are active; none are affected by paralysis; only voluntary muscles are paralyzed. In addition, in the care of apneic patients, ventilator malfunction or disconnection can lead to death.

Synchronized Intermittent Mandatory Ventilation

Synchronized intermittent mandatory ventilation (SIMV) may be used as a means of providing partial or full ventilatory support.[9] With SIMV, the machine breath may be volume or pressure targeted; in adults, it is typically a volume-targeted

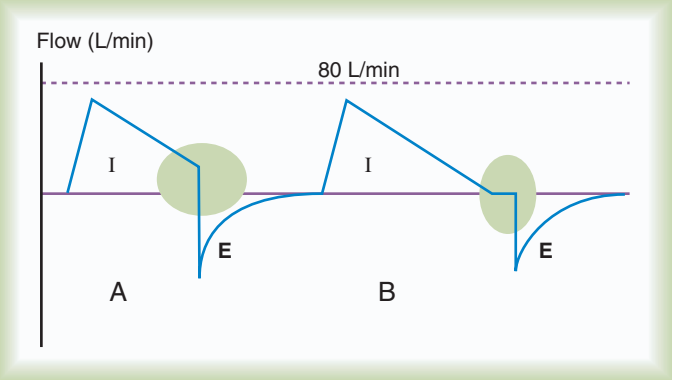

FIGURE 48-2 Flow versus time waveform during PCV. *Curve A* shows a flow pattern during controlled ventilation in which inspiratory time is inadequate to ensure maximum V_T has been delivered. During inspiration, flow does not decrease to zero before exhalation occurs, so the preset pressure has not equilibrated to that in the lung. *Curve B* shows an increase in inspiratory time from *curve A*. Inspiratory flow reaches zero maximizing V_T delivery and allows the preset pressure to equilibrate in the lungs. Exhaled V_T is greater for *curve B* than for *curve A* despite the pressure setting not changing.

breath. SIMV often is combined with pressure support to overcome the imposed work of breathing (WOB_I) during spontaneous breathing owing to the artificial airway. SIMV allows the clinician to vary the amount of support provided from minimal to full ventilatory support. Disadvantages of SIMV include possible development of respiratory muscle dysfunction, especially in patients with rapid, shallow spontaneous breathing patterns; acute hypoventilation with use of low rates if patients do not continue to do their share of breathing; and an increase in WOB secondary to lack of ventilatory support during spontaneous breaths unless pressure support is applied.[9] SIMV also delays weaning compared with spontaneous breathing trials or pressure support.[14,15] The advantages and disadvantages of assist/control and SIMV modes are summarized in Table 48-2. Outside of the United States, SIMV is an infrequently used mode of ventilation because of the above-mentioned problems.

TABLE 48-2

Advantages and Disadvantages of Synchronized Intermittent Mandatory Ventilation

Advantages	Disadvantages
Lower mean airway pressure may result than is achieved with assist/control ventilation	SIMV with PSV may increase mean airway pressure
Ventilatory muscle activity, strength, and coordination are maintained	Ventilatory muscle fatigue may occur
Level of support to maintain adequate levels of alveolar ventilation is easy to titrate	Acute hypoventilation may occur, especially with lower machine rates (<8-10 breaths/min)
Weaning protocols are easy to apply	Weaning is prolonged
Spontaneous breathing, which is physiologic, is incorporated	Addition of pressure support often is required to overcome WOB_I
Patients tend not to hyperventilate and may not fight the ventilator, as they may do with assist mode	Patients may have difficulty adjusting to the ventilator; breath stacking is possible with intermittent mandatory ventilation
Sedation or paralysis is not required, as it is in control mode	Patients may experience or continue a rapid, shallow breathing pattern or continue to make spontaneous breathing efforts during delivery of a "machine breath"
Full or partial ventilatory support and level of support can be titrated according to patient's need	Patient's workload increases considerably when SIMV rate decreases to approximately 50% of full ventilatory support value

Pressure Support Ventilation

Pressure support ventilation (PSV) assumes minimal control over the patient's ventilatory pattern. Specifically, only the level of pressure applied is controlled by the ventilator, and all other aspects of gas delivery are controlled by the patient. However, PSV is very similar to PA/C. The primary difference is that in PSV flow terminates the breath, whereas in PA/C time terminates the breath. Other than this, PA/C has a backup rate, and with pressure support an apnea mode of ventilation is set.[16] PSV can reduce work of breathing and may improve patient-ventilator synchrony by placing more control with the patient.[17] Many clinicians use PSV simply to overcome WOB imposed by the artificial airway.[17] The PSV level needed to overcome WOB_I may be estimated as follows:

$$PSV = \frac{(PIP - P_{plat}) \times \dot{V}_I \text{ spontaneous}}{\dot{V} \text{ ventilator}}$$

where PSV is the pressure support level needed to overcome WOB_I, PIP is the peak inspiratory pressure during a volume-control machine breath, P_{plat} is the plateau pressure after an inspiratory pause (usually >1 second), $\dot{V}_I$ is the patient's spontaneous peak inspiratory flow (L/sec), and $\dot{V}$ ventilator is the ventilator peak inspiratory flow rate (L/sec) with a square wave inspiratory flow waveform. An example of the calculations for PSV needed to overcome WOB_I is presented in Box 48-6.

PSV can and is increasingly being used as a primary mode of ventilation. PSV is essentially the only mode of ventilation used during noninvasive ventilation. It is also an acceptable mode of ventilation for any patients capable of triggering ventilatory support who have an intact ventilatory drive. Many clinicians use this mode in the initial phases of ventilatory support and following the most acute phase of ventilatory failure. The actual PSV level needed is based on the desired V_T. PSV is adjusted to ensure the desired V_T is delivered, and rise time and termination criteria are set to avoid asynchrony. Few clinicians at the present time attempt to calculate PSV level based on the previously listed formula.

High-Frequency Oscillatory Ventilation

High-frequency oscillatory ventilation (HFOV) is the primary approach to high-frequency ventilation used in adults. Respiratory rates range from about 3 Hz (180/min) to about 8 Hz

Box 48-6 Calculation of Pressure Support Ventilation Level Needed to Overcome Imposed Work of Breathing and during Synchronized Intermittent Mandatory Ventilation

- Machine delivered V_T during VA/C: 450 ml
- Machine inspiratory flow rate: 50 L/min (1 L/sec)
- Flow pattern: Square wave
- PIP: 25 cm H_2O
- P_{plat}: 23 cm H_2O
- Patient's spontaneous inspiratory flow rate: 30 L/min (0.5 L/sec)

$$PSV = \frac{(PIP - P_{plat}) \times \dot{V}_1 \text{ spontaneous}}{\text{Ventilator inspiratory flow}}$$
$$= \frac{(40 - 30 \text{ cm } H_2O) \times 0.5 \text{ L/s}}{1 \text{ L/s}}$$
$$= \frac{10 \text{ cm } H_2O \times 0.5 \text{ L/s}}{\text{L/s}} = 5 \text{ cm } H_2O$$

(480/min), and very small V_T, often approaching anatomic dead space, is delivered.[18] Gas transport during HFOV is due to conventional bulk flow, longitudinal (Taylor) dispersion, pendelluft, asymmetric velocity profiles, cardiogenic mixing, or enhanced molecular diffusion.[18] Although high-frequency ventilation has been shown to be safe and effective in maintaining oxygenation and ventilation in various patients,[18-20] HFOV has not been shown to be superior to conventional ventilation. In fact, two recent randomized controlled trials indicate that HFO in adults may negatively affect outcome.[21,22] In one of these trials those ventilated with HFO had a higher mortality than patients managed with conventional ventilation.[21] The primary setting where HFOV has been used is in the treatment of ARDS.

Initial Choice of Mode

Most patients who need mechanical ventilation in the acute care setting initially are managed with volume or pressure ventilation in the assist/control mode or with PSV.[7,13] SIMV may also be used, but it has no advantage over these modes, and it has considerable disadvantages. However, there is no evidence suggesting any of the modes are more beneficial in terms of patient outcomes except that weaning is delayed with SIMV.[14,15] Consequently, the choice of initial ventilator mode is primarily one of clinician preference and patient tolerance. Once the patient is stabilized on a ventilator mode, decisions can be made regarding the use of other, newer modes of ventilation, such as PRVC, volume support, adaptive support ventilation, PAV, or NAVA.

RULE OF THUMB

For most patients, begin mechanical ventilatory support with VA/C, PA/C, or PSV. When the patient is stabilized, other modes of ventilation can be considered.

Tidal Volume and Rate

V_T and machine rate should be chosen concurrently because these are the two major determinants of minute ventilation. Normal spontaneous V_T for unstressed adults is on average 6.3 ml/kg IBW (approximately 5 to 7 ml/kg IBW) with a respiratory rate of 12 to 18 breaths/min establishing a minute ventilation of approximately 100 ml/kg IBW per minute.[23] In the past, the Radford nomogram was used to estimate V_T and rate on the basis of estimated body weight (Figure 48-3). In modern practice, acceptable V_T for mechanical ventilation usually ranges from 4 to 8 ml/kg IBW,[1,5] V_T larger than 8 ml/kg IBW is harmful in patients with ALI/ARDS[2,24,25] and is mostly harmful to any patient in acute respiratory failure regardless of the cause of the failure.

Generally, regardless of mode, an initial V_T of 6 to 8 ml/kg IBW with a rate of 12 to 16 breaths/min is suggested for patients without acute restrictive disease.[5,26] After initiation of ventilation, the P_{plat} can be assessed, and V_T can be adjusted downward, as needed, for maintenance of a P_{plat} less than 28 cm H_2O and driving pressure less than 15 cm H_2O. A smaller initial V_T (4 to 6 ml/kg IBW) is appropriate for patients with ALI/ARDS[2,23,24] and a high P_{plat} and is usually necessary in patients with severe acute asthma. Table 48-3 lists V_T values for men and women according to calculated IBW.

RULE OF THUMB

When starting ventilatory support for most adult patients, use an initial V_T of 6 to 8 ml/kg (IBW) and a respiratory rate of 12 to 16 breaths/min.

V_T times rate (f) determines minute ventilation ($\dot{V}_E$). As a rule, for adult patients, the resultant minute ventilation should be approximately 100 ml/kg IBW per minute.[9] A 70-kg adult (IBW) would have a minute ventilation of approximately 7000 ml/min. Patients with elevated CO_2 production ($\dot{V}CO_2$) or increased physiologic dead space (V_{Dphys}) need a larger minute ventilation to maintain acceptable $PaCO_2$. Minute volume should be increased by increasing the rate, not the V_T.

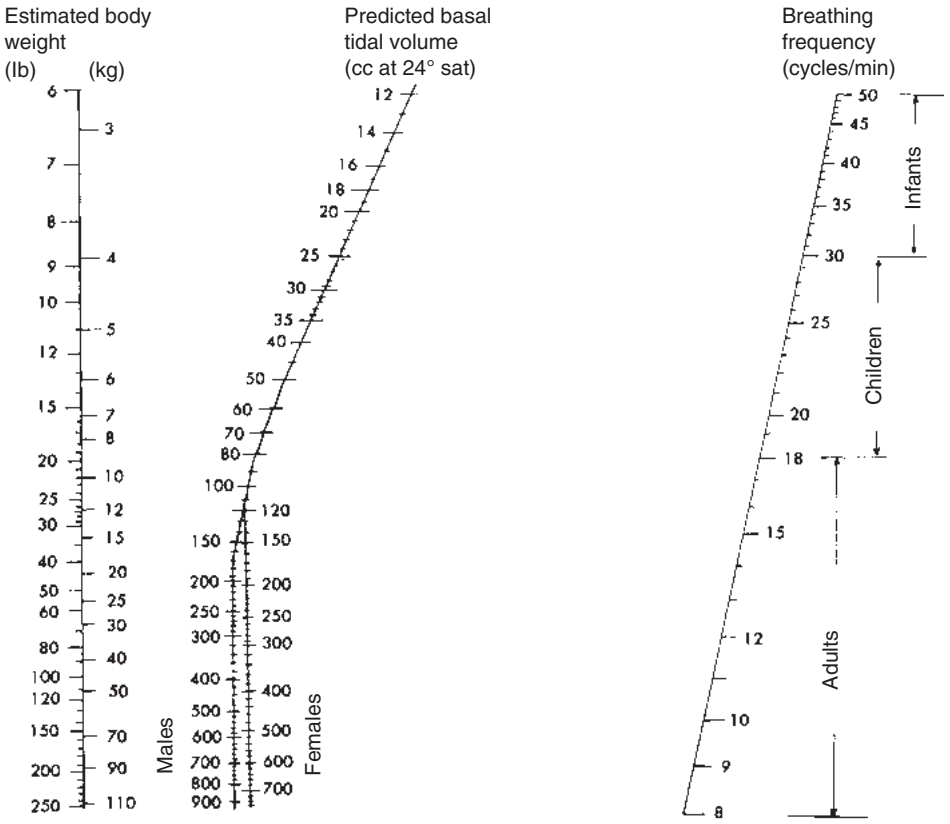
In SIMV, the total minute ventilation is composed of spontaneous tidal volume (V_{Tsp}), spontaneous rate (f_{sp}), machine tidal volume (V_{Tmach}), and machine rate (f_{mach}). For SIMV, total minute ventilation ($\dot{V}_{E\,TOT}$) is described as follows:

$$\dot{V}_{E\,TOT} = \dot{V}_E \text{ machine} + \dot{V}_E \text{ spontaneous}$$

and

$$\dot{V}_E = (V_{Tmach} \times f_{mach}) + (V_{Tsp\text{-}average} \times f_{sp})$$

For PA/C or PSV, the delivered V_T depends on the pressure limit, the inspiratory time, and the patient's lung mechanics. Generally, the pressure limit is increased or decreased to achieve a target V_T while a P_{plat} of less than 28 cm H_2O and a driving pressure less than 15 cm H_2O is maintained. A good initial pressure setting is to start at 10 cm H_2O (above baseline pressure) and observe the resulting V_T. Pressure is increased or decreased



Corrections of predicted basal tidal volumes.

For patients not in coma: add 10%

Fever: add 5% for each °F above 99 (rectal)
add 9% for each °C above 37 (rectal)

Altitude: add 5% for each 2000 feet above sea level
add 8% for each 1000 meters above sea level

Intubation: subtract volume equal to one-half body weight in pounds
subtract 1 cc/kg of body weight

Dead space: add equipment dead space

FIGURE 48-3 Radford nomogram. Although first published in 1955, normal resting V_T can still be accurately predicted using this nomogram. (Modified from Radford EP Jr: Ventilation standards for use in artificial respiration. J Appl Physiol 7:451–460, 1955.)

to achieve the desired volume. As with VA/C, minute ventilation with PA/C is simply rate multiplied by V_T ($\dot{V}_E = f \times V_T$). Recommended initial V_T and frequency for various patient types are described in Table 48-4.

Patients with ALI/ARDS may need lower V_T to avoid further lung injury and a higher rate to maintain effective alveolar ventilation while P_{plat} is maintained less than 28 cm H_2O and driving pressure less than 15 cm H_2O. Results of multicenter studies suggest V_T of 4 to 8 ml/kg IBW for patients with ARDS.[2,23,24] Machine rates of 25 to 35 breaths/min may be needed in patients with ALI/ARDS to maintain adequate minute ventilation. Box 48-7 summarizes the ARDS Clinical Network guidelines for initial ventilator setup.[2]

Trigger Sensitivity

Trigger sensitivity should be set at the most sensitive level avoiding autotriggering to minimize trigger work and missed triggering. With flow triggering, the trigger should be set at 1 to 2 L/min, and with pressure triggering, the range is generally −0.5 to −1.5 cm H_2O. However, because of pin holes in disposable ventilator circuits, the sensitivity may need to be adjusted to 3 or 4 L/min or −2 cm H_2O to avoid autotriggering. The increased use of ventilator graphics packages has led to the recognition that patients' inspiratory efforts often are insufficient to trigger the ventilator.[9] Factors that can prolong ventilator response time include large V_T, low trigger sensitivity, auto-PEEP, high bias circuit flow, and abdominal paradox (Box 48-8) (see Chapter 47).

Many ventilators offer the option of a pressure or a flow trigger. With older generation intensive care unit (ICU) ventilators, flow triggering offered slightly lower trigger work than pressure triggering,[27-29] although the gain in terms of the patient's total WOB was slight. Newer ventilators with fast pressure-triggering capabilities are as sensitive as flow-triggered

devices.[30,31] However, no triggering mechanism can reduce the WOB that is a result of auto-PEEP. Auto-PEEP must be addressed by other means (see Chapter 47). Flow-trigger settings vary by ventilator. Generally, for flow triggering, the trigger flow should be set 1 to 2 L/min below baseline or bias flow.

Inspiratory Flow, Time, and Inspiratory-to-Expiratory Ratio for Volume Ventilation

Most modern critical care ventilators allow the clinician to select peak flow, V_T, and rate *or* inspiratory time (or percentage inspiratory time, V_T, and rate). For most adults, an initial inspiratory time of approximately 0.8 second (range 0.6 to 1.0 second) with a resultant inspiratory-to-expiratory (I:E) ratio of 1:2 or lower is a good starting point. This value corresponds to an initial peak flow setting of approximately 60 L/min (range 40 to 80 L/min) and a down ramp or square flow waveform. Higher flow (≤100 L/min) may improve gas exchange in patients with chronic obstructive pulmonary disease (COPD).[10]

Inspiratory flow rate should be adjusted to ensure that the flow provided meets or exceeds the patient's spontaneous inspiratory flow[1] (see Chapter 47). A less sensitive trigger level and lower ventilator inspiratory flow tend to increase the patient's WOB. Common ventilator configurations and related controls that determine inspiratory flow, time, and I:E ratio are described in Figure 48-4.

For ventilators with V_T, peak flow, and rate controls, inspiratory time is determined by V_T, peak flow, and flow pattern. To

Box 48-7 Initial Ventilator Setup and Management of Oxygenation, Plateau Pressure, and pH

1. Calculate predicted (ideal) body weight as follows:
   - Men: Weight in kilograms = 50 + 2.3 (height in inches – 60)
   - Women: Weight in kilograms = 45.5 + 2.3 (height in inches – 60)
2. Select assist/control mode.
3. Set V_T to 8 ml/kg of predicted body weight.
4. Reduce V_T by 1 ml/kg at intervals of ≤2 hours until V_T is 6 ml/kg.
5. Set initial rate to achieve baseline minute ventilation ($\dot{V}_E$). Rate only limited by the development of auto-PEEP.
6. Adjust V_T and rate to achieve pH of 7.30 to 7.45 while maintaining P_{plat} of ≤28 cm H_2O.
7. Set inspiratory flow rate above patient demand (may be >80 L/min).
8. For oxygenation to achieve PaO_2 of 55 to 80 mm Hg or SpO_2 88% to 95%, use the following incremental FiO_2/PEEP combinations. Higher PEEP options (lower row) decrease FiO_2 and may be preferred in patients with high FiO_2 who can tolerate higher PEEP (stable blood pressure, no barotrauma). Survival is similar with both PEEP approaches.

FiO_2	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
Low PEEP	5	5	8	8	10	10	10	12
High PEEP	12-14	14	16	16	18-20	20	20	20
FiO_2	0.7	0.8	0.9	0.9	0.9	1.0	1.0	1.0
Low PEEP	14	14	14	16	18	20	22	24
High PEEP	20	20-22	22	22	22	22	22	24

9. Check P_{plat}, SpO_2, respiratory rate, V_T, and pH (if available) at least every 4 hours and after each change in PEEP or V_T:
   - If P_{plat} is >28 cm H_2O, decrease V_T by 1-ml/kg steps (minimum 4 ml/kg)
   - If P_{plat} is <25 cm H_2O and V_T is <6 ml/kg, increase V_T by 1-ml/kg steps until P_{plat} is >25 cm H_2O or V_T is 6 ml/kg
   - If P_{plat} is <20 and breath stacking occurs, V_T may be increased in 1-ml/kg increments (maximum 8 ml/kg)
10. The pH goal is 7.30 to 7.45.
    For acidosis management (pH < 7.30):
    - If pH is 7.15 to 7.30, increase the rate until pH is >7.30 or $PaCO_2$ is <25 mm Hg; if rate is 35 and $PaCO_2$ is <25 mm Hg, $NaHCO_3$ may be given
    - If pH is <7.15, increase rate to 35; if pH remains <7.15 and $NaHCO_3$ is considered, V_T may be increased in 1-ml/kg steps until pH is >7.15 (P_{plat} target may be exceeded)

    For alkalosis management (pH > 7.45), decrease ventilator rate, if possible.

Adapted from National Institutes of Health (NIH) National Heart Lung and Blood Institute (NHLBI) ARDS Clinical Network Mechanical Ventilation Protocol Summary (Mechanical Ventilation Protocol Summary, revised 25 January 2005).

Box 48-8 Factors That Can Prolong Ventilator Response Time

- Low trigger sensitivity
- Large V_T (causing air trapping)
- Abdomen–rib cage paradox
- Auto-PEEP (dynamic hyperinflation)
- High tubing compliance
- High circuit dead space
- High bias flow in the circuit
- Mechanical malfunction

TABLE 48-4 Suggested Initial Tidal Volume and Frequency for Mechanical Ventilation Based on Disease State or Condition

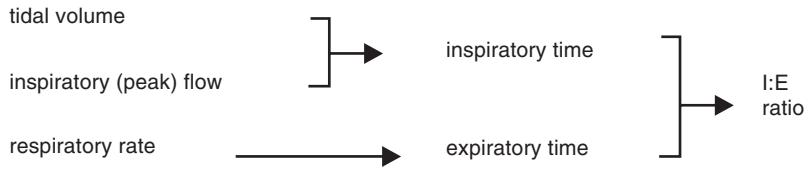
Patient Type	Tidal Volume (ml/kg)	Frequency (breaths/min)
Adults		
Normal lungs	6-8	12-16
Neuromuscular disease, postoperative period, or with normal pulmonary mechanics in which maintaining lung volume is a concern	6-8	12-16
Acute restrictive disease, ALI/ARDS	4-8*	20-35
Obstructive lung disease (COPD)	6-8	10-12†
Acute severe asthma exacerbation	4-6	10-12
Children		
Age 8-16 yr	6-8	20-30
Age 0-8 yr	6-8	25-35

*For ALI/ARDS, maintain P_{plat} at <28 cm H_2O. V_T begins at 8 ml/kg and is gradually reduced to 6 ml/kg. V_T of 4 ml/kg may be required in the care of these patients to avoid ventilator-induced lung injury.
†For patients with obstructive disease, ensure a short inspiratory time and long expiratory time to avoid air trapping and minimize auto-PEEP. Lower V_T and rate may be necessary in acute asthma to avoid further lung overinflation.

decrease inspiratory time, one may increase peak flow, decrease V_T, or change from a down ramp to a square wave flow pattern. Expiratory time and I:E ratio are determined by inspiratory time and rate. To increase expiratory time (and decrease I:E ratio), one may decrease the inspiratory time as described earlier or increase the expiratory time by decreasing the rate.[1]

For ventilators with V_T (or minute ventilation), percentage inspiratory time, and rate controls, the inspiratory time and V_T determine the inspiratory flow rate. On these ventilators, one can directly increase or decrease the percentage inspiratory time. At the same rate, as inspiratory time (or percentage inspiratory time) decreases, expiratory time and inspiratory flow rate increase, and I:E ratio decreases. An increase in V_T at the same percentage inspiratory time and rate also increases inspiratory flow rate with no change in I:E ratio. Box 48-9 shows

A. Tidal volume, peak flow, and rate determine inpiratory time, expiratory time, and I:E ratio.



↑ tidal volume → ↑ inspiratory time → ↓ expiratory time→ ↑ I:E ratio

↓ tidal volume → ↓ inspiratory time → ↑ expiratory time → ↓ I:E ratio

↑ peak flow → ↓ inspiratory time → ↑ expiratory time → ↓ I:E ratio

↓ peak flow → ↑ inspiratory time → ↓ expiratory time → ↑ I:E ratio

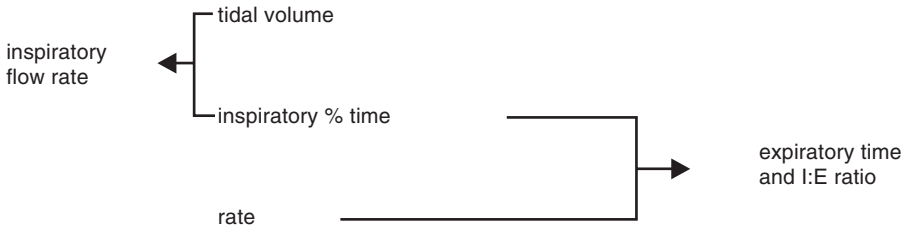
↑ rate → ↓ expiratory time → ↑ I:E ratio

↓ rate → ↑ expiratory time → ↓ I:E ratio

 to  or  → ↑ inspiratory time → ↓ expiratory time → ↑ I:E ratio

 or  to  → ↓ inspiratory time → ↑ expiratory time → ↓ I:E ratio

B. Tidal volume, % inspiratory time, and rate determine inspiratory flow rate, expiratory time, and I:E ratio.



↑ tidal volume → ↑ inspiratory flow rate → no change in inspiratory time, expiratory time, or I:E ratio

↓ tidal volume → ↓ inspiratory flow rate → no change in inspiratory time, expiratory time, or I:E ratio

↑ rate → ↓ expiratory time → I:E ratio constant or ↑*

↓ rate → ↑ expiratory time → I:E ratio constant or ↓*

↑ inspiratory % time → ↓ expiratory time

↓ inspiratory % time → ↑ expiratory time

*In the VC-CMV mode, ventilators with a percent inspiratory time control will maintain a constant I:E ratio with changes in rate. For the Servo 900C, 300, 300A, and Hamilton Veolar, changes in SIMV rate will alter I:E ratio in the SIMV mode, as described.

FIGURE 48-4 Relationship between V_T, inspiratory flow, inspiratory time, expiratory time, and I:E ratio in various ventilator systems. *A,* Effects of V_T, flow, and respiratory rate on inspiratory time, expiratory time, and I:E ratio. Some ventilators provide V_T, inspiratory flow, and rate control in volume control (VC) and SIMV modes. *B,* Effects of volume, inspiratory time, and rate on inspiratory flow, expiratory time, and I:E ratio. Other ventilators provide controls for inspiratory time (or percentage inspiratory time), V_T (or minute ventilation), and rate in the VC and SIMV modes. In the VC mode (controlled ventilation), ventilators with a percentage inspiratory time control maintain a constant I:E ratio with changes in respiratory rate. In the SIMV mode, changes in SIMV rate alter I:E ratio on these machines.

Box 48-9 Calculation of Inspiratory Flow Rate from Percentage Inspiratory Time

The effect of percentage inspiratory time on inspiratory flow rate can be estimated as follows:

$$\text{Inspiratory flow rate} = \frac{\text{Set minute ventilation}}{\text{Percentage inspiratory time} \times 0.01}$$

For example, a patient being treated with a Servo ventilator may have the following ventilator settings:

- Set minute ventilation = 12 L/min
- Set CMV rate = 20 breaths/min
- Resulting V_T = 12 L/20 breaths/min = 0.6 L or 600 ml
- Set time inspiratory percentage = 25%
- Set pause time percentage = 0%

$$\text{Inspiratory flow rate} = \frac{12\,\text{L/min}}{25\% \times 0.01} = \frac{12\,\text{L/min}}{0.25} = 48\,\text{L/min}$$

CMV, Continuous mechanical ventilation.

Box 48-10 Guidelines for Selecting Inspiratory Flow Waveforms During Volume Ventilation

CONSTANT FLOW WAVEFORM

- Alternative terms: Square wave, rectangular wave, constant flow generator
- Advantages: High flow provided with a reduced inspiratory time and improved I:E ratio; may decrease mean airway pressure, which may be helpful in terms of venous return and cardiac output in compromised patients
- Disadvantages: Increased PIP may lead to excessive pressure; lower mean airway pressure may affect oxygenation

DECREASING FLOW WAVEFORM

- Alternative terms: Down ramp, decelerating flow, descending ramp
- Advantages: Lower PIP and higher mean airway pressure; this flow waveform may improve gas distribution, oxygenation, and patient-ventilator synchrony
- Disadvantages: Increased mean airway pressure may impede venous return and cardiac output in compromised patients; in ventilators that have a peak flow control, the down ramp increases inspiratory time and I:E ratio and decreases expiratory time

the calculation of inspiratory flow rate based on percentage inspiratory time settings. To alter I:E ratio on these ventilators, one simply adjusts inspiratory percent time. Decreasing rate at the same inspiratory percent time setting does not affect I:E ratio, and both inspiratory time and expiratory time increase owing to a longer respiratory cycle. Changing the inspiratory flow waveform on these ventilators has no effect on inspiratory time, expiratory time, or I:E ratio; however, flow waveform changes affect peak and mean airway pressure.

Flow Waveform

Flow waveform options on mechanical ventilators vary from a preset square wave to seven adjustable waveforms on older ventilators. Common choices available on current generation ventilators for waveform are square or down ramp (decreasing or "decelerating" waveform). Pressure support and pressure-controlled modes also deliver decreasing flow waveforms, but the decrease is patient-specific and not programmed into the gas delivery. The literature on clinical application of specific waveforms is mixed.[32] However, as one moves from an increasing ("accelerating") flow waveform to a square wave to a decreasing flow waveform, while holding inspiratory time constant, there tends to be a predictable decrease in peak airway pressure and a corresponding increase in mean airway pressure.[32] Increases in mean airway pressure may improve oxygenation, while further impeding venous return to the heart.[32] At least as far as inspiratory flow patterns are concerned, what is good for the lungs may be bad for the heart. We suggest a decreasing, or down ramp, flow waveform when the goal is optimization of the distribution of inspired air and improvement in oxygenation. A square waveform may be useful in reducing mean airway pressure in patients with severe hypotension or cardiovascular instability. Figure 48-5 compares the effect of ventilator flow waveforms on peak and mean airway pressure. Box 48-10 describes guidelines for selecting flow waveform during volume ventilation.

During PCV or PSV, a decreasing flow waveform is delivered. The initial peak flow typically is reached rapidly. Flow decreases throughout inspiration until the breath is terminated. With PSV, inspiration ends when the flow decreases to a preset value, typically adjustable from 5% to 85% of the peak flow in some newer ventilators. With PCV, flow continues to decrease until the inspiratory time has elapsed. In the PCV mode, increasing inspiratory time tends to increase V_T until zero flow is reached at end inspiration. Further increases in inspiratory time do not increase V_T, although distribution of inspired air may improve, and mean airway pressure does increase.

Inspiratory Pause

In addition to inspiratory time or flow, most ventilators have an option for setting an inspiratory pause or hold in the volume-control mode. A brief inspiratory pause (up to 10%) has been recommended in the past for improving the distribution of the inspired air and PaO_2.[33] Use of an inspiratory pause has been suggested for administration of bronchodilators to improve medication delivery. However, in COPD patients, an inspiratory pause did not result in significant improvement in bronchodilator effectiveness.[9] If a brief inspiratory pause is used, I:E ratio and mean airway pressure increase. An inspiratory pause of 0.5 to 2 seconds applied for a single breath is used for measurement of P_{plat} and in estimation of airway resistance (Raw):

$$\text{Raw} = \text{PIP} - P_{plat} / \text{Inspiratory flow (L/sec)}$$

where PIP is peak inspiratory pressure. An inspiratory pause should never be set in a spontaneously breathing patient except for a single breath in attempts to measure P_{plat} because it increases the level of asynchrony causing the patient to fight the pause and to try to exhale during the pause.

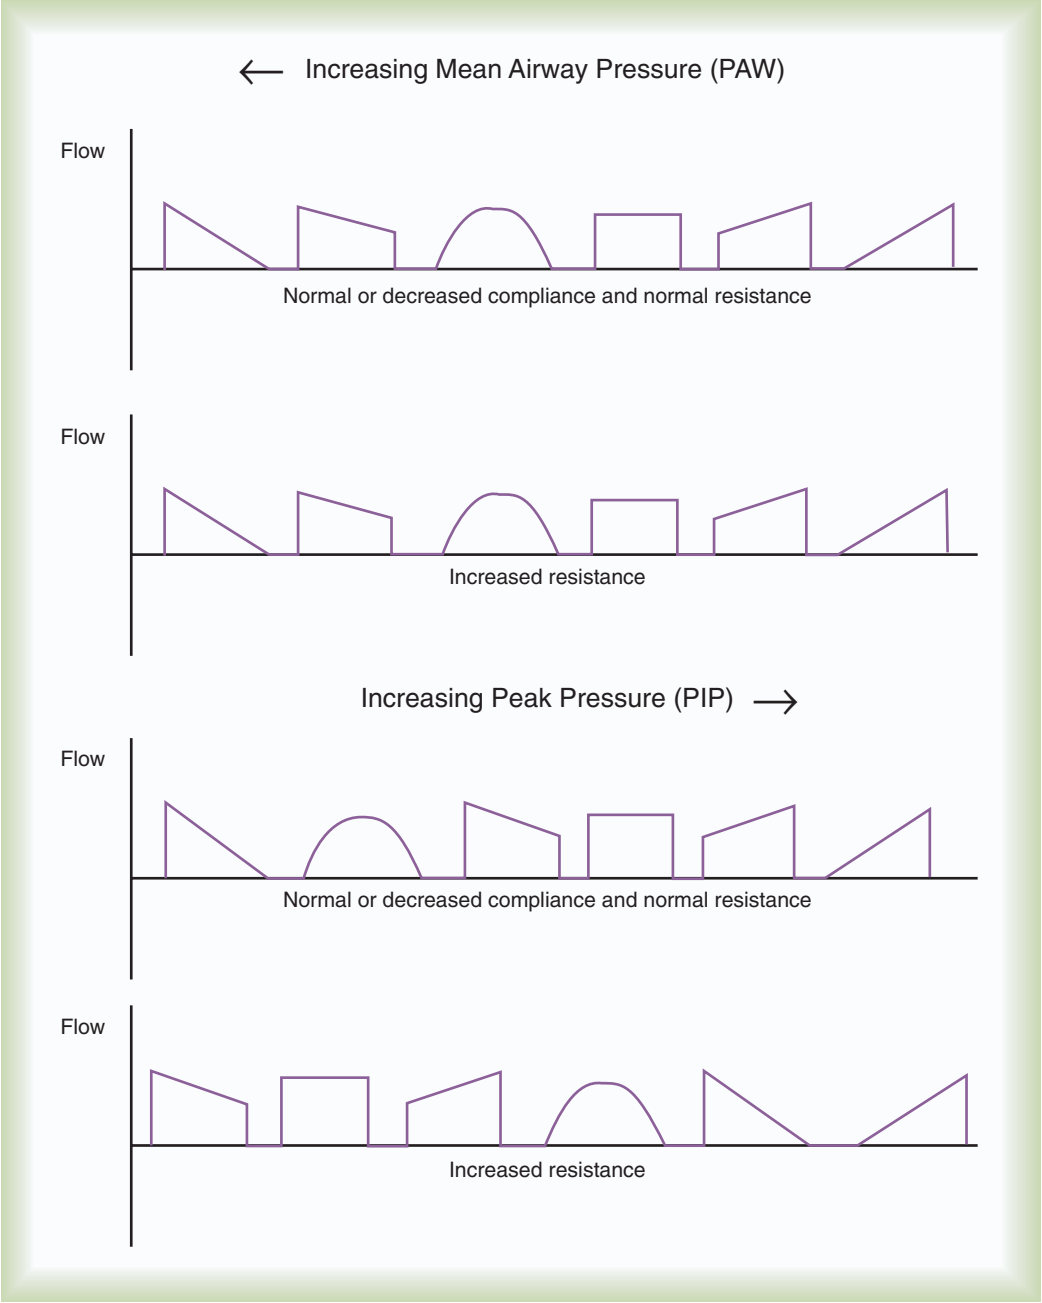


FIGURE 48-5 Effect of ventilator flow waveform on peak and mean airway pressure with changing lung mechanics. Generally, flow waveforms that tend to increase mean airway pressure also decrease peak pressure (PIP) and vice versa. Consequently, if increasing mean airway pressure is the goal, decelerating (down ramp) flow waveforms may be helpful. However, in the care of patients with cardiovascular compromise, in whom reducing mean airway pressure may be helpful, a square wave may be valuable. Accelerating flow waveforms are no longer available on newer critical care ventilators. (Modified from Rau JL, Shelledy DC: The effect of varying inspiratory flow waveforms on peak and mean airway pressures with a time-cycled volume ventilator: a bench study. Respir Care 36:347, 1991.)

An inspiratory pause can also be used to ensure a full inspiration before a chest radiograph is obtained, and this step may improve the quality of the resulting radiograph.[34] Use of an extended inspiratory pause should be limited because of the resultant increase in mean airway pressure and risk of impeding venous return and cardiac output, especially in patients who are hypovolemic or hypotensive or whose condition is hemodynamically unstable.

RULE OF THUMB

An end inspiratory pause should be used only to estimate the end inspiratory P_{plat}. It should never be applied continuously to a patient actively triggering the ventilator.

Oxygen Percentage (Fractional Inspired Oxygen)

FiO_2 selected on initiation of mechanical ventilation varies with the patient's condition. If little is known about the patient or if the patient's condition appears to be grave, 100% O_2 is the preferred starting point. Examples of disease states or conditions that typically warrant initial FiO_2 of 1 include acute pulmonary edema, ARDS, near drowning, cardiac arrest, severe trauma, suspected aspiration, severe pneumonia, carbon monoxide poisoning, and any disease state or condition resulting in a large right-to-left shunt. After initiation of mechanical ventilation with FiO_2 of 1, the FiO_2 should be reduced as soon as is practical to avoid O_2 toxicity and absorption atelectasis. In most patients, FiO_2 should always be adjusted to ensure PaO_2 of 60 mm Hg or greater or oxygen saturation by pulse oximeter (SpO_2) of 90% or greater.

Patients who have undergone previous blood gas measurement or oximetry who are doing well clinically and patients with disease states or conditions that normally respond to low to moderate concentrations of O_2 may begin ventilation with a lower O_2 concentration (50% to 70% O_2). These typically are patients with normal ventilation/perfusion ($\dot{V}/\dot{Q}$) or a $\dot{V}/\dot{Q}$ imbalance without shunt ($\dot{V}/\dot{Q}$ <1 but >0). Patients who often do well with low to moderate concentrations of O_2 include patients with acute exacerbation of COPD, emphysema, chronic bronchitis, drug overdose without aspiration, or neuromuscular disease and postoperative patients with normal lungs. For example, a patient with an acute exacerbation of COPD who needs mechanical ventilatory support may have had PaO_2 of 50 mm Hg with a nasal cannula at 4 L/min before intubation and mechanical ventilation. This patient would probably do well with FiO_2 of about 0.50 when adequate ventilation is restored. The patient can begin with 50% O_2 and be immediately assessed for assurance of adequate SpO_2. FiO_2 can be adjusted according to the patient's response.

Positive End Expiratory Pressure and Continuous Positive Airway Pressure

PEEP and CPAP are effective techniques for improving and maintaining lung volume and improving oxygenation for patients with acute restrictive disease such as pneumonia, pulmonary edema, and ARDS.[1,9] PEEP and CPAP should be cautiously applied in the treatment of patients with an already elevated FRC, such as patients with COPD or acute asthma, except at levels that are applied to offset auto-PEEP and air trapping.[9] Generally, the indication for PEEP or CPAP is inadequate arterial O_2 with moderate to high concentrations of O_2 caused by unstable lung units that are collapsed. PaO_2 less than 50 to 60 mm Hg with FiO_2 greater than 0.40 is a good general starting place for considering use of PEEP or CPAP.

In terms of ventilator initiation, initial PEEP or CPAP levels usually are 5 cm H_2O even in the absence of unstable lung units or auto-PEEP. Most experts advocate for the use of 5 cm H_2O "physiologic" PEEP for all patients who have an artificial airway in place. Intubation results in small reductions in FRC,[1,9] which can be balanced with the application of PEEP or CPAP. Whether the application of physiologic PEEP has important benefits in terms of patient outcome is unknown.

PEEP has been advocated in the presence of auto-PEEP, in particular, in the care of patients with obstructive lung disease.[35]Applied PEEP in the presence of auto-PEEP is indicated only if the patient has difficulty triggering the ventilator. During controlled ventilation, increasing PEEP in the presence of auto-PEEP is usually not indicated. See Chapter 47 for auto-PEEP details. An absolute contraindication to PEEP is an uncontrolled tension pneumothorax. However, PEEP should be cautiously applied in any patient with severe intrinsic lung disease, hypotension, and elevated intracranial pressure.

Open Lung Strategy, Recruitment Maneuvers, and Positive End Expiratory Pressure

In the care of patients with ARDS, it is usually necessary to initiate PEEP at 10 to 15 cm H_2O.[24,25,36,37] However, many clinicians use the ARDS Clinical Network PEEP/FiO_2 tables to set PEEP initially during the establishment of ventilatory support (see Box 48-7). When patients are stabilized, the use of an open lung ventilation strategy in early-stage ARDS has been recommended.[1,5] Such a strategy incorporates V_T of 4 to 8 ml/kg IBW with either pressure-targeted or volume-targeted ventilation and a PEEP level set after a lung recruitment maneuver using a decremental PEEP trial.[1,5,38] The lung recruitment maneuver is intended to open collapsed lung units, and the setting of PEEP using a decremental PEEP trial is intended to apply PEEP based on the patient's lung mechanics to keep the lung units recruited open.

Although all patients with ARDS require PEEP, not all patients with ARDS respond to low-level PEEP, and patients with pulmonary (vs. nonpulmonary) causes of ARDS, such as pneumonia, may be less likely to respond to low to moderate levels of PEEP.[12] Nonpulmonary causes of ARDS (e.g., extrathoracic trauma, intraabdominal sepsis) seem to respond well to PEEP.[12] In practice, some authors have suggested that higher levels of PEEP (>15 cm H_2O) be reserved for patients with a high percentage of recruitable lung.[39] High levels of PEEP have been shown to improve outcomes in ARDS in patients with the most severe forms of ARDS (PaO_2/FiO_2 < 150 mm Hg).[40,41] (See later section on the performance of recruitment maneuvers and the setting of PEEP by decremental trial.)

Pressure Rise Time or Slope

Most newer critical care ventilators include an inspiratory pressure rise time or pressure slope. This control functions only with pressure-limited breaths (PSV, PCV, PRVC, volume support, airway pressure release ventilation, pressure SIMV). The purpose of this control is to adjust the rate at which flow increases from baseline to peak.[42-44] See Chapter 47 for details.

Limits and Alarms

Ventilator alarms and limits warn of ventilator malfunction and changes in patient status. Ventilator malfunction alarms include

power or gas supply loss and electronic or pneumatic malfunction. These alarms usually are preset by the manufacturer.

Patient status alarms usually are set by the respiratory therapist (RT). These include maximum inspiratory pressure, low-pressure and low-PEEP alarms, high-volume and low-volume and rate alarms, O_2 and humidification alarms, and apnea alarms. After initiation of ventilation, alarms and limits are readjusted as needed. Alarms usually are set so that they warn the clinician of important changes or problems. Without proper setting, these alarms can become a nuisance by falsely signaling problems that are not real.[9]

In volume ventilation, a pressure limit should be set. Generally, before the patient is connected to the ventilator, the limit should be set at 40 cm H_2O to avoid overpressuring the system when the patient is connected. After the patient is connected to the ventilator, the peak and plateau pressures should be assessed. If P_{plat} is greater than 30 cm H_2O, consideration should be given to decreasing the set V_T. If P_{plat} is less than 30 cm H_2O, the high pressure limit can be adjusted to 10 to 15 cm H_2O above PIP. One can decrease peak pressure by decreasing the peak flow rate, increasing the inspiratory time, changing the inspiratory flow waveform from a square to a down ramp, or decreasing the delivered V_T. For spontaneously breathing patients, inspiratory flow and time must meet or exceed the patient's inspiratory demand to ensure one does not increase the patient's WOB further (see Chapter 47 for details). Preset or adjustable alarms common to most ventilators include pressure (high-low), volume (high-low V_T, minute ventilation), apnea, O_2 percentage, and temperature. Suggested initial settings for these alarms and backup ventilator settings are presented in Table 48-5.

Humidification

Humidification is required during both invasive and noninvasive mechanical ventilation. A heated humidifier or a heat and moisture exchanger (HME) should provide a minimum of 30 mg/L of water with a temperature of 30° C or greater.[45] Use of HMEs should be avoided in the care of patients with secretion problems and patients with low body temperature (<32° C), high spontaneous minute ventilation (>10 L/min), or air leaks in which exhaled V_T is less than 70% of delivered V_T.[45] Heated humidifiers may be used to deliver 100% body humidity at 37° C. Current clinical practice guidelines suggest an inspired gas temperature of 35° C ± 2° C.[45] We prefer an optimal humidity approach and use of a heated humidifier to deliver gas in the range of 35° C to 37° C at the airway in most intubated patients and at a temperature consistent with patient comfort during noninvasive ventilation. However, in patients without primary pulmonary dysfunction and short-term ventilation, HMEs are very useful; generally, these are postoperative patients after elective surgery, patients in the emergency department, and patients recovering from an overdose.

TABLE 48-5

Alarm and Backup Ventilation Setting of Initial Ventilatory Setup (Adults)

Low pressure	5-10 cm H_2O below PIP
Low PEEP/CPAP	3-5 cm H_2O below PEEP
High pressure limit	50 cm H_2O, which is adjusted to 10-15 cm H_2O above PIP
Low exhaled V_T	100 ml or 50% below set V_T
Low exhaled minute ventilation	2-5 L/min or 50% below minimum SIMV or assist/control backup minute ventilation
High minute ventilation	50% above baseline minute ventilation
O_2 percentage (FiO_2)	5% above and below set O_2 percentage
Temperature	2° C above and below set temperature, high temperature not to exceed 37° C
Apnea delay	20 sec
Apnea values	V_T and rate set to achieve full ventilatory support (V_T 8-10 ml/kg; rate 10-12 breaths/min) with 100% O_2

Periodic Sighs

Constant, monotonous tidal ventilation at a small volume (<7 ml/kg) may result in progressive atelectasis.[9,46] Periodic deep breaths or sighs taken every 6 to 10 minutes reverse this trend.[9,46] During the 1960s and 1970s, it was common to ventilate patients with a smaller V_T (5 to 7 ml/kg) and no PEEP. As a result, an intermittent sigh function was incorporated into most volume ventilators. Sighs were programmed at 1½ to 2 times the set V_T at an interval of every 6 to 10 minutes. Sometimes multiple sighs were included at a preset interval of up to 10 times per hour. Because of the use of PEEP, sighs are no longer routinely included. PEEP prevents the formation of atelectasis in a patient on ventilation with constant small V_T. This is the primary reason why 5 cm H_2O of PEEP is routinely used on patients, including patients with healthy lungs. General guidelines for the initial ventilator settings for most adult patients are described in Box 48-11.

ADJUSTING VENTILATORY SUPPORT

After ventilator initiation, the patient should be carefully assessed and the ventilator adjusted so that patient-ventilator synchrony is ensured; WOB is minimized; and oxygenation, ventilation, and acid-base balance are optimized while harmful cardiovascular effects are minimized. Initial patient evaluation should include physical assessment, assessment of ventilator settings, cardiovascular assessment, oximetry, and measurement of arterial blood gases (Box 48-12).

Physical assessment should include general appearance, level of consciousness, signs of anxiety or dyspnea, color, extremities (temperature, edema, capillary refill), heart rate and blood pressure, respiratory rate and pattern, inspection of the neck for jugular venous distention, and chest examination. Cyanosis is associated with hypoxemia. Use of accessory muscles, tachypnea, retractions, or paradoxical abdomen movement may indicate increased WOB. Unilateral or unequal lung expansion is associated with bronchial intubation, pneumothorax, and other unilateral disorders.

Breath sounds should be assessed for good aeration, and absent, diminished, or abnormal breath sounds should be

Box 48-11 General Guidelines for Initial Ventilator Settings for Adult Patients

MODE
- Assist/control volume or pressure targeted
- Pressure support
- SIMV with or without pressure support volume or pressure targeted

TIDAL VOLUME
- 4 to 8 ml/kg IBW
- Avoid overdistention
- Maintain P_{plat} <28 cm H_2O
- For COPD, V_T 6 to 8 ml/kg IBW in assist/control or pressure support mode with adequate expiratory time for reducing air trapping is suggested
- For ARDS, begin at 6 to 8 ml/kg IBW; adjust as indicated to maintain P_{plat} <28 cm H_2O
- For acute asthma, V_T 4 to 6 ml/kg IBW is indicated to maintain P_{plat} <28 cm H_2O

RATE
- 18 (asthma) to 40 breaths/min
- Minimize auto-PEEP
- Set initial rate and V_T to maintain baseline minute ventilation (approximately 100 ml/kg IBW for most healthy adults)

PEEP
- 5 cm H_2O in most patients ventilated without acute lung injury
- 10 cm H_2O in patients with mild ARDS
- 15 to 20 cm H_2O in most patients with moderate to severe ARDS
- 5 cm H_2O in patients with COPD/asthma, adjust as indicated to offset effect of auto-PEEP on ventilator triggering
- Trigger sensitivity –0.5 to –1.5 cm H_2O or flow trigger 1 to 2 LPM; minimize trigger work without autocycle
- Inspiratory flow and time 60 to 100 L/min
- Inspiratory time 0.6 to 1.0 second; inspiratory flow must meet or exceed patient's spontaneous inspiratory flow demand
- Resultant I:E ratio should be ≤1:2

Box 48-12 Initial Assessment of Ventilatory Support

- Inspection, palpation, and auscultation
- Assessment of position of artificial airway and cuff inflation
- Assessment of pulse, blood pressure, oximetry, and electrocardiogram
- Inspection of patient-ventilator system breathing circuit, humidifier, ventilator settings, and findings
- Analysis of arterial blood gas values
- Inspection of chest radiograph

documented. Palpation should be performed as appropriate for tracheal position, chest wall motion, and presence of subcutaneous air. Percussion of the chest should be performed for assessment of resonance, dullness, or hyperresonance. Key findings at initial assessment of a patient undergoing ventilation are described in Table 48-6.

MINI CLINI

Humidification of the Airways During Mechanical Ventilation

PROBLEM: A mechanically ventilated patient is in the medical ICU recovering from acute respiratory failure secondary to aspiration pneumonia. The patient currently needs airway suctioning every 30 to 60 minutes according to the RT and staff nurse caring for the patient. Both caregivers note that the secretions are thick and copious. Current ventilator settings are as follows:
Mode: Assist/control volume ventilation
V_T: 500 ml (6.8 ml/kg IBW)
Preset rate: 16 breaths/min
Total rate: 26 breaths/min
FiO_2: 0.50
PIP: 31 cm H_2O
V_E: 13 L/min

The RT is asked to place an HME on the ventilator circuit at the "wye." Is this an appropriate action?

Solution: Humidification can be provided with either a heated humidifier or an HME. Although useful in some instances, placement of an HME would be contraindicated in this case for several reasons. Adequate humidification for a patient with an artificial airway is critical in preventing inspissation of airway secretions, injury to and destruction of the airway epithelium, and atelectasis.

The patient information in this clinical scenario points to several potential problems with use of an HME, the most obvious one being copious, thick airway secretions. The HME may not provide sufficient water vapor and heat output, and secretions could be retained. The airway secretions could be coughed into the HME, causing increased resistance to flow and possible obstruction. Because the patient has high ventilatory requirements, as evidenced by an elevated exhaled minute ventilation, it is important that the humidification system be able to maintain adequate heat and moisture output when demands dictate.

Other situations in which an HME should not be used are administration of aerosol treatments through the ventilator tubing circuit, high minute ventilation (>10 L/min), and body temperature less than 32°C.

Ventilator settings that should be assessed after initiation of mechanical ventilation include peak, plateau, and mean airway pressures; exhaled volumes (spontaneous and machine V_T, minute ventilation); respiratory rate (spontaneous and machine rate); baseline pressures (PEEP, CPAP, auto-PEEP); trigger effort; O_2 concentration; inspiratory time; flow; I:E ratio; humidification; airway temperature and airway cuff pressure. In addition, patient-ventilator interaction should be assessed to ensure that a spontaneously breathing patient is able to trigger a breath easily and that inspiratory flow and time are such that WOB is minimized. When using pressure ventilation, the patient should also be evaluated to ensure ease of cycling to expiration. Factors that may affect patient-ventilator interaction are discussed in detail in Chapter 47.

TABLE 48-6

Assessment of Ventilatory Support

Ancillary equipment in room	Crash cart (patient's condition unstable); cardiac monitor; chest tubes (pneumothorax, chest drainage, thoracic surgery); aortic balloon pump (heart failure); cooling blanket (fever); other
General appearance	Resting quietly, calm, relaxed (no distress); restless, anxious, distressed (pain, anxiety, inadequate oxygenation or ventilation)
Level of consciousness	Alert, awake, and oriented to person, place, and time (good mental status, neurologic function); confused (neurologic problems, hypoxia, low cardiac output, drugs); sleepy (tired, sedatives, narcotics); lethargic (exhaustion, impaired CNS status, sedation); somnolent (CNS impairment, sedation); coma (CNS malfunction, heavy sedation, severe hypoxia)
Extremities	Cyanosis (hypoxemia); pale, cold, and clammy (poor cardiac output, low blood pressure, shock); edema (fluid overload)
Respiratory rate and pattern	Normal (good cardiopulmonary status); tachypnea (pain, anxiety, hypoxemia, acidosis, CNS problems); bradypnea or apnea (severe hypoxia, CNS problems, heavy sedation, paralysis)
Head, eyes, ears, nose, and throat	Cyanotic lips and gums (hypoxemia); pupils dilated (drugs, severe hypoxia, low cardiac output, cardiac arrest); pupils dilated and fixed (brain death); pupils contracted (drugs, light); response to light (good if responsive)
Neck	Accessory muscle use (increased WOB, respiratory distress); jugular vein distention (right-sided heart failure, positive pressure impeding venous return)
Chest inspection	Right-left chest wall synchrony (normal); right-left chest wall asynchrony (right main stem intubation, pneumothorax, large unilateral pleural effusion, flail on one side); chest-diaphragm synchrony (normal); chest-diaphragm asynchrony—abdominal paradox (increased WOB, diaphragmatic fatigue)
Chest auscultation	Good bilateral breath sounds (normal); decreased breath sounds unilaterally (right main stem intubation, pneumothorax, unilateral lung disease); bilaterally decreased or absent breath sounds (inadequate or decreased ventilation, large leak, ventilator malfunction or disconnect, misplaced endotracheal tube); air leak around cuff (underinflation, cuff malfunction); wheezing (bronchospasm, tumor, narrowing of airway); bibasilar crackles in patients with congestive heart failure (pulmonary edema); rhonchi, coarse crackles (secretions in the larger airways); bronchial breath sounds (consolidation or microatelectasis)
Palpation	Subcutaneous air (pneumothorax, pneumomediastinum); tracheal shift (tension pneumothorax, large area of atelectasis); right-left chest motion symmetry (normal); right-left asymmetric breathing (unilateral disease, pneumothorax, bronchial intubation)
Percussion	Resonant over lung tissue (normal); dull (pleural effusion, lobar infiltrates, consolidation, atelectasis); hyperresonant (pneumothorax, overinflation—COPD, asthma exacerbation)
Vital signs	Normal heart rate and rhythm (normal); tachycardia (hypoxemia, pain, anxiety, distress); hypertension (anxiety, cardiovascular disease, head trauma); bradycardia (severe hypoxia, severe hypercapnia, cardiac disease); hypotension (blood loss, shock, gram-negative sepsis, heart failure)

CNS, Central nervous system.

The artificial airway should be assessed for proper placement, patency, and cuff inflation. Size, position, and depth of the endotracheal tube and cuff pressure, including volume used to inflate the cuff, should be recorded. An extra endotracheal tube or tracheostomy tube of the correct size should be placed at the patient's bedside, and the equipment needed to replace the airway must be available and easily accessible. A clean, functioning manual resuscitator with O_2 supply and suction equipment including an appropriate supply of suction catheters, sterile water or saline solution, and sterile gloves also must be placed near the bedside. Patients requiring high levels of PEEP (>5 cm H_2O) should have PEEP valves attached to the manual ventilator.

Cardiovascular assessment should include observation of heart rate, blood pressure, and electrocardiogram for the presence of arrhythmias. Tachycardia, ST segment elevation, and frequent premature ventricular contractions may indicate myocardial ischemia. If the patient has a central venous line or pulmonary arterial catheter, hemodynamic variables may be assessed, including central venous pressure, pulmonary arterial pressure, wedge pressure, and cardiac output.

Continuous monitoring with pulse oximetry is recommended for patients receiving mechanical ventilatory support in the ICU, and arterial blood gases should be measured 30 to 60 minutes after initiation of mechanical ventilation. A chest radiograph should be obtained to verify proper endotracheal tube placement and to evaluate the chest. After the initial assessment, the method and level of ventilatory support are adjusted to optimize oxygenation, ventilation, WOB, acid-base balance, and cardiovascular status. The ventilatory adjustments for each of these areas are discussed next.

Patient-Ventilator Interaction

Patient-ventilator interaction refers to patient comfort, WOB, and synchrony during ventilator-assisted breaths. Generally, ventilatory support should be initially adjusted to minimize the WOB and to allow the ventilatory muscles to rest.[47] See Chapter 47 for a detailed discussion.

OXYGENATION

Oxygen Concentration

Initiation of treatment for most patients in the acute care setting is with 100% O_2, unless detailed information identifying precise FiO_2 needed is available. FiO_2 is titrated to achieve PaO_2 of 60 to 80 mm Hg with SaO_2 or SpO_2 90% or greater. Estimate of O_2 needs can be derived as follows:

$$FiO_2 = \left(\frac{PaO_2 \text{ desired}}{PaO_2/PAO_2 \text{ ratio}} + PaCO_2 \times 1.25 \right) \times \frac{1}{P_B - P_{H_2O}}$$

where FiO_2 required is the FiO_2 needed to achieve a desired PaO_2, PaO_2/PAO_2 is the initial PaO_2 divided by the initial alveolar partial pressure of oxygen (PAO_2), $PaCO_2$ is the initial $PaCO_2$, PB is barometric pressure, and P_{H_2O} is water vapor pressure. A simpler but less accurate calculation is the following:

$$\underset{\text{Initial}}{PaO_{2(1)}}/\underset{\text{Initial}}{FiO_2(1)} = \underset{\text{Desired}}{PaO_{2(2)}}/\underset{\text{Desired}}{FiO_2(2)}$$

Instead of a formula, a nomogram can be used to predict a patient's required FiO_2 (Figure 48-6). In either case, it is suggested that O_2 levels be titrated down from 100% to minimal FiO_2 required in decrements not to exceed 20%; titration is followed by oximetry or measurement of blood gases. When titrating FiO_2 downward, the clinician should wait at least 20 minutes between changes in FiO_2 to allow O_2 levels to stabilize. Patients with obstructive disease need a longer period for equilibration after a change in FiO_2.

When minimal FiO_2 is identified, further reduction in FiO_2 should be in steps of 5% to 10% followed by pulse oximetry measurements. Box 48-13 lists a conservative method of titrating O_2 concentration down from an initial FiO_2 of 1 on the basis of PaO_2.

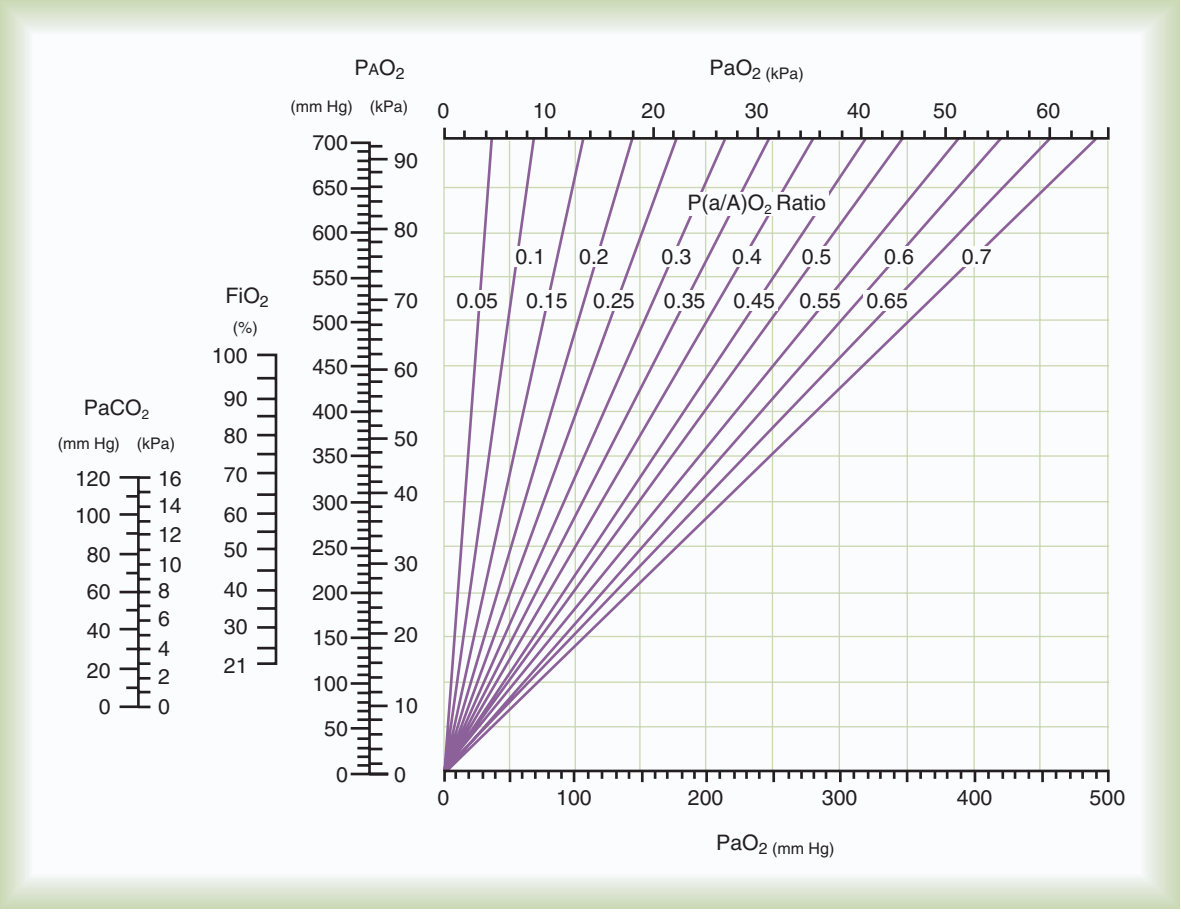

FIGURE 48-6 Nomogram for computing PaO_2/PAO_2 ratio and predicting FiO_2 required for desired PaO_2. To use the nomogram, first align the patient's current $PaCO_2$ and FiO_2 *(left two columns)* with a straight edge. This line intersects the vertical line corresponding to the patient's PAO_2 *(third column)*. Draw a horizontal line from this point to the vertical line corresponding to the patient's PaO_2. The diagonal line at this point (or one interpolated from the nearest diagonal lines bracketing it) is the PaO_2/PAO_2 ratio. $PaCO_2$ of 40 mm Hg and FiO_2 of 50% give PAO_2 of about 310 mm Hg. If PaO_2 is 50 mm Hg, PaO_2/PAO_2 is about 0.15. To predict FiO_2 required for PaO_2 of 70 mm Hg, follow the diagonal line representing 0.15 up to where it intersects the vertical line representing PaO_2 = 70 mm Hg. From this point, draw a horizontal line to the left intersecting the PAO_2 column at about 450 mm Hg. Connect this point to the present $PaCO_2$ (40 mm Hg) and note that the line passes through the required FiO_2 of about 70%. (From Chatburn RL, Lough MD: Handbook of respiratory care, Chicago, 1990, Year Book Medical Publishers.)

Box 48-13 Titrating Fractional Inspired Oxygen Down from an Initial Starting Point of 1.0 According to Initial PaO_2 and Pulse Oximetry Findings

Initial PaO_2 on FiO_2 1.0 (mm Hg)	FiO_2				
	Step 1	Step 2	Step 3	Step 4	Step 5
>300	0.80	0.60	0.50	0.40	0.35*
200-300	0.80	0.60	0.50	0.40*	—
150-199	0.80	0.60*	—	—	—
100-149	0.80*	—	—	—	—

Decrease FiO_2 to the target value in steps, and perform pulse oximetry or arterial blood gas measurements. Patients should continue to receive a given FiO_2 long enough to ensure equilibration and acceptable SpO_2 before further reductions are made in FiO_2. This procedure takes 20 minutes per FiO_2 change for most patients and up to 30 minutes for patients with obstructive disease. It usually is safe to continue to decrease FiO_2 as long as SpO_2 is greater than 95% (which should correspond to a PaO_2 > 90 mm Hg) for most patients. When SpO_2 is less than 95%, increase or decrease FiO_2 in steps of 0.05 per change.

*Target FiO_2 based on initial PaO_2.

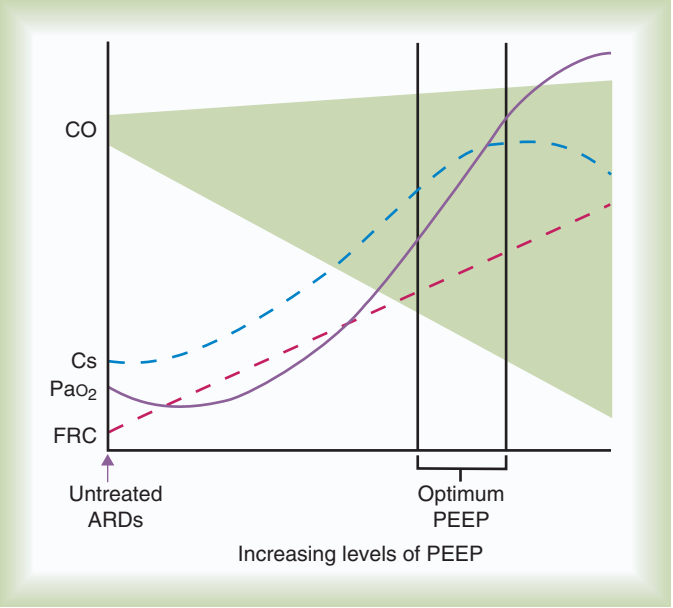

FIGURE 48-7 Curves represent the physiologic factors that change during the application of PEEP and CPAP. As PEEP level is increased, PaO_2, FRC, and static compliance (Cs) normally increase. Cardiac output (CO) *(shaded area)* can increase slightly, stay the same, or decrease. Optimum PEEP level can be expected to occur when PaO_2, FRC, and Cs are high. CO should be maintained near normal so that O_2 transport to the tissues remains high. (Modified from Pilbeam SP: Mechanical ventilation: physiological and clinical applications, ed 3, St Louis, 1998, Mosby.)

Once the desired PaO_2 and saturation are reached, monitoring should be continued. Generally, O_2 levels are titrated up and down as needed with adjustments in FiO_2 of 0.05 to 0.10 to maintain PaO_2 of 60 to 80 mm Hg with SpO_2 of 90% to 95%. Titration is followed by pulse oximetry. SpO_2 of 88% to 90% may be acceptable for patients who need FiO_2 of 0.60 or more.

RULE OF THUMB

If a patient's oxygenation status is unknown, or if the patient's condition is unstable or critical, begin ventilatory support with FiO_2 of 1 until PaO_2, SaO_2, or SpO_2 can be assessed.

Positive End Expiratory Pressure and Continuous Positive Airway Pressure

Various approaches to adjusting PEEP or CPAP have been suggested over the years, including minimum PEEP, optimal or best PEEP, use of PEEP tables, PEEP titrated by compliance or pressure-volume curves, and decremental PEEP trials. With acute restrictive disease, as PEEP or CPAP levels are increased, PaO_2, SpO_2, and static compliance tend to improve until the point at which lung overinflation occurs.[47,48] As mean airway pressure increases, venous return decreases. The result may be a decrease in cardiac output. Figure 48-7 shows the physiologic factors that change during application of PEEP or CPAP. Several approaches to adjusting PEEP or CPAP are described later.

Minimum Positive End Expiratory Pressure

Minimum PEEP can be defined as the minimal PEEP needed to maintain recruited lung open and achieve adequate PaO_2 (and SpO_2) with FiO_2 less than 0.6. Generally, the PEEP level needed to achieve PaO_2 of at least 60 mm Hg (SpO_2 ≥90%) with FiO_2 of 0.40 to 0.50 or less is the minimum PEEP. With this approach, the least PEEP or CPAP level needed to achieve this therapeutic end point is applied.[1]

Optimal or Best Positive End Expiratory Pressure Based on Oxygen Delivery

Optimal or best PEEP may be defined as the PEEP that maximizes oxygen delivery (DO_2). Oxygen delivery is calculated as cardiac output ($\dot{Q}_T$) multiplied by oxygen content (CaO_2):

$$DO_2 = \dot{Q}_T \times CaO_2$$

For the optimal PEEP level, PEEP is increased in increments of 2 cm H_2O. Blood pressure, mixed venous O_2 levels (partial pressure of oxygen in mixed venous blood [$P\bar{v}O_2$], mixed venous oxygen saturation [$S\bar{v}O_2$], arteriovenous oxygen content difference [$C(a-\bar{v})O_2$]) cardiac output, and cardiac index are assessed. PEEP is increased incrementally until there is a decline in O_2 delivery, at which point the best or optimal PEEP has been exceeded. PEEP is adjusted down to the previous level that represents the "best" PEEP. Table 48-7 shows an example of a PEEP study for determining optimal PEEP based on O_2 delivery. In Table 48-7, as PEEP is increased from 8 cm H_2O to 10 cm H_2O to 12 cm H_2O, $P\bar{v}O_2$, $S\bar{v}O_2$, and O_2 delivery increase with

MINI CLINI

Adjustment of Oxygen Concentration Down from 100%

PROBLEM: At 9:00 AM, mechanical ventilation is initiated with the following settings for a 70-kg (IBW) patient:
Mode: VA/C with the patient actively triggering the ventilator
V_T: 420 ml/ 6.0 ml/kg /IBW
Rate: 20 to 26 breaths/min
FiO_2: 1
PEEP: 5 cm H_2O

An arterial blood gas is obtained 20 minutes after ventilator initiation:
FiO_2: 1
PaO_2: 225 mm Hg
pH: 7.42
$PaCO_2$: 40 mm Hg
HCO_3: 24 mEq/L
Base excess: +1 mEq/L

Calculated alveolar PAO_2 and PaO_2/PAO_2 ratios are:

$$PAO_2 = FiO_2\,(PB - P_{H_2O}) - PaCO_2 \times 1.25 = 663$$
$$PaO_2/PAO_2 = 225/663 = 0.34$$

What FiO_2 is needed to achieve a target PaO_2 of 80 mm Hg?

Solution: The following equation and normal barometric pressure ($P_B = 760$), lead to the calculation:

$$FiO_2 \text{ required} = \left(\frac{PaO_2 \text{ desired}}{PaO_2/PAO_2 \text{ ratio}} + PaCO_2 \times 1.25\right) \times \frac{1}{P_B - P_{H_2O}}$$
$$= \left(\frac{80}{0.34} + 40 \times 1.25\right) \times \frac{1}{760 - 47} = 0.40$$

An alternative calculation would be:

Initial	Desired
PaO_2/FiO_2	$= PaO_2/FiO_2$
225/1	$= 80/FiO_2$ desired

$$FiO_2 \text{ desired} = 80 \times (1/225) = 80/225 = 0.36$$

What should the clinician do now?

The target O_2 concentration to achieve a PaO_2 in the range of 60 to 80 mm Hg (with 80 mm Hg as the specific target for the purpose of this calculation) would be approximately 40%. However, it is suggested that for adjusting down from 100% after initial ventilator setup, changes in FiO_2 be limited to 0.20 in the range of FiO_2 1 to 0.50 and 0.10 to 0.05 below FiO_2 of 0.50. Each change in FiO_2 should be followed by oximetry and patient assessment.

In this example, the FiO_2 can be decreased in a stepwise manner, as follows:

Time	FiO_2	SpO_2 (%)
9:30 AM	1	99
9:45 AM	0.80	99
10:00 AM	0.60	98
10:15 AM	0.50	97
10:30 AM	0.45	97
10:45 AM	0.40	95

Arterial blood gas on FiO_2 of 0.40 reveals a PaO_2 of 80 mm Hg.

MINI CLINI

Adjusting Fractional Inspired Oxygen

PROBLEM: A 65-kg (IBW) patient in the ICU is receiving mechanical ventilation in the VA/C mode. The patient's arterial blood gas values and related ventilator settings are:
Mode: VA/C the patient is not breathing spontaneously
FiO_2: 0.40
PaO_2: 50 mm Hg
V_T: 450 ml (7ml/Kg IBW)
pH: 7.4
Rate: 22 breaths/min
$PaCO_2$: 40 mm Hg
PEEP: 10 cm H_2O
HCO_3: 24 mEq/L
Base excess: +1 mEq/L

What FiO_2 would be required to increase this patient's PaO_2 to 60 mm Hg?

Solution: First, calculate the patient's current PAO_2 and PaO_2/PAO_2 ratio:

$$PAO_2 = FiO_2\,(PB - P_{H_2O}) - PaCO_2/0.8$$
$$= 0.40\,(760 - 47) - 40/0.8$$
$$= 285 - 50 = 235 \text{ mm Hg}$$
$$PaO_2/PAO_2 = 50/235 = 0.21$$

Next, calculate the FiO_2 needed to achieve the desired PaO_2 of 60 mm Hg:

$$FiO_2 \text{ required} = \left(\frac{PaO_2 \text{ desired} + PaCO_2 \times 1.25 \times 1}{PaO_2/PAO_2 \text{ ratio } P_B - P_{H_2O}}\right)$$
$$= \left(\frac{60 + (40 \times 1.25) \times 1}{0.21760 - 47}\right)$$
$$= \frac{335.7 \times 1}{713} = 0.47$$

For this patient, if the FiO_2 is increased from 0.40 to 0.50, the PaO_2 should increase from 50 to 60 mm Hg. An alternative calculation, based on PaO_2/FiO_2 ratio, would be:

Actual	Desired
PaO_2/FiO_2	$= PaO_2/FiO_2$

Solving for FiO_2, this becomes:

$$FiO_2 \text{ required} = PaO_2 \text{ desired} \times (FiO_2 \text{ actual}/PaO_2 \text{ actual})$$
$$= 60 \times (0.40/50) = 0.48$$

To increase this patient's PaO_2 to greater than 60 mm Hg would require increasing FiO_2 to approximately 0.50. Although FiO_2 of 0.50 or less is acceptable, as an alternative, the RT may consider increasing PEEP to 12 cm H_2O and then perform a clinical assessment, including evaluation of the effect of the increase on blood pressure, compliance, and arterial blood gases.

TABLE 48-7

Example of an Incremental Positive End Expiratory Pressure Study Including Ventilation, Oxygenation, and Hemodynamic Data*

Value	PEEP = 8	PEEP = 10	PEEP = 12	PEEP = 14	PEEP = 16
Time (min)	0	20	40	60	80
V_T (L)	0.6	0.6	0.6	0.6	0.6
f (breaths/min)	16	16	16	16	16
FiO_2 (%)	80	80	80	80	80
PEEP (cm H_2O)	0	5	10	15	20
I:E ratio	1:2.7	1:2.7	1:2.7	1:2.7	1:2.7
P_{peak} (cm H_2O)	30	32	35	42	50
P_{plat} (cm H_2O)	25	27	29	36	43
Cs (ml/cm H_2O)	24	27	32	29	26
$PaCO_2$ (mm Hg)	43	42	43	42	44
pH	7.38	7.37	7.39	7.35	7.32

SaO_2 (%)	86	92	96	97	98
$P\bar{v}O_2$ (mm Hg)	32	35	37	37	36
$S\bar{v}O_2$ (mm Hg)	61	66	71	69	64
Blood pressure (mm Hg)	131/78	133/82	130/79	125/74	110/69
Cardiac output (L/min)	5.9	5.7	5.9	5.4	4.8
DO_2 (ml/min)	989	1022	1105	1021	917

*When first reviewing a PEEP study, observe changes in the following: (1) airway pressure, (2) blood pressure, (3) arterial oxygen (PaO_2, SaO_2) and mixed venous oxygenation ($P\bar{v}O_2$, $S\bar{v}O_2$), and (4) oxygen transport (DO_2). With increases in PEEP, PaO_2 and saturation improve; airway pressure increases; compliance improves and then decreases at higher levels of PEEP; and oxygen transport (DO_2) improves and then declines. Optimum PEEP for this patient is 12 cm H_2O because it provides the best arterial oxygenation (PaO_2, SaO_2) without a decline in cardiac output.

no decline in cardiac output ($\dot{Q}_T$) or blood pressure. However, when PEEP is increased to 14 cm H_2O, $S\bar{v}O_2$, O_2 delivery, $\dot{Q}_T$, and blood pressure decline, indicating that optimal PEEP for this patient has been exceeded. The best PEEP for this patient would be 12 cm H_2O. Before determining PEEP using this approach, it is critical that the patient's hemodynamic status is stabilized. Patients with a compromised hemodynamic status generally do not tolerate PEEP titration without further compromise.

Compliance-Titrated Positive End Expiratory Pressure

With the compliance-titrated technique, PEEP is increased in increments of 2 cm H_2O, and the patient's estimated static compliance (Cs) is measured:

$$Cs = \frac{\text{Volume delivered (ml)}}{P_{plat} - P_{baseline}\ (PEEP/CPAP)}$$

where total PEEP equals the sum of applied PEEP plus auto-PEEP.

Best PEEP has been exceeded at the point where an increase in PEEP is followed by a decrease in compliance. PEEP is reduced to the previous level, and this is optimal PEEP based on compliance.[48] For the example shown in Table 48-7, the best PEEP based on compliance would be 12 cm H_2O. Regional lung overdistention and declines in cardiac output can occur at levels less than compliance-titrated best PEEP, and consequently hemodynamic status should be optimized before any PEEP trial.

Positive End Expiratory Pressure Titrated With Pressure-Volume Curves as Part of a Lung Protective Strategy

A lung protective strategy that has been shown to improve outcome in ARDS includes use of a low V_T (4 to 8 ml/kg) and PEEP set 2 cm H_2O above the lower inflection point (P_{flex}) on a pressure-volume curve.[24,25] This strategy requires the use of static pressure-volume curves or slow-flow pressure-volume curves to determine best PEEP. To obtain a static pressure-volume curve, the RT passively inflates the patient's lungs with varying volumes in increasing increments of 50 to 100 ml. At each end point, static pressure is obtained by means of application of an end inspiratory pause, and the resultant pressure-volume curve is plotted (Figure 48-8). Upper and lower inflection points typically can be determined. The lower inflection point is thought to be the point at which alveolar recruitment begins. The upper inflection point indicates lung overdistention. PEEP is set at approximately 2 cm H_2O above the lower inflection point (P_{flex}). Determining PEEP level using the P_{flex} value may be done after a lung recruitment maneuver (see later). V_T is adjusted to ensure that the upper inflection point is not exceeded during inspiration.

Calculating the static pressure-volume curve is technically difficult and time-consuming.[12] An alternative is to use the slow-flow pressure-volume curve. A slow-flow curve (≤6 L/min) may also identify the lower inflection point for the purposes of setting PEEP (Figure 48-9). However, in either case, some patients do not have a lower inflection point. In about 25% of patients, the P_{flex} cannot be identified from the

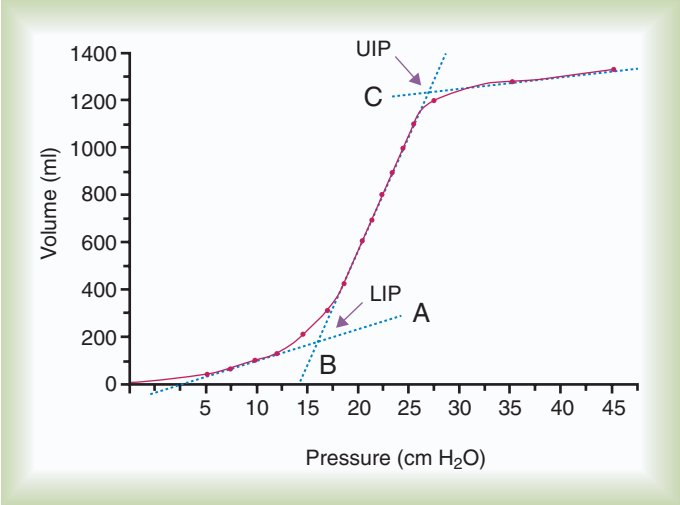

FIGURE 48-8 Static pressure-volume curve of a patient with ARDS. Volume is increased in increments of approximately 100 ml, inspiratory P_{plat} is measured, and a pressure-volume curve is plotted. Straight lines (*A, B,* and *C*) are drawn tangent to the curve, and the lower inflection point *(LIP)* and the upper inflection point *(UIP)* are identified. PEEP is adjusted to approximately 2 cm H_2O above the *LIP*.

Box 48-14 Performing a Lung Recruitment Maneuver and Decremental Positive End Expiratory Pressure Trial

- General approach: PCV
- PEEP: 20 to 25 cm H_2O
- Pressure control setting: 15 cm H_2O
- Inspiratory time: 1 to 2 seconds
- Rate: 15 to 20/min
- Duration 2 to 3 min

Immediately followed by a decremental PEEP trial

- Mode: Volume control
- PEEP: 20 to 25 cm H_2O
- V_T: 4 to 6 ml/kg IBW
- Rate: Highest rate avoiding auto-PEEP
- Ventilate until dynamic compliance stabilizes 1 to 2 minutes
- Record compliance
- Decrease PEEP by 2 cm H_2O
- Ventilate until dynamic compliance stabilizes 1 to 2 minutes
- Decrease PEEP by 2 cm H_2O
- Ventilate until dynamic compliance stabilizes 1 to 2 minutes
- Continue this until PEEP level that results in the best compliance is identified
- Repeat the recruitment maneuver
- Set PEEP at best compliance PEEP plus 2 to 3 cm H_2O

Before performing a recruitment maneuver, ensure that the patient is hemodynamically stable and sedated to apnea.

pressure-volume curve.[25] In addition, observer variability in identifying the lower inflection point can be significant.[50]

Positive End Expiratory Pressure and Lung Recruitment Maneuvers

Various lung recruitment maneuvers have been suggested for improving $\dot{V}/\dot{Q}$ and reducing shunting in patients with ARDS. These maneuvers include several variations that incorporate CPAP[25,51,52] or the use of PCV with high PEEP levels.[49,53] Regardless of approach, before any lung recruitment maneuver is performed, the patient must be hemodynamically stable and sedated to apnea. Neuromuscular paralysis is unnecessary, but the patient must be accepting of passive ventilation at high pressures. Hemodynamic stability is crucial because of the high intrathoracic pressures established during all recruitment maneuvers, although the few data that are available indicate that pressure control recruitment maneuvers are better tolerated than CPAP recruitment maneuvers.[54,55] The original recruitment techniques applied 40 to 45 cm H_2O CPAP for 30 to 40 seconds.[25,51,52] For recruitment maneuvers to be successful, they should be performed as early as possible after the patient is stabilized on the ventilator.[51-53] The longer the length of mechanical ventilation before the recruitment maneuver, the greater the likelihood that the maneuver will fail. See Box 48-14 for details on the performance of lung recruitment maneuvers and decremental PEEP trials.

The most widely accepted approach to recruiting the lung is the use of PCV. With this approach, PEEP is set higher than levels needed to maintain the recruited lung open, usually between 20 cm H_2O and 25 cm H_2O; a pressure control level 15 cm H_2O above this is then set. Ventilation is provided with an I:E of 1:1 to 1:2 at a rate of 15 to 20 per minute. All recruitment maneuvers are performed with 100% O_2. If this initial approach to lung recruitment does not open the lung, PEEP can be set higher in increments of 5 cm H_2O, and the recruitment repeated after the patient has totally stabilized from the previous maneuver (>30 minutes). The maximum safe peak pressure during a recruitment maneuver is 50 cm H_2O. Peak pressures greater than 50 cm H_2O increase the likelihood of barotraumas during the maneuver.[52,53]

The best method of establishing optimal PEEP after recruitment is a decremental PEEP trial.[49,51,53,56] It is best to perform the trial in volume ventilation because the easiest bedside method of identifying the optimal PEEP is to determine the best compliance PEEP. The best oxygenation PEEP can also be determined. It takes only about 1 to 2 minutes for the compliance to stabilize when PEEP is changed, but at least 20 minutes is required for PaO_2 to stabilize after a PEEP adjustment.

To perform the trial, PEEP should begin at 20 to 25 cm H_2O but always at PEEP higher than expected necessary to maintain the lung open. V_T during the decremental PEEP trial is usually set at 4 to 6 ml/kg IBW depending on P_{plat}. Inspiratory time is set at 0.6 to 0.8 second, and rate is at the highest level that does not result in auto-PEEP. First, the compliance is recorded at these settings after stabilization. Then the PEEP is decreased 2 cm H_2O, and the compliance again is allowed to stabilize. The process is continued until the best compliance PEEP can be identified. Generally, compliance is low at the starting PEEP (20 to 25 cm H_2O) because of overdistention. As PEEP is decreased, compliance improves until it peaks and then starts to decrease

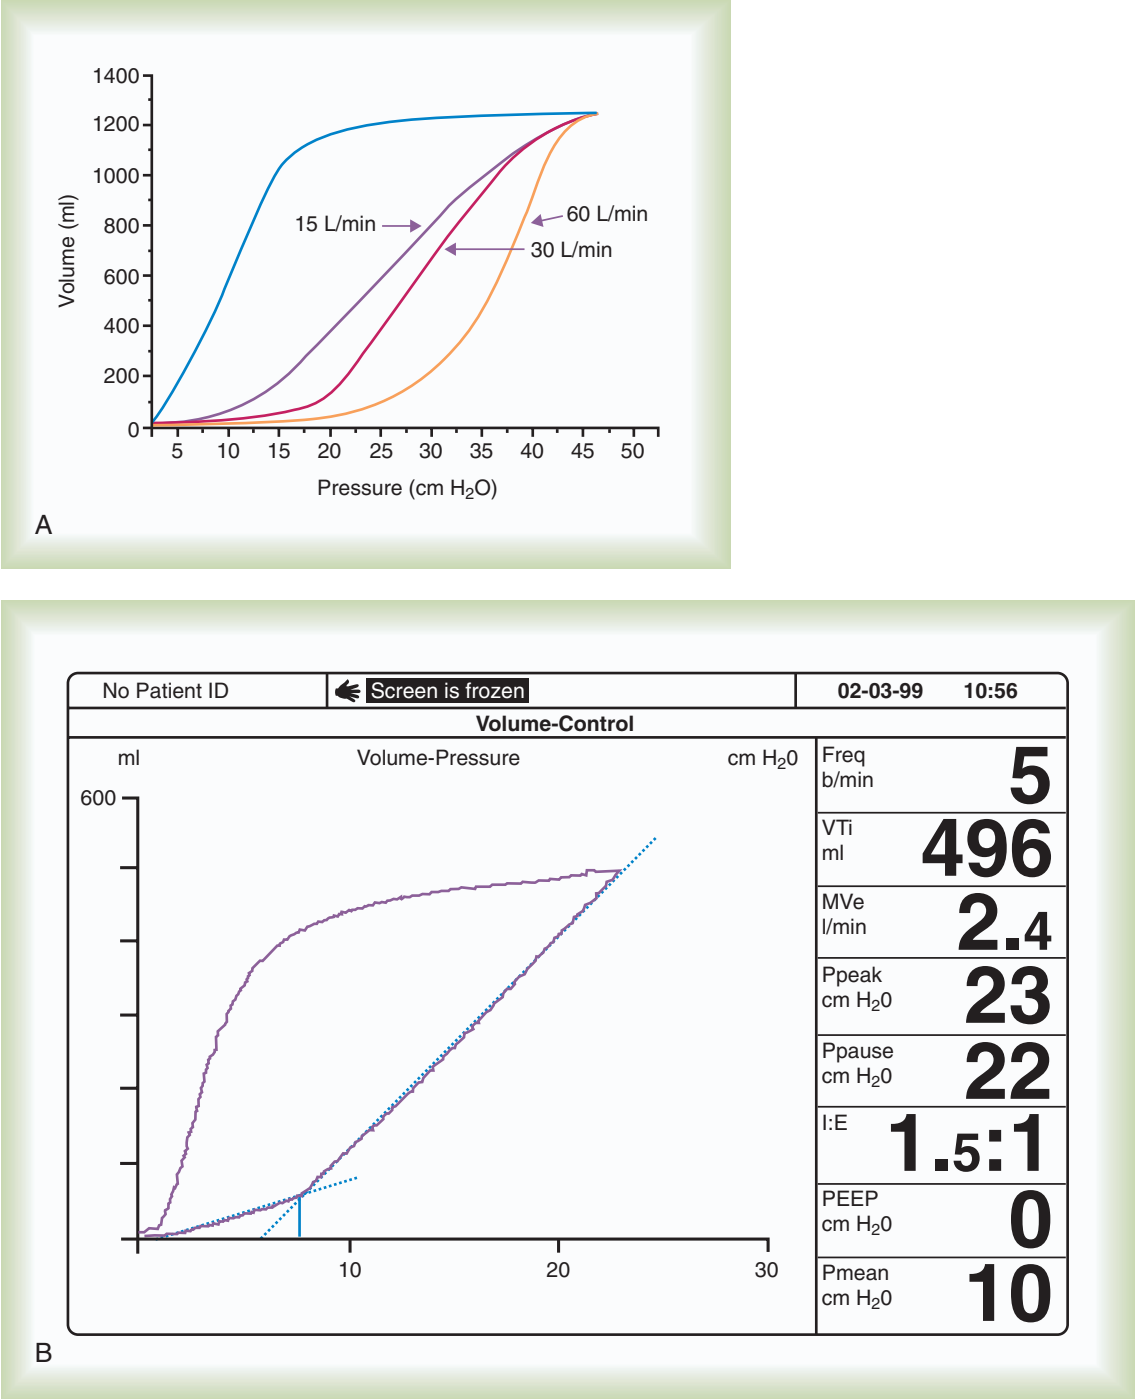

FIGURE 48-9 **A,** Pressure-volume curves generated by a ventilator graphics package with the flow set at 60 L/min, 30 L/min, and 15 L/min. As flow is decreased, the curve shifts to the left and more closely approximates a static pressure-volume curve. Flow of less than 6 L/min is recommended for identifying the lower inflection point *(LIP)* from a slow-flow pressure-volume curve. **B,** Slow-flow pressure-volume curve with use of a set rate of 5 breaths/min, I:E ratio of 1.5:1, and V_T of 500 ml. LIP is approximately 8 cm H_2O. The respiratory cycle time is 12 seconds (cycle time = 60/f = 60/5 = 12 seconds). An I:E ratio of 1.5:1 results in an inspiratory time of 4.8 seconds. Inspiratory flow is V_T/T_i = 0.5 L/4.8 sec = 0.104 L/sec, or approximately 6 L/min.

because of derecruitment and atelectasis.[49] The best compliance PEEP is increased by 2 to 3 cm H_2O because the best compliance PEEP underestimates the best oxygenation PEEP by 2 to 3 cm H_2O.[49] After identifying the optimal PEEP level, the lung must be recruited again because derecruitment occurred during the decremental PEEP trial. After this second recruitment, PEEP is set at the optimal level determined during the decremental trial.

A recruitment maneuver should be stopped if there is a decrease in SpO_2 to less than 85%, a significant change in heart

rate (>140 beats/min or <60 beats/min), a significant change in mean arterial blood pressure (<60 mm Hg or a decrease >20 mm Hg from baseline), the development of cardiac arrhythmia, or any indication that barotraumas occurred.[51] More recent meta-analyses indicate that the use of high PEEP benefits patients with moderate to severe ARDS but does not benefit patients with mild ARDS.[40,41]

Positive End Expiratory Pressure Tables

The ARDS Clinical Network study used an FiO_2-PEEP table to adjust PEEP levels.[2] Using this approach, PEEP and FiO_2 are alternately adjusted to obtain PaO_2 of 60 to 80 mm Hg or SpO_2 90% or greater (see Box 48-7). The table offers higher and lower PEEP options. For the lower PEEP option, PEEP is set at 5 to 10 cm H_2O with FiO_2 of 0.30 to 0.70; the higher PEEP option sets PEEP at 12 to 20 cm H_2O in the same FiO_2 range. The higher PEEP option should be reserved for patients who may benefit from higher PEEP in terms of lung recruitment and who have a stable blood pressure and no barotrauma. Of all the approaches to setting PEEP, this is the approach least based on the physiology of the patient. It is a reasonable approach to establish initial PEEP, but it is generally a poor choice for further adjustment of PEEP.

Other Techniques for Improving Oxygenation

The primary techniques for optimizing oxygenation in patients receiving mechanical ventilatory support are adjusting FiO_2 and PEEP. Other techniques that may be helpful in improving arterial O_2 levels include optimizing the patient's hemodynamic status, providing good bronchial hygiene, prone positioning, and extracorporeal membrane oxygenation (ECMO). Some clinicians have also used techniques to prolong inspiratory time and reverse the I:E ratio. However, approaches focused on increasing inspiratory time have not been shown to be better than properly set PEEP and are associated with marked hemodynamic compromise.

Bronchial Hygiene

In many patients, turning, sitting up, and getting out of bed into a chair can be helpful in improving oxygenation. Upright positioning (30 to 45 degrees) seems to be beneficial for ventilated patients, and supine positioning may increase the risk of pneumonia, especially in patients receiving enteral feeding or with a decreased level of consciousness.[57] Elevation of the head of the bed greater than 30 degrees has been recommended in all ventilated patients to reduce the incidence of ventilator-associated pneumonia. Special rotational beds can be used to optimize PaO_2 in selected patients. Postural drainage, adequate humidification, and bronchodilator therapy all may improve oxygenation and should be considered in the care of ventilated patients when not specifically contraindicated.

Prone Positioning

Prone positioning may be an effective technique for improving oxygenation in some patients with ARDS.[58-61] Prone positioning may improve PaO_2, decrease shunt fraction, and reduce mortality in patients with severe ARDS when it is initiated early and applied for most of the day.[62] Although improvement in PaO_2 may be dramatic and sustained (up to 12 hours), not all patients benefit from prone positioning. The procedure is not without risk. Care must be taken to ensure that endotracheal tubes, intravenous lines, and catheters are not blocked or dislodged. The patient may also have skin breakdown at specific pressure points (face, sternum, hips, knees), and facial or eyelid edema may occur, although the latter is primarily a cosmetic concern that resolves quickly when the patient returns to a supine or sitting position.[63] The most serious complication is corneal abrasion necessitating corneal transplantation.[63,64] Prone positioning is labor-intensive, often requiring two nurses, an RT,

MINI CLINI

Use of Positive End Expiratory Pressure

PROBLEM: A 30-year-old, 80-kg (IBW) man is in the critical care unit because of blunt trauma to the chest after a motor vehicle accident. The patient's initial mechanical ventilatory support settings are as follows:

Mode: = Assist/control volume ventilation, V_T: 500 ml (6 ml/kg IBW)
Rate: 20 breaths/min
FiO_2: 0.70
PIP: 35 cm H_2O
P_{plat}: 30 cm H_2O
PEEP: 0

Arterial blood gas analysis yielded the following results:

pH: 7.38
PaO_2: 48 mm Hg
$PaCO_2$: 36 mm Hg
SaO_2: 81%

The RT considers a recommendation that PEEP be instituted. What are the goals of this type of adjunctive therapy, and what are some of the potential adverse effects of PEEP of which the RT should be aware?

Solution: The general goals of PEEP are to stabilize and maintain open alveolar units to achieve adequate oxygenation and to avoid potentially unsafe levels of FiO_2 and inflation pressure. Improvement is most commonly assessed with PaO_2 or SpO_2, compliance and measurement of blood pressure and cardiac output.

At least 5 cm H_2O PEEP should be used in all acutely ventilated patients unless the patient is too hemodynamically unstable to tolerate the use of PEEP. When PaO_2 does not respond to a high FiO_2, the condition is referred to as *refractory hypoxemia*. An appropriate initial PEEP for this patient would be 10 cm H_2O because of the patient PaO2/FiO2 ratio of 69, severe ARDS, and arterial blood gases, P_{plat}, and blood pressure, should be assessed. As the level of PEEP is increased, the RT must be alert for signs of decreased cardiac output. Measurement of effective compliance and P_{plat} is also indicated. In all cases, the lowest PEEP level that provides acceptable oxygenation should be selected.

and a physician to "flip" the patient. Numerous early randomized controlled trials have evaluated the impact of prone positioning on survival in ARDS[58-61]; however, none of the trials have shown improved outcome. A more recent meta-analysis indicated improved survival in patients with the most severe lung injury—patients with PaO_2/FiO_2 ratio less than 100 mm Hg.[62] A recent randomized control trial verified the meta-analysis finding.[65] As a result, prone positioning should be reserved for severe ARDS (PaO2/FiO2 < 100 mmHg) and after lung recruitment and appropriate PEEP titration has been preformed. Similar to all lung protective approaches to ventilatory support, prone positioning should be used early in the course of ARDS if it is to be beneficial.

The mechanism of action of prone positioning is unclear. In ARDS, dorsal lung injury tends to increase shunt and decrease $\dot{V}/\dot{Q}$, resulting in hypoxemia. Supine positioning tends to increase regional pressure in the dependent, or dorsal, portions of the lungs. Prone positioning may improve $\dot{V}/\dot{Q}$ and reduce shunting by removing the pressure of the heart on the dorsal regions, causing regional dorsal traction, which may promote lung opening. The recommended technique for prone positioning is outlined in Box 48-15.

VENTILATION

Alveolar ventilation is determined by respiratory rate, V_T, and dead space and is described by the following equation:

$$\dot{V}_A = (V_T - V_{Dphys})f$$

where $\dot{V}_A$ is alveolar ventilation, V_T is tidal volume, V_{Dphys} is physiologic dead space, and f is respiratory frequency or rate.

Box 48-15 Prone Positioning

Preparation for prone positioning includes the following:
- Adequate sedation of patient
- Clear assignment of responsibilities between team members
- Moving the patient to one side of the bed
- Checking all lines for length
- Checking the security of the endotracheal tube
- Endotracheal suctioning
- Preoxygenation with 100% O_2
- Checking all vital signs

The turn includes:
- Tipping the patient to the side
- Securing electrocardiogram leads
- Turning the patient prone
- Turning the patient's head toward the ventilator

Care after the turn includes:
- Checking artificial airway
- Checking all lines
- Checking ventilator pressure and volume
- Monitoring vital signs
- Repositioning and recalibrating pressure transducers
- The patient needs supports (pillows) for each side of chest and forehead so that the endotracheal tube and head are not compromised.

The relationship between arterial $PaCO_2$, alveolar ventilation ($\dot{V}_A$), and CO_2 production ($\dot{V}CO_2$) is described as follows:

$$PaCO_2 = (0.863)(\dot{V}CO_2)/\dot{V}_A$$

Arterial $PaCO_2$ is considered the best index of effective ventilation. Increases in $\dot{V}_A$ or decreases in $\dot{V}CO_2$ result in a decrease in $PaCO_2$, whereas increases in $\dot{V}CO_2$ or decreases in $\dot{V}_A$ result in an increase in $PaCO_2$. If there is no change in $\dot{V}CO_2$, the following relationships can be used to estimate the effect of changes in $\dot{V}_A$ on $PaCO_2$:

$$\begin{matrix}\text{Initial} & & \text{Desired}\\ PaCO_{2(1)} \times \dot{V}_{A(1)} & = & PaCO_{2(2)} \times \dot{V}_{A(2)}\end{matrix}$$

The foregoing predictive equation can be used during mechanical ventilation with the following modifications:

$$PaCO_{2(1)}(V_{T(1)} - V_{Dphys(1)})f_{(1)} = PaCO_{2(2)}(V_{T(2)} - V_{DSphys(2)})f_{(2)}$$

For changes in rate alone, if there is no change in $\dot{V}CO_2$ or V_{Dphys}, this becomes:

$$\begin{matrix}\text{Initial} & & \text{Desired}\\ PaCO_{2(1)} \times f_{(1)} & = & PaCO_{2(2)} \times f_{(2)}\end{matrix}$$

For changes in VT alone, this becomes:

$$\begin{matrix}\text{Initial} & & \text{Desired}\\ PaCO_{2(1)} \times V_{T(1)} & = & PaCO_{2(2)} \times V_{T(2)}\end{matrix}$$

A major goal of mechanical ventilatory support is optimization of the patient's ventilation and $PaCO_2$; however, this does not mean normalization of $PaCO_2$. Acceptable arterial pH and alveolar PCO_2 are assessed by P_{plat}. For many patients, the level of ventilatory support is adjusted to achieve a $PaCO_2$ of 35 to 45 mm Hg with a pH of 7.35 to 7.45. In the care of patients with acute exacerbation of COPD and accompanying chronic ventilatory failure, the clinician may target ventilatory support to achieve the patient's "normal" $PaCO_2$ and pH. For patients with COPD and chronic hypercapnia, the target $PaCO_2$ may be 50 to 60 mm Hg with a pH of 7.30 to 7.35. In patients with severe ARDS, a $PaCO_2$ of 70 mm Hg with an acidic pH may have to be accepted to protect the lung from ventilator-induced lung injury. The sicker the patient, the more likely the clinician is to accept oxygenation and acid-base values that greatly deviate from normal. Regardless of the patient's condition, optimizing pH is more important than targeting a specific $PaCO_2$ value.[1,9] Box 48-16 presents an example of the effect of change in $\dot{V}_A$ on $PaCO_2$.

Box 48-16 Example of the Effect of Change in $\dot{V}_A$ on $PaCO_2$

If a patient has an initial $PaCO_2$ of 50 mm Hg with a corresponding alveolar ventilation ($\dot{V}_A$) of 4 L/min, what level of alveolar ventilation is required to decrease the $PaCO_2$ to 40 mm Hg (if there is no change in $\dot{V}_ACO_2$)?

If the patient's $\dot{V}_A$ is increased from 4 L/min to 5 L/min, the $PaCO_2$ should decrease from 50 mm Hg to 40 mm Hg.

Adjusting Tidal Volume and Rate

V_T and rate may be adjusted for a desired level of ventilation as assessed by $PaCO_2$. V_T usually is based on specific patient considerations but ideally should never result in P_{plat} greater than 28 cm H_2O. Respiratory rate is adjusted to achieve the desired $PaCO_2$. Normal resting V_T of healthy individuals is 6.3 ml/kg IBW. In most critically ill patients, V_T should be in the range of 4 to 8 ml/kg IBW. In patients with improving respiratory function ready for extubation, V_T of 9 to 10 ml/kg IBW may be acceptable; however, V_T greater than 10 ml/kg IBW should never be selected for a critically ill patient.

Apnea (Controlled Ventilation)

In an apneic patient, precise control of $PaCO_2$ usually can be achieved with pressure or volume ventilation because the ventilator rate and V_T are determined directly or indirectly by the clinician.

Rate. In the care of apneic patients, the clinician has complete control over the patient's rate, and changes in ventilator rate can be used precisely to alter $PaCO_2$. For rate changes alone (V_T held constant):

$$\begin{array}{cc} \text{Initial} & \text{Desired} \\ PaCO_{2(1)} \times f_{(1)} & = PaCO_{2(2)} \times f_{(2)} \end{array}$$

For example, if a patient's initial rate was 18 breaths/min and resultant $PaCO_2$ was 50 mm Hg, the rate change needed to decrease the patient's $PaCO_2$ to 40 mm Hg could be calculated as follows:

$$\begin{array}{cc} \text{Initial} & \text{Desired} \\ PaCO_{2(1)} \times f_{(1)} & = PaCO_{2(2)} \times f_{(2)} \\ 50 \times 18 & = 40 \times f_{(2)} \end{array}$$

$$f_{(2)} = (50 \times 18)/40 = 23 \text{ breaths/min}$$

For this patient, an increase in machine rate from 18 to 23 breaths/min would decrease $PaCO_2$ from 50 mm Hg to 40 mm Hg. Two warnings must be kept in mind in the use of this predictive equation. First, it is assumed that $\dot{V}CO_2$ is constant. If there is an increase or decrease in $\dot{V}CO_2$, the resultant $PaCO_2$ would be different from the predicted value. Common causes of increased $\dot{V}CO_2$ in the ICU include pain, agitation, anxiety, fever, overfeeding, increased activity, and fighting the ventilator. Decreases in $\dot{V}CO_2$ may be caused by decreased activity, sedation, paralysis, anesthesia, or sleep. Second, the equation is based on the assumption that the patient is apneic. Patients who are triggering the ventilator in the assist/control mode determine their own $PaCO_2$ on the basis of the assist rate. Patients in the SIMV mode who are spontaneously breathing may simply increase or decrease their level of spontaneous breathing and make $PaCO_2$ prediction difficult. In addition, the primary factor that limits the selection of rate is the development of auto-PEEP. If auto-PEEP develops, plateau pressure increases in volume ventilation and tidal volume decreases in pressure ventilation.

Tidal Volume. Changes in V_T can be used to alter $PaCO_2$. For a patient 80 kg IBW receiving ventilation in the control mode with V_T of 600 ml (7.5 ml/kg) and resultant $PaCO_2$ of 30 mm Hg, the change in V_T to achieve a PaO_2 of 40 mm Hg would be calculated as follows:

$$\begin{array}{cc} \text{Initial} & \text{Desired} \\ PaCO_{2(1)} \times V_{T(1)} & = PaCO_{2(2)} \times V_{T(2)} \\ 30 \times 600 & = 40 \times V_{T(2)} \end{array}$$

$$V_{T(2)} = (30 \times 600)/40 = 450 \text{ ml}$$

For this patient, a decrease in V_T from 600 ml to 450 ml results in an increase in $PaCO_2$ from 30 mm Hg to 40 mm Hg. This is directly altered in volume ventilation by changing the tidal volume or indirectly by decreasing the pressure control level in pressure ventilation. Several warnings should be kept in mind for changes in V_T. First, V_T should be within the preferred range for a given patient condition. In the example, new V_T (450 ml) represents 5.6 ml/kg IBW, which is an acceptable value. V_T should be small enough to avoid lung injury and maintain P_{plat} at less than 28 cm H_2O. Second, in this equation, $\dot{V}CO_2$ and V_{Dphys} are assumed to be constant because changes in $\dot{V}CO_2$ or V_{Dphys} affect $PaCO_2$. Activity, agitation, fever, and overfeeding may increase $\dot{V}CO_2$, whereas sedation, paralysis, or sleep may decrease $\dot{V}CO_2$. V_{Dphys} changes with changes in airway pressure, and increases in ventilator V_T may result in increased dead space. Development of pulmonary emboli or hemodynamic instability may abruptly increase V_{Dphys}.

Mechanical Dead Space. Mechanical dead space is defined as the volume of gas rebreathed as the result of a mechanical device. Large-bore tubing attached between the patient "wye" and the patient connection serves as mechanical dead space, and 6 inches (15 cm) of large-bore tubing represents a volume of approximately 50 to 70 ml.

For ventilation of tracheostomy patients, 6 inches (15 cm) of mechanical dead space often is used to keep the weight of the "wye" connection and tubing off of the tracheostomy tube and to give additional flexibility to the circuit for patient movement. Mechanical dead space usually is not used for endotracheally intubated patients, and the addition of mechanical dead space can serve as a cause for an increase in $PaCO_2$. Mechanical dead space is a primary concern in patients with severe ARDS in whom V_T is 4 to 6 ml/kg IBW, and as a result $PaCO_2$ is elevated. The simple removal of mechanical dead space in these patients in some cases can markedly improve CO_2 elimination. HME filters are another major cause of mechanical dead space. Depending on the brand, 80 ml of dead space can be added by these devices.

In healthy persons, V_{Dphys} and anatomic dead space are approximately the same and can be estimated at approximately 1 ml/lb or 2.2 ml/kg IBW. Although healthy persons have a dead space-to-tidal volume (V_D/V_T) ratio of approximately 0.20 to 0.40, a V_D/V_T ratio greater than 0.50 is common among ventilated patients.

Control of $PaCO_2$ in Synchronized Intermittent Mandatory Ventilation Mode

In the SIMV mode, machine breaths are interspersed with spontaneous breathing, and the spontaneous breaths may be

MINI CLINI

Adjusting $PaCO_2$ During Volume Ventilation

PROBLEM: A 22-year-old man, 5 ft 10 in (178 cm) tall, being treated for a drug overdose is being ventilated with the following settings:
Mode: VA/C
FiO_2: 0.40
V_T: 600 ml
Rate: 15 breaths/min
PIP: 20 cm H_2O
P_{plat}: 13 cm H_2O
PEEP: 5 cm H_2O

The patient's lungs are clear to auscultation, and there is no evidence of aspiration. Arterial blood gas values obtained 15 minutes ago were:
PaO_2: 80 mm Hg
$PaCO_2$: 30 mm Hg
SaO_2: 95%
HCO_3: 24 mEq/L
pH: 7.52
Base excess: +2 mEq/L

The physician asks the RT to normalize this patient's oxygenation and ventilatory status. What should the RT do?

Solution: At this time, the patient is making no spontaneous breathing efforts. The patients' oxygenation status is fine, and no adjustments are needed. In the absence of spontaneous breathing in the VA/C mode, $PaCO_2$ can be adjusted by changing machine rate (f) or V_T. Because the V_T is large (600 ml), the correct adjustment would be to decrease the V_T.

For prediction of the needed change in V_T to increase $PaCO_2$ to 40 mm Hg, the following calculation could be performed:

$$\begin{array}{cc} \text{Actual} & \text{Desired} \\ V_{T(1)} \times PaCO_{2(1)} = V_{T(2)} \times PaCO_{2(2)} & \end{array}$$

$$V_{T(2)}\ \text{Desired} = (V_{T(1)} \times PaCO_{2(1)})/PaCO_{2(2)}$$

$$V_{T(2)}\ \text{Desired} = (600 \times 30)/40 = 458\ \text{ml}$$

If V_T is decreased to 450 ml, $PaCO_2$ and pH should normalize.

PSV. $PaCO_2$ can be decreased by increasing V_T, increasing PSV for spontaneous breaths, or increasing the machine rate. Levels of $PaCO_2$ may be increased by reducing the machine rate, decreasing V_T, or decreasing the level of PSV for spontaneous breaths. As with apneic (control) ventilation, an appropriate V_T should be selected on the basis of the patient's condition and with the goal of keeping P_{plat} less than 28 cm H_2O with V_T ideally 4 to 8 ml/kg IBW depending on the patient's pulmonary status. PSV level in the SIMV mode should be adjusted to overcome WOB_I; the usual range is 5 to 15 cm H_2O, although higher levels may be needed by patients with high resistance. PSV should be adjusted to ensure that during spontaneous breathing, WOB is not excessive. Accessory muscle use or suprasternal, intercostal, or substernal retractions during spontaneous breathing indicate the need to increase the PSV level. When appropriate V_T and PSV level are selected, the primary method for adjusting $PaCO_2$ is to increase or decrease SIMV rate.

After ventilator initiation, two different approaches may be taken. For full ventilatory support, an initial SIMV rate and V_T are selected to provide 100% of the patient's ventilatory requirements; for most adults, this means starting with V_T of 6 to 8 ml/kg IBW with SIMV rate of 15 to 20 breaths/min. Generally, a minute ventilation of approximately 100 ml/kg IBW is achieved with these initial settings. Arterial blood gas values are obtained 20 to 30 minutes after initiation of mechanical ventilation, and SIMV rate is titrated up or down in increments of 2 breaths/min until desired $PaCO_2$ is achieved. Monitoring is continued, and adjustments are made by increasing or decreasing SIMV rate to maintain full ventilatory support until the patient's condition improves and ventilator discontinuation is considered.

Partial ventilatory support in the SIMV mode requires a different initial approach. Ventilation begins with V_T and machine rate sufficient to provide full ventilatory support, and arterial blood gases are measured. If $PaCO_2$ is adequate, the patient is immediately challenged with a decrease in SIMV rate of 2 breaths/min. This procedure is followed by patient assessment and measurement of arterial blood gases, as indicated. If the resultant assessment values remain adequate, the patient continues to be challenged with decreases in SIMV rate until $PaCO_2$ increases. At that point, the patient's ventilatory capacity has been exceeded, and SIMV rate is returned to the previous value. Box 48-17 provides an example of titration of the SIMV rate for partial ventilatory support after ventilator initiation in a spontaneously breathing patient.

Assist/Control Mode Volume Ventilation and $PaCO_2$

Ventilator initiation in the VA/C mode begins with selection of initial V_T and backup control rate to ensure a safe minimum level of ventilation. In PA/C, a pressure control level sufficient to establish desired V_T is selected along with a backup as in VA/C. The patient is allowed to trigger the machine as often as desired above this backup rate, and the resultant assist rate is determined by the patient's ventilatory drive. If the respiratory drive is intact, patients tend to trigger the ventilator at an appropriate rate to achieve adequate $PaCO_2$ and pH. By allowing patients to set their own rates, the level of ventilation increases or decreases on the basis of the patient's physiologic needs. Should the patient become apneic owing to sedation or sleep, a minimum backup control rate is provided.

Because the patient determines the level of ventilation, $PaCO_2$ levels are regulated by the patient. However, problems arise when the patient triggers the ventilator at an inappropriately rapid rate. Pain, anxiety, hypoxemia, secretions in the airway, and metabolic acidosis may contribute to an excessive trigger rate. The result can be an inappropriate I:E ratio and an inadequate expiratory time. These abnormal values may increase mean airway pressure, reduce venous return, and result in auto-PEEP and overinflation and associated missed triggering of the ventilator, especially in patients with obstructive disease. Patients may fight the ventilator, resulting in high inspiratory

Box 48-17 Partial Ventilatory Support With Synchronized Intermittent Mandatory Ventilation

Mechanical ventilation is initiated in the SIMV mode for a 70-kg, spontaneously breathing 38-year-old man. Before initiation of ventilation, the patient's spontaneous rate was 30 breaths/min with a spontaneous V_T of 200 ml. Initial ventilator settings are:

V_T: 500 ml
SIMV rate: 14 breaths/min
FiO_2: 0.40
PSV: +8 cm H_2O
PIP: 24 cm H_2O
P_{plat}: 18 cm H_2O
PEEP: 8 cm H_2O

Arterial blood gases are obtained in 20 minutes, with the following results:

PaO_2: 88 mm Hg
SaO_2: 97%
pH: 7.38
$PaCO_2$: 40 mm Hg
HCO_3: 24 mEq/L
Base excess: +1 mEq/L

The decision is made to provide partial ventilatory support for this patient, and the SIMV rate is titrated as follows:

Time	V_T (ml)	SIMV Rate	Total Rate	$PaCO_2$ (mm Hg)
9:00 AM	600	14	20	40
9:30 AM	600	12	15	38
10:00 AM	600	10	18	38
10:30 AM	600	8	24	46
11:00 AM	600	10	18	42

The patient's condition should now be stabilized at a rate of 10 breaths/min with titration of SIMV to the patient's needs with observation and measurement of arterial blood gases. When the rate is decreased to 8 breaths/min, $PaCO_2$ begins to increase. The rate is increased to the previous setting of 10 breaths/min. Titrating the level of SIMV support to the patient's needs is not the same as weaning the patient. After improvement in the patient's condition, weaning may be tried (see Chapter 52) with a daily spontaneous breathing trial.

pressure. In the event that a patient receiving ventilation in the assist/control mode is triggering the ventilator at an inappropriately high rate, the first step the RT should take is to identify the cause of the increased rate. Patient anxiety may be diminished with simple reassurance and encouragement to relax and "let the machine breathe for you." Hypoxemia should be managed with appropriate O_2 therapy and PEEP, if indicated. Secretions should be removed by suctioning, and bronchial hygiene techniques should be applied. The cause of metabolic acidosis should be identified and managed, if possible.

In some patients, appropriate sedation improves the ventilatory rate. Patients who begin fighting the ventilator after a previous period of calm may have a new and potentially life-threatening complication. If a patient begins fighting the ventilator, a careful assessment should be made to identify the problem. Often, careful attention to the ventilator trigger sensitivity, flow rate, volume, and pressure is helpful, and administration of analgesic and sedative agents may be needed.[12] If sedation is required, the use of intermittent sedation with daily interruption using a sedation protocol may reduce the duration of mechanical ventilation.[66,67] A last resort is pharmacologic controlled ventilation.[12] In the presence of a metabolic acidosis, a sudden change from assisted ventilation at a rapid rate with the associated hyperventilation to controlled ventilation at a slower rate can result in severe acidosis, which can be life-threatening. Other problems with controlled ventilation include patient safety, ventilatory muscle atrophy, and prolonged muscle weakness if paralytic agents are used for a prolonged period.

Pressure Support Ventilation and $PaCO_2$

PSV is normally set at the level needed to establish a normal V_T of 4 to 8 ml/kg IBW. To increase or decrease V_T, the clinician simply increases or decreases the PSV level and observes the resultant V_T on the ventilator exhaled volume monitoring screen. Because PSV is an assist mode, the patient is allowed to trigger the ventilator as desired. The result should be an adequate $PaCO_2$ and pH. In patients with an unstable ventilatory drive or periods of apnea, PSV should be avoided.

Pressure-Controlled Ventilation and $PaCO_2$

Management of ventilation and $PaCO_2$ during PCV is similar to PSV; the only difference between these two modes in a spontaneously breathing patient is the method of breath termination. With PSV, the breath is terminated as a result of the patient's inspiratory flow decreasing to the termination cycling flow, whereas in PA/C, the breath is terminated when the inspiratory time is reached. No other real differences in these modes exist in a spontaneously breathing patient.

To increase or decrease $PaCO_2$ in the PCV mode, the RT can simply increase or decrease the pressure limit while observing the exhaled V_T on the ventilator display monitor until desired V_T is obtained. The most important problem with the use of V_T to adjust $PaCO_2$ in the PCV mode is that the peak pressure should not be increased greater than 28 cm H_2O to avoid ventilator-induced lung injury.

In a patient receiving PCV, a change in the rate affects $PaCO_2$ in the same manner as in **volume-controlled ventilation**. If V_T remains constant, an increase in rate decreases $PaCO_2$ and vice versa. However, in the PCV mode, percent inspiratory time ($\%T_i$) and I:E ratio may be fixed. If $\%T_i$ is constant, and respiratory rate is increased, actual inspiratory time decreases, and V_T also may decrease. Decreases in rate ($\%T_i$ and pressure limit constant) may result in an increase in delivered V_T. The following example shows this principle.

A patient receiving ventilation in the PCV mode has a pressure control setting of 15 cm H_2O, PEEP of 5 cm H_2O, $\%T_i$ of 50%, I:E ratio of 1:1, and rate of 20 breaths/min. In this example, respiratory cycle time can be calculated as follows:

$$\text{Respiratory cycle} = 60/f = 60/20 = 3 \text{ seconds}$$

Inspiratory time (T_i) would be:

$$T_i = \%T_i \times \text{Respiratory cycle} = 0.50 \times 3 = 1.5 \text{ seconds}$$

A pressure of 25 cm H_2O applied for 1.5 seconds might achieve V_T of 400 ml for this patient.

If the rate were increased to 30 breaths/min, what would happen to respiratory cycle time, inspiratory time, and delivered V_T? Respiratory cycle and inspiratory time are calculated for a rate of 30 breaths/min as follows:

$$\text{Respiratory cycle} = 60/f = 60/30 = 2 \text{ seconds}$$
$$T_i = \%T_i \times \text{Respiratory cycle} = 0.50 \times 2 = 1 \text{ second}$$

At a constant pressure control setting of 15 cm H_2O, a decrease in inspiratory time from 1.5 seconds to 1 second may reduce delivered V_T. An increase in respiratory rate may reduce delivered V_T and increase (rather than decrease) $PaCO_2$.

When using PCV, the RT should observe the effect of inspiratory time and pressure limit on the patient's flow and volume curves as displayed by a ventilator graphics monitoring package. Generally, as inspiratory time increases at a given pressure, volume also increases until an inspiratory plateau or hold is reached. This point can be identified by observing the inspiratory flow curve. If the inspiratory flow curve decreases to zero and holds that value for a time before exhalation begins, an inspiratory plateau is present (Figure 48-10). Further increases in inspiratory time do not result in additional V_T. Conversely, if an inspiratory plateau or hold is present, a decrease in inspiratory time does not decrease V_T (at the same pressure limit) until the inspiratory plateau is no longer present (see Figure 48-10). Table 48-8 summarizes methods of altering $PaCO_2$ during VCV and PCV.

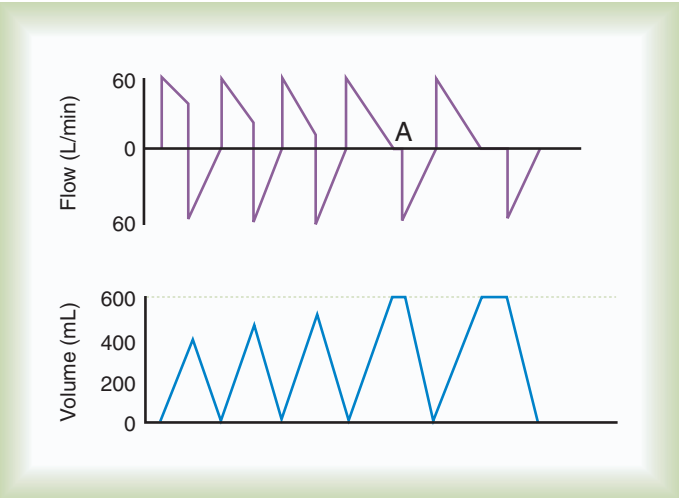

FIGURE 48-10 Effect of inspiratory time and inspiratory plateau on delivered V_T in the PCV mode. Initially, as inspiratory time is increased, V_T increases. When an inspiratory plateau *(A)* is achieved, a further increase in inspiratory time does not result in increased V_T. The same effect occurs as inspiratory time is decreased. Initially, with small decreases in inspiratory time, there would be no change in V_T as long as an end inspiratory plateau was maintained. When the inspiratory time is less than that needed for an inspiratory plateau, further decreases in inspiratory time result in a decrease in V_T at the same pressure.

$PaCO_2$ When Using Lung Protective Strategies for Acute Lung Injury and Acute Respiratory Distress Syndrome

Ventilation strategies for lung protection include low V_T, rapid respiratory rates, and permissive hypercapnia if necessary to avoid overdistention (P_{plat} > 28 cm H_2O).

Open Lung Approach

The use of a high PEEP, low V_T lung protective strategy using V_T of 4 to 8 ml/kg and PEEP set after a lung recruitment maneuver and decremental PEEP as discussed previously may improve mortality in patients with persistent ARDS.[24,25] Because V_T is reduced, respiratory rate should be increased incrementally up to 35 to 40 breaths/min. The limitation on rate is the development of auto-PEEP; if auto-PEEP does not develop, the rate can be increased. The primary concern in patients with severe ARDS is acidosis. However, most patients without severe sepsis, cardiovascular dysfunction, or renal failure can tolerate severe acidosis. The ARDS Clinical Network defined the limit for acidosis as pH less than 7.15.[2] $PaCO_2$, although important, should be allowed to increase before accepting V_T that results in P_{plat} greater than 28 mm Hg. The need to allow $PaCO_2$ to increase to avoid inducing lung injury is referred to as *permissive hypercapnia*. However, the goal is not to allow the $PaCO_2$ to increase but to avoid P_{plat} that may induce lung injury. With this approach in severe ARDS, V_T is frequently 4 to 5 ml/kg IBW, and $PaCO_2$ is greater than 60 mm Hg. Table 48-9 compares the effect of acute changes in $PaCO_2$ on pH.

TABLE 48-8

Changing Ventilation and $PaCO_2$

Mode	Ventilation (↓ $PaCO_2$)	Decrease Ventilation (↑ $PaCO_2$)
Increase		
Volume-Controlled Ventilation		
VC-CMV control	↑ V_T; ↑ f; remove V_{Dmach}	↓ V_T; ↓ f
VC-CMV assist control	↑ V_T; ↑ f (to greater than assist rate); remove V_{Dmach}	↓ VT; ↓ f (may require sedation, control mode)
SIMV	↑ VT; ↑ f; add/increase PSV; remove V_{Dmach}	↓ VT; ↓ f; reduce PSV
Pressure-Controlled Ventilation		
PCV*	↑ ΔP; ↑ f (maintaining same T_i); remove V_{Dmach}	↓ ΔP; ↓ f (maintaining same T_i)
PSV	↑ ΔP; remove V_{Dmach}	↓ ΔP
Bilevel PAP	↑ IPAP (↑ ΔP); remove V_{Dmach}	↓ IPAP (↓ ΔP)
APRV	↑ ΔP ↑ release frequency	↓ ΔP ↓ release frequency

Note: In assist (patient-triggered) mode, the patient may simply alter the trigger rate after a ventilator change, and it becomes difficult to predict the results of a ventilator change on $PaCO_2$ in the assist mode.
APRV, Airway pressure release ventilation; *IPAP,* inspiratory positive airway pressure.
*In PCV, if $\%T_i$ is preset, an increase in respiratory rate results in a decrease in inspiratory time and may reduce V_T. If $\%T_i$ is set at 50% in PCV mode, an increase in rate from 15 to 20 breaths/min causes inspiratory time to decrease from 2 seconds (50% of 4 seconds) to 1.5 seconds (50% of 3 seconds). If the pressure limit is not changed, V_T is likely to decrease.

MINI CLINI

Adjusting Ventilation in PA/C Mode

PROBLEM: A 70-kg (IBW) patient with ARDS is receiving PCV in the control mode with the following ventilator settings:
Pressure: 15 cm H_2O
Rate: 25 breaths/min
Inspiratory time: 0.8
FiO_2: 0.60
PEEP: 12 cm H_2O
V_T (exhaled): 425 ml

Arterial blood gas values with these ventilator settings are as follows:
PaO_2: 60 mm Hg
SaO_2: 90%
pH: 7.30
$PaCO_2$: 50 mm Hg
HCO_3: 23 mEq/L
Base excess: −2 mEq/L

The physician requests that the respiratory rate be increased to 18 breaths/min to decrease the patient's $PaCO_2$ to 40 mm Hg and normalize the pH. What should the RT do?

Solution: This patient has a PaO_2/FiO_2 ratio of 100 (60/0.60), which is consistent with the diagnosis of ARDS. Special considerations for the ventilatory management of ARDS include maintaining P_{plat} less than 28 cm H_2O. V_T is started at 8 ml/kg IBW and gradually reduced to 6 ml/kg IBW to achieve this goal and minimize ventilator-induced lung injury. Respiratory rate may be increased to maintain $PaCO_2$ and pH closer to normal, as long as volume and P_{plat} are acceptable. $PaCO_2$ may be allowed to increase if necessary to maintain P_{plat} less than 28 cm H_2O as long as pH is acceptable for the patient (usually >7.25). Oxygenation problems are managed initially with PEEP to achieve PaO_2 of 60 mm Hg or more with acceptable FiO_2. If PEEP fails to improve PaO_2, lung recruitment maneuvers and prone positioning may be used.

For this patient, the V_T is acceptable at approximately 6 ml/kg (70 kg × 6 ml/kg = 420 ml), and P_{plat} is 27 cm H_2O. $PaCO_2$ (50 mm Hg) and pH (7.30) are acceptable, and PEEP of 12 cm H_2O may be appropriate for a patient with ARDS. To decrease $PaCO_2$, the rate could be increased as follows:

$$\begin{array}{cc} \text{Initial} & \text{Desired} \\ f_{(1)} \times PaCO_{2(1)} = & f_{(2)} \times PaCO_2 \end{array}$$

$$25 \times 50 = f_{(2)} \times 40$$

$$f_{(2)}\ \text{Desired} = (25 \times 50/40) = 31.25$$

If V_T is maintained at 425 ml, a rate of 30 to 32 breaths/min should bring $PaCO_2$ and pH into normal range. However, if respiratory rate is increased, air trapping and auto-PEEP may develop. If auto-PEEP develops, V_T is likely to decrease. In pressure ventilation, an auto-PEEP increase is equal to an equivalent decrease in pressure control level, decreasing V_T. Rate should be increased cautiously, constantly evaluating the impact of the rate increase on V_T. More importantly, there is no reason to try to normalize $PaCO_2$ in this patient. $PaCO_2$ of 50 mm Hg with pH of 7.30 is acceptable.

TABLE 48-9

Effect of Acute Changes in $PaCO_2$ on pH

$PaCO_2$	pH
80	7.16
70	7.22
60	7.28
50	7.34
40	7.40
35	7.45
30	7.50
25	7.55
20	7.60

From Malley WJ: Clinical blood gases: assessment and intervention, ed 2, Philadelphia, 2005, Saunders.

When applying this approach, PEEP is set after it is determined by a lung recruitment maneuver and a decremental PEEP trial. V_T or pressure level is adjusted ensuring that P_{plat} or pressure control setting is less than 28 cm H_2O. Because V_T is small, inspiratory times can be short (frequently 0.6 to 0.8 second). The respiratory rate is set to achieve CO_2 elimination with its limit the development of auto-PEEP. Initially, FiO_2 is set to 1.0 but then titrated downward until PaO_2 is greater than 55 mm Hg. Generally, PEEP is sustained at the set level until FiO_2 is less than 0.5, and when PEEP is decreased, it should be decreased in increments of 2 cm H_2O no more frequently than about every 6 to 8 hours. If PaO_2 decreases when PEEP is decreased, the correct decision is to reestablish PEEP level, *not* increase FiO_2, because if this occurs, the lung is derecruited, and lung volume needs to be reestablished.

When to repeat a recruitment maneuver is a difficult question to answer, and data are insufficient at this time to provide an answer. However, if the PaO_2 does not decrease after the lung recruitment maneuver, there is no reason to perform an additional recruitment maneuver. Suctioning may cause derecruitment and hypoxemia, and ventilator discontinuation always results in derecruitment. If either of these situations occurs, the lung needs to be recruited again, but PEEP is reestablished at the previous PEEP level because the hypoxemia was *not* a result of deterioration in lung function. A recruitment maneuver and decremental PEEP trial should be repeated only if the patient's lung function deteriorates.

In all patients with severe ARDS, mechanical dead space should be eliminated, in-line suction catheters should be in place, and airway suctioning should be performed only to the level of the main stem bronchus. In addition, ideally the ventilator circuit should not be disconnected.

Other Lung Protective Strategies

Alternative techniques for facilitating CO_2 removal during lung protective ventilation in patients with ARDS include extracorporeal CO_2 removal (ECMO, see Chapter 50) reduction of CO_2 production by control of fever, avoidance of overfeeding, and neuromuscular paralysis. Patients with severe ARDS (PaO_2 < 150 mm Hg), should receive neuromuscular paralysis for the

first 12 to 48 hours to allow for stabilization and titration of therapy. This has been shown to improve mortality in these patients.[68] Other authors have advocated the use of HFOV.[69-71] However, recent data in adults indicate that the use HFOV in ARDS patients results in poorer outcome then the continued use of conventional ventilation.[21,22] As a result, HFOV cannot be recommended in the management of ARDS.

SUMMARY CHECKLIST

- P_{plat} should ideally be maintained at less than 28 cm H_2O in all patients to prevent ventilator-induced lung injury.
- PEEP is used primarily to maintain lung volume resulting in improved oxygenation and lower FiO_2 in patients with severe oxygenation problems and refractory hypoxemia.
- Initially, all acutely ill patients should be ventilated with V_T of 4 to 8 ml/kg IBW with a respiratory rate to maintain adequate CO_2 removal.
- Patients with ARDS may begin mechanical ventilation with V_T of 8 ml/kg but may need volume adjusted to less than 6 ml/kg IBW to maintain P_{plat} less than 28 cm H_2O.
- Lung protective strategies in the management of ARDS include use of lower V_T (6 ml/kg), maintaining P_{plat} less than 28 cm H_2O, permissive hypercapnia, and PEEP set above the lower inflection point on the static pressure-volume curve.
- An open lung approach to mechanical ventilation includes the application of lung recruitment maneuvers, decremental PEEP trial, choosing V_T that maintains P_{plat} less than 28 cm H_2O, and accepting permissive hypercapnia.
- Inspiratory flow for most adult patients should be initially set at approximately 60 L/min or greater to achieve an inspiratory time of approximately 0.6 to 1 second.
- Patient ventilator synchrony is a major problem in patients during patient-triggered ventilation.
- In all modes of pressure ventilation, the pressure level should be set to ensure that V_T of 4 to 8 ml/kg IBW is delivered.
- When in doubt, initial FiO_2 should be set at 1.0.
- Auto-PEEP is a problem in patients with obstructive lung disease (COPD, asthma).
- In spontaneously breathing patients with COPD and auto-PEEP, applied PEEP should be added to ensure that all patient efforts result in triggering of the ventilator.
- An appropriate goal of PEEP would be to achieve PaO_2 60 to 80 mm Hg with FiO_2 less than 0.50.
- Alternative lung protective strategies in patients with ARDS include prone positioning and ECMO.
- Careful attention to acid-base homeostasis and the effect of $PaCO_2$ on pH is an essential part of ventilator management.

CHAPTER 49

Noninvasive Ventilation

PURRIS F. WILLIAMS

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- List the goals and benefits of noninvasive ventilation (NIV).
- Discuss indications for NIV and the relative strength of the supporting evidence for each indication.
- List the selection and exclusion criteria for successful NIV.
- List the factors that predict successful NIV.
- Identify the types of patient interfaces available for NIV and how to choose an appropriate interface for a patient.
- Discuss the types of mechanical ventilators and ventilation modes used to provide NIV.
- Describe the role of the respiratory therapist during the initial application of NIV.
- Describe the ongoing ventilator management of NIV in the acute care setting.
- List potential complications associated with NIV, and suggest possible solutions.

CHAPTER OUTLINE

KEY TERMS

chest cuirass
continuous positive airway pressure (CPAP)
hypercapnic respiratory failure
hypoxemic respiratory failure
inspiratory positive airway pressure (IPAP)
iron lung
negative pressure ventilator
nocturnal hypoventilation
noninvasive positive pressure ventilation (NPPV)
noninvasive ventilation (NIV)
pneumobelt
rocking bed
Trendelenburg position

Noninvasive ventilation (NIV) is a means of delivering ventilatory support without using an invasive artificial airway, such as an endotracheal or tracheostomy tube. NIV can be provided by applying either negative or positive pressure to the airways. Almost any type of mechanical ventilator can be used to deliver NIV, and many noninvasive patient interfaces are available. However, at the present time, NIV is almost always delivered with a positive pressure ventilator designed specifically for noninvasive use or an ICU ventilator in conjunction with an oronasal or nasal mask. *NIV* is generally understood to include both **noninvasive positive pressure ventilation (NPPV)** and the noninvasive application of **continuous positive airway pressure (CPAP)**.

Interest in NIV has increased in recent years with the publication of findings from clinical trials using NIV in the management of respiratory failure. At the same time, technologically advanced noninvasive ventilators were introduced. Most intensive care unit (ICU) ventilators now include a specific noninvasive mode of ventilation. Improvements in the design of patient interfaces have made them more comfortable so that patients can tolerate NIV for longer periods. The net effect of these developments is that clinicians are using NIV more often than ever before in both acute and long-term care settings.[1] This chapter reviews the evidence supporting the use of NIV to manage various disease processes and makes recommendations on the types of patients and specific techniques for its successful application.

HISTORY AND DEVELOPMENT OF NONINVASIVE VENTILATION

Some early devices used for NIV relied on the intermittent application of abdominal pressure and the force of gravity to accomplish inspiration and expiration. These devices are most effective when used for patients with neuromuscular or neurologic disease in the absence of primary pulmonary disease. They are capable of generating tidal volume (V_T) in the range of 4 to 6 ml/kg predicted body weight (PBW) in appropriately selected patients.

First described in the 1930s, the **pneumobelt** consists of a rubber bladder that is strapped around the abdomen and connected to a positive pressure ventilator (Figure 49-1).[2] The pneumobelt is properly positioned above the pelvic arch and below the umbilicus. When inflated, the rubber bladder compresses the abdomen, pushes the diaphragm upward, and assists exhalation. On deflation of the rubber bladder, the abdominal contents and diaphragm move down, facilitating inspiration.[2] Because this device requires gravity to be effective, the patient must be sitting at an angle of at least 30 degrees.[3] Some abdominal mass is necessary for the pneumobelt to be effective. It does not work well in thin patients. Some patients with neuromuscular or neurologic disease and long-term dependence on a ventilator prefer the pneumobelt during daytime hours when they are out of bed and in a chair.[4]

The **rocking bed** (Figure 49-2) periodically rocks from the **Trendelenburg position** to reverse Trendelenburg position, using gravity to produce exhalation and inspiration. Rocking beds were used in the 1950s to wean patients from negative pressure ventilators and to provide long-term ventilatory support to patients following recovery from polio.[2] The main problem associated with the rocking bed is motion sickness. It can prevent patients from tolerating the device despite adequate ventilation.

Negative pressure ventilators were widely used from the late 1920s through the 1960s during the polio epidemic.[2] A **negative pressure ventilator** generates negative pressure within a chamber that surrounds the thorax. When pressure in the chamber decreases, the chest wall expands and intraalveolar pressure becomes negative, causing air to flow into the lung

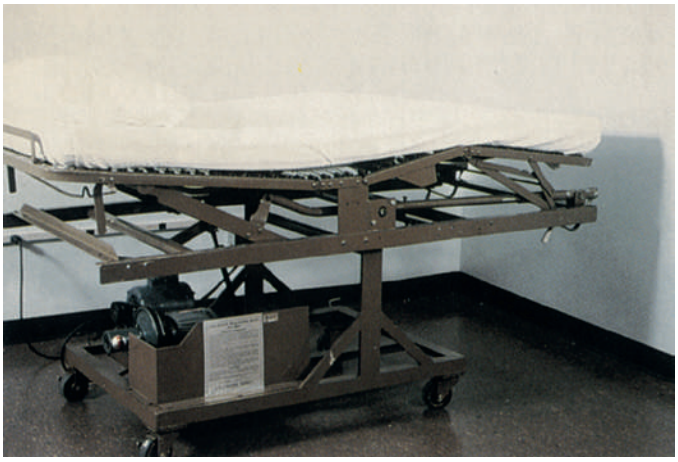

FIGURE 49-2 **A,** Rocking bed. **B,** Time-lapsed photography of the rocking bed in motion.

during inspiration. When the negative pressure is released, elastic recoil causes the lungs and chest wall to return to their normal size, resulting in passive exhalation. The first electrically powered negative pressure ventilator, known as the **iron lung** (Figure 49-3), surrounded the entire body from the neck down. Other designs were developed during that time, including the **chest cuirass**, which enclosed only the chest, the Porta-Lung, and the poncho wrap.[2] Effective negative pressure ventilation can be challenging to achieve if the device has air leaks or does not fit properly. Negative pressure ventilators that enclose the body limit caregiver access to the patient. In addition, collapse of the upper airway can occur during inspiration when excessive negative pressure is applied. With the development of positive pressure ventilators and the expanded use of NPPV, interest in negative pressure ventilation has greatly diminished.[2] Negative pressure ventilators are seldom seen in hospitals but some

continue to be used in the home by patients with chronic respiratory failure from neuromuscular diseases, such as polio.

The first reported use of NPPV was in 1780, when Chaussier used a bag and face mask during resuscitation.[1] However, widespread clinical use of NPPV did not begin until much later, with the introduction of intermittent positive pressure breathing in 1947.[1,2] Intermittent positive pressure breathing was primarily used to deliver aerosolized medications. The use of intermittent positive pressure breathing declined significantly in the mid-1980s[2] when the results of a randomized, controlled trial involving the treatment of patients with chronic obstructive pulmonary disease (COPD) showed no benefit compared to aerosol medication delivery with a small volume nebulizer.[5] Around this time, nasal mask CPAP was suggested as a therapy for obstructive sleep apnea.[6] Nasal masks also were used nocturnally in conjunction with positive pressure ventilators to provide rest for the respiratory muscles in patients with neuromuscular disorders.[7] In 1989, NPPV was used successfully to support 8 of 10 patients with acute respiratory failure (ARF).[8] Those positive findings renewed the interest in NIV that continues today. NIV has been used to treat a wide variety of clinical conditions in numerous trials during the past 20 years. The next section provides background and discussion focusing on the most relevant studies. Study findings are evaluated, and evidence-based recommendations for NIV are provided for each indication.

INDICATIONS FOR NONINVASIVE VENTILATION

Goals and Benefits of Using Noninvasive Ventilation

The hallmark of ARF is impaired gas exchange. The standard treatment to improve gas exchange in severe ARF is endotracheal intubation and mechanical ventilation. The primary goal of NIV is to improve gas exchange without endotracheal intubation. Significant complications associated with intubation can be prevented if NIV is applied successfully. The potential benefits of using NIV in the acute care setting include improving survival, decreasing the length of mechanical ventilation, decreasing the length of hospitalization, and decreasing the incidence of ventilator-associated pneumonia. In the long-term care setting, major goals are improving the patient's quality of life and relieving symptoms of hypoventilation. The goals of NIV in acute and long-term care settings are listed in Box 49-1.

The primary indication for NIV is **hypercapnic respiratory failure** secondary to COPD exacerbation. Hypercapnic ARF is characterized by inadequate alveolar ventilation, elevated arterial PCO_2 and decreased arterial pH. Hypoxemia may be present, but is easily treated by increasing the inspired oxygen concentration. Although patients with acute hypercapnic respiratory failure are the most likely to benefit from the use of NIV, it is also indicated for selected patients with hypoxemic respiratory failure or with respiratory failure resulting from numerous other conditions (Box 49-2).[2,9]

Box 49-1 Goals of Noninvasive Ventilation

ACUTE CARE SETTING
- Improve gas exchange
- Avoid intubation
- Decrease mortality
- Decrease length of time on ventilator
- Decrease length of hospitalization
- Decrease incidence of ventilator-associated pneumonia
- Relieve symptoms of respiratory distress
- Improve patient-ventilator synchrony
- Maximize patient comfort

LONG-TERM CARE SETTING
- Relieve or improve symptoms
- Enhance quality of life
- Avoid hospitalization
- Increase survival
- Improve mobility

Modified from Mehta S, Hill NS: Noninvasive ventilation. Am J Respir Crit Care Med 163:540, 2001.

Box 49-2 Acute and Chronic Disease Processes for Which Noninvasive Ventilation May Be Indicated

ACUTE CONDITIONS
- Hypercapnic respiratory failure
- COPD exacerbation
- Asthma
- Facilitation of extubation, especially in COPD
- Hypoxemic respiratory failure but cautiously
- Acute cardiogenic pulmonary edema
- Respiratory failure in immunocompromised patients
- End-of-life care and DNI orders
- Postoperative respiratory failure
- Prevention of reintubation in high-risk patients
- Postextubation respiratory failure

CHRONIC CONDITIONS
- Nocturnal hypoventilation
- Restrictive thoracic disease
- ALS
- COPD
- OHS

Acute Care Indications

Hypercapnic Respiratory Failure

Chronic Obstructive Pulmonary Disease. NIV should be considered the standard of care for treatment of hypercapnic respiratory failure secondary to COPD exacerbation and should be available as first-line therapy in all institutions treating patients with COPD. The use of NIV in the management of COPD exacerbation is strongly supported by the evidence in numerous randomized, controlled trials.[10-16] Systematic review and meta-analyses of the data from fourteen studies concluded that patients with COPD and ARF require intubation less often when they receive NIV. Other benefits of NIV use in this group

of patients include lower risk of mortality, fewer complications and reduced length of hospital stay.[10-13]

Early intervention with NIV should be considered before severe respiratory acidosis develops. However, NIV can be used successfully and safely in much sicker patients. Successful application of NIV has occurred in patients with hypercapnic coma and in awake, noncomatose patients. Severe hypercapnea and decreased level of consciousness should not be considered absolute contraindications to a cautious trial of NIV in selected patients.

RULE OF THUMB

All patients with an acute COPD exacerbation should be evaluated for NIV as an alternative to intubation and invasive mechanical ventilation. NIV is the standard of care in these patients.

Asthma

The evidence for NIV use in the management of ARF caused by severe asthma is inconclusive. Meduri and colleagues[17] reported positive results in an uncontrolled study using NIV to treat 17 patients in status asthmaticus. Other studies have reported using NIV successfully to manage ARF in patients with asthma[18-21] but no randomized, controlled trials have been performed. The role of NIV in this patient population remains controversial because of weak supportive evidence. Routine management with NIV is not recommended in asthmatic patients with ARF. If patients with severe asthma receive a trial of NIV, they must be monitored closely. Significant improvement in the symptoms of respiratory failure should be evident within 1 to 2 hours, and if improvement is not evident, intubation should proceed without delay.

Facilitation of Weaning in Chronic Obstructive Pulmonary Disease

Several randomized controlled studies have reported success using NIV to facilitate weaning from mechanical ventilation in patients with COPD who failed at least one spontaneous breathing trial (SBT).[15,22,23,24] In addition, NIV was associated with more successful weaning and lower mortality after 60 days. There is reasonable evidence that difficult-to-wean patients with COPD who were intubated for ARF and subsequently failed SBTs should be considered for an elective trial extubation directly to NIV. Ideally, the patients selected should have used NIV previously and should meet none of the NIV exclusion criteria. The failure of NIV to prevent intubation does not preclude its successful use at a later time.

RULE OF THUMB

A trial extubation directly to NIV should be considered for patients with COPD and hypercapnic ARF who are likely to receive a tracheostomy for failure to wean.

Hypoxemic Respiratory Failure

Hypoxemic respiratory failure, defined by a PaO_2/fractional inspired oxygen (FiO_2) ratio less than 300, can result from several distinct causes. Clinical trials of NIV to manage acute hypoxemic respiratory failure have yielded conflicting results. The efficacy of NIV largely depends on the etiology of the hypoxemia. Further study is needed to determine clearly the types of patients who would benefit from NIV.

Acute Cardiogenic Pulmonary Edema

In 1991, mask CPAP was shown to improve hypoxemia and reduce the need for intubation in patients with severe cardiogenic pulmonary edema.[25] Similar findings in other randomized controlled trials provide strong evidence that both CPAP[25-27] and NPPV[28-30] improve outcomes in these patients compared with simple oxygen (O_2) therapy.[31-35] Mask CPAP of 8 to 12 cm H_2O and 100% O_2 is first-line therapy to treat hypoxemia associated with severe cardiogenic pulmonary edema. NPPV should be reserved for patients with both hypercapnia and hypoxemia. Extra caution is recommended for patients who present with cardiac ischemia, hemodynamic instability, arrhythmias, or depressed mental status. Patients with these risk factors should be intubated and invasively ventilated.[31]

RULE OF THUMB

CPAP of 8 to 12 cm H_2O with 100% O_2 should be considered first-line therapy in acute pulmonary edema. NPPV should be used only when hypercapnia is present.

Pneumonia

NIV has been used in the management of severe community-acquired pneumonia, but with mixed results. Similar to other applications of NIV for hypoxemic respiratory failure, care should always be exercised and clinicians should always error on the conservative side. That is, if the patient's status does not improve within a few hours of application, invasive ventilation should be initiated. Additional studies are needed. The current recommendation for the use of NIV in pneumonia is to limit its routine use to patients who also have COPD.[36]

Acute Lung Injury and Acute Respiratory Distress Syndrome

Several studies have reported failure rates greater than 50% when NIV is used to treat acute lung injury (ALI) and acute respiratory distress syndrome (ARDS).[37-40] Patients with risk factors such as hemodynamic instability, metabolic acidosis, or profound hypoxemia are more likely to fail NIV.[38] Survey data from centers in the United States and Europe with extensive experience using NIV indicate that more than 60% of patients with hypoxemic respiratory failure required intubation, with greater than 60% mortality.[40] More recently, positive findings were reported in a prospective multicenter survey that used NIV

as the first-line intervention in selected patients with ALI/ARDS.[41] Results showed that 54% avoided intubation with improved outcome. Failure was predicted if PaO_2/FiO_2 ratio was less than 175 after the first hour of NIV. Three randomized controlled trials in patients with ALI/ARDS found that NIV decreased intubation rate and mortality, resulting in improved outcome.[40,42,43] However, a meta-analysis of these trials indicated that NIV did not decrease mortality despite a reduction in intubation rate,[42] and this analysis was consistent with other reports.[42]

Another randomized controlled trial[44] in patients with hypoxemic respiratory failure but no hypercapnia showed that mask CPAP significantly improved PaO_2/FiO_2 ratio within the first hour but failed to reduce the intubation rate, length of ICU stay, or hospital mortality. In this study, many patients who failed CPAP sustained cardiac arrest during intubation.[44] It is thought that clinicians delayed intubation because they did not readily accept the failure of NIV to correct hypoxemia in these patients. The evidence to date does not support routine NIV use in patients with ALI/ARDS, but randomized controlled trials focusing exclusively on ALI/ARDS are needed.[9] The data suggest that a closely monitored trial of NIV in carefully selected patients may be appropriate. If NIV does not markedly improve hypoxemia within 1 to 2 hours, patients should be intubated.

Respiratory Failure in Immunosuppressed Patients

The risk of developing nosocomial infections, including ventilator-associated pneumonia, is decreased when NIV is used compared with intubation and invasive mechanical ventilation. Randomized controlled trials involving immunosuppressed patients and patients awaiting solid organ transplantation[45-50] who developed hypoxemic respiratory failure found decreased intubation rates and mortality with NIV compared with standard therapy. NIV in patients with AIDS and *Pneumocystis carinii* pneumonia showed similar results.[49] Despite the small numbers of patients in these single-center trials, NIV is accepted as first-line therapy in immunosuppressed patients because it avoids the risk of infection[50-52] associated with intubation in a setting where an infection can have devastating consequences.

Palliative Care and Do-Not-Intubate Orders

The use of NIV in patients with do-not-intubate (DNI) orders and end-stage disease remains controversial. Patients with DNI orders may receive NIV either for supportive treatment of a nonterminal, reversible event or for palliative care. There is evidence that NIV in patients with end-stage disease provides an effective method of support with some relief from associated symptoms.[53] Two more recent case series[52,53] support the use of NIV in the management of ARF in patients with DNI orders. Schettino and colleagues[52] and Levy and coworkers[53] showed that more than 65% of patients with COPD or cardiogenic pulmonary edema and DNI status were successfully managed with NIV. Palliative care focuses on relieving the symptoms and stress from serious diseases. The goals of NIV in this setting are to minimize feelings of dyspnea and improve the patient's comfort. If the patient is not more comfortable with NIV, it should be discontinued.

The primary controversy over the use of NIV in patients with DNI orders involves patient consent. NIV can be beneficial in the care of patients with DNI orders if a patient understands that NIV is a form of life support and that its goal is either to reverse an acute disease process or to provide comfort at the end of life.[54] Clinicians should take the time to explain NIV and its goals as part of the discussion with the patient and family about wishes for life-sustaining treatment.

Postoperative Respiratory Failure

A number of investigators have used NIV in the postoperative period.[55-57] In these studies NIV was beneficial in the postoperative management of obese patients post gastroplasty, or following other major abdominal surgery and thoracic surgery.

MINI CLINIC

Noninvasive Ventilation to Treat Hypoxemic Acute Respiratory Failure

PROBLEM: A patient with acute hypoxemic respiratory failure is receiving NIV via nasal mask with a noninvasive ventilator. The ventilator is delivering PSV with peak inspiratory pressure set at 12 cm H_2O and end expiratory pressure set at 5 cm H_2O. O_2 at 6 L/min is flowing into the nasal mask. After 40 minutes on NIV, the patient continues to have signs of respiratory distress (dyspnea, tachypnea with respiratory rate 30, heart rate 120 beats/min, SpO_2 88%, and cyanosis). The patient is having difficulty keeping his mouth closed, and there is a large air leak as a result. An arterial blood gas was drawn, and PaO_2 is 50 mm Hg.

Solutions

1. Change the interface to a full-face mask to prevent the air leak and provide more effective ventilator support. A chin strap could be tried but is not likely to be successful. Dyspneic patients tend to breathe through their mouths preferentially.
2. Change to a ventilator that can provide precise, high FiO_2; displays graphics; calculates exhaled volumes; and has alarms. Bleeding in O_2 to the mask or circuit provides only low, inconsistent FiO_2. Additional information from waveforms and calculated values can help provide better assessments and interventions. For a patient this sick, alarms are an important consideration.
3. Increase PEEP to 8 to 10 to maintain alveoli open and improve severe hypoxemia; 5 cm H_2O is probably inadequate in this situation.
4. If these interventions do not result in significant improvement in oxygenation within 30 to 45 minutes, the patient should be electively intubated and ventilated. Delaying intubation is associated with greater risk of death during intubation. Such delays can result if clinicians do not recognize an unsuccessful NIV trial in the setting of hypoxemia.

Although the results of these studies are encouraging, additional randomized trials are needed to identify specific postoperative populations that would benefit from NPPV or CPAP. At the present time, there is insufficient evidence to support routine postoperative use of NIV.

Prevention of Reintubation in High-Risk Patients

Reintubation has been associated with increased mortality, longer hospital stay, and a greater need for long-term care than in patients who are initially successfully extubated. In recent studies, Nava and colleagues[58] and Ferrer and coworkers[59] randomly assigned patients at risk for reintubation to NIV or standard care; both studies showed lower reintubation rates with NIV. Patients with hypercapnia gained the most benefit from NIV. Risk factors associated with extubation failure included a diagnosis of COPD or congestive heart failure, age older than 65 years, ineffective cough and excessive secretions, upper airway obstruction, history of one or more weaning failures, one or more comorbid conditions, and Acute Physiology and Chronic Health Evaluation (APACHE) II score greater than 12 on the day of extubation.

Sufficient evidence exists to support selective application of NIV to avoid reintubation and its associated negative impact on outcome. NIV should be started after extubation of patients with multiple risk factors, especially patients with COPD, congestive heart failure, or hypercapnia. These patients should be monitored closely and reintubated promptly if NIV does not prevent respiratory distress.

Postextubation Respiratory Failure

The use of NIV to manage postextubation hypoxemic respiratory failure requires a cautious approach. Two randomized controlled trials[60,61] indicated no benefit or worse outcome when NIV was used to manage hypoxemic ARF. Keenan and associates[60] compared NIV and standard therapy in patients who developed hypoxemic respiratory failure during the first 2 days after extubation and observed a 70% reintubation rate in both groups. Esteban and colleagues[61] randomly assigned patients to standard therapy or NIV at the first sign of postextubation respiratory distress. Both groups had a 50% reintubation rate, but the group managed with NIV had higher mortality. This finding was attributed to the delay in reintubation that occurred in the NIV group. Relatively few patients with COPD were included in these two studies. The use of NIV to treat postextubation ARF generally should be reserved for patients with COPD and hypercapnic respiratory failure or patients with congestive heart failure. If hypoxemia does not significantly improve with NIV, these patients should be reintubated without delay.

RULE OF THUMB

Before using NIV in the management of ARF, be sure the process causing respiratory failure is reversible, selection criteria are met, and exclusion criteria are absent.

Long-Term Care Indications

Nocturnal Hypoventilation

Nocturnal hypoventilation is common with neuromuscular diseases, severe kyphoscoliosis, COPD, obesity, and central and obstructive sleep apnea.[62] Patients with these disorders are able to breathe spontaneously without assistance but typically have symptoms related to hypoventilation and sleep-disordered breathing. These symptoms may include excessive sleepiness during daytime hours; fatigue; morning headaches; and cognitive dysfunction, such as difficulty concentrating.[63]

Normally, the onset of sleep is characterized by a slight increase in $PaCO_2$ followed by a further increase in hypercapnia during rapid eye movement (REM) sleep. It is thought that the increased work of breathing associated with obesity and COPD or the muscle weakness caused by neuromuscular diseases results in greater levels of hypercapnia. Some of these patients are hyporesponsive to carbon dioxide (CO_2), which contributes to even more CO_2 retention. In response, the kidneys attempt to compensate by retaining bicarbonate, reducing respiratory drive further. This vicious cycle progressively worsens, leading to pulmonary hypertension, cor pulmonale, CO_2 narcosis, and eventually death.[64,65] There is strong evidence that the cycle can be stopped if breathing is assisted by NIV for 4 hours per night for 1 to 3 months.[66,67] One study suggested that NIV use during the daytime hours promotes similar improvement in gas exchange during periods of unassisted ventilation as seen when NIV is used at night.[68]

Three mechanisms have been proposed to explain the positive effects of NIV on nocturnal hypoventilation. First, it was thought that NIV rests fatigued respiratory muscles, improving their performance during the day.[69,70] Common sense supports this hypothesis, but few studies have been able to show significant or sustained improvement in muscle strength after using NIV.[71] Second, NIV reduces $PaCO_2$ and may reset the central ventilatory controller to a lower baseline $PaCO_2$. Current evidence suggests that NIV is effective because it prevents nocturnal hypoventilation and preserves ventilatory response to increases in CO_2 in patients with COPD or restrictive thoracic diseases.[65,68-71] Third, the improvements in lung compliance, lung volume, and dead space that result from NIV may be beneficial.[66]

Restrictive Thoracic Diseases

Restrictive thoracic diseases successfully managed with NIV include postpolio syndrome, neuromuscular diseases, chest wall deformities, spinal cord injuries, and severe kyphoscoliosis.[66] Patients with severe kyphoscoliosis showed improved nighttime and daytime gas exchange, fewer symptoms of hypoventilation, and increased spontaneous V_T and FVC after using NIV.[68-71] A study of eight patients with Pompe disease found that NIV corrected arterial blood gas abnormalities and resolved cor pulmonale 3 to 6 months after starting NIV.[72] Disease progression was not slowed by NIV. Diaphragmatic weakness is characteristic of this disease, in contrast to most other neuromuscular diseases.[72] In patients with Duchenne muscular dystrophy, a rapidly

progressive neuromuscular disorder, nocturnal NIV failed to slow progression of the disease and was associated with a higher mortality.[73]

The current recommendation for patients with restrictive thoracic disorders is to initiate NIV when patients develop symptoms of nocturnal hypoventilation. There is little evidence to support prophylactic NIV in patients with most restrictive thoracic diseases.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), also known as *Lou Gehrig's disease,* is a neurodegenerative disease that affects motor neurons, resulting in progressive skeletal muscle weakness and paralysis. Mean survival time is 3 to 5 years after diagnosis. All patients with ALS eventually need full ventilatory support to survive. NIV is probably effective in prolonging the lives of patients with ALS.[74]

In a randomized controlled trial, Bourke and associates[75] found that patients with ALS who used NIV gained a median survival benefit of 205 days but only in the absence of bulbar dysfunction. Evidence suggests that using NIV slows the rate of lung function decline as indicated by FVC measurement.[75,76] Lung function decline occurs more slowly and survival benefit increases when NIV is used for more than 4 hours per day.[76] Several factors influencing compliance with NIV of patients with ALS have been identified. Early intervention[77] and orthopnea[78] correlated with better tolerance of NIV, whereas bulbar involvement[75,79] and the presence of cognitive or executive dysfunction[80] negatively affected compliance with NIV.

In contrast to other restrictive thoracic diseases, there may be a survival benefit when NIV is initiated earlier in the course of ALS. In one study, patients experiencing more than 15 episodes of nocturnal O_2 desaturation per hour were started on NIV.[81] This "early" intervention resulted in survival lasting 11 months longer and suggested that NIV may also provide some benefit in patients with bulbar involvement.[81] More studies are needed to assess the effects of early NIV initiation.

Clinicians in the acute care setting have conflicting feelings about initiating NIV in patients with ALS, expressing concerns about the patients' quality of life and eventual dependence on NIV. Four studies found that NIV had a positive effect on patients' quality of life.[78,81,82,83] Positive changes associated with NIV included relief from dyspnea, increased energy and vitality, better concentration, less physical fatigue, and fewer symptoms of hypoventilation.[34] There was no difference in the perceived quality of life of patients using NIV compared with patients who received invasive mechanical ventilation through a tracheostomy.[83] However, invasive ventilation through a tracheostomy tube may have a negative effect on caregivers' quality of life. Most patients were comfortable with their decisions involving assisted ventilation with 94% of patients receiving NIV and 81% of patients with a tracheostomy indicating that they would choose ventilation again.[83]

There is good evidence that using NIV lengthens survival and slows the decline of lung function of patients with ALS. In its evidence-based Practice Parameters, the American Academy of Neurology recommended considering NIV for all patients with ALS and respiratory failure.[78] NIV is typically started when pulmonary function declines significantly (FVC < 50%). Although the evidence supporting early NIV initiation is weak, starting NIV at the first sign of nocturnal hypoventilation may be considered to improve compliance with NIV.

RULE OF THUMB

Patients with restrictive thoracic disorders should have symptoms of nocturnal hypoventilation before NIV is considered.

Chronic Obstructive Pulmonary Disease in Patients Needing Long-Term Care

There are two proposed hypotheses to explain how patients with severe COPD benefit from the use of NIV.[66] First, positive inspiratory pressure improves gas exchange and may unload the respiratory muscles, allowing them to recover, gain strength, and reduce fatigue resulting in improved quality of life. Second, NIV should decrease the symptoms of nocturnal hypoventilation and sleep-disordered breathing, improving sleep quality and daytime gas exchange.[66]

The use of NIV in the management of stable COPD is controversial. Struik and colleagues conducted a systematic review of 7 randomized controlled studies of NIV used by patients with stable COPD.[84] They found no significant improvement in $PaCO_2$ and PaO_2; pulmonary function measurements, exercise tolerance, or perceived quality of life after 3 or 12 months on NIV use. The authors did note that lower $PaCO_2$ was associated with high IPAP setting (18 cm H_2O), compliance with therapy (5 hours of NIV per night), and higher baseline $PaCO_2$ (55 mm Hg). At the present time, there is not enough evidence to support routine treatment with NIV in patients with stable COPD.[85,86]

RULE OF THUMB

NIV should be considered for management of respiratory failure in patients with ALS because it probably slows the rate of decline of lung function and lengthens survival.

Obesity-Hypoventilation Syndrome

Obesity-hypoventilation syndrome (OHS) is defined as chronic daytime hypoventilation ($PaCO_2$ >45 mm Hg) associated with obesity (body mass index >30 kg/m^2) when no other known cause for hypoventilation is present. Approximately 0.5% of women and 1% of men in the general population are estimated to have OHS.[87] Evidence suggests that OHS is a common yet underdiagnosed condition in extremely obese patients.[88] Obese patients consume many health care resources before a diagnosis of OHS is made,[89] which is a cause for concern as obesity becomes more prevalent in the United States. In a study of

hospitalized obese patients, Nowbar and colleagues[90] found that hypercapnia with no other reason for hypoventilation was present in approximately one-third of patients with body mass index greater than 35 kg/m^2 and almost one-half of patients with body mass index greater than 50 kg/m^2.

Several studies showed improved daytime gas exchange and relief of symptoms associated with nocturnal hypoventilation within 1 to 4 months of initiation of NIV.[91-93] A randomized trial of CPAP versus NPPV in patients with OHS without severe nocturnal desaturations found that both modes were equally effective in decreasing daytime $PaCO_2$.[93] At the present time, nocturnal NPPV is recommended for OHS when nasal CPAP and other first-line therapies fail to alleviate the hypoventilation.[66,94]

MINI CLINI

Preventing a High-Risk Patient from Requiring Reintubation

PROBLEM: A 74-year-old man was intubated for hypercapnic respiratory failure 3 days ago. Past medical history is significant for hypertension, coronary artery disease, COPD, and former cigarette smoker ×35 years (quit 10 years ago). He is currently on low-level PSV (PSV 8, PEEP 5 cm H_2O, FiO_2 0.3). Vital signs are heart rate 80 beats/min, blood pressure 130/70 mm Hg, respiratory rate 16 breaths/min, and SpO_2 95%. Endotracheal suctioning has been performed every 2 to 3 hours for moderate to large amounts of yellow secretions. Ipratropium MDI, 2 puffs every 6 hours, is ordered. He was placed on a spontaneous breathing trial this morning and passed; however, his ability to clear secretions is a concern. After much discussion among the patient care team, the decision was made not to extubate as planned.

Solutions

1. Extubate and immediately start NIV. Evidence supports using NIV to prevent reintubation in high-risk patients. Patients with hypercapnia are most likely to benefit. Other factors associated with high risk of extubation failure are age older than 65, COPD, and excessive secretions.
2. Continue aerosolized bronchodilators by delivering the MDI to a collapsible holding chamber added to the NIV circuit. Place the chamber between the exhalation port and the mask. Coordinate MDI actuation as closely as possible to the patient's own inspiration. Shake the MDI canister between each actuation to mix the propellant and the drug. These three points are important to deliver maximum medication to the patient.

SELECTING APPROPRIATE PATIENTS FOR NONINVASIVE VENTILATION

Acute Care Setting

The success or failure of NIV depends to a large degree on the clinician's clinical judgment in choosing appropriate patients. The primary selection criterion is the need for ventilatory assistance resulting from ARF. Patients who are unable to ventilate adequately on their own typically show signs and symptoms of respiratory distress, including use of accessory muscles, paradoxical breathing, tachypnea, and dyspnea.[2,9] In addition, patients in ARF are unable to maintain normal gas exchange and usually develop respiratory acidosis or severe hypoxemia (Box 49-3).[2,9]

NIV exclusion criteria include apnea, hemodynamic or cardiac instability, lack of cooperation by the patient, conditions that preclude use of a noninvasive interface, copious amounts of secretions, and high risk of aspiration (Box 49-4).[2,9] Decreased level of consciousness should not be considered an exclusion criterion for NIV in patients with COPD.[95,96] If the selection criteria are met and there are no contraindications, NIV should be considered.

It is important to consider the cause of ARF because the efficacy of NIV varies depending on the underlying condition being treated. In the acute care setting, most evidence supports the use of NIV in patients with COPD exacerbations or acute cardiogenic pulmonary edema. There is less evidence supporting NIV for the other indications discussed earlier; however, it is being used more frequently for patients with DNI orders, to facilitate extubation of high-risk patients, and as a means of preventing extubation failure and reintubation. Several studies identified potential predictors of success during NIV (Box 49-5). Early initiation of NIV is encouraged in patients with

Box 49-3 Noninvasive Ventilation Selection Criteria for Patients With Acute Respiratory Failure

Two or more of the following should be present:

- Use of accessory muscles
- Paradoxical breathing
- Respiratory rate ≥25 breaths/min
- Moderate to severe dyspnea (increased dyspnea in COPD patients)
- $PaCO_2$ >45 mm Hg with pH <7.35
- PaO_2/FIO_2 ratio <200

Modified from Mehta S, Hill NS: Noninvasive ventilation. Am J Respir Crit Care Med 163:540, 2001.

Box 49-4 Exclusion Criteria for Noninvasive Ventilation in Patients With Acute Respiratory Failure

- Apnea
- Inability to protect airway/high aspiration risk
- Hemodynamic or cardiac instability
- Lack of patient cooperation
- Inability to use a noninvasive interface because of facial burns, trauma, or abnormal anatomy
- Excessive amounts of secretions

Modified from Mehta S, Hill NS: Noninvasive ventilation. Am J Respir Crit Care Med 163:540, 2001.

Box 49-5 Predictors of Noninvasive Ventilation Success in the Acute Care Setting

- Minimal air leak
- Low severity of illness
- Respiratory acidosis ($PaCO_2$ >45 mm Hg but <92 mm Hg)
- pH <7.35 but >7.22
- Improvement in gas exchange within 1 to 2 hours of initiation
- Improvement in respiratory rate and heart rate

Modified from Mehta S, Hill NS: Noninvasive ventilation. Am J Respir Crit Care Med 163:540, 2001.

ARF because severe hypercapnia and acidosis are predictors of NIV failure.[97] Significant improvements in $PaCO_2$ and pH after 30 to 120 minutes of NIV are predictive of success.[98-100] In some cases, clinical judgment precludes an NIV trial based on the severity of the respiratory failure or the presence of comorbid conditions that increase the likelihood of failure to respond to NIV. However, in many situations, a reasonable plan would be a trial of NIV for 1 to 2 hours, with periodic reassessment and plans to intubate if the patient's condition does not significantly improve. Successful application of NIV includes short-term goals of improving gas exchange and preventing endotracheal intubation and long-term goals of improved outcome, decreased length of stay, and decreased mortality.

Long-Term Care Setting

The current recommended selection guidelines for NIV in restrictive thoracic disease may be separated into two parts. First, patients should have symptoms of chronic hypoventilation and lack of sleep quality. Second, patients should meet one of the following measurable parameters: $PaCO_2$ 45 mm Hg or greater, nocturnal O_2 saturation less than 88% for 5 minutes, maximal inspiratory pressure less than 60 cm H_2O, or FVC less than 50% of predicted.[66] Although a decline in pulmonary function has been associated with CO_2 retention, more evidence is needed to support the use of a declining maximal inspiratory pressure or FVC as an indication for NIV.[2]

Recommendations for use of NIV in the management of nocturnal hypoventilation caused by disorders other than restrictive lung disease and COPD include documentation of a disorder that causes hypoventilation and failure of the disorder to respond to first-line therapy. First-line therapy includes weight loss, O_2 therapy, respiratory stimulants, and CPAP. NIV is recommended as the initial therapy for moderate to severe cases of nocturnal hypoventilation.[66]

Patients with COPD and signs and symptoms of chronic hypoventilation and poor quality of sleep should receive optimal medical treatment before NIV is recommended.[66] If symptoms remain despite optimal management, the presence of one of the following selection criteria indicates the need for NPPV: $PaCO_2$ 55 mm Hg or greater or $PaCO_2$ 50 to 54 mm Hg with recurrent hospitalizations or nocturnal desaturation.[66] Recurrent hospitalization is defined as two or more hospitalizations for hypercapnic respiratory failure in a 12-month period. Nocturnal desaturation is defined by a pulse oximeter reading of less than 89% for 5 minutes with administration of at least 2 L/min of O_2.[62]

In long-term care settings, a follow-up examination is suggested 1 month or so after starting NIV to help the patient acclimate to the device. A 2-month follow-up is recommended to determine compliance with NIV and to assess benefit.[66]

Exclusion Criteria for Noninvasive Ventilation in a Long-Term Care Setting

Relative contraindications for the use of NIV for restrictive thoracic disease, nocturnal hypoventilation, and chronic COPD include an unsupportive family, copious amounts of secretions, uncooperative behavior on the part of the patient, high risk of aspiration, and any anatomic abnormality that interferes with gas delivery.[2]

EQUIPMENT USED FOR NONINVASIVE VENTILATION

Many factors, including the choice of patient interface, ventilator, mode of ventilation, and initial ventilator settings, play a role in determining whether NIV will be successful in a given patient. This section discusses the equipment and modes of ventilation used in the application of NIV.

Patient Interfaces

Various devices are available to provide a noninvasive interface between the patient and the ventilator. When selecting an interface, clinicians should evaluate the fit and air leak associated with the interface. These factors have a major impact on the efficacy of NIV. Patient comfort is also an important consideration because it influences patient compliance with therapy, particularly in the long-term care setting. Other considerations include volume of dead space and position of the exhalation port in the interface and whether the interface functions properly with the type of ventilator to be used. The most common noninvasive patient interfaces used in the acute care setting are full-face or oronasal masks followed by nasal masks. An oronasal mask is usually the best choice when NIV is used to treat ARF.

Nasal and Oronasal Masks

Nasal and oronasal masks are typically manufactured in two parts. The body of these devices is made of clear, hard plastic. Surrounding the outer edge of the mask body is either a soft plastic or silicone lip or a cushion filled with hydrogel, silicone gel, or air. The best design has a soft inner lip that forms a seal with the patient's face. When a higher positive pressure is applied, the mask fits more closely to the face. The opposite effect occurs when resuscitation masks are used for positive pressure ventilation. Higher airway pressures tend to force this type of mask away from the face, increasing the air leak.

NIV masks incorporate straps and headgear to maintain and stabilize the mask's position on the face (Figure 49-4). It is

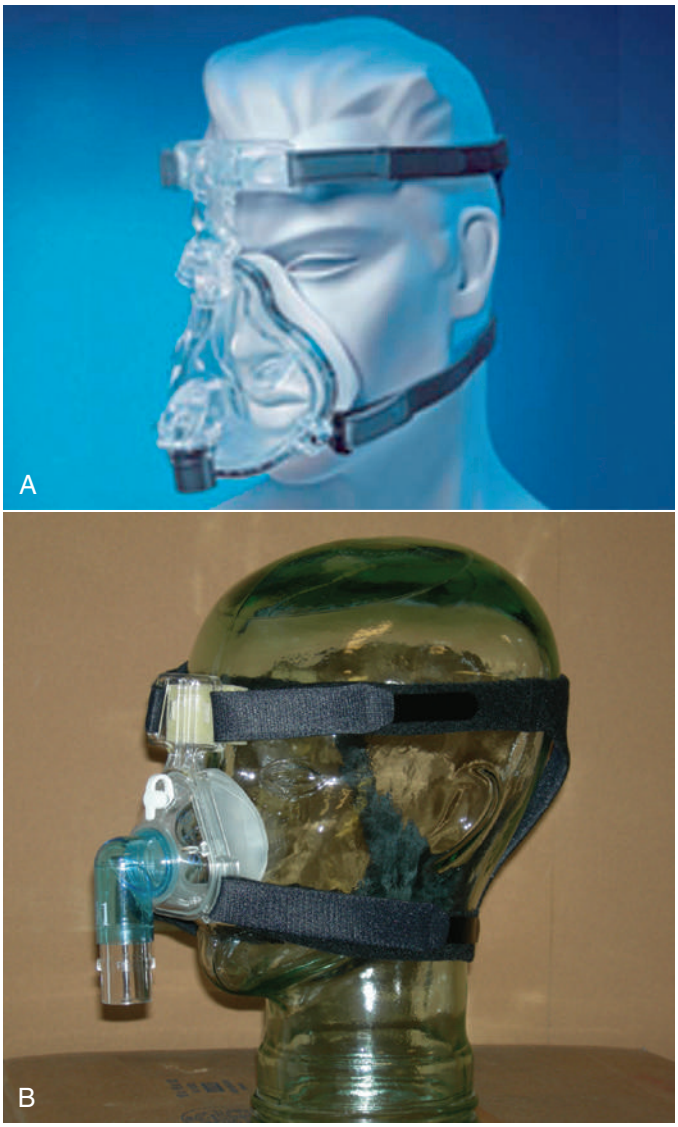

FIGURE 49-4 **A,** Nasal mask that incorporates adjustable forehead support to minimize pressure on the bridge of the nose. **B,** Nasal mask designed for small size and minimal facial contact. (**A,** Courtesy ResMed Corp, San Diego, CA. **B,** Courtesy of Phillips Respironics, Murrysville, PA.)

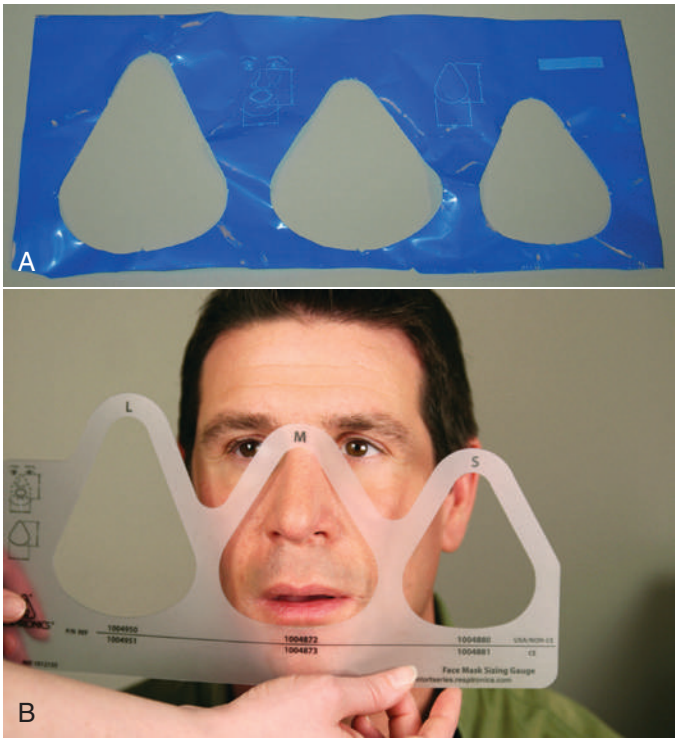

FIGURE 49-5 **A,** Templates help clinicians select an appropriately sized mask. **B,** Oronasal masks should rest on the bridge of the nose between the eyes and in the indentation between the chin and the lower lip. (Courtesy ResMed Corp. San Diego, CA.)

important to avoid tightening the straps more than necessary. A perfect seal between the mask and the face is not required because ventilators used for NIV are designed to function properly in the presence of small air leaks. Pulling the straps excessively tight is likely to result in pressure-related damage to the skin on the bridge of the nose or sometimes on the cheeks. Clinicians must be vigilant for early signs of skin damage and take steps to minimize damage and prevent development of pressure ulcers. An area of reddened skin that persists after removal of the mask is usually the first sign of pressure-related skin damage. A liquid skin barrier and a hydrocolloid patch may be applied to protect the reddened area.

To address the problem of skin breakdown, most masks incorporate some means of minimizing pressure on the skin. These include foam wedges used as spacers and adjustable mechanical controls that prevent the apex of the mask from being pulled too close to the face. Some masks have foam pads that rest on the forehead to help maintain proper mask positioning. An easy way to check for excessive tightness is to insert two fingers between the straps and the patient's face. If the straps are too tight it is not easy to do this, and they should be loosened slightly. A strategy for minimizing the risk of pressure ulcer formation is to alternate the use of two or more masks with different points of facial contact.

A key factor in patient tolerance and NIV efficacy is the choice of an appropriately sized mask. Most masks include sizing templates that can be used before removing the mask from its packaging (Figure 49-5). Nasal masks should be sized so that the cushion starts one-third of the way down from the top of the bridge of the nose and fits closely along the lateral aspects of the nose and rests above the upper lip, just under the nose. Oronasal masks fit similarly except the bottom of the mask rests in the depression above the chin and just below the lower lip. Mask sizes range from extra small to large, but for many individuals, a small or medium-small mask is a good fit. Ill-fitting masks can allow air leaks into the eyes, leading to poor tolerance. Small leaks around the mouth are generally less problematic because most ventilators used for NIV are designed to function with a baseline leak.

Nasal masks are more prone to air leaks than full-face masks, especially for patients who are mouth breathers. Chin straps are

available that provide tension to help keep the mouth closed, but in practice, they seldom work well. Oronasal masks are less prone to mouth leaks because both the mouth and the nose are covered. Disadvantages associated with oronasal masks include increases in dead space, risk of aspiration, and feelings of claustrophobia. Nasal masks may be better tolerated by patients with claustrophobia. Oronasal masks interfere with patients' ability to communicate, eat, drink, and expectorate secretions without removing the mask.

In the past few years, new types of patient interfaces have been introduced in various designs, sizes, and shapes that are intended to promote more comfort and better tolerance. The respiratory therapist (RT) should be aware of all available designs to choose a relatively comfortable, well-tolerated, correctly fitted interface through which the needed level of ventilatory support can be delivered.

Nasal Pillows

Nasal pillows (Figure 49-6) are round, soft cushions that fit directly into the nares. Specially designed headgear holds the prongs in place. This interface is used most often during nasal CPAP by patients with chronic disease who do not tolerate a nasal mask. Nasal pillows are often a good option for patients with skin necrosis on the bridge of the nose or to deliver nocturnal CPAP to patients who prefer to sleep on their side. A newer design is the wedge-shaped mini-nasal mask that covers only the end of the nose. Another is the hybrid mask (Figure 49-7), which covers the mouth with a small mask and seals the nares with nasal pillows connected to the top. This interface allows ventilation with fewer leaks, similar to an oronasal mask that does not have contact with the skin on the bridge of the nose. Besides the advantage of decreased risk of tissue damage, this design allows patients to wear glasses during NIV.

Other Interfaces

The total face mask surrounds the entire face (Figure 49-8) without applying pressure to the bridge of the nose. For this reason, it is often a good choice for patients with severe skin breakdown. A soft, flexible layer around the edge of the mask forms a seal and prevents leaking when the mask is pressurized. The total face mask comes in one size, which allows quick application in the emergency department or critical care unit. Because it does not obstruct the patient's vision, this mask may help patients who feel claustrophobic when wearing other masks.

The helmet is an interface that is unavailable in the United States at the present time (Figure 49-9). This interface surrounds the entire head like a plastic bubble. The only point where the patient experiences stress is in the axillary area where the two straps holding the helmet in place cross. Numerous recent studies have evaluated the effectiveness of the helmet during CPAP and NPPV.[101-105] Results indicated that the helmet

FIGURE 49-9 The helmet is used in Europe to provide continuous high-flow CPAP. (Courtesy Intersurgical Nederland, B.V.)

is more effective for CPAP than NPPV.[104] However, CPAP must be applied with a high continuous flow to prevent CO_2 from accumulating inside the helmet.[105] If CPAP is provided by a ventilator, the patient is likely to rebreathe CO_2 because of the large capacitance of the helmet.[105] During NIV with the helmet, CO_2 is not eliminated as effectively compared with full-face masks, and triggering and cycling the ventilator can be adversely affected.[104]

Face masks are specifically designed for use with either ICU or noninvasive ventilators (Figure 49-10). Face masks for noninvasive ventilators have entrainment valves that prevent asphyxia if the ventilator fails or the tubing becomes disconnected. Full-face masks designed for ICU ventilators do not have this feature. In addition, noninvasive ventilators using a single-limb circuit require a leak port either in the tubing or in the mask itself (Figure 49-11). Masks with leak ports should be used only with noninvasive ventilators because the leak interferes with the function of ICU ventilators.

Few data are available in the literature to help guide the choice of an interface for NIV. One study compared 30 minutes of full-face mask, nasal mask, and nasal pillows applied in random order to hypercapnic patients.[106] The investigators reported that the full-face mask and nasal pillows improved ventilation more than the nasal mask but that the nasal mask was better tolerated.[106] Use of a full-face mask also was associated with a significant increase in V_T compared with the nasal mask.[106] Similar findings were reported in a more recent study of 90 patients with hypercapnic ARF randomly assigned to full-face mask or nasal mask.[107] Both studies support the belief that full-face masks may be more effective for patients in the acute care setting.[106,107] There is no perfect NIV interface that meets the needs of every patient. Success is more likely if the interface can be tolerated for long periods and only a small air leak is present. A full-face mask is the interface of choice for patients requiring NIV for ARF. For patients who cannot tolerate a full-face mask, a nasal mask should be tried before accepting failure.

RULE OF THUMB

Use a full-face mask for patients in ARF. If the patient is unable to tolerate a full-face mask, try a nasal mask before accepting NIV failure.

Types of Mechanical Ventilators and Modes of Ventilation

Three types of ventilators are used for NIV: noninvasive ventilators, critical care ventilators, and portable home care ventilators. This section describes the characteristics and function of the three types of ventilators.

Noninvasive Ventilators

Most noninvasive ventilators are electrically powered, blower-driven, and microprocessor-controlled (Figure 49-12). These devices deliver a continuous but variable flow of gas to the patient through a single-limb circuit without an exhalation valve. To function properly, noninvasive ventilators must have a continuous air leak through one or more small ports either in the ventilator circuit or in the patient interface. The ports also provide the outlet through which the patient's exhaled gas is vented from the circuit. The main advantage of noninvasive ventilators over other types of ventilators is the ability to trigger

MINI CLINI

Problems With Triggering During Noninvasive Ventilation

PROBLEM: A patient with COPD is receiving NIV with a noninvasive ventilator using a full-face mask. The ventilator settings are as follows: PSV mode, peak pressure 14 cm H_2O, PEEP 4 cm H_2O, backup rate 10 breaths/min. Arterial blood gas was obtained after 30 minutes on NIV. $PaCO_2$ was 75 mm Hg, essentially unchanged since NIV was initiated. The RT notices that the ventilator is not triggering with every patient effort, and his respiratory distress has not improved. What should the RT do?

Solutions

1. The problems of failure to trigger and ineffective ventilation could be caused by a large air leak. Determine if an air leak is present. If so, reposition, refit, or select a better fitting mask; adjust strap tension; and consider adding a forehead spacer to minimize the leak.
2. These two problems could be related to intrinsic PEEP. Carefully observe the patient and ventilator graphics, if available, for missed trigger attempts. The ventilator should trigger with every inspiratory effort by the patient. Try increasing PEEP slowly from 4 cm H_2O to 6 cm H_2O or 8 cm H_2O. If the applied PEEP from the ventilator is set to minimize the difference between end expiratory pressure and the patient's intrinsic PEEP, the ability to trigger should improve. In some ventilators, increasing or decreasing PEEP in pressure-targeted ventilation modes does not also affect the peak pressure. In this case, increasing PEEP could result in a decrease in the ventilating pressure and V_T. Check the peak pressure to determine if the ventilating pressure has changed, and increase the peak pressure by the same amount as PEEP is increased. Effective ventilation is usually achieved if the exhaled V_T is about 4 to 6 ml/kg.

FIGURE 49-12 Examples of noninvasive ventilators with monitoring and alarm capabilities. (Courtesy Phillips Respironics, Murrysville, PA.)

and cycle appropriately when small to moderate air leaks are present.

The microprocessor controls gas delivery to the patient. Although flow and pressure are measured internally, the design of these ventilators maintains a low resistance between the patient and the ventilator at all times. Key factors are the absence of valves in the ventilator circuit, smooth internal lumen tubing for the circuit, and use of only low-resistance heated humidifiers. As a result, noninvasive ventilators are sensitive to changes in flow and pressure and can respond quickly to patient demands. Noninvasive ventilators used in the acute care setting for patients who would otherwise need intubation should meet a few safety requirements, including minimal CO_2 rebreathing and alarms for circuit disconnection, loss of power, and battery failure if a battery is present. An internal battery allows safe patient transport without interruption of NIV. Low baseline pressure settings have been associated with significant rebreathing of CO_2 in single-limb circuits.[108,109,] A setting of at least 3 to 5 cm H_2O PEEP generates adequate flow to flush exhaled gas from the ventilator circuit and prevent rebreathing of CO_2.[108] For this reason, the expiratory pressure can be set no lower than 4 cm H_2O on many noninvasive ventilators. Masks used with noninvasive ventilators typically include an antiasphyxia valve that opens automatically in the event of power loss or circuit disconnection.

Ideally, noninvasive ventilators should have an internal blending device, capable of providing FiO_2 ranging from 0.21 to about 1. Simply adding an additional flow of O_2 into the ventilator circuit or mask results in maximum FiO_2 of about 0.5,[110] which is prone to wide fluctuations from variations in patient inspiratory flow rates, patient effort, and leaks. Other capabilities such as graphics monitoring; and display calculated volumes that estimate leak, V_T, and minute ventilation are useful when adjusting NIV settings to enhance patient-ventilator synchrony.

Modes available on noninvasive ventilators usually include CPAP, spontaneous (pressure support), and timed (pressure assist/control). Depending on the ventilator used, the ventilating pressure is referred to as **inspiratory positive airway pressure (IPAP)**, equal to peak airway pressure, or pressure support,

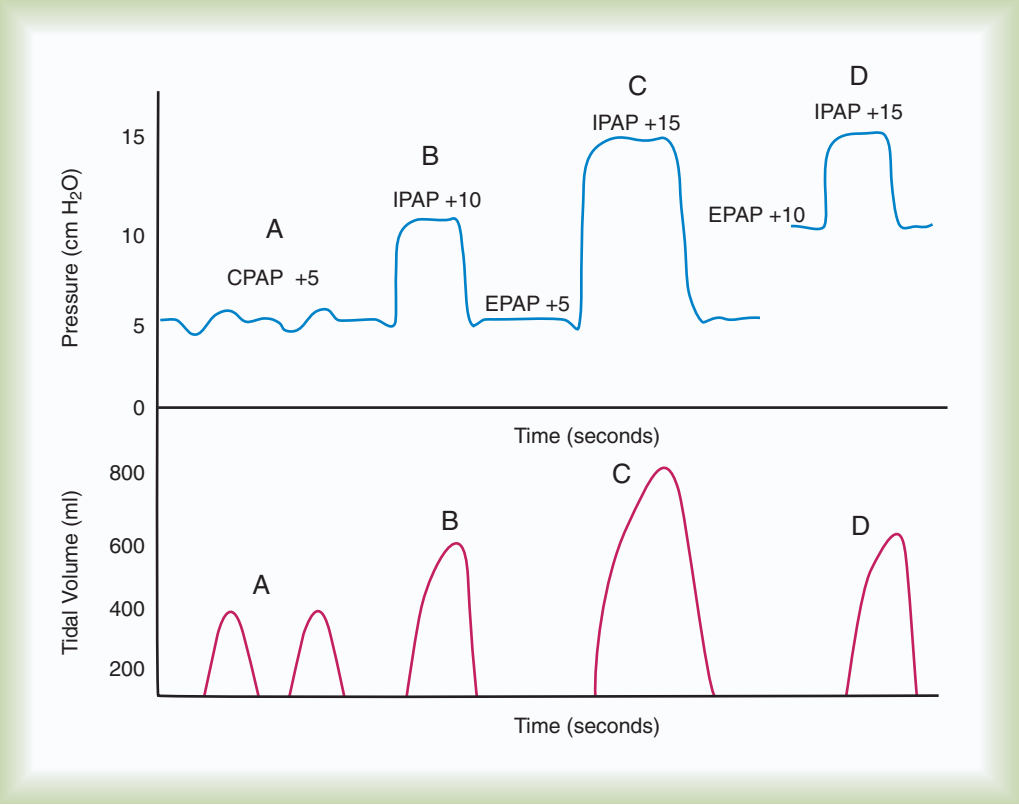

FIGURE 49-13 The effects of changing noninvasive ventilator settings (IPAP and EPAP). **A,** Spontaneous breathing on CPAP of 5 cm H_2O. **B,** Adding IPAP of 10 cm H_2O results in higher V_T. **C,** Increasing IPAP to 15 cm H_2O delivers even higher V_T. **D,** Increasing the baseline EPAP without a corresponding increase in IPAP results in lower V_T because the difference between IPAP and EPAP is less. which is the change in pressure above PEEP. In either case, this type of breath is usually pressure-limited and flow-cycled or time-cycled (Figure 49-13). With pressure support and spontaneous modes, inspiration is patient-triggered. With pressure assist/control or spontaneous-timed modes, inspiration is either patient-triggered or time-triggered.

Critical Care Ventilators

Critical care ventilators with noninvasive modes that compensate for leaks can be used to deliver NIV effectively but there is wide variability in their performance (Figure 49-14). These ventilators are equipped with internal air-oxygen blenders, graphics, and alarms, and are capable of delivering high inspiratory flow rates that meet patient demand. They generally use dual-limb circuits that prevent rebreathing of exhaled CO_2.

The main problem with using older critical care ventilators to provide NIV is their inability to compensate for leaks. Air leaks around the mask can cause problems including auto-triggering and failure to cycle. State-of-the-art critical care ventilators now have ventilation modes designed for noninvasive application. With a few models, the NIV mode activates only new alarms (low pressure) and deactivates low V_T and minute volume alarms. However, most models incorporate some level of leak compensation during triggering, cycling, or both. A common feature of NIV modes is the ability to set a maximum inspiratory time during PSV. This setting does not deactivate flow cycling but provides an additional limit for inspiration in the presence of a large leak.

To deliver NIV, ICU ventilators can be set in PSV mode, which is a patient-triggered, pressure-limited, flow-cycled mode. During inspiration, a high gas flow is delivered until the preset pressure limit is achieved. At that point, the flow begins to decrease until a predetermined level of flow is reached, cycling the breath to exhalation. Depending on the specific ventilator used, this flow level can be a fixed flow rate (e.g., 5 L/min) or a percentage of the peak flow (e.g., 25%). The flow-cycling mechanism of PSV can cause problems during NIV. In the presence of a large air leak, the flow may not decrease to the level necessary to cycle the breath to expiration. In this case, the patient may have to exhale actively, using abdominal muscles to increase airway pressure to cycle the ventilator to exhalation using secondary criteria.[111,112] This action increases work of breathing and can lead to failure of NIV.

Active exhalation can be recognized on the ventilator graphics by a spike in airway pressure at the end of the breath (Figure 49-15). There are two ways to correct this problem so that the patient can exhale passively again. First, inspiration can be time-cycled instead of flow-cycled by decreasing the maximum inspiratory time setting. Time-cycled (instead of flow-cycled), pressure-limited ventilation markedly improves patient-ventilator synchrony and patient comfort and compliance with therapy in the presence of air leaks.[113]

FIGURE 49-14 Examples of critical care ventilators that can be used to provide noninvasive ventilation. (Courtesy Medtronic, Boulder, CO.)

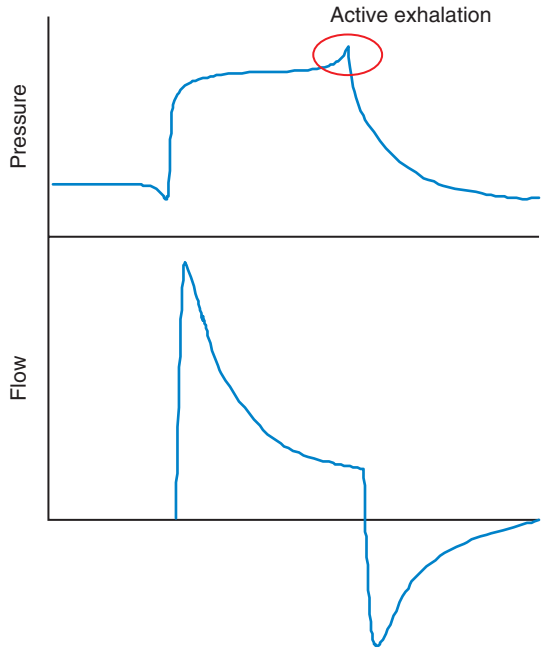

FIGURE 49-15 Active exhalation is recognized by the spike on the pressure waveform at the end of inspiration. The patient uses abdominal muscles to increase airway pressure and cycle the ventilator into exhalation.

The second option is to adjust the termination criterion[114] by changing the percentage of the peak inspiratory flow that terminates the breath. Most current generation ICU ventilators allow adjustment of the termination criterion setting over a wide range (Figure 49-16). To prevent active exhalation, the percentage is simply increased until the spike disappears from the pressure waveform. Proper adjustment of the termination criterion can markedly improve patient-ventilator synchrony during NIV.

PSV is the ventilation mode commonly used for NIV. Most RTs are familiar with using pressure-targeted ventilation for NIV on ventilators designed specifically for noninvasive application. The current recommendation by an international consensus conference on NIV in ARF is as follows: "Choice of mode should be based on local expertise and familiarity, tailored to the etiology and severity of the pathophysiological process responsible for ARF."[115] If a critical care ventilator is used for NIV, pressure ventilation makes sense because leak compensation is provided, triggering and cycling can be adjusted to suit patient needs, and minute ventilation and end expiratory pressures are preserved. Volume-controlled modes are not recommended for NIV. Inability to compensate for the decrease in minute ventilation and loss of pressure caused by large leaks are major problems when volume targeted modes are used for NIV.

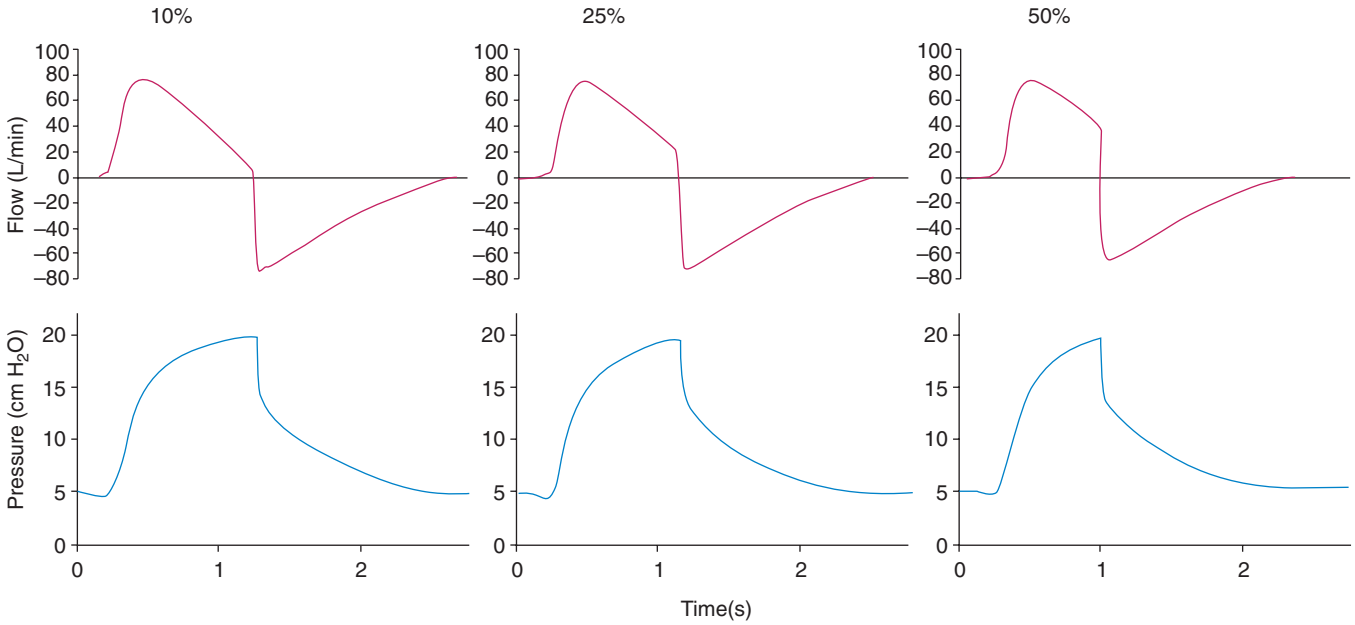

FIGURE 49-16 Effects of changing the termination criteria during PSV. Changing to a setting that ends inspiration at a higher percentage of peak flow results in shorter inspiratory time and lower tidal volume. This change is sometimes needed to improve patient-ventilator synchrony.

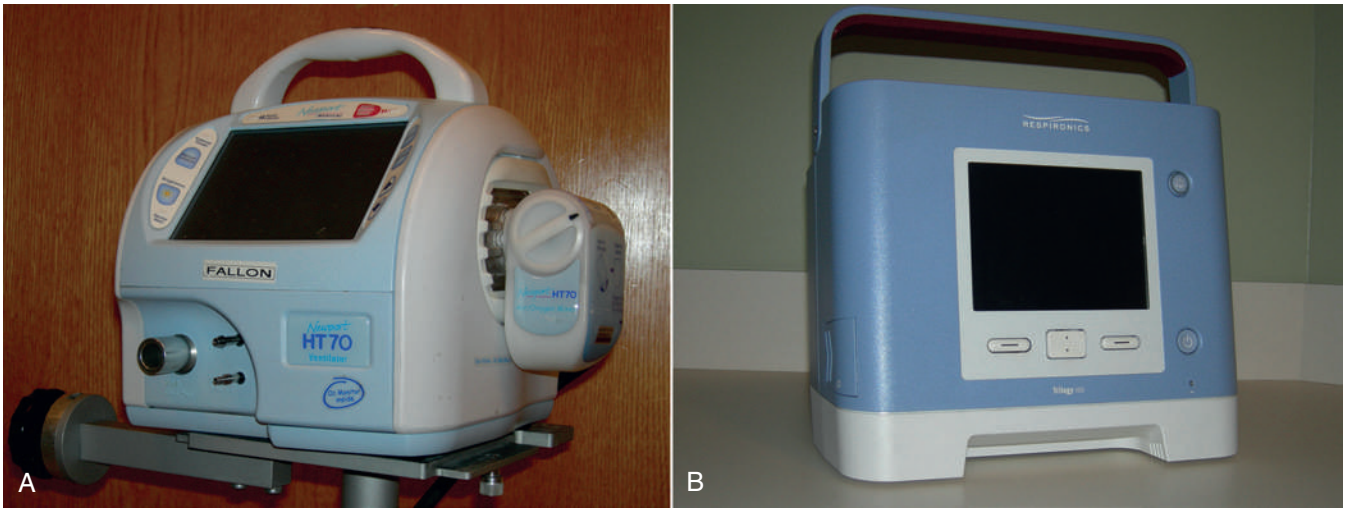

FIGURE 49-17 Two examples of new generation portable ventilators that can be used in acute care, home care, or transport settings. (**A,** Courtesy Covidien, courtesy Phillips Respironics, Murrysville, PA.)

In the long-term care setting, volume ventilation is sometimes used for patients with neuromuscular weakness.[3] Volume ventilation may allow a patient to stack breaths, increasing lung volume to near inspiratory capacity and resulting in improved cough peak flow. High cough peak flow should enhance secretion clearance. In patients with limited muscle strength, pressure-controlled ventilation does not allow breath stacking because inspiratory pressure is held constant, in contrast to volume ventilation, in which delivered V_T is constant. However, there is no proven advantage of one mode versus another in the long-term care setting.[2] Enhanced secretion clearance is easily provided using a mechanical cough-assist device.

Portable Home Care or Transport Ventilators

Most portable home care ventilators (Figure 49-17) are electrically powered and microprocessor-controlled. These devices can operate from alternating current (AC) or, if equipped with internal or external batteries, direct current (DC) power sources. The batteries usually can provide power for several hours. Batteries add a measure of safety in areas where AC power outages occur regularly. They also allow the patient to be more mobile, which may improve their quality of life. These ventilators use a single-limb or double-limb ventilator circuit with an exhalation valve that prevents rebreathing of CO_2. Updated technology has

improved the performance characteristics of these ventilators to a level comparable to critical care ventilators with the added advantages of small size, light weight, and battery power that allow portability. Most newer models incorporate an NIV mode with the ability to compensate for leaks. Some models with adjustable bias flow settings improve the ability of the ventilator to sense patient triggering. Similar to critical care ventilators, additional features, such as variable termination criteria and maximum inspiratory time, are available on some of these devices to enhance breath termination in PSV.

Portable home care ventilators are currently recommended for patients who need continuous ventilatory support or high ventilating pressures, such as patients with severe chest wall deformities or obesity or for patients who want greater mobility.[2] For acute care, these ventilators could easily be used to initiate NIV in nontraditional locations and allow transport to an emergency department or ICU without the need to interrupt ventilation.

Heated Humidifiers

An increase in nasal resistance and congestion has been reported with CPAP in patients with mouth leaks.[116] The addition of heated humidity relieves nasal resistance and congestion. Cold passover humidification does not provide relief.[117,118] The use of heated humidity during nasal CPAP in patients with sleep apnea and nasal symptoms (sneezing, nasal draining, nasal and oral dryness, and nasal obstruction) has significantly improved patients' compliance with this therapy.[119] It seems likely that the same effect would occur in NPPV. To avoid the negative effect on patient compliance caused by this common complaint and the accumulation of dried retained secretions in the back of the oral pharynx, humidified gas, heated to a temperature that is comfortable to the patient (usually about 30° C), should be the standard when using NIV.

RULE OF THUMB

Heated humidity (about 30° C) should always be provided with NIV to avoid nasal symptoms, to avoid the accumulation of secretions in the back of the oral pharynx, and to enhance patient tolerance.

MANAGEMENT OF NONINVASIVE VENTILATION

Initial Application of Noninvasive Ventilation

Starting NIV requires the selection of a ventilator and an interface and a significant time commitment from the RT. The patient should be seated in a chair or bed at an angle of 30 degrees or greater (Box 49-6).[2] The RT should always explain the procedure and answer any questions about NIV before placing the mask on the patient. Clinicians should recognize that dyspnea can cause feelings of anxiety and fear. For this reason, the RT or the patient should hold the mask in place when applying the mask for the first time. Holding the mask allows it to be removed quickly if the patient begins to panic or wishes to communicate. A strategy of starting with low pressures can help patients adjust to NIV more readily. Ventilating pressures should be set as low as possible initially, especially if the patient is unfamiliar with the sensation of positive pressure ventilation. Then the ventilating pressures can be adjusted in small increments over 1 to 2 minutes until exhaled V_T is 4 to 6 mL/kg predicted body weight or respiratory distress improves. During this time, the RT should assess the patient frequently, adjusting the ventilator settings to synchronize breath delivery with the patient's breathing pattern and providing instructions and coaching as needed. The mask should not be strapped on until the patient is comfortable with the application of NIV and the RT has adjusted pressures to provide proper ventilation.

Box 49-6 Initiation of Noninvasive Ventilation

1. Choose a location with appropriate monitoring based on the severity of the patient's condition.
2. Position the patient with the head of the bed elevated ≥30 degrees.
3. Select a ventilator and an appropriately sized interface.
4. Turn on the ventilator and humidifier, and connect the interface.
5. Set initial settings at a low level of support: PEEP 0 to 4 cm H_2O, ventilatory pressure 2 to 4 cm H_2O.
6. Hold the mask on the patient's face or have the patient hold the mask until he or she is comfortable with the sensation of NIV.
7. Adjust FiO_2 or bleed in O_2 flow to keep SpO_2 >90%.
8. After the patient becomes comfortable with the initial settings, increase inspiratory pressure until V_T is about 4 to 6 ml/kg predicted body weight or signs of respiratory distress improve. Increase PEEP to reduce asynchrony from air trapping or to improve oxygenation.
9. Check for air leaks, especially around the eyes; adjust mask as needed.
10. Reassess frequently for tolerance and efficacy of NIV (at least every 30 minutes) for the first 1 to 2 hours.

The specific airway pressures needed to support the patient during NIV are best determined by bedside assessment of the patient's response and tolerance. They cannot be determined with accuracy before NIV is started. However, most patients require PEEP levels of 5 to 8 cm H_2O and ventilating pressure of 8 to 12 cm H_2O. Peak airway pressures greater than 20 cm H_2O are rarely needed. To avoid gastric distention, ventilating pressure should be less than the normal esophageal opening pressures of 20 to 25 cm H_2O.[120] If the patient has a nasogastric tube in place, the probability of gastric distention increases dramatically, as does the probability of NIV failure.

Final adjustment of the ventilator should deliver a V_T of about 4 to 6 ml/kg ideal body weight with a respiratory rate less than 30 breaths/min. The goal of NIV is not to deliver a large V_T but rather to maintain normal ventilatory patterns with acceptable gas exchange and decrease the work of breathing. FiO_2 should be titrated to PaO_2 of at least 60 mm Hg or SpO_2 88% to 95%.

RULE OF THUMB

Most patients with ARF can be stabilized with an expiratory pressure setting of 5 to 8 cm H_2O and ventilating pressure of 8 to 12 cm H_2O. Avoid using peak pressures greater than 20 cm H_2O.

Clinical Assessment Criteria to Identify Success or Failure of Noninvasive Ventilation

Careful monitoring and frequent reassessment are very important during the first 1 to 2 hours of NIV. Successful application of NIV is easy to recognize—gas exchange improves, $PaCO_2$ decreases, pH normalizes, and PaO_2 and SpO_2 increase. Along with improvement of these measured values, the patient's clinical presentation improves; respiratory rate decreases, V_T increases, accessory muscle use decreases or is eliminated, and pulse rate and blood pressure normalize. If clinical status and gas exchange have not improved after 1 to 2 hours of NIV, intubation should be considered. This is especially true if the indication for NIV was hypoxemic respiratory failure. Evidence suggests an increased risk of cardiac arrest in patients with hypoxemic respiratory failure who do not improve after a trial of NIV for 1 to 2 hours.[46]

Adjusting Noninvasive Ventilator Settings

Ventilator settings may need to be adjusted after the patient stabilizes and acclimates or when arterial blood gas analysis reveals gas exchange problems. Hypercapnia is addressed first by minimizing air leaks and if necessary, by increasing the ventilating pressure. The result is an increase in the delivered V_T and minute ventilation and a decrease in $PaCO_2$. NIV is typically delivered in a spontaneous mode, where all breaths are patient-triggered and none are mandatory, so adjusting the ventilator frequency is not an option. For patients with chronic hypercapnia, ventilation should be adjusted to maintain an acceptable pH. No attempt should be made to normalize the $PaCO_2$ in such patients.

Increasing PEEP increases the patient's functional residual capacity, mean airway pressure, and PaO_2. Higher PEEP should also improve trigger synchrony in the setting of air trapping. Decreasing PEEP theoretically should cause the opposite effects. In clinical practice, decreasing PEEP may not affect PaO_2 as the disease process resolves and alveolar stability improves.

If the assist/control mode is used for NIV, the rate should be set at a level below the patient's spontaneous rate, allowing the patient to trigger the ventilator as needed. Setting the rate in this manner provides a backup rate for safety if apnea occurs and avoids overventilating the patient. If the patient's disease process limits the ability to trigger or breathe spontaneously, as in some neuromuscular disorders, the set rate has a direct relationship to minute ventilation and an inverse relationship to $PaCO_2$. These relationships may not always be the case in clinical practice and in a spontaneously breathing patient. Table 49-1 summarizes ventilator adjustments during NIV.

TABLE 49-1

Expected Results of Changing Noninvasive Ventilator Settings

Setting	Adjustment	Anticipated Result
IPAP	↑	↑ V_T, ↑ minute ventilation, ↓ $PaCO_2$
	↓	↓ V_T, ↓ minute ventilation, ↑ $PaCO_2$
EPAP	↑	↑ FRC, ↑ PaO_2, ↓ V_T If intrinsic PEEP is present, fewer missed trigger attempts and improved patient-ventilator synchrony
	↓	↓ FRC, ↓ PaO_2, ↑ V_T, ↓ $PaCO_2$ Possible rebreathing of CO_2 if EPAP <4 cm H_2O
FiO_2	↑	↑ PaO_2; if bleeding O_2 into circuit, maximum expected FiO_2 is approximately 0.5; increasing O_2 flow >15 L/min may adversely affect triggering
	↓	↓ PaO_2
Rate control*	↑	↑ minute volume in timed modes, ↓ $PaCO_2$
	↓	↓ minute volume in timed modes, ↑ $PaCO_2$

FRC, Functional residual capacity.
*Rate control is generally set at 8 to 10 as a backup rate and not changed in spontaneous/timed mode.

Aerosolized Medication Delivery

For patients on intermittent NIV, aerosol medications are often administered while the patient is off the ventilator. Removal of assisted ventilation from patients in ARF makes little sense and is unnecessary. Aerosol therapy can be delivered in the usual manner through an ICU ventilator used for NIV. With a noninvasive ventilator, positioning the nebulizer between the exhalation port and mask maximizes drug delivery.[121] If the exhalation port is located in the mask or any other position distal to the nebulizer, much of the drug is lost via the exhalation port during both inspiration and expiration. A metered dose inhaler (MDI) can be administered by placing an adapter or collapsible holding chamber in the same position in the circuit. Drug delivery should improve because the MDI is actuated only during inspiration. However, dosing can safely be doubled and should be adjusted based on patient response to compensate for loss through leaks in the system and other inefficiencies.

Safe Delivery of Noninvasive Ventilation

Monitoring During Noninvasive Ventilation

In acute care or long-term care applications, clinicians must not lose sight of the goals of NIV.[2] The RT should confirm ventilator function and assess the patient on a regular basis for leaks, accessory muscle use, ventilator synchrony, comfort, and

MINI CLINI

Improving Patient-Ventilator Synchrony During Noninvasive Ventilation

PROBLEM: An oncology patient with DNI orders is receiving NIV from a critical care ventilator with a full-face mask. The ventilator is set in the PSV mode. Peak inspiratory pressure is 15 cm H_2O, PEEP is 5 cm H_2O, and flow trigger is 2 L/min. The patient has a nasogastric tube in place that is causing a large leak. The ventilator is self-triggering and fails to cycle into expiration when the patient exhales. The patient is dyspneic and appears uncomfortable.

Solutions Large leaks can cause patient-ventilator asynchrony with ventilators that do not have leak compensation. Triggering and cycling are affected because the ventilator is no longer sensitive to changes in flow or pressure changes generated by the patient.

1. Repositioning the mask and placing a flat piece of gauze or hydrocolloid dressing between the mask and the nasogastric tube and another between the nasogastric tube and the patient's face may help reduce the leak.
2. Change to a critical care ventilator with a noninvasive mode or a noninvasive ventilator designed for ICU use.
3. If switching ventilators is not feasible, and a large leak is still present, adjusting the termination criterion to a higher setting can shorten inspiratory time, allowing breath termination to occur at a higher percentage of the peak flow.
4. If termination criteria are not adjustable, change to pressure assist/control mode. Observe the ventilator graphics to determine the patient's desired inspiratory time, and set the inspiratory time on the ventilator accordingly. Typically, critically ill patients should have inspiratory times of about 0.7 to 1 second (in some cases, 0.5 second).

changes in vital signs and gas exchange. In the acute care setting, respiratory rate, heart rate, and gas exchange should improve within 1 to 2 hours after initiation of NIV. If there is no improvement after 1 to 2 hrs on optimal settings, intubation should be considered. At a minimum, SpO_2 must be continuously monitored. In the acute care setting, continuous monitoring of heart rate and blood pressure is the safest practice. A current consensus statement recommends a higher level of monitoring for patients with acute hypoxemia, worsening condition, involvement of nonrespiratory organ systems, or persistent acidosis.[122] If the patient cannot sustain ventilation independent of NIV for at least 1 hour, the same level of monitoring as any intubated patient should occur.

In the long-term care setting, improvement in gas exchange may require weeks to several months depending on daily use and compliance with the prescribed therapy.[2] Clinicians providing follow-up treatment in the long-term care setting should determine usage with the elapsed time indicator on the ventilator. The patient should be assessed for complications, symptoms of hypoventilation and poor sleep quality, patient-ventilator synchrony, and other factors that affect compliance.

Patient Location

NIV can be initiated in any acute care location, including the emergency department, ICU, or general care floor.[54] After NIV is initiated, patients should be transferred to an ICU or other inpatient location with continuous monitoring capabilities, skilled staff, and access to endotracheal intubation if needed.[2,54] Hypercapnic patients with COPD and a pH of 7.30 or greater and patients who can sustain ventilation without NIV for at least 1 hour can be managed safely on a general care floor.[54] It is important that staff members be adequately trained before caring for patients on NIV. Another consensus conference recommendation calls for one-to-one monitoring of NIV patients for the first few hours by a trained, experienced RT, nurse, or physician.[54]

Weaning from Noninvasive Ventilation

At the present time, there is no standard approach to weaning from NIV. One weaning strategy is to decrease high levels of inspiratory and baseline pressure gradually to minimal settings as the acute disease process resolves. The length of time off the ventilator can be increased gradually as tolerated. Another approach is to continue NIV until there is a need to remove the mask. Patients often request to remove the mask after several continuous hours of NIV. The patient's ability to ventilate adequately is reassessed after 5 to 30 minutes based on tolerance and NIV is either discontinued or restarted.

COMPLICATIONS OF NONINVASIVE VENTILATION

The reported failure rate of NIV ranges from 7% to 70%.[2] Serious complications such as aspiration or pneumothorax occur less than 5% of the time. The undesired side effects of NIV are less serious, although more common. These side effects can be grouped into categories related to the noninvasive interface and to gas flow and airway pressures. Table 49-2 lists the complications, frequency of occurrence, and suggested remedies.

Air leaks can cause several problems of various levels of concern, ranging from eye irritation and dry mouth to inability to trigger inspiration. Small air leaks should be expected during NIV. Large air leaks should be addressed immediately before they lead to patient-ventilator asynchrony or worsening gas exchange.[3] Air leaks often can be avoided by selecting an appropriately sized mask. If excessive airflow is leaking through the mouth, changing to a full-face mask should be helpful. If the problem persists, one can reposition the mask, add a forehead spacer, and readjust strap tension. Sometimes, ventilator settings must be adjusted if ventilation is adversely affected by the leak. Using a ventilator with leak compensation should resolve problems with leaks.

Mask-related side effects are the most common problems. Mask discomfort may be reported by up to 50%[2] of patients receiving NIV, and excessive discomfort decreases patient tolerance for NIV. Switching to a correctly sized mask or loosening the straps slightly is often all that it takes to resolve this issue. Skin damage is a problem that is only going to get worse if not

TABLE 49-2

Side Effects and Complications of Noninvasive Ventilation

	Incidence*	Possible Solutions
Interface-Related Side Effects		
Discomfort	Common	Loosen straps Refit, reposition, or change interface
Erythema	Common	Apply skin barrier or hydrocolloid dressing or both Loosen straps, adjust forehead support, or add spacer Alternate the use of 2 masks
Claustrophobia	Infrequent	Change interface Consider anxiolytic
Pressure ulcer	Infrequent	Apply hydrocolloid dressing Change interface
Skin rash	Infrequent	Apply topical steroid or antibiotic
Air Pressure–Related or Flow-Related Side Effects		
Nasal congestion	Common	Administer inhaled corticosteroid or decongestant
Nasal dryness	Common	Avoid by using heated humidification with NIV Administer saline nasal spray
Sinus or ear pain	Common	Decrease ventilating pressure
Eye irritation	Common	Refit, reposition, or change interface
Gastric distention	Infrequent	Administer simethicone Lower pressures
Serious Complications		
Aspiration	Rare	Avoid through careful patient selection Stop NIV, if status will allow
Pneumothorax	Rare	Decrease ventilating pressure Place chest tube, if tension pneumothorax
Hypotension	Rare	Decrease inflation pressure

From Mehta S, Hill NS: Noninvasive ventilation. Am J Respir Crit Care Med 163:540, 2001.
**Common*—occurs in 30% to 50% of patients; *infrequent*—occurs in approximately 5% to 20% of patients; *rare*—occurs in <5% of patients.

addressed immediately for patients who need to continue using NIV. RTs should keep a watchful eye on reddened areas, usually on the bridge of the nose. A liquid skin barrier should be applied to protect the area. Applying "artificial skin" or a hydrocolloid dressing or patch is a good idea to provide further protection. These patches should also be used if a pressure ulcer forms. Taking steps to minimize pressure such as loosening the straps and adding a forehead spacer are important. Other strategies to reduce the risk of pressure ulcers include alternating use of two or more different masks and removing the mask every 4 to 6 hours for a few minutes if the patient can tolerate being off the ventilator without increased respiratory distress.

Complications related to air pressure and flow include nasal congestion, upper airway dryness, sinus and ear pain, eye irritation, and gastric insufflation.[2] Usually, nasal congestion and upper airway dryness can be prevented by using heated humidity whenever NIV is initiated. Decongestants and saline spray are sometimes needed to relieve symptoms of congestion. Sinus and ear pain may be related to high inspiratory pressure; use of the lowest effective inspiratory pressure may prevent or alleviate this problem.

Clinically significant gastric insufflation is a rare occurrence in patients using NIV.[2] Use of the lowest effective pressure may prevent gastric insufflation. Routine use of a nasogastric tube is not recommended. A nasogastric tube increases the risk of gastric insufflation, adversely affects mask fit, and usually causes a large air leak, increasing the likelihood of NIV failure.

Most major complications can be avoided with careful patient selection and use of the lowest inspiratory pressure that improves the patient's gas exchange and relieves symptoms. NIV should be avoided if the patient is a high aspiration risk or is hemodynamically unstable. The risk of aspiration increases if inspiratory pressures greater than 20 cm H_2O are used. In general, the head of the bed should be maintained at 30 degrees to reduce the risk of aspiration during NIV.

TIME AND COSTS ASSOCIATED WITH NONINVASIVE VENTILATION

The cost-effectiveness of NIV is linked to appropriate patient selection, familiarity of staff members with NIV, and the success or failure of NIV in preventing endotracheal intubation.[122,123] Staff time is one of the most valuable and expensive resources in hospitals. Time required by nurses and physicians during the first 48 hours of NIV is similar to the time required for invasive mechanical ventilation, but the time required by RTs for NIV is considerably greater than for invasive mechanical ventilation.[124] However, another study showed that the time required by RTs was significantly greater for the first 8 hours but significantly lower during the next 8 hours.[122] The increased time requirement associated with starting NIV is due to mask fitting, gradual upward adjustment of ventilator settings, and remaining at the bedside to provide coaching and encouragement to patients as they acclimate to NIV. After the patient begins to improve, the time required to maintain NIV should decrease to a level similar to invasive ventilation.

SUMMARY CHECKLIST

- NIV is the application of positive pressure ventilation or CPAP with a mask or other noninvasive interface to improve gas exchange or decrease the work of breathing.
- The use of NIV to manage ARF has improved patient outcomes.
- Evidence supports NIV as the standard of care for managing patients with COPD exacerbations and acute cardiogenic pulmonary edema. There is less evidence supporting other indications for NIV.
- NIV may be justified in the management of ARF if selection criteria (see Box 45-2) are present, exclusion criteria (see Box 45-3) are absent, and the disease process is reversible.
- Acute cardiogenic pulmonary edema should be managed initially with CPAP of 8 to 12 cm H_2O. NPPV should be considered only if hypercapnia is present.

- NIV is beneficial in the management of patients extubated but at risk of reintubation and patients with DNI orders.
- Patients with ALS should receive NIV because it probably prolongs their lives.
- Caution should be used in applying NIV to patients with acute hypoxemic respiratory failure.
- NIV is most successful in the acute care setting when air leaks are minimal, the patient's severity of illness is moderate, respiratory acidosis is present, and improvement in gas exchange and vital signs occurs within 1 to 2 hours after NIV initiation.
- When NIV is used for hypoxemic ARF, intubation and invasive ventilation should be initiated if gas exchange and patient presentation does not improve within 1 to 2 hrs of NIV.
- NIV is typically administered in the PSV mode with PEEP.
- Airway pressure during NIV should be kept as low as possible to achieve therapeutic goals (ideally <20 cm H_2O).
- Although any ventilator can be used for NIV, ventilators designed to compensate for leaks can be expected to perform best.
- Heated humidity (about 30° C) should always be provided with NIV.
- Aerosolized drugs can be administered without interrupting NIV.
- The initiation of NIV requires significant staff time, but after patients stabilize, the time required to maintain NIV is similar to invasive ventilation.

CHAPTER 50

Extracorporeal Life Support (ECLS)

CLORINDA SUAREZ AND PATRICIA ENGLISH

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe two primary goals of extracorporeal membrane oxygenation (ECMO).
- List indications for initiating ECMO.
- Differentiate between venovenous (VV), venoarterial (VA), and arteriovenous (AV) ECMO.
- Discuss ECMO physiology.
- Identify components of a typical ECMO circuit and their functions.
- List risks and complications of ECMO.
- Discuss when and how to wean off of ECMO.
- Describe the respiratory therapist role as an ECMO specialist.
- Describe safety system incorporated in or added to ECMO systems.
- Identify typical sites for cannula placement for VA support.
- Identify typical sites for cannula placement in VV support.
- Describe the reasons ECMO patients need to be anticoagulated.
- Describe how anticoagulation is typically monitored during ECMO.
- Discuss the significance of ventilator support and management during ECMO.

CHAPTER OUTLINE

KEY TERMS

activated clotting time
afterload
arteriovenous (AV)
extracorporeal life support (ECLS)
extracorporeal membrane oxygenation (ECMO)
cardiac output
cannulation
decannulation
membrane pressures
oxygen content
oxygen delivery
preload
pump flow
recirculation
sweep flow
tamponade
venoarterial (VA)
venous reservoir
venovenous (VV)

Extracorporeal life support (ECLS) encompasses several forms of mechanical support, all of which involve circulating blood from a patient to outside the body, through a mechanical gas exchanger, and returning it back to the patient. The most common form of ECLS is **extracorporeal membrane oxygenation (ECMO)**. There are three general types of ECMO support, **venoarterial (VA)**, **venovenous (VV)**, and the emerging **arteriovenous (AV)** support. Distinctions between the three types will be outlined later in this chapter.

ECMO is typically considered only in conditions when maximum conventional support has not been successful in delivering oxygen, removing CO_2 or providing adequate cardiac function. ECMO itself does not heal or fix the condition but rather is life-saving support for the most severe forms of acute heart and/or lung failure. Patients can be placed on ECMO for either cardiac or respiratory support, though at times both cardiac and respiratory support are indicated. ECMO will allow the heart and/or lungs to rest and help avoid the damage that can result from high levels of conventional treatments. The primary goals of ECMO are to provide adequate **oxygen delivery** and remove carbon dioxide while the lungs and/or heart recover, or in some cases until the lungs or heart can be transplanted.

RULE OF THUMB

ECMO is an option for the management of severe respiratory failure or cardiogenic shock refractory to conventional treatments for patients with reversible conditions or those eligible for transplantation.

THE RESPIRATORY THERAPIST AS ECMO SPECIALIST

ECMO is provided to patients with life-threatening conditions. These situations require intense monitoring by clinicians with good critical thinking skills, strong knowledge of cardiopulmonary physiology, and technical adeptness. Clinicians who perform this role are referred to as ECMO specialists. Respiratory therapists (RTs) are often viewed as ideal professionals for this role due to their primary training. RTs have a strong science background, a thorough understanding of cardiopulmonary physiology, and the ability to handle and manage highly technical equipment. In many ECMO centers RTs play a significant role in the ECMO program. They assist in the initiation of ECMO, provide hour-to-hour management of the ECMO support, and provide ECMO education for the many clinical services involved in the care of ECMO patients. Experienced RTs with good critical thinking skills receive additional training to take on the role of ECMO specialist. The specific role of a specialist varies among ECMO institutions but the essential education most often provided for this role follows the Extracorporeal Life Support Organization (ELSO) (see Box 50-1).

Total	65,171	46,490	71%	38,636	59%

ECLS Registry Report, International Summary, January, 2015.

INTERNATIONAL REGISTRY

With the development of an international ECLS registry in the late 1980s, centers providing ECMO began submitting data on the patients supported in centers from around the world. Since that time patient information, including patient age, diagnosis, type of support, complications, and outcomes have been compiled by the registry. Table 50-1 shows a summary of patients entered into the registry and their outcomes.[1]

PATIENTS RECEIVING ECMO

Newborns

In the 1980s ECMO support was almost exclusively used for newborns with respiratory failure.[2] The primary conditions of patients placed on ECMO were meconium aspiration syndrome, respiratory distress syndrome, sepsis, congenital diaphragmatic hernia, and primary pulmonary hypertension.[2] Many of these patients also had pulmonary hypertension

Box 50-2 Indications for ECMO in Newborns

- Birth weight >2 kg
- Gestational age ≧34 weeks
- Maximum conventional ventilation
- Failure of optimal medical support including INO
- Lung disease considered reversible
- Absence of uncontrolled bleeding
- No uncorrectable cardiac anomalies
- No other lethal anomalies

Box 50-3 Indications for ECMO in Adult Patients

- Acute hypoxic or hypercarbic respiratory failure
  - Sat <88 on FiO_2 1.0 with PEEP 15 cm H_2O
  - With plateau pressure >30 and trail of INO or epoprostenol
  - Respiratory acidosis with pH ≤7.20
- Normal RV/LV function
- Murray Score >3

secondary to their primary condition. Improving oxygen delivery using ECMO support can greatly reduce pulmonary hypertension. ECMO often was the best option to improve oxygen delivery while the heart and lungs healed from the primary insult. According to the ECLS registry more than 27,000 newborns have received ECMO for respiratory failure with survival rates to hospital discharge from 51% to 94% depending on the specific diagnosis.[1] Criteria for ECMO in newborns with respiratory failure are well established and are outlined in Box 50-2.[3] Contraindications for offering ECMO in the newborn population fall into two categories: absolute and relative. Absolute contraindications include lethal congenital anomalies, severe irreversible brain damage, and Grade lll or higher intracranial hemorrhage (ICH).[4] Relative contraindications include birth weight <1.6 kg, gestational age <34 weeks, irreversible organ damage (unless a transplant candidate), mechanical ventilation with 100% oxygen for >13 days, and some coagulopathies.[4] The data collected over 25 years have been instrumental in establishing guidelines for newborn ECMO.

Development of less risky and less invasive therapies such as surfactants, nitric oxide, and improved ventilator strategies have decreased the number of newborns considered for ECMO.[5] ECMO support for newborn respiratory failure over the last few years has decreased significantly to only approximately 800 cases per year worldwide.[1]

Pediatric and Adult Patients

Although the number of newborns receiving ECMO continues to decline, ECMO cases in pediatric and adult patients are on the rise. This trend is likely due to improved strategies in ECMO management and advances in technology which has led to better equipment for long-term support. During the past five years the number of centers developing ECMO programs has increased greatly. Many new centers are providing ECMO primarily to pediatric and adult patients, with the largest increases in two categories: ECMO for cardiac support and ECMO as a bridge for lung transplant.[6] Unfortunately, guidelines for initiating ECMO support in pediatric and adult patients are less clear than the well-established guidelines for newborns. Criteria are generally associated with the type of support needed and are not always the same from center to center.[7] Box 50-3 provides an example of general indications for adult VA and VV ECMO. Contraindications for pediatric and adult patients generally fall into the absolute and relative categories. Absolute contraindications typically include acute ICH or stroke, mechanical ventilation >7 days, paralytics and steroids >48 hours, in hospital CPR >60 minutes, severe aortic insufficiency, end stage liver disease, BMI >40, contraindication to anticoagulation or refusal to receive blood products.[3] Relative contraindications are age >70 years old, active cancer, multiple suicide attempts, chronic kidney disease, and multiorgan system failure >3 organs.[3]

PHYSIOLOGY

To understand ECMO physiology it is essential to understand normal cardiopulmonary physiology. During normal circulation blood is pumped from the right side of the heart to the lungs where oxygen and carbon dioxide are exchanged. From the lungs, blood is returned to the left side of the heart. The left heart then pumps oxygenated blood to the major organs and tissues. The amount of oxygen contained in blood leaving the heart is the arterial oxygen content. The absolute amount of blood pumped from the heart is **cardiac output**. Oxygen content times cardiac output equals the amount of oxygen delivered to the tissues.

Oxygen content is rarely measured directly at the bedside but it is critical in managing severely ill patients. Oxygen is carried in the blood in two forms: dissolved in plasma and in red blood cells bound to hemoglobin (as a percentage of the maximum saturation). These two components make up the total **oxygen content** in the blood. The amount of oxygen dissolved in plasma is a very minor portion of the total oxygen content. The dissolved portion is represented by the PO_2 (mm Hg) × 0.003. The majority of oxygen is bound to hemoglobin and is represented by the equation Hb × % SaO_2 × 1.34. Total oxygen content is calculated using the following equation

$$O_2 \text{ Content } [(P02 \times .003) + (Hg \times SaO_2 \times 1.34)]$$

Therefore with inadequate levels of hemoglobin, oxygen content is significantly diminished.

To understand the importance of hemoglobin, consider the following: A patient with a PO_2 of 40 mmHg, with a typical oxygen saturation of 70% and a normal hemoglobin level (15 gms) has more oxygen than a patient with a PO_2 of 100 (saturation 100%) and a low hemoglobin level (8 gms). See Chapter 12 for more complete details on oxygen content and oxygen delivery.

MINI CLINI

PROBLEM: Hemoglobin level in a patient who is bleeding has dropped from 15 to 10 g/dl. His PO_2 remains unchanged at 90 mm Hg. How much would his O_2 content change?

Calculate the change in O_2 content.

$$(PO_2 \times .003) \times (Hg \times SaO_2 \times 1.34)]$$

The O_2 content with a hemoglobin of 15 is 20.37.
The O_2 content with a hemoglobin of 10 is 13.67.

Discussion: This clearly demonstrates the importance of hemoglobin in providing adequate oxygen content. Delivery of oxygen is dependent on the oxygen content and the cardiac output. When oxygen content is low, the body will normally respond by increasing the cardiac output. Total delivered oxygen can be calculated using the following equation:

$$O_2 \text{ Delivery } [(PO_2 \times .003) + (Hg \times SaO_2 \times 1.34)] \times (HR \times SV) = DO_2$$

MINI CLINI

PROBLEM: The patient has a cardiac output of 5 L/min and is on 4 L/min of VA ECMO support. Eighty percent of the patient's cardiac output is therefore oxygenated by the artificial oxygenator and is 100% saturated. The patient has essentially no lung function. His SvO_2 is 65% with a PO_2 of 35 mm Hg. Twenty percent of the patient's cardiac output goes through the nonfunctional native lungs where no oxygen is added.

What is the patient's SaO_2 when blood from the ECMO-supported cardiac output and the native cardiac output mix?

Discussion: The combined saturation can be calculated by multiplying the % saturation of each portion of the cardiac output. This patient's combined saturation can be determined by multiplying the 80% (4 of 5 L/min) of the cardiac output that becomes 100% saturated by the ECMO oxygenator (0.8 x 1), and then multiplying the 20% (1 of 5 L/min) of the output that returns to the native lungs 65% saturated, (0.2 x 0.65) and adding the results of each

$$(0.8 \times 1) + (0.2 \times 0.65) = 0.93$$

The mixed saturation of this patient would be 93%. To achieve a higher saturation a larger portion of the cardiac output could be pumped through the oxygenator and saturated to 100%. The portion of cardiac output that would remain through the native lungs would decrease. With a smaller portion of blood saturated to only 65% the combined saturation would increase.

When cardiac function is impaired the ability to increase cardiac output is altered and will result in inadequate amounts of oxygen delivered to the tissues. When this happens, anaerobic metabolism occurs and lactic acid is produced. Alternatively, carbon dioxide is produced from systemic metabolism. With normal adequate lung function and normal blood flow through the lungs appropriate amounts of carbon dioxide are excreted and spontaneous ventilation keeps PCO_2 within acceptable ranges. When altered states of metabolism increase CO_2 production it is imperative that the lungs are able to remove more CO_2. In diseased lungs or conditions that alter blood flow to the lungs, higher levels of CO_2 remain in the blood. When maximum conventional support fails to provide adequate delivery of oxygen to the tissue or inadequate removal of carbon dioxide occurs, a patient who has no absolute contraindications can be considered for ECMO.

EQUIPMENT

ECMO systems are intended to temporarily support the cardiac and pulmonary function of the patient who cannot maintain adequate tissue oxygen delivery. Basically, ECMO has the task of pumping the blood, delivering oxygen to the blood, and removing CO_2. The circuit consists of polyvinylchloride (PVC) tubing segments that have different inner diameters depending on the patient's size: ¼-inch for a neonate to ⅜-inch for pediatric/adult sized patients. Some circuits contain a heparin-based coating to reduce the response of blood to nonendothelial surfaces and to decrease the risk of clot formation. The circuit is generally custom designed using the shortest amount of tubing necessary to allow less resistance to flow and to decrease circuit volume. This is of particular importance for the newborn population because larger circuit volumes result in hemodilution and require additional transfusion of blood products. Infusion ports can be added along the tubing for infusing medications in patients who have limited IV access. These ports can also be an option for access when continuous veno venous hemofiltration (CVVH) is required. Blood is drained from the patient into the circuit by either a centrifugal or roller pump. From the pump it goes through an artificial lung, referred to as an oxygenator, where oxygen is added and CO_2 removed (Figure 50-1).

In some systems a **venous reservoir**, referred to as a bladder, is placed before the pump to help with assessing available blood volume. The bladder is then connected to a pressure monitor which can be set to keep the pump from rotating too quickly and exerting an excessive negative pressure on the cannulated vessel (Figure 50-2). Newer systems that combine pressure monitors and servo regulation are more efficient and are eliminating the need for bladders. Bladders are most often used with roller pumps and are not typically needed with centrifugal pumps.

The ECMO system is powered by the blood pump. The pump function is to draw blood in, either from a venous reservoir (the bladder) or directly from the venous circulation, pump it through the oxygenator, and then back into the patient. The two types of pumps frequently used are the centrifugal (or vortex) pump and the roller (or occlusive) pump.

The centrifugal pump is made up of polycarbonate cones attached to a magnetic disk that is attached to a controller (Figure 50-3). The cones spin at an adjustable rate when

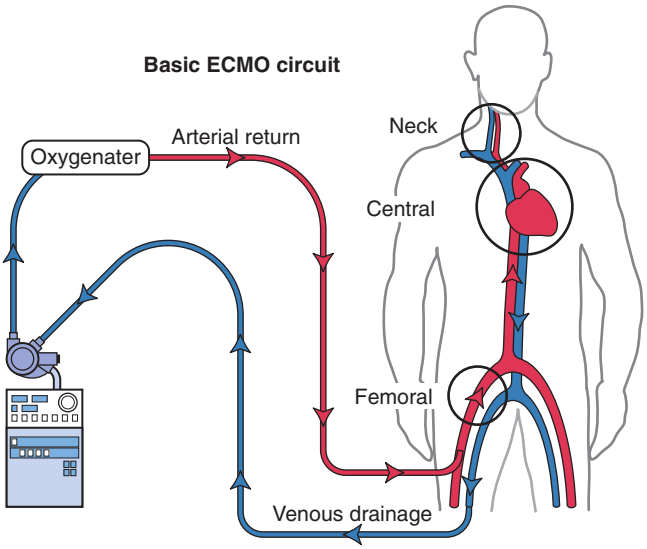

FIGURE 50-1 Illustration of the blood pathway of an ECMO circuit. Blood drains through the circuit to a blood pump which pushes it through an artificial lung oxygenating the blood and removing CO_2 before returning the blood to the body.

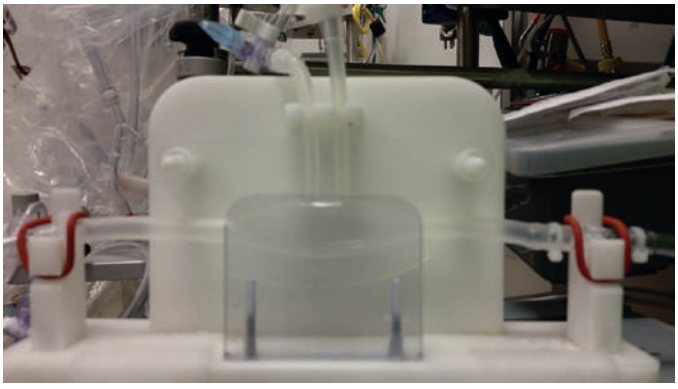

FIGURE 50-2 Venous bladder reservoir; some circuits incorporate a bladder which acts as a reservoir and helps to assess blood volume available for the pump.

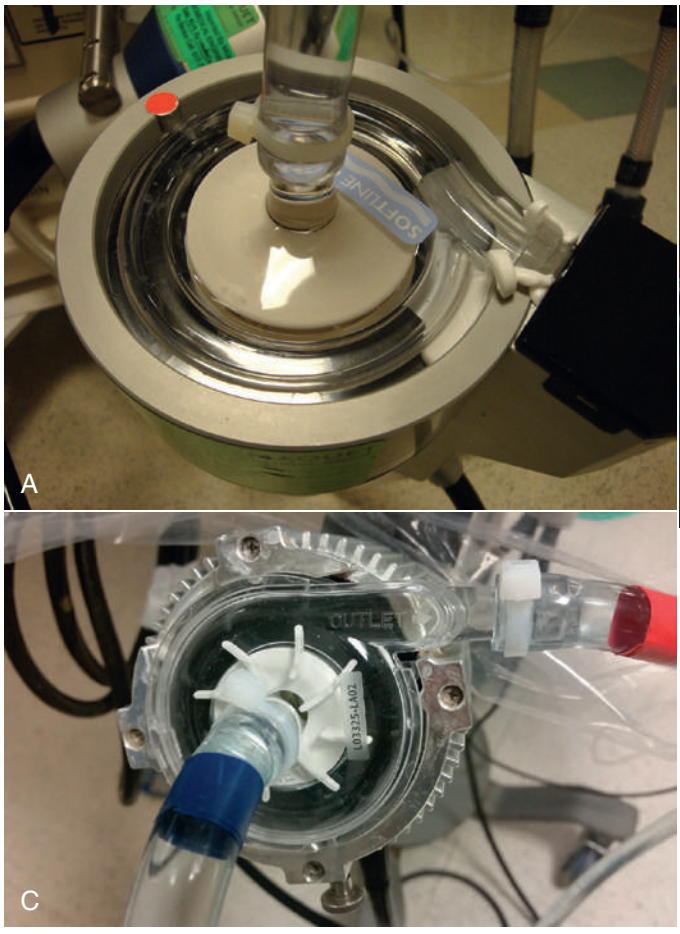

FIGURE 50-3 The centrifugal pump is made up of polycarbonate cones, attached to a magnetic disk that is attached to a controller. The cones will spin at an adjustable rate when attached to the controller and produce forward flow by imparting kinetic energy to the fluid (blood) in a rotating pump head.

attached to the controller and produce forward flow by imparting kinetic energy to the fluid (blood) in a rotating pump head. The **pump flow** provided is therefore dependent on both the patient's **preload** (the volume in the right side of the heart) and **afterload** (the resistance against the pump outlet from the left side of the heart). Because the centrifugal pump is not occlusive (like the roller pump), pump flow will vary despite a set rate per minute (RPM). A decrease in preload or increase in afterload can cause a decreased pump flow. Centrifugal pumps have the advantage of not being affected by gravity for drainage. However, pump flow can change drastically at a set RPM with changes in preload and afterload. Therefore a mechanism for monitoring pump flow changes is essential. Centrifugal pumps can operate at a wide range of RPMs—often as high as 5000—but higher RPMs can result in significant hemolysis.

The roller pump functions by occluding a segment of the circuit tubing called the *raceway*. Blood is drained by gravity from a venous cannula into the venous reservoir, and then pulled into the pump at a given RPM (Figure 50-4). The pump contains two rollers positioned opposite each other. Blood is displaced by the appropriate compression of the rollers on the tubing. This compression setting is called the *occlusion setting* and must be precisely set to produce an accurate flow. Blood is pumped forward under positive pressure. The pump flow is reliant on the diameter of the raceway tubing, the roller occlusion, and the set RPM. The pump will continue to spin despite a low blood volume state if not appropriately monitored. Servo regulation is commonly used as a safety mechanism to prevent excessive negative pressure on the right atrium in the presence of inadequate volume. This situation can result from hypovolemia, insufficient height of the patient (poor gravity-assisted flow), or a kink in the cannula or circuit tubing. The ECMO specialist must be vigilant that servo regulation is appropriately set to stop or slow the pump when there is inadequate blood volume. Without appropriate controls set the pump will continue to spin and cause cavitation, the formation of gas bubbles in the blood, causing significant risk of air embolization to the patient. Roller pumps work well for infants on relatively low flows because they are not affected by afterload and will provide a consistent pump flow.

Blood moves from the system pump to an oxygenator which functions as the lung of the ECMO system. The oxygenator contains hollow fibers for blood and gas to pass through. Gas flow referred to as the **sweep flow** is provided by a blender flowing in the opposite direction of blood flow (Figure 50-5). The blender is adjusted to ensure the hemoglobin of the blood leaving the oxygenator is 100% saturated with a PO_2 >250 mm Hg. As poorly saturated venous blood with very low partial pressure of oxygen is pumped into the oxygenator it traverses through fibers that are aligned with other fibers containing gas with a high partial pressure of oxygen. Oxygen diffuses from the fibers with a high concentration of oxygen to the blood with a lower concentration. There is no CO_2 in the sweep flow. Therefore the carbon dioxide in the blood diffuses into the

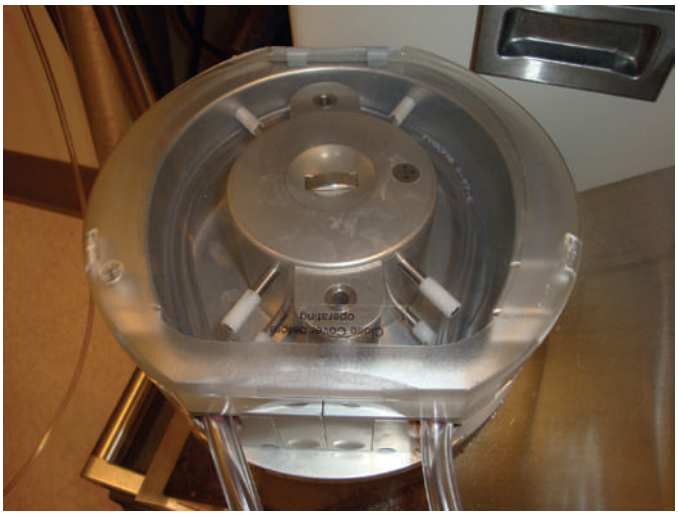

FIGURE 50-4 The roller pump contains two rollers positioned opposite each other. Blood is displaced by the appropriate compression of the rollers on the ECMO circuit, called the *occlusion*.

FIGURE 50-5 An oxygen flowmeter is connected to the circuit blender. Sweep flow is delivered into the artificial lung delivering up to 100% oxygen. A second flowmeter allows for analysis of the actual percent of oxygen delivered.

TABLE 50-2

Examples of Oxygenator Specifications

Oxygenator	Prime Volume	Maximum Sweep	Minimum Blood Flow	Maximum Blood Flow
Quadrox iD Adult	250 cc	15 lpm	500 cc/min	7 lpm
Quadrox iD Pediatric	81 cc	5.6 lmp	200 cc/m	2.8 lpm

sweep fibers and is flushed out of the oxygenator. The higher the sweep flow is set, the more CO_2 is eliminated. There is a range of effective sweep flows along with maximum blood flow for the different sizes of oxygenators (Table 50-2). From the oxygenator, fully saturated blood with the desired carbon dioxide level is pumped back to the patient either to a vein (VV support) or to an artery (VA support). The pump speed (RPM) is adjusted to allow the appropriate amount of the patient's blood volume to be oxygenated while the sweep flow rate is adjusted to maintain the desired CO_2 level.

RULE OF THUMB

The ratio of sweep flow to pump flow is often 1 : 1. When using 4 L/min pump flow, typically the sweep flow would be initiated at 4 L/min. The oxygenator functions to provide gas exchange much like native lungs perform gas exchange—oxygen diffuses into the blood from a gas source with a higher partial pressure and carbon dioxide diffuses out of the blood into a gas source with a lower partial pressure.

Additional equipment used with ECMO support includes a thermoregulation device referred to as the heater/cooler (Figure 50-6). As blood leaves the patient and circulates through the ECMO circuit, a considerable decrease in blood temperature can occur as the tubing that blood flows through is exposed to ambient temperature. Gas flow through the oxygenator is also cool, resulting in evaporative losses. Therefore, especially in neonates, active warming is required to maintain a normal body temperature. Temperature adjusted sterile water circulates around the fibers containing blood and allows appropriate temperature control of the blood returning to the patient. These devices have the potential to maintain hypothermic states when appropriate. Recent evidence has demonstrated that mild decreases in core temperature may have a salvaging effect on the brain[8] and can be easily achieved during ECMO support.

Pressure monitoring is a standard part of the circuit. Circuit pressures are measured before and after the oxygenator and indicate the absolute pressure in the circuit along with changes in resistance across the oxygenator (Figure 50-7). The change in resistance most often indicates development of clots within the oxygenator. Changes in pressures can alert the ECMO specialist to identify emerging situations such as kinks, clots, and in VA support, changes in hemodynamics.

FIGURE 50-6 Blood warmer/cooler, a device that will warm or cool the blood, circulates sterile water **(A)** and sends the heated or cooled fluid through hoses attached to the artificial lung and surrounds the fibers containing the blood to warm or cool it **(B)** (right figure).

RULE OF THUMB

Monitor pre and post oxygenator pressures frequently. Changes will alert clinicians to clots in the oxygenator. Increases in pre **membrane pressure** only = increased resistance within the oxygenator. Increases in pre AND post membrane pressures = increased resistance AFTER the oxygenator.

A pressure monitor can also be placed on the drainage line to detect excessive siphon on the system. Alarms and servo regulation can be used in association with these pressure monitors to create safer systems. Pressure monitoring is either integrated into the ECMO system or additional pressure transducers can be added.

As noted earlier, blood flow is regulated by dialing in a set RPM which results in flow. The flow is monitored using ultrasonic devices that are either incorporated into the system or

FIGURE 50-7 Oxygenator/pressure monitoring. Pressure transducers are attached to ports before and after the artificial lung with reading displayed on the bedside monitor. "SP5" indicates the pressure before the oxygenator and "SP6" indicates the pressure after the oxygenator. The difference between the two pressures is an indication of the resistance to blood flow through the oxygenator. Increases in pressure difference usually are a result of clot formation.

FIGURE 50-8 Example of inline oxygen saturation monitoring that can be used to trend the saturation of blood draining into the ECMO circuit.

FIGURE 50-9 Two types of point of care activated clotting time (ACT) devices with their cartridges.

added to the circuit. Many systems will display a calculated flow but the accuracy of that flow is dependent on many factors. Flow is measured to assure appropriate occlusion when using roller pumps and to check variations in flow common with centrifugal pumps. Audible alarms are usually set to alert the ECMO specialist of changes in pump flow.

Air (bubble) detectors can be useful in identifying the presence of air in the ECMO circuit. They can be used on either the arterial or venous side of the circuit and detect inadvertent air passing through the system. These devices can function to stop support when air is detected or sound an alert. False alarms can be problematic because support to the patient is stopped and will often produce significant instability for the patient until support is resumed. The ECMO specialist must be able to immediately distinguish true presence of air bubbles from false alarms rapidly and take the appropriate action for either situation.

Additional blood parameter monitoring can be incorporated into an ECMO system by insertion of an indwelling optical cable. These devices help to trend continuous values such as venous saturations, arterial saturations, hemoglobin, hematocrit, and temperature (Figure 50-8). They are generally considered optional and the use of each varies from institution to institution.

Unlike some of the optional parameters monitored during ECMO support, monitoring of anticoagulation parameters on a routine basis is essential. The **activated clotting time** (ACT) is most often used as the primary test for anticoagulation at the bedside. The ACT is a low cost point of care test that gives a quick assessment of anticoagulation. There are several types of devices using a small volume of blood that can determine the number of seconds it takes for blood to clot (Figure 50-9). It is most often used in conjunction with other parameters to assess the patient's overall state of anticoagulation.

ANTICOAGULATION MANAGEMENT

Anticoagulation of the ECMO patient is a vital part of an ECMO run starting at **cannulation**. The blood's natural reaction is to activate coagulation when exposed to the nonbiologic surfaces of the cannulas and circuit. Therefore, anticoagulation is essential prior to cannula insertion and throughout the ECMO course. Heparin, the most commonly used anticoagulant, is easily reversed and widely available. It is prepared from bovine lung or porcine intestines and can be monitored at the bedside. Heparin inhibits the conversion of prothrombin

TABLE 50-3

Example of Anticoagulation Protocol

Laboratory Test	Frequency	Goals	Normal
ACT	Q1 until results in desired range ×2 hrs, then Q4 while on heparin	As ordered, typically 160-200 (as low as 140 in bleeding patients, 200-240 at pump flows <2 L/min	90-120 sec
ATIII	Pre-ECMO baseline Monday, Wednesday, and Friday at 8 AM	Level maintained >40%	40-100%
anti-Xa	Q 24 hrs at 8 AM	Target levels of 0.3-0.7 IU/mL	N/A
aPTT	Q 24 hrs	50-80 seconds	22-35 sec
PT	Q 24 hrs	Normal	11-14
Fibrinogen	Q 24 hrs	Keep in normal range (250-300 mg/dL)	250-300
Platelets	Q 6 hrs	>60,000/μL	150-400/μL

to thrombin and activates antithrombin III (ATIII). It does not break up clots, but rather decreases the risk of their occurrence. A bolus of heparin is administered just prior to cannulation. ACT levels are assessed shortly after to ensure the desired levels of anticoagulation have been achieved. The bolus dose can vary based on the patient's baseline state of coagulation. Once the patient is on ECMO, periodic ACTs help assess the trend in coagulation and assist in fine-tuning the heparin maintenance doses. The ACT can be affected by many factors including anemia, hypofibrinogenemia, hypothermia, hemodilution, thrombocytopenia, qualitative platelet abnormality, and other coagulation factor deficiencies. Reports in the literature[9] and the anticoagulation guidelines recently published from ELSO[10] suggest that using more than one parameter may be helpful in the assessment of anticoagulation during long-term support. Monitoring of additional parameters on a routine basis and implementing a guideline in response to the combined results may be useful in assessing the overall coagulation/anticoagulation status of patients requiring long-term extracorporeal support. An example of an anticoagulation protocol can be seen in Table 50-3.

MINI CLINI

PROBLEM: Patient is being maintained on a heparin infusion to achieve the prescribed ACT range of 180-200 seconds. Over the past 2 hours, chest tube output has increased significantly, resulting in a decrease in hemoglobin, necessitating multiple blood transfusions.

Discussion: The ECMO specialist recommends lowering the desired ACT range in order to decrease the amount of bleeding. This can be achieved by lowering the hourly heparin infusion rate and repeating the ACT to assess the change. Vigilance in assessing the circuit for evidence of increased clot formation in the circuit is essential.

Heparin levels (anti Xa) may more accurately assess heparin-induced anticoagulation and are less affected by abnormal physiologic states than are ACT values. ACT levels may better reflect the overall anticoagulation status of the patient, but are not specific for heparin effects versus clotting deficiencies. The two values may be used together to better assess appropriate heparin and blood product needs. A number of studies in ECLS patients have shown a superior correlation of the anti Xa assay to heparin dose.[11] The presence of antithrombin III (AT III) in blood is also essential to achieve the desired levels of anticoagulation. AT III levels may be increased by infusing fresh frozen plasma (FFP), a blood product that contains AT III, or using recombinant AT concentrate, a concentrated form of AT III that is more effective than FFP. However, AT concentrate is significantly more costly, therefore the cost-benefit ratio is often considered. Thermoelastogram (TEG) is an emerging method of assessing anticoagulation.[10] A small sample of blood is taken from a patient and rotated gently in a specific fashion to imitate sluggish venous flow and activate coagulation. TEG provides comprehensive whole blood hemostasis testing that can help assess bleeding and thrombotic risks, and also monitor antithrombotic therapies. Some more common coagulation values assessed during an ECMO run include prothrombin time (PT) and activated partial thromboplastin time (aPTT). The aPTT may not be as accurate at assessing anticoagulation during ECMO in newborns and small children when heparin is used as the anticoagulant.[12] However, it can be a better assessment of anticoagulation when direct thrombin inhibitors are used to anticoagulate ECMO patients who have a sensitivity to heparin.[13] Patients with sensitivity to heparin, identified by heparin-induced thrombocytopenia, may be managed on ECMO through the use of direct thrombin inhibitors, such as lipirudin and bivalrudin. When using these forms of direct thrombin inhibitors the accuracy of ACTs is less dependable. Despite diligence with maintaining appropriate levels of anticoagulation, clot formation within the circuit remains a major complication during ECMO.[1]

RULE OF THUMB

Patients receiving ECMO support require significant levels of anticoagulation making bleeding a risk and common complication incurring during ECMO.

CANNULAS

Cannulas are inserted to provide direct access to the patient. Cannula size is crucial to the amount of support an ECMO system can provide. The smaller the internal diameter of a cannula, the higher the resistance of the flow. When placing venous cannulas, the largest possible cannula should be placed to ensure adequate flows. Cannulas are sized by their outer diameter, in French units. All cannulas are tested for their pressure/flow relationship and an M number determined. The M number represents a resistive factor that can be used to approximate the expected flow at a specific pressure difference. Cannula characteristics vary in internal size, length, port placement, size, and number (Table 50-4). This information is important to know during the cannula selection process. Selection of the appropriate cannulas is dependent on the intended insertion sites, age/size of the patient, and the type and amount of support needed. They are designed to be placed through a surgical cut-down, via sternotomy or by percutaneous insertion.

There are two types of venous cannulas: single and double lumen. Venous cannulas have several ports to allow for maximal drainage. Many are wire reinforced to decrease the potential for kinking. Some are coated to avoid an antiinflammatory response and decrease the risk of clot formation. Two types of double-lumen cannulas (DLC) are available for VV support (Figure 50-10). Newborn DLCs are inserted into a single vein and allow drainage of desaturated blood and return of oxygenated blood through the same vessel. They have multiple side ports to drain blood. The drainage lumen is typically larger than the return lumen, which allows for better drainage of venous blood. The return lumen has a single outlet and blood is pumped through the cannula by the positive pressure created from the pump's rotation.

The BiCaval DLC is another approach to VV support. It needs to be inserted under fluoroscopy or echocardiography guidance (Figure 50-11) because appropriate positioning is crucial and can be difficult without imaging. The drainage ports are positioned in both the superior and inferior vena cava with the return lumen positioned at the entry of the right atrium. These double-lumen cannulas are a single cannula with two lumens, the drainage lumen and the return lumen. Recirculation is expected when using a double-lumen cannula.

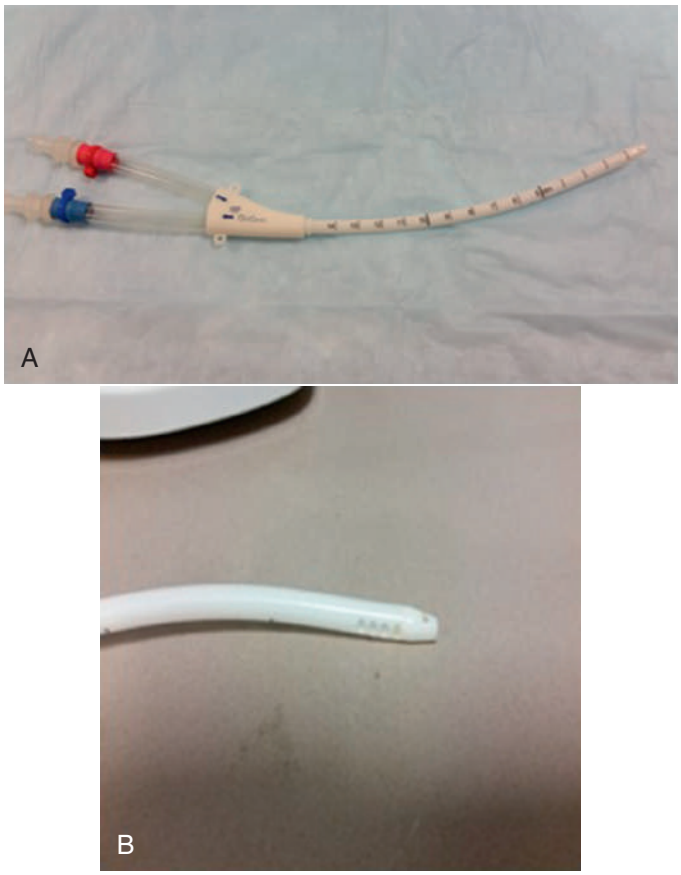

FIGURE 50-10 Double-lumen, single-vessel cannulas used for VV ECMO. **A,** Ports on one side of the cannula sit in the right atrium are used to drain blood into the circuit. **B,** The end return port is where blood is returned back into the RT Atrium and directed toward the tricuspid valve.

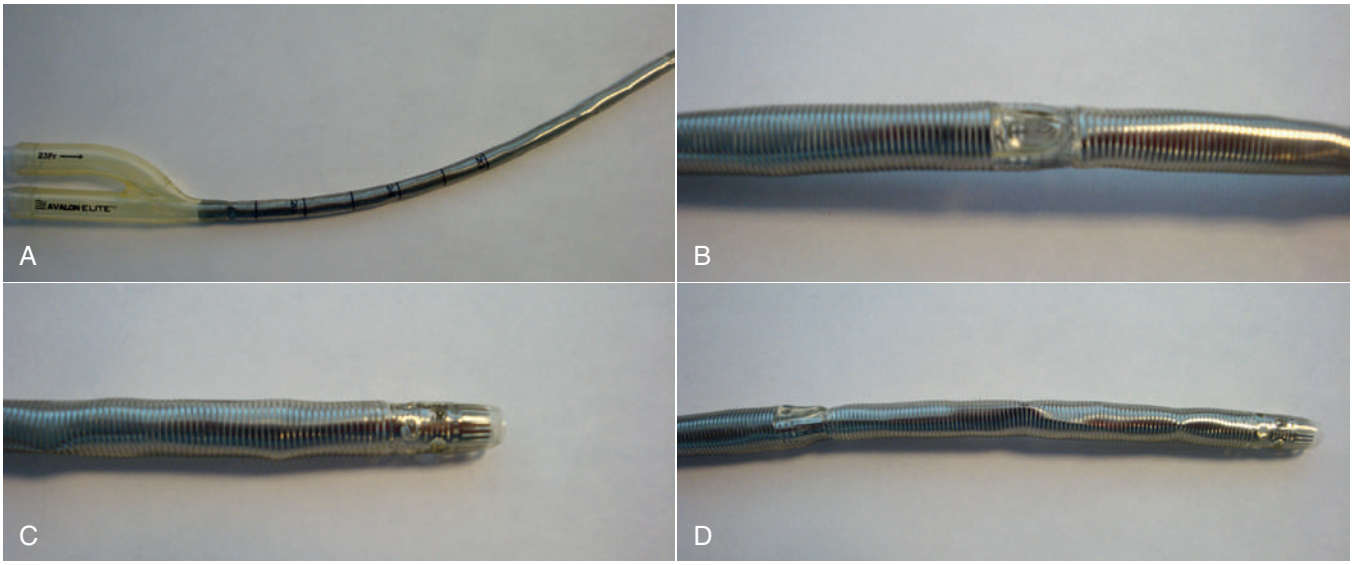

FIGURE 50-11 The BiCaval double-lumen cannula is inserted under fluoroscopy or echocardiography guidance. Drainage ports, seen on the right, are located in both the superior and inferior vena cava. The return lumen, seen on the left, is positioned in the right atrium across from the tricuspid valve.

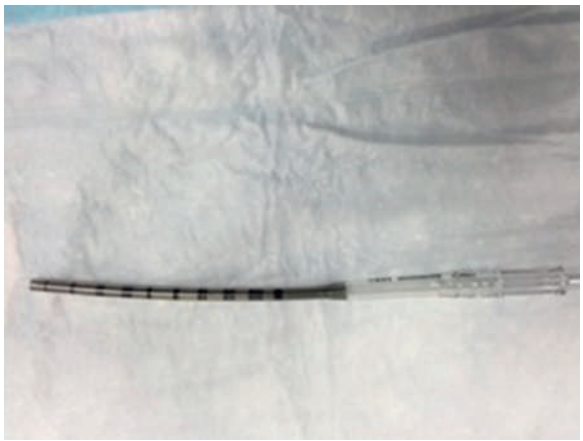

FIGURE 50-12 Arterial cannula with a single end port.

Recirculation occurs when oxygenated blood from the return lumen is siphoned back into the drainage side of the cannula. This is apparent when both drainage and return lines appear similar in color, with the patient showing signs of oxygen desaturation. Position is critical in a double-lumen cannula to avoid recirculation. Careful monitoring of the cannula is essential. Excessive recirculation will occur if the cannula is rotated out of optimal position, resulting in inadequate support.

Arterial cannulas typically have a single outlet. They are often wire reinforced and coated. Ideal arterial cannulas should be as short as possible and have thin walls. The size inserted is based on the internal diameter of the artery selected for cannulation. The narrow diameter of the arterial cannula creates the highest amount of resistance in the ECMO circuit. It is the conduit that allows for the return of oxygenated blood back to the patient's circulation (Figure 50-12).

TYPES OF SUPPORT

There are two primary types of ECMO support: VA and VV. VA support is partial cardiopulmonary bypass, providing both cardiac and pulmonary support. The degree of bypass depends on the underlying condition. VV does not bypass the cardiopulmonary circulation, thus only provides pulmonary support. A third, emerging type is AV ECMO, which is also referred to as pumpless ECMO. AV ECMO is primarily for CO_2 removal at low pump flows and requires the patient's own hemodynamics to pump blood through the oxygenator. This type of support is most effective at achieving adequate ventilation when native lung function is significantly impeded.[7]

Venoarterial ECMO

In VA ECMO a portion of the patient's blood volume is drained from the venous circulation to the ECMO circuit where gas exchange occurs (Figure 50-13). Fully saturated blood is returned through a cannula in the arterial circulation, which results in hemodynamic support. In VA ECMO a minimum of two cannulas are placed, with at least one in an artery and one in a vein. The cannulas can be placed via a surgical cut-down, through a sternotomy or percutaneously. The diameter, length, and position of the cannula will determine the potential flow that can be achieved. The typical artery accessed in the newborn would be the right common carotid artery. In larger patients placement can be in a left or right femoral artery, axillary artery or placed transthoracicly, directly into the aorta. When the femoral artery is cannulated, it is prudent to place a small reperfusion line to supplement blood flow to the lower leg and decrease the risk of limb ischemia (Figure 50-14). In some patients only a portion of their cardiac output is pumped through the ECMO circuit while some blood flow continues

FIGURE 50-13 VA ECMO with drainage from the right femoral vein and right atrium with blood being returned to the left femoral artery.

FIGURE 50-14 A secondary blood return line (reperfusion line) is placed in this femoral artery cannula to supplement blood flow to the lower limb and prevent limb ischemia.

through the native circulation. The blood from the ECMO circuit returns to the patient, bypassing the heart and lungs, and mixes with the native circulation. The total oxygen content depends on the proportions of blood through the two circulations. Similarly, the measured PCO_2 in the patient's arterial circulation will be a result of the combined relatively low PCO_2 returned from the ECMO circuit and the PCO_2 in the blood coming through the native circulation. The primary advantages

FIGURE 50-15 Common cannula used for VV ECMO support in newborns. Babies are often cannulated with a double-lumen cannula through the right internal jugular for VV ECMO.

Box 50-4 Characteristics of VA and VV Support

VENOARTERIAL ECMO
- Typically used for patients with cardiovascular failure
- Partial cardiopulmonary bypass
- Decreases preload
- Increases afterload
- Effects hemodynamics

VENOVENOUS ECMO
- Typically used for patients in respiratory failure
- Can be done with multiple cannnulas or a DLC
- Provides no hemodynamic support
- RV function may improve with increased S_VO_2

of VA ECMO are that it allows the heart to rest and reduces cardiac oxygen consumption while providing adequate systemic organ perfusion with oxygenated blood. There is no chance of recirculation and less ventilator support is needed. VA ECMO is best indicated for cardiogenic shock, as a bridge to a ventricular assist device or heart transplantation. A disadvantage of VA ECMO is the need to cannulate an artery which will require repair or ligation when support is no longer needed. See Box 50-4 for differences in VA and VV support.

Venovenous ECMO

As in VA ECMO, VV support involves a portion of the patient's blood volume being drained from the venous circulation to the ECMO circuit where gas exchange occurs. However, blood is returned back to the venous circulation either through the same cannula via the return lumen or via a separate cannula into another vein (Figure 50-15). The typical cannulation site for the newborn is in the right internal jugular vein. In larger patients, common sites are the right and left femoral veins, right internal jugular vein, pulmonary artery, or right atrium. Pulmonary artery and right atrium cannulations involve cannula placement via hemisternotomy or open chest surgery. Unlike VA ECMO, blood is returned to the venous circulation, therefore providing no direct cardiac support. Oxygenated blood that is lower in

CO_2 returns to the venous circulation and mixes with the remaining cardiac output. The total oxygen content and measured CO_2 is a result of this mix and can be affected by the patient's mechanical ventilation settings or spontaneous minute ventilation. Two distinct advantages of VV ECMO are lower risk of cerebral air embolism and no need to ligate or repair an artery. VV ECMO is often indicated for patients with acute respiratory failure due to viral or bacterial pneumonias.[14] VV is emerging as a bridge to lung transplant.[15] ECMO in the pre–lung transplant patient allows for improved gas exchange and decreases the risk of complications from high levels of mechanical ventilation. It can also prevent further deconditioning. The patient on VV ECMO can be extubated, awake, and ambulated while waiting for available lungs.[16]

Arteriovenous ECMO

AV ECMO is a more recent type of support. Unlike VA or VV support, AV support is low flow ECMO that provides gas exchange and relies on the patient's cardiac function to generate pump flow. It is a more compact system with shorter segments of circuit tubing that is attached to the oxygenator and blood is circulated via arterial blood pressure (Figure 50-16). The patients most likely to benefit from this type of support are COPD and pre–lung transplant patients.[7] In addition, ongoing clinical trials are determining if AV ECMO is useful in the management of patients with severe ARDS who require high airway pressure to adequately ventilate.[17] This form of ECMO requires that the patient has adequate cardiac function.

RULE OF THUMB

VA ECMO is primarily used to support patients with cardiac failure. VV ECMO is used primarily to support patients with respiratory failure.

INITIATION OF SUPPORT

ECMO is frequently initiated in the ICU. Specific circumstances may dictate ECMO being initiated in the operating room, cardiac catherization lab, emergency room or many other locations in the hospital. A formal activation guideline should be established so that access to the ECMO team and equipment can be rapidly deployed.

Cannulas are inserted in the appropriate vessels and then attached to an ECMO circuit. The circuit is assembled using sterile technique, de-aired, and crystalloid primed. Newborn circuits are often primed with blood to decrease the hemodilution effect that can be encountered with a crystalloid primed circuit. The circuit is attached to the cannulas and ECMO support commences. Pump flows are adjusted according to the type of support the patient is receiving and vary based on the underlying diagnosis. Patients needing cardiac support (VA) will often need a large portion of their cardiac output supported while patients on VV support may be maintained on a relatively lower amount of pump flow. As the pump flow increases, a larger portion of the patient's desaturated blood flows through the oxygenator and returns to the patient fully saturated. Box 50-5 shows sample target pump flows for different age groups. Once pump flow is at the desired level, alarms should be set appropriately to alert the ECMO specialist of any acute changes

Box 50-5 Target Pump Flows for Age Groups

- Infants: 120-150 cc/kg/min
- Children: 100-120 cc/kg/min
- Adults: 70-80 cc/kg/min
- Attempt to reach maximal flow early in run to determine buffer

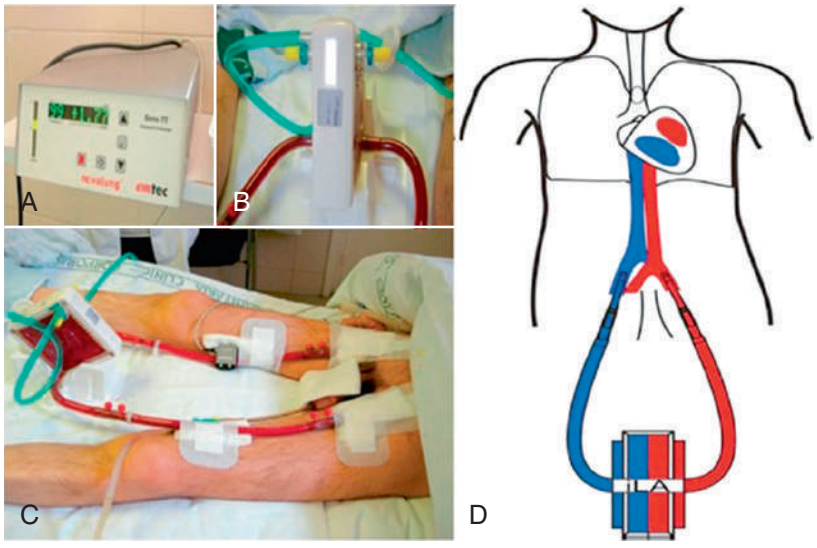

FIGURE 50-16 Arteriovenous ECMO without a pump; blood flow is maintained by the patient's "normally" functioning heart.

in pump support. Sweep flow is attached to the oxygenator and adjusted based on guidelines to achieve target CO_2.

RULE OF THUMB

The ratio of sweep flow to pump flow is often 1:1. When using 4 L/min pump flow, typically the sweep flow would be initiated at 4 L/min.

Consideration of adjustments in ventilator support is necessary to avoid hyper- and hypoventilation. Patients' ventilator settings can gradually be weaned to "rest settings" as the sweep flow is increased. Rest settings are intended to minimize lung trauma while avoiding atelectasis. Typically the FiO2 from the ventilator can be reduced to 0.4 to 0.6. The goal for some long-term patients (i.e., pre–lung transplant) is often extubation to allow for activities of daily living to be maintained in conjunction with physical therapy and ambulation while on ECMO support. Circuit temperature is adjusted to maintain patients at the intended body temperature. A chest x-ray is done to assess cannula placement. Serial blood gases and chemistries are obtained to ensure patient lab values are within acceptable ranges. Pump flow, sweep flow, and medications can be adjusted as needed. Blood products are transfused to maintain desired parameters. Baseline anticoagulation levels are obtained and a heparin infusion initiated at the dose necessary to achieve adequate anticoagulation. Sedation levels are adjusted to the appropriate level that will allow intermittent or continuous assessment of neurologic status. Levels of analgesia are provided as needed or as pain scores indicate. Emergency preparedness is an essential component of an ECMO start. Procedures to handle any complications during initiations should be developed for every ECMO center. Backup circuit components should be in a nearby location along with an alternative means to support the patient in the event of pump hardware failure.

MAINTENANCE OF AN ECMO RUN

ECMO runs can be expected to last from a few days to as long as several months. An established flow sheet to document key variables should record the trends in specific parameters. Monitoring the changes in these parameters allows the ECMO specialist to better assess a patient's progress, identify goals on a daily basis, and coordinate the best approach during the patient's course on ECMO (Box 50-6). Daily, the patient will receive a CXR to reaffirm cannula position and lung status. Periodic arterial blood gases are obtained as well as ACTs and other labs run at appropriate intervals to ensure values are maintained within desired range. Interdisciplinary team rounds occur at the bedside daily. Every discipline should be encouraged to contribute their perspective and together a well-defined strategy is formed. It is at these rounds that clear patient goals can be identified and a plan of care is established for the day. In addition to patient trends, documentation should also be maintained on various aspects of the active ECMO system (Box 50-7). Frequent circuit assessments, from the drainage cannula through the entire system and back to the return cannula, are essential. Specialists must be mindful of the many risks and potential complications associated with extracorporeal support. Diligence with frequent inspections and evaluation of components as well as ensuring the proper backup equipment should be part of the daily task of an ECMO specialist.

Certain categories of ECMO patients may require procedures unique to their condition. Open chest cardiac patients might need to travel to the OR for a chest washout or explorations to stop bleeding and, depending on the urgency, some surgical procedures may have to be done at the bedside. Bedside echocardiograms are done to assess any changes in cardiac function and sometimes to rule out **tamponade**. Cardiac catherization lab visits may also be necessary for procedures required during the ECMO run. Bronchoscopies and bronchial lavages are a little more common in patients being supported for respiratory failure. As with any ICU run there is a potential need to travel to CT scan or interventional radiology for diagnostic testing.

TRANSPORTING A PATIENT ON ECMO

Most ECMO systems are designed for intrahospital transport. However, detailed guidelines should be followed when preparing for transport. These should include a fully charged battery, adequate gas supply, transport ventilator, cardiac monitors, and defibrillator. A travel kit is advisable that includes connectors, clamps, additional medications, IV fluid, and other items that might be needed on route or at the destination. Provisions for temperature control may be necessary because the blood warmer/cooler may not be supported during the transport. Travelling on ECMO carries significant risks, and team work is essential to successful travel. Roles should be established prior to moving. It is wise to minimize the time of the transport by clearing hallways in advance and gaining easy access to elevators. During the transport, constant assessment of the patient along with battery charge level, gas supply, and close monitoring of the circuit should be practiced. When the destination is reached, close attention to detail should be made and reestablishment of piped gas and AC power obtained as soon as possible. Intrahospital transport includes elective patient ambulation in the ICU.

Preparing a patient to ambulate on ECMO takes collaboration among all services involved (Box 50-8). An agreement must be made on destination and maximum duration of time out of the patient's room. Roles of all providers should be clear. All necessary equipment should be identified and checked for function prior to beginning ambulation. There should be specific reasons to abort the exercise such as tachycardia, desaturation, patient fatigue or concerns for equipment or patient safety.

RISKS AND COMPLICATIONS

ECMO poses significant risks. The complications can be classified as mechanical as a result of equipment failure or patient from clinical issues. Box 50-9 outlines ECMO complications.[1]

ECMO specialists are clinicians specifically trained in all aspects of ECMO. It is essential that the ECMO specialist have a thorough understanding of ECMO physiology and ECMO patient management. These individuals must have critical thinking skills and be technically adept at assessing all components of the ECMO circuit. Monitoring and frequent inspection of the circuit and evaluating circuit functions are among the primary roles of the ECMO specialist. The risk of the many complications inherent in providing ECMO support diminishes with diligence on the part of the specialist.

Box 50-8 Guidelines for Ambulating With Patients on VV ECMO (Central-Peripheral)

I. Patient Assessment:
   a. Patient is able to participate in care
   b. Patient is able to be safely directed
   c. Demonstrates stability on ECMO
      1. Consider the following parameters
      2. Discuss with medical team if falls outside criteria

II. Prepare for Ambulation:

Hematologic	ECMO	General Considerations
No sign of bleeding over 12 hrs	Stability of flow, speed & sweep for 6hrs	Airway clearance
Plts > 50	Cannulas: sites have been stable—no migration or bleeding	Afebrile
Hgb ≥ 8-9		Tolerated HOB up, dangling, OOB to chair
ACT at goal		

   a. Obtain MD order for ambulation after assessment by RN, PT, RT
   b. Ensure ECMO cannulas, airway and all other lines are secured
   c. Equipment checklist:
      1. Full O_2 tank
      2. Clamps
      3. Portable SpO_2 monitor
      4. Wheelchair/recliner
      5. ECMO emergency equipment
      6. Assess battery life for all equipment
   d. Contingency plan:
      1. Identify red plug outlets
      2. Identify location of backup circuit
   e. Team discussion prior to take off to include destination & roles*
      - RN: IVs, tubing, chest tubes
      - RT: ECMO pump/cannula (circuit), monitor flow/speed, airway
      - PT: manages patient mobility
      - A minimum of 3 staff must be present during ambulation
      - *Each discipline to monitor hemodynamic parameters and alert team members if significant changes noted
   f. Ensure hallways are clear of obstruction
   g. Limit ambulation to within the ICU

III. Ambulate

IV. Documentation per each discipline's standards

Box 50-9 Common Complications

MECHANICAL COMPLICATIONS
- Pump failure
- Tubing rupture
- Cannula problems
- Oxygenator failure

PHYSIOLOGIC COMPLICATIONS
- Seizures
- Hemolysis
- Renal failure
- Bleeding; intracranial, surgical site
- Neurologic complications
- Arrhythmias
- Pneumothorax

The most common mechanical complication during ECMO is clot formation.[1] Clot can occur anywhere in the circuit but more frequently occurs in the oxygenator, at connectors, in the circuit bladder or any place with relatively low flow. Clots can result in increased resistance and may impede flow, limiting support of the patient. Clot formation within the fibers of the oxygenator will reduce gas exchange and if significant may require the oxygenator to be replaced (Figure 50-17). Inadvertent **decannulation** and pump failure are other significant complications that can cause circuit interruption and require immediate attention. These conditions might result in the need for an entire circuit to be replaced. Replacement of oxygenators or circuits requires the patient to be briefly removed from support. Practitioners trained in this procedure need to maintain competency to efficiently change out the oxygenator or circuit in the least amount of time to minimize patient decompensation from interruption of support. Proper coordination with the team caring for the patient is essential during this loss of support.

Air in the circuit is a major risk during ECMO. Despite the ECMO system being a closed system, air emboli can occur when air is entrained into the system. This can occur inadvertently through cavitation—air being pulled out of a solution due to increased negative pressure—if venous return is inadequate. It can occur from drainage ports of a cannula migrating out of a vessel or from access lines, such as through the CVVH port, infusion lines or other monitoring lines. The presence of air in the circuit, if not redirected or withdrawn, may enter the patient's circulation. In VA ECMO this is particularly life threatening because air will not be filtered through the pulmonary circulation as it is in VV ECMO. As with most mechanical complications, prevention is vital.

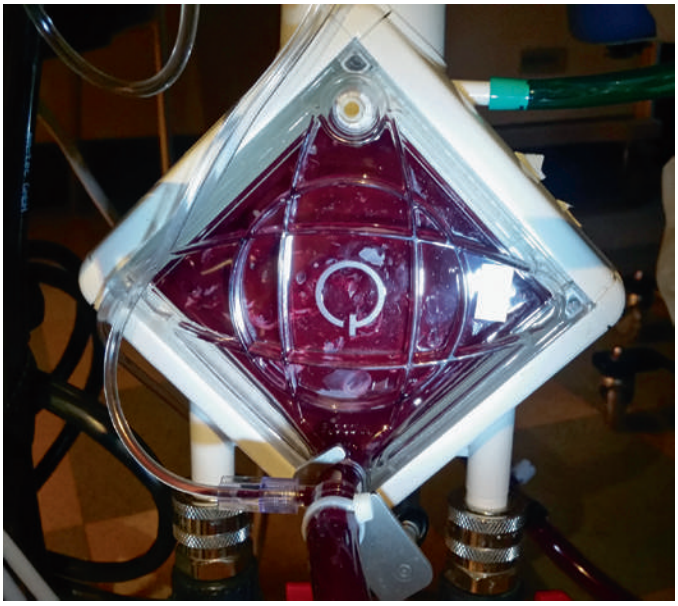

FIGURE 50-17 Oxygenator with significant clot accumluation.

Bleeding is a common risk of ECMO due to anticoagulation and the multiple surgical sites where bleeding can easily occur. Bleeding in the chest can lead to the complication of cardiac tamponade, an emergency needing immediate intervention, without which the patient will not likely survive. Cannula placement in the awake and active patient on ECMO can also contribute to the occurrence of tamponade. Loss of pump flow, hemodynamic changes with a narrowing of pulse pressure, arrhythmias, and decreases in hemoglobin and hematocrit levels are symptomatic of tamponade. Bleeding from any source resulting in low pump flow not only causes risks to the patient but to the circuit as well. Lower flows result in higher potential for clot formation in a circuit. The drop in hemoglobin is also a major concern because the oxygen carrying capacity is greatly reduced. Bleeding can occur from any surgical site, including cannula sites, chest tubes, or IVs. Bleeding becomes a risk with any venopuncture, NG or OG tube placement, rectal tube placement, suctioning, or anything that might cause mild trauma to the tissues. Internally, intracranial hemorrhage, GI and pulmonary bleeding are also bleeding risks associated with ECMO.

BLOOD PRODUCTS DURING ECMO

The most common blood product used during an ECMO run is packed red blood cells (PRBCs). PRBCs are transfused to maintain adequate levels of hemoglobin to ensure adequate oxygen carrying capacity. Typically hemoglobin is maintained at approximately 8 to 10 g/dl. Platelets, fresh frozen plasma, and cryoprecipitate are often used to target specific clotting factors. Protocols identify when transfusion of each individual product is indicated. Albumin may also be used intermittently throughout the run for volume expansion.

WEANING AND DECANNULATION

Daily assessments for the possibility of weaning should be made first by considering why the patient was initially placed on ECMO and whether or not the problem has been resolved. Other questions to consider are if additional issues have been identified that either indicate the necessity to continue support or identify the need to discontinue support. Throughout the run the team must consider if the risks of ECMO outweigh the benefits. The process of weaning off of ECMO is different in VA support than in VV support. During VA weaning, the function of the heart must be assessed as increased blood flow is redirected to the native circulation. This evaluation is often accomplished via cardiac ultrasound while pump flow is decreased. At the same time, hemodynamic stability, RV, LV function, and the degree of pulmonary hypertension should be evaluated. Ventilator support may need to be adjusted as pump flows are decreased, particularly ventilator FiO_2 to supplement the decrease in pump flow. At this time, the risk of clots developing in the circuit at the low flow states is present. Therefore, the duration of the wean should be limited to no more than an hour with close attention to anticoagulation.

For the patient who requires VA ECMO for both cardiac and pulmonary support, there is the option to convert to VV ECMO if the heart function recovers before adequate lung function is achieved. The patient can be supported on VV ECMO until there is further evidence of lung improvement. Patients on VV ECMO must demonstrate improvement in their pulmonary status before weaning can be considered. This includes an increase in lung compliance, improved aeration on CXR, and the ability for effective gas exchange on conventional ventilator settings that are not likely to produce lung injury. A test to evaluate the native lung's ability to oxygenate can be achieved while maintaining the same ECMO support and obtaining an arterial blood gas with the ventilator FiO_2 at 1.0. A daily assessment using this "100% gas" can demonstrate the improvement in oxygenation. Early stages of support will not reveal much change, but as the lungs improve significant increases in the PaO_2 will be obvious. The process of weaning off of VV ECMO involves maintaining pump flow and weaning sweep flow to assess the native lung's ability to remove CO_2. Adjustments in ventilator support to accommodate the decrease in sweep flow should be made at this time. Once there is an improvement in ventilation evidenced by reasonable levels of PCO_2 on moderate ventilator settings with an improvement in the 100% oxygen gas, the sweep flow can be removed. The pump flow continues while a period of assessment off of ECMO occurs to determine if the patient is ready for decannulation. The decannulation approach will be determined by the cannulation sites. Percutaneously inserted cannulas may be simply withdrawn at the bedside if vascular repair is not anticipated. If surgical repair or reconstruction of the vessel is needed or if the patient is centrally cannulated, decannulation typically will take place in the operating room. Post-decannulation anticoagulation is most often discontinued or adjusted to desired levels.

MINI CLINI

PROBLEM: A patient is cannulated for VV ECMO due to acute lung injury secondary to H1N1 flu. The patient initially required a pump flow of 4 L/min and sweep of 10 L/min to achieve the desired gas exchange. After 5 days on resting ventilator settings, an improvement in both CXR and lung compliance is noted. Additionally, PaO_2 with the ventilator FiO_2 at 1.0 is markedly improved: on day 1 it had been 50 mm Hg and after 5 days is now 220 mm Hg. What changes should be made to assess the patient's readiness to wean off of VV support?

Discussion: Gradual decreases in sweep flow will allow assessment of the patient's native lung ability to effectively ventilate. Simultaneously, ventilator adjustments should be made to support the transition when ECMO is discontinued. The patient is ready to be decannulated when gas exchange can be maintained without sweep flow and ventilator settings that will not induce any further lung injury (i.e., plateau pressures less than 30 and FiO_2 less than 0.6).

RULE OF THUMB

Weaning from VA support is accomplished by turning down the pump flow and assessing hemodynamics. Weaning from VV support is accomplished by turning down the sweep flow and assessing gas exchange.

SUMMARY CHECKLIST

- ECMO is an option for newborn, pediatric, and adult patients with severe cardiac or respiratory failure who meet the criteria outlined in Boxes 50-2 and 50-3 and who otherwise have no absolute contraindications.
- The primary goals of ECMO are to deliver adequate amounts of oxygen, remove carbon dioxide, and in cases of VA ECMO, provide hemodynamic support. ECMO physiology mimics native cardiopulmonary physiology in that it allows oxygen to diffuse into the blood and carbon dioxide to be removed. This is accomplished through a circuit that contains a pump and an artificial oxygenator.
- The patient is cannulated with either a double-lumen cannula or multiple single-lumen cannulas.
- During VV support cannulas are usually placed in the right internal jugular vein, right atrium, left or right femoral veins. In VA support, the venous cannulas are placed in the same locations as with VV support with the arterial cannula inserted into the aorta or either femoral artery.
- Blood is either drained or siphoned into the pump, which propels it forward into an oxygenator. The oxygenator provides gas exchange before returning the blood to the patient containing hemoglobin that is fully saturated and has the desired carbon dioxide level.
- A blood warmer/cooler keeps the blood at the desired temperature and additional monitors provide clinicians with valuable information regarding circuit pressures, flows, and additional lab values. Several of the monitors can be set to sound audible alarms when the values of certain parameters are outside of the acceptable range.
- The circuit and cannulas are made of materials foreign to blood. These surfaces will cause the normal activation of blood clotting reactions. Anticoagulation is necessary to decrease the risk of clots in the circuit, cannulas, and most importantly in the patient.
- Bedside coagulation testing is typically performed at regular intervals to keep a close watch on the level of anticoagulation, along with frequent inspection for clot development in any of the circuit components.
- A major advantage of ECMO is that ventilator support can be decreased once ECMO is initiated, thus reducing the potential of ventilator-induced lung injury. At times the ventilator can even be discontinued, reducing the potential of ventilator-associated pneumonia and allowing the patient to more actively participate in activities of daily living. This is of particular importance in the pretransplant patient.
- As technology advances and proper candidate selection is achieved, ECMO is certain to be more frequently utilized in ICU management of the critically ill patient.

CHAPTER 51

Monitoring the Patient in the Intensive Care Unit

THOMAS PIRAINO

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the principles of monitoring the respiratory system, cardiovascular system, neurologic status, renal function, liver function, and nutritional status of patients in intensive care.
- Identify the risks and benefits of intensive care unit (ICU) monitoring techniques.
- Explain why the caregiver is the most important monitor in the ICU.
- Describe how to evaluate measures of patient oxygenation in the ICU.
- Explain why $PaCO_2$ is the best index of ventilation for critically ill patients.
- Describe the approach used to evaluate changes in respiratory rate, tidal volume, minute ventilation, $PaCO_2$, and end-tidal PCO_2 values for monitoring purposes.
- Identify monitoring techniques used in the ICU to evaluate lung and chest wall mechanics and work of breathing.
- Describe the importance of measuring transpulmonary pressure in select patients.
- Discuss the importance of monitoring peak and plateau pressures in patients receiving mechanical ventilatory support.
- Identify monitoring techniques that have become available more recently, such as lung stress and strain, functional residual capacity, stress index, electrical impedance tomography, and acoustic respiratory monitoring.
- Describe the approach used to interpret the results of ventilator graphics monitoring.
- Describe the cardiovascular monitoring techniques used in the care of critically ill patients and how to interpret the results of hemodynamic monitoring.
- Discuss the importance of monitoring neurologic status in the ICU and the variables that should be monitored.
- Discuss evaluation of renal function, liver function, and nutritional status in the ICU.
- List and discuss the use of composite and global scores to measure patient status in the ICU, such as the APACHE severity of illness scoring system.
- Discuss monitoring and troubleshooting of the patient-ventilator system in the ICU.

CHAPTER OUTLINE

KEY TERMS

acoustic respiratory monitoring (ARM)
afterload
alveolar and arterial oxygen tension difference ($P(A-a)O_2$)
APACHE scoring system
artifacts
bladder pressure
capnography
capnometry
cardiac output
contractility
dead space/tidal volume (V_D/V_T) ratio
driving pressure
electrical impedance tomography (EIT)
esophageal balloon
factitious events
Fick equations
frequency/tidal volume (f/V_T) ratio
Glasgow Coma Scale (GCS)
Harris-Benedict equation
lung ultrasonography
lung stress and strain
maximal inspiratory pressure (MIP)
maximum voluntary ventilation (MVV)
mean airway pressure (MAP)
Murray lung injury score
oxygen consumption ($\dot{V}O_2$)
PaO_2/FiO_2 ratio
physiologic shunt ($\dot{Q}_S/\dot{Q}_T$)
preload
pressure-time product (PTP)
respiratory inductive plethysmography
stress index
Swan-Ganz catheter
systematic errors
tissue oxygen sensing
transpulmonary pressure
venous admixture
vital capacity (VC)

When patients are admitted to the intensive care unit (ICU) it is generally for the purpose of providing interventions that require continuous or periodic monitoring of physiologic parameters. Patients may require medications, fluid resuscitation to treat severe hypotension, or require noninvasive or invasive ventilatory support for respiratory failure. The monitoring of these patients is essential to assess the effectiveness of treatment in the ICU and to minimize, limit, or prevent adverse events.

Although diagnostic procedures such as radiographic imaging can be used to monitor the progression of disease over time, this chapter will focus on the periodic and/or continuous monitoring of the respiratory system, cardiovascular system, neurologic function, renal function, liver function, and nutritional status of patients in the ICU.

PRINCIPLES OF MONITORING

Monitoring options in the ICU always carry the risk of providing incorrect values, or having their values misinterpreted. Other risks of monitoring depend on the level of invasiveness. Noninvasive monitoring is monitoring that may or may not come in contact with the body, whereas invasive monitoring involves placement of the monitoring device/probe within the body. The best monitoring options provide detailed, easily interpreted data, obtained noninvasively. A monitoring tool that is highly invasive and carries a certain level of risk with use must provide a high level of valuable and required information to make the benefit of using it outweigh the risk.

New advancements in technology aim to make monitoring less invasive and at the same time provide the most clinically

relevant data. The data provided should be accurate (reflect the true value) and precise (not vary widely when repeated). Many devices may require zeroing or calibration to minimize **systematic errors**.

Monitoring techniques utilized in the ICU also need to be validated and continually evaluated for their usefulness in guiding therapy and practice. When monitoring results of blood test values, interpretation may seem as simple as determining whether the values are within normal range. However, these acceptable ranges may change when new research becomes available, and generally require an understanding of the patient's "global status" to truly understand their relevance. When monitoring involves images, graphs, or waveforms, the data must be easily distinguishable from **artifacts**, **factitious events**, or normal variation, and still require an understanding of the overall status of the patient to understand their significance. Generally, the interpretation of monitored values requires skill and training to understand when something is considered abnormal and requires intervention. Interpretation also requires the use of multiple monitoring tools to help piece together more complicated conditions.

The best monitor in the ICU is the caregiver who understands how to use and interpret the various monitoring tools and techniques available to them. Caregivers may be the best monitors, but they cannot stand at the bedside continuously. Also, monitoring devices allow us to "see" the unseen. Values such as cardiac rhythms (ECG), respiratory system compliance, or alveolar ventilation would not be known using basic physical examination. Monitoring devices may require alarms to alert caregivers when values are outside of acceptable ranges for the patient. However, the skilled caregiver must understand the most appropriate setting for these alarms, and also be able to distinguish false alarms from those requiring immediate action. Devices also may prioritize alarms into low, medium, and high priority and alert clinicians with different sounds and visuals to assist with recognition in an environment filled with a variety of noise.

As monitoring devices become more advanced there is an increased risk of the clinicians ignoring the importance of physical assessment. Observing a monitor while ignoring the patient does not take into consideration the global status of the patient. We must combine the "seen" with the "unseen" to truly understand the patient (Box 51-1).

RULE OF THUMB

The caregiver must understand and interpret the information provided through monitoring. The key to proper interpretation of information is understanding how it applies to the global status of the individual patient.

PATHOPHYSIOLOGY AND MONITORING

The problem often faced at the bedside when presented with monitoring data is that clinicians may begin treating the numbers rather than the underlying pathophysiology. For example, when a patient is mechanically ventilated and the SpO_2 level drops you may improve the SpO_2 by increasing FiO_2, but adjusting the positive end expiratory pressure (PEEP) may be more appropriate if the SpO_2 drop was secondary to a change in lung mechanics. Treating the patient rather than the number requires the clinician to consider the underlying cause rather than implement a quick fix.

Box 51-1 Monitors and Monitoring Data

- Monitored values can exhibit physiologic and instrument variability.
- Monitoring devices can be noninvasive or invasive.
- Alarm systems should be set to alert caregivers properly yet avoid false alarms.
- Monitors can run continuously and measure what caregivers cannot see.
- The best monitors are caregivers who can assess and make decisions based on understanding the global status of the patient.

RESPIRATORY MONITORING

The function of the lungs is the uptake of oxygen and the removal of carbon dioxide. The arterial blood gas (ABG) gives valuable information regarding the effectiveness of the exchange (discussed in Chapter 19). Although ABGs can be drawn at the bedside, they usually require processing outside of the patient's room, either at a point-of-care machine or by the hospital laboratory. The most common bedside monitoring surrogates for O_2 uptake and CO_2 clearance are the SpO_2 (oxygen saturation) and respiratory rate (minute ventilation when the patient is mechanically ventilated). Both monitoring options have benefits, but with considerable limitations.

Monitoring Oxygenation

Tissue oxygenation depends on FiO_2, inspired partial pressure of oxygen (PiO_2), alveolar oxygen tension (PAO_2), arterial oxygenation (PaO_2, SaO_2, oxygen content of arterial blood [CaO_2]), oxygen delivery, tissue perfusion, and O_2 uptake.

Arterial Pulse Oximetry

Pulse oximetry uses a color spectrum measurement of pulsing arterial blood for continuous assessment of arterial oxygenation (SpO_2). ABG analysis has been the accepted method of detecting hypoxemia in critically ill patients, but obtaining arterial blood can be painful and cause complications, and ABG analysis does not provide immediate or continuous data. For these reasons, SpO_2 has become the standard for a continuous, noninvasive assessment of SaO_2. However, SpO_2 does not measure $PaCO_2$, and patients breathing an elevated FiO_2 can retain CO_2 (increased $PaCO_2$), although SpO_2 values are acceptable. Ventilatory failure may go unnoticed unless ABGs are measured.

SpO_2 measurements are based on spectrophotometric principles, which are based on the law of Beer-Lambert. Lightweight

probes direct filtered light of specific wavelengths (usually two) through a digit, the bridge of the nose, or an earlobe or reflected from a forehead sensor. The relative absorption of these spectrophotometric beams after passing through the tissue (which differs for O_2 saturated and desaturated blood) is converted into the appropriate saturation value with processor-stored algorithms.

Tissue O_2 sensors designed to measure SaO_2 of muscle or the brain were developed more recently.[1] Brain oxygenation is crucial, and deep muscle tissue in compartment syndromes can become deoxygenated. This **tissue oxygen sensing** technique involves positioning of an emitter and detector (of usually four wavelengths) on the skin surface over the tissue or organ of interest. Light from the emitter reflects from tissue at a depth of one-third the distance between the emitter and detector. The light received by the detector is read, and algorithms determine tissue oxygenation, not SpO_2.

RULE OF THUMB

There are two very important problems with relying on SpO_2 to monitor adequate respiratory function: (1) SpO_2 values reflect oxygenation, not ventilation; and (2) SpO_2 measurement is susceptible to numerous factors that can produce false values.

Although SpO_2 has been universally adopted, it does have limitations (Box 51-2).[2,3] Motion artifact is an important problem, resulting in inaccurate readings and false alarms. Motion artifacts are common because of shivering, seizure activity, pressure on the sensor, or transport of the patient. The choice of probe site may also affect accuracy. Finger probes appear to be more accurate than forehead, nose, or earlobe probes during low perfusion states. Intense daylight and fluorescent, incandescent, xenon, and infrared light sources have caused errors in SpO_2 readings. Anemia and deeply pigmented skin can affect the accuracy of SpO_2; however, the effect of anemia is not clinically significant until the hemoglobin level is markedly reduced. Carboxyhemoglobin and methemoglobin can produce falsely high SpO_2 values, and some colors of nail polish, particularly blue, green, and black, interfere with light transmission and absorbency, as do some blood-borne dyes, such as indocyanine green and methylene blue, which tend to produce falsely low SpO_2 values. Although rare, exposure to numerous toxins and drugs, including topical benzocaine, can elevate methemoglobin and produce falsely elevated SpO_2 values.

Box 51-2 Values Affecting Pulse Oximetry

- Motion artifact
- Environmental light (e.g., sunlight, fluorescence)
- Anemia
- Deeply pigmented skin
- Carboxyhemoglobin, methemoglobin
- Nail polish
- Blood-borne dyes

MINI CLINI

Trusting the Pulse Oximeter

PROBLEM: A 32-week-gestation newborn is intubated and receiving CPAP therapy. The patient appears to be in mild to moderate respiratory distress, yet SpO_2 is 98%. Hurricane spray (20% benzocaine) had been used to reduce the irritation of the endotracheal tube. Analysis of ABG values reveals PaO_2 325 mm Hg, and the cooximeter shows a methemoglobin value of 38%.

Solution: The most common problems with the fidelity of pulse oximeter readings are motion artifacts, interference by external light sources, or malposition of the sensor. Each of these problems can be easily and quickly assessed. In this case, the clinical symptoms did not correlate with an acceptable SpO_2 value. Because adequate O_2 delivery is the ultimate goal, CO and O_2-carrying ability must be considered as causes of the respiratory distress. The high methemoglobin value necessitates immediate therapy with methylene blue dye. Although the pulse oximeter has provided an excellent, safe means of monitoring blood oxygenation, there must be a wary vigilance about trusting the values.

Oxygen Consumption

Oxygen consumption ($\dot{V}O_2$) is the volume of O_2 consumed by the body in milliliters per minute. Normal resting $\dot{V}O_2$ is approximately 250 ml/min, and $\dot{V}O_2$ increases with activity, stress, and temperature. The acquisition of O_2 from the lungs into the circulatory system is described by the **Fick equations**:

$$\dot{V}O_2 = \dot{Q}_T\,(CaO_2 - C\bar{v}O_2)\ or\ \dot{Q}_T = \dot{V}O_2/(CaO_2 - C\bar{v}O_2)$$

in which $\dot{Q}_T$ is cardiac output (CO), and CaO_2 and $C\bar{V}O_2$ are arterial and mixed venous oxygen contents. If the values for $\dot{Q}_T$, CaO_2, and $C\bar{V}O_2$ are normal, this becomes:

$$\begin{aligned}\dot{V}O_2 \text{ in ml/min} &= \dot{Q}_T\,(CaO_2 - C\bar{v}O_2)\\ &= (5000\text{ ml/min})\,(20\text{ ml}/100\text{ ml} - 15\text{ ml}/100\text{ ml})\\ &= (5000\text{ ml/min})\,(5\text{ ml}/100\text{ ml})\\ &= 250\text{ ml/min}\end{aligned}$$

Simply stated, deoxygenated venous blood is converted to oxygenated arterial blood when O_2 in the alveoli diffuses into mixed venous blood flowing by at the pace of CO.

An alternative calculation for $\dot{V}O_2$ that does not require an arterial or mixed venous blood sample or measurement of **cardiac output** (CO) is:

$$\dot{V}O_2 = [(FiO_2)\,(\dot{V}_I)] - [(F_{\bar{E}}O_2)\,(\dot{V}_E)]$$

where FiO_2 and F_EO_2 are the mean inspired and expired fractional concentrations of oxygen, and $\dot{V}_I$ and $\dot{V}_E$ are the inspired

and expired minute ventilations. If $\dot{V}_I$ equals $\dot{V}_E$ (normally $\dot{V}_I$ is slightly greater than $\dot{V}_E$, but the difference is small), this becomes:

$$\dot{V}O_2 = (FiO_2 - F_EO_2)\,\dot{V}_E$$

If the values for minute ventilation and inspired and expired gas concentrations are normal, this becomes:

$$\dot{V}O_2 = (0.21 - 0.168)\,(6\ \text{L/min}) = 0.252\ \text{L/min},$$
$$\text{or approximately } 250\ \text{ml/min}$$

A normal resting $\dot{V}O_2$ of 250 ml/min represents approximately 25% of normal O_2 delivery (1000 ml/min). The blood carries a large reservoir of O_2 that can diffuse into deoxygenated tissues under high O_2 demand conditions.

$\dot{V}O_2$ may be useful in determining nutritional requirements and adequacy of O_2 delivery and may occasionally help determine the cause of a high ventilation requirement. If there is a stable tissue demand for O_2, measurements of $\dot{V}O_2$ may be used to follow the hemodynamic response to therapeutic interventions.

Alveolar-Arterial Oxygen Tension Difference

The **alveolar and arterial oxygen tension difference (P(A – a) O2)** is a useful measurement of the efficiency of gas exchange. A healthy person breathing room air has $P(A-a)O_2$ of approximately 5 to 15 mm Hg. This value increases with age to approximately 10 to 20 mm Hg in elderly adults. $P(A-a)O_2$ also increases normally with an increase in FiO_2. A healthy person has $P(A-a)O_2$ of 5 to 15 mm Hg while breathing room air; however, $P(A-a)O_2$ increases to 100 to 150 mm Hg when the person is breathing 100% O_2.

Most importantly, an abnormal increase in $P(A-a)O_2$ is associated with gas-exchange problems. If PaO_2 is 80 mm Hg while the patient is breathing 100% O_2, a significant gas-exchange problem is present even though oxygenation seems acceptable.

If PaO_2 is 80 mm Hg, $PaCO_2$ is 40 mm, FiO_2 is 1, and barometric pressure (PB) is 760 mm Hg, then:

$$PAO_2 = PiO_2 - (PaCO_2)\,(1.25)$$
$$PiO_2 = [(PB - P_{H_2O})\,(FiO_2)] = 713$$
$$PAO_2 = [(760 - 47)\,(1)] - (40)\,(1.25) = 663\ \text{mm Hg}$$
$$P(A-a)O_2 = PAO_2 - PaO_2 = 663 - 80$$
$$P(A-a)O_2 = 583\ \text{mm Hg}$$

where P_{H2O} is water vapor pressure. $P(A-a)O_2$ is markedly elevated considering that normal $(A-a)O_2$ is 100 to 150 mm Hg while the patient is breathing 100% O_2. $(A-a)O_2$ also can be used to give a rough estimate of percentage shunt, where:

$$\text{Shunt} \cong \frac{[P(A-a)O_2 \text{ on } 100\%\ O_2]}{20}$$

In this example, percentage shunt would be approximately 29%: $P(A-a)O_2/20 = 583/20 = 29.2\%$.

$P(A-a)O_2$ takes into account $PaCO_2$ and eliminates hypoventilation and hypercapnia from consideration as the sole cause of hypoxemia. Although $P(A-a)O_2$ is infrequently calculated, astute experienced clinicians consciously or subconsciously can estimate $P(A-a)O_2$ from a blood gas value.

PaO_2/FiO_2 Ratio

The **PaO_2/FiO_2 ratio** has become important for the determination of the extent of acute respiratory distress syndrome (ARDS) in multicenter collaborative studies.[4,5] A normal PaO_2/FiO_2 ratio while breathing room air is about 400 to 500 mm Hg. The PaO_2/FiO_2 ratio provides an index for the effect of O_2 on PaO_2 when a range of FiO_2 settings may be prescribed. The index allows comparisons of severity between patients or if FiO_2 is changed in the same patient. The PaO_2/FiO_2 ratio is easy to calculate and a reliable index of gas exchange. The level of applied **mean airway pressure (MAP)**, which is strongly affected by PEEP, must also be considered as an independent factor that influences the PaO_2/FiO_2 ratio. This is done by calculating the oxygenation index (OI). Evidence suggests that the OI seems to have an independent effect on mortality when considering the use of rescue strategies in neonates.[6] In addition, a change in the FiO_2 can also affect the PaO_2/FiO_2 ratio. Some recommend that in ARDS the PaO_2/FiO_2 ratio should be determined at a specific FiO_2 and PEEP level.

RULE OF THUMB

The Berlin definition of ARDS includes:

- Bilateral infiltrates on chest radiograph
- Absence of left ventricular failure
- PaO_2/FiO_2 200 to 300 mm Hg for mild ARDS (previously considered acute lung injury or ALI)
- PaO_2/FiO_2 100 to 200 mm Hg for moderate ARDS
- PaO_2/FiO_2 less than 100 mm Hg for severe ARDS

Oxygenation Index

Calculation of oxygenation index (OI) by the following equation provides an index that accounts for FiO_2 and MAP:

$$OI = \frac{FiO_2 * MAP}{PaO_2}$$

Quantification of Shunt

The most accurate and reliable measure of oxygenation efficiency is direct computation of the **physiologic shunt** ($\dot{Q}_S/\dot{Q}_T$). The physiologic shunt is computed as follows:

$$\dot{Q}_S/\dot{Q}_T = (CcO_2 - CaO_2)/(CcO_2 - C\bar{v}O_2)$$

Where CcO_2 is the oxygen content of alveolar capillary blood, CaO_2 is the oxygen content of arterial blood, and $C\bar{V}O_2$ is the oxygen content of mixed venous blood, all expressed in milliliters of O_2 per 100 ml of blood. When the patient is breathing 100% O_2, $\dot{Q}_S/\dot{Q}_T$ can be estimated as follows:

$$\dot{Q}_S/\dot{Q}_T = [(P(A-a)O_2)]\,[0.003]/[(P(A-a)O_2)]\,[0.003] + [CaO_2 - C\bar{v}O_2]$$

For measurement of physiologic shunt, both an arterial and a mixed venous blood sample must be obtained. A true mixed

venous blood sample can be obtained only from the distal sample port of an indwelling pulmonary arterial catheter. The total O_2 content of the arterial, mixed venous blood, and pulmonary capillary blood (CaO_2, $C\dot{V}O_2$, CcO_2) is calculated in the same manner as any O_2 content calculations:

$$O_2 \text{ content} = (1.34)(Hb)(SO_2) + (0.003)(PO_2)$$

where Hb is the hemoglobin concentration, SO_2 is the oxygen saturation, and PO_2 is the partial pressure of oxygen. If the patient is breathing 100% O_2, the capillary saturation is 100%, the PCO_2 (capillary PO_2) being the calculated PAO_2 value. Samples should be obtained and analyzed quickly to avoid error from continued metabolism. Similar to $P(A-a)O_2$, $\dot{Q}_S/\dot{Q}_T$ is influenced by $\dot{V}/\dot{Q}$ mismatching and by fluctuations in mixed venous oxygen saturation ($S\bar{v}O_2$) and FiO_2. A "shunt" calculation when FiO_2 is less than 1.0 is defined as **venous admixture**. If venous admixture is elevated but all alveoli are patent, venous admixture decreases toward the normal value (<5%) as FiO_2 is increased. Conversely, if increased venous admixture is caused by a true shunt such as an intracardiac defect or atelectasis, there would be no change in venous admixture as FiO_2 is increased.

Murray Lung Injury Score

ARDS is a syndrome of severe lung injury that was originally described by Ashbaugh and Petty in 1970.[7] Evaluating and treating a patient with ARDS is a primary challenge for the ICU clinician. To monitor the severity of this disease, Murray and colleagues[8] developed a lung injury score that is often calculated in studies of ARDS. The **Murray lung injury score** quantifies the injury level using the following four factors: chest radiographic findings, PaO_2/FiO_2 ratio, positive end expiratory pressure (PEEP) setting, and compliance. The Murray lung injury score is an example of a composite score that allows quantification of lung status according to different aspects of the injury—gas exchange, radiographic findings, and mechanics. This score is used as an index of the effectiveness of therapy or for interstudy comparisons. The method for calculating the Murray lung injury score is shown in Box 51-3. Other measures of lung injury are listed in Box 51-4.

Monitoring Ventilation

Similar to oxygenation, the adequacy and efficiency of ventilation is routinely evaluated in the ICU (Box 51-5). Monitoring of patients receiving mechanical ventilatory support in the ICU includes measurement of the patient's tidal volume (V_T), respiratory rate (f), and minute ventilation ($\dot{V}_E$) where:

$$\dot{V}_E = (f) * (V_T)$$

However, effective ventilation depends on alveolar ventilation ($\dot{V}_A$), as follows:

$$\dot{V}_A = (V_T - V_{Dphys})(f)$$

where V_{Dphys} is physiologic dead space, and:

$$\dot{V}_A = (0.863 * \dot{V}CO_2)/PaCO_2$$

Box 51-3 Murray Lung Injury Score

Component	Value
1. Chest Radiograph	
No alveolar consolidation	0
Alveolar consolidation confined to 1 quadrant	1
Alveolar consolidation confined to 2 quadrants	2
Alveolar consolidation confined to 3 quadrants	3
Alveolar consolidation in all 4 quadrants	4
2. Hypoxemia Score	
PaO_2/FiO_2 > 300	0
PaO_2/FiO_2 225-299	1
PaO_2/FiO_2 175-224	2
PaO_2/FiO_2 100-174	3
PaO_2/FiO_2 < 100	4
3. PEEP Score (When Ventilated)	
PEEP ≤5 cm H_2O	0
PEEP 6-8 cm H_2O	1
PEEP 9-11 cm H_2O	2
PEEP 12-14 cm H_2O	3
PEEP > 15 cm H_2O	4
4. Respiratory System Compliance Score (When Available)	
Compliance ≥80 ml/cm H_2O	0
Compliance 60-79 ml/cm H_2O	1
Compliance 40-59 ml/cm H_2O	2
Compliance 20-39 ml/cm H_2O	3
Compliance ≤19 ml/cm H_2O	4

The final value is obtained by dividing the aggregate sum by the number of components used.

SCORE
No lung injury—0
Mild to moderate lung injury—0.1-2.5
Severe lung injury (ARDS) —>2.5

Box 51-4 Measures of Decreased Blood Oxygenation or Lung Injury

↓ SpO_2
↓ PaO_2
↑ $P(A-a)O_2 - (PAO_2 - PaO_2)$
↓ P/F ratio – (PaO_2/FiO_2)
↑ Shunt/venous admixture
↑ Murray lung injury score

Box 51-5 Monitoring the Adequacy of Ventilation

- Respiratory volume and rate (V_T, f, $\dot{V}_E$)
- $PaCO_2$
- V_D/V_T
- Capnometry (not for routine use but in special situations, such as ensuring tracheal intubation and cardiac blood flow in resuscitation efforts)

where $\dot{V}CO_2$ is CO_2 production in milliliters per minute, and 0.863 is a conversion factor. With a normal $PaCO_2$ and $\dot{V}CO_2$, this becomes:

$$\dot{V}_A = (0.863 * 200\ ml/min)/40\ mm\ Hg = 4.3\ L/min$$

Ventilation is adequate if $PaCO_2$ is associated with a normal arterial pH. For healthy persons, $PaCO_2$ is between 35 mm Hg and 45 mm Hg, resulting in an arterial pH of 7.35 to 7.45. An elevated $PaCO_2$ with normal pH is common in patients with chronic obstructive pulmonary disease (COPD). It is generally accepted that pH becomes the goal during mechanical ventilation of the critically ill patient rather than $PaCO_2$. However, it is important to consider the acceptance of a lower pH level (7.25 to 7.35) when approaching the safe upper limits of mechanical ventilation that can occur in patients with ARDS.

Capnography

Capnometry is the measurement of CO_2 at the airway opening during the ventilatory cycle. **Capnography** refers to plotting CO_2 concentration against time or against exhaled volume. The normal CO_2 waveform is displayed in Figure 51-1. The height of the capnogram (the peak value) indicates the end-tidal CO_2 value. $P_{ET}CO_2$ normally is 1 to 5 mm Hg less than $PaCO_2$, ranging between 35 mm Hg and 43 mm Hg. Because $P_{ET}CO_2$ in healthy persons closely approximates $PaCO_2$, this measure is a potentially useful noninvasive index of the adequacy of ventilation.[9] Abnormal waveform contours can indicate changes in the distribution of ventilation and perfusion, or airway obstruction. These changes typically are an irregular increase in CO_2 level and a lower than normal end-tidal CO_2 level. Positive pressure ventilation (especially with PEEP), pulmonary embolism, cardiac arrest, and pulmonary hypoperfusion also may cause an increase in $PaCO_2$ to $P_{ET}CO_2$ difference [$P(a-ET)CO_2$].[10] Exercise and a large V_T can reverse the $P(a-ET)CO_2$ difference, and $P_{ET}CO_2$ can exceed $PaCO_2$ temporarily.

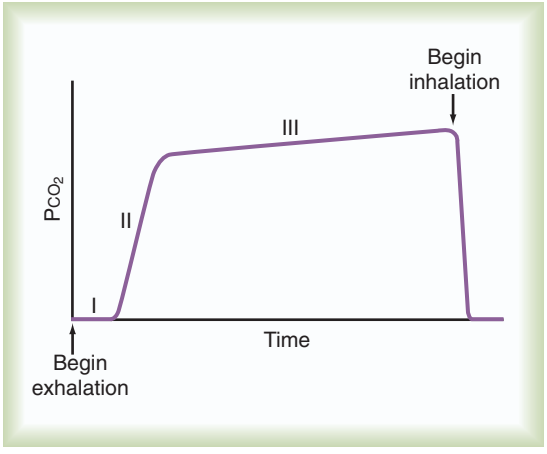

FIGURE 51-1 Time-based capnograph. *Phase I,* Anatomic dead space; *phase II,* transition from anatomic dead space to alveolar plateau; *phase III,* the alveolar plateau.

Patients for whom capnometry may be a useful monitoring tool include patients with normal lungs but an unstable ventilatory drive who are breathing spontaneously or receiving low-level ventilatory support. In these patients, capnometry readings should initially be validated by comparison with $PaCO_2$. Changes in $P_{ET}CO_2$ can be used to alert the clinician to potential changes in patient ventilation. Thereafter, periodic reevaluation should be performed as the patient's clinical state changes. Capnometry has been extremely useful in emergency situations, such as verification of endotracheal intubation and assessment of blood flow during or after cardiac arrest. Small in-line CO_2 monitors that employ colorimetry are now routinely used to verify endotracheal intubation.[11]

Although $P_{ET}CO_2$ and $PaCO_2$ values tend to correlate at a single point in time, correlation between changes in $P_{ET}CO_2$ and changes in $PaCO_2$ tend to be weaker.[12] Decreases in ventilation are reflected by increases in $P_{ET}CO_2$ and $PaCO_2$. However, with very small V_T, $PaCO_2$ increases, whereas $P_{ET}CO_2$ may decrease. Although the appropriate role of capnometry in critical care may be unclear, integration of capnometry into modern ventilators is reasonable because the primary role of the ventilator is CO_2 elimination. As a guide for clinicians, the American Association for Respiratory Care (AARC) has created clinical practice guidelines for the use of capnometry in ventilated patients.[13] Box 51-6 lists common causes of changes in monitored $P_{ET}CO_2$ values.

Volumetric CO_2 monitoring holds promise in the continuous monitoring of ventilation efficiency. VCO_2 can be continuously monitored in a patient being weaned from mechanical ventilation as an indicator of adequate or improving ventilatory efficiency.[14] The volumetric capnogram has been examined as a potential tool for detecting a pulmonary embolism,[15] tracking the efficiency of mechanical ventilation,[15] and calculating dead space.[17] The relationship between VCO_2 and dead space also makes it a valuable tool in PEEP optimization.

Box 51-6 Causes of Increased and Decreased End-Tidal Carbon Dioxide Values

INCREASED $P_{ET}CO_2$
- Decreased effective ventilation ($\downarrow V_T$, $\downarrow \dot{V}_E$, $\downarrow \dot{V}_A$, $\uparrow PaCO_2$)
- Increased CO_2 production ($\dot{V}CO_2$) (agitation, stress, shivering, fighting the ventilator, pain, anxiety, recovery from sedation or paralysis)

DECREASED $P_{ET}CO_2$
- Increased effective ventilation ($\uparrow V_T$, $\uparrow \dot{V}_E$, $\uparrow \dot{V}_A$, $\downarrow PaCO_2$)
- Marked decrease in effective ventilation ($\downarrow\downarrow \dot{V}_T$ approaching dead space volume; rapid shallow breathing)
- Decreased CO_2 production ($\dot{V}CO_2$) (sedation, sleep, cooling)
- Decrease in lung perfusion (pulmonary embolus, decreased CO)

ABSENT $P_{ET}CO_2$
- Apnea
- Cardiac arrest
- Ventilator disconnect or malfunction
- Airway obstruction

Dead Space

The **dead space/tidal volume (VD/VT) ratio** is a measure of the efficiency of gas exchange. This ratio is an estimate of the proportion of ventilation participating in diffusion of CO_2. V_D/V_T can be calculated from the Enghoff modification of the Bohr equation as follows:

$$V_D/V_T = (PaCO_2 - P_ECO_2)/PaCO_2$$

Where P_ECO_2 is the CO_2 concentration in mixed expired gas. A rapid response capnometry or exhaled flow analysis provides a volumetric CO_2 method for attaining P_ECO_2 values.[7] Research has shown that using the fraction of VCO_2 to exhaled minute ventilation (V_E) can be used to estimate P_ECO_2 using the following equation (assuming PB is 760 mm Hg)[17]:

$$P_ECO_2 = (760 - 47) \times VCO_2/V_E$$

When P_ECO_2 is determined, a specimen of arterial blood should be drawn for ABG analysis. When the gas and blood samples are analyzed, the preceding formula can be used to calculate V_D/V_T.

In healthy persons who are sitting, the V_D/V_T ratio is 0.20 to 0.40. This value varies little with age, position, exercise, V_T, or breath holding. In the setting of critical illness, however, the V_D/V_T ratio commonly exceeds 0.6. Frequently, the V_D/V_T ratio is increased in patients with congestive heart failure, pulmonary embolism, ARDS, or pulmonary hypertension and in patients undergoing mechanical ventilation. The V_D/V_T ratio has been used to evaluate patients being considered for weaning from mechanical ventilation. A V_D/V_T ratio greater than 0.60 generally requires continuation of ventilatory support. Increased V_D/V_T in the early phase of ARDS has been associated with an increased risk of death.[8,10]

Monitoring of Inspired and Exhaled Gas Volumes

Although the best index of effective ventilation is measurement of $PaCO_2$, measurement of inspired and expired gas volumes is an important aspect of monitoring patients receiving mechanical ventilatory support. For patients receiving controlled mechanical ventilation, minute ventilation ($\dot{V}_E$), respiratory rate (f), and V_T are assessed by:

$$\dot{V}_E = (V_T)(f) \textit{ and } V_T \text{ average} = \dot{V}_E/f$$

With an adequate V_T, increases in minute ventilation tend to increase alveolar ventilation and decrease $PaCO_2$, whereas decreases in minute ventilation tend to have the opposite effect. However, in the presence of rapid shallow breathing with normal or elevated minute ventilation, a decrease in effective ventilation can result in an increase in $PaCO_2$. This effect is caused by ineffective shallow tidal breaths that are at or below dead space volume. Spontaneous respiratory rate often is a sensitive indicator of the need for mechanical ventilation. Rates greater than 20 breaths/min may indicate distress, and a rate greater than 30 breaths/min with a spontaneous V_T of less than 300 ml often indicates the need for mechanical ventilatory support in adults because a large proportion of ventilatory effort is being expended to move dead space gases.

Inspired Versus Expired Tidal Volume

Normal inspired V_T and expired V_T should be nearly the same. However, in the presence of an air leak, inspired V_T may be larger than expired V_T, and measurement of delivered V_T versus exhaled V_T may be useful in detecting and quantifying the size of a leak—a situation that may require immediate attention.

Monitoring Lung and Chest Wall Mechanics

Ventilation of the lungs involves overcoming the flow-resistive, inertial, and elastic properties of the respiratory system. In a ventilated patient, change in airway pressure during ventilation is used to determine the compliance of the total respiratory system. Pressure changes measured by an esophageal balloon reflect compliance of the chest wall. The difference between the compliance of the respiratory system and chest wall is the lung compliance (lung compliance can also be measured in the passively ventilated patient using the change in transpulmonary pressure).

One method to assess the compliance of the respiratory system and its relation to lung volume is through the use of a P-V curve. There is normally a difference in the P-V relationship during inflation and deflation. However, a large difference between inflation and deflation, called *hysteresis*, typically implies lung units have been recruited after a threshold level of pressure was applied.

To measure a static P-V curve of a ventilated patient from resting (at functional residual capacity [FRC]) to total lung capacity, a calibrated syringe, referred to as a *supersyringe* ranging from 1.5 to 3 L, was used until more recently to inject 50- to 100-ml increments into the lungs while airway pressure was recorded. A P-V curve can be measured more easily by the continuous delivery of a low flow of gas into the lung (<5 L/min) with the simultaneous recording of system pressure change. Current ICU ventilators allow the determination of an inflation P-V curve using this approach. The P-V curve is plotted as part of the ventilator graphics package with cursors available to identify specific points on the curve. Patients should be sedated during the maneuver mostly because the flow delivered would be insufficient to satisfy patient demand. Also, the amount of pressure or volume applied during the maneuver would likely cause discomfort.

The inflation P-V curve often, but not always, reveals two points at which the slope of the curve changes. The lower point at which the slope changes is called the *lower inflection point*. As depicted in Figure 51-2 , a lower inflection point may occur over the lower range of volumes, indicating a pressure above which total respiratory system compliance is improved owing to the beginning of alveolar recruitment or the peripheralization of secretions.[16] A recommended strategy is to set PEEP slightly above the lower inflection point with the goal of maintaining recruitment and stabilization of dependent alveoli that may otherwise sustain injury from repetitive opening, closing, and

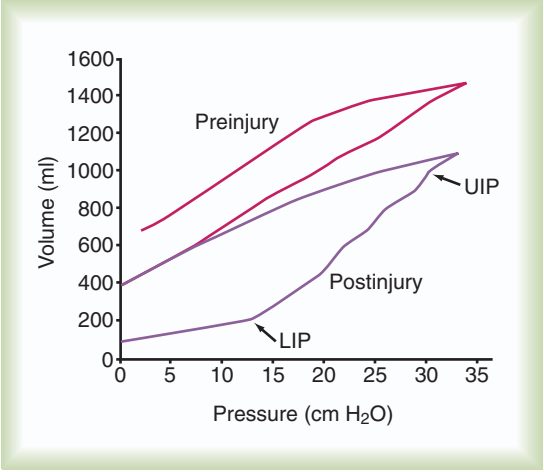

FIGURE 51-2 P-V curves generated by a normal lung (preinjury) and after oleic acid injury (postinjury). In the preinjury curve, the linear relationship between pressure and volume with minimal hysteresis is evident. The postinjury curve displays marked hysteresis and two changes in compliance on the inspiratory limb: a lower inflection point *(LIP)* and upper inflection point *(UIP)*.

reopening during tidal ventilation. The other pressure change in the slope, called an *upper deflection point,* may be seen at a higher volume, indicating where compliance decreases owing to alveolar overdistention or a slowing of lung recruitment. Although the risk of alveolar overdistention is generally reduced if the end inspiratory plateau pressure (P_{plat}) is less than 30 cm H_2O in patients with ARDS.[18] More recently, attention has been focused on the deflation area of the curve and what is called the *critical closing pressure,* the area of the deflation curve where there is significant loss in compliance.[19] The rationale for this is that when there is a significant amount of recruitment (showing as hysteresis), the amount of pressure required to maintain an open lung may be lower than during the inflation curve. The deflation area of the curve will be further discussed later in this chapter.

Respiratory System Compliance

Respiratory system compliance should be routinely monitored in all ventilated patients. To attain an accurate assessment of compliance (static compliance), two maneuvers must be performed: an end inspiratory hold, and an end expiratory hold. An end inspiratory hold maneuver in a passive, ventilated patient allows equilibration of pressure across the lung and an estimation of peak alveolar pressure or the end inspiratory P_{plat}. An end expiratory hold is required to assess the total PEEP ($PEEP_{-T}$) when auto-PEEP is present. Compliance (C) is calculated as follows:

$$C = \Delta V / \Delta P$$

Where V_T (corrected for tubing compliance) is ΔV and ΔP is $P_{plat} - PEEP_T$.

Normal compliance ranges from 60 to 100 ml/cm H_2O. Diseases of the lung parenchyma, such as pneumonia, pulmonary edema, and any chronic disease causing fibrosis, cause decreased effective compliance. Acute changes, such as atelectasis, pulmonary edema, ARDS, and lung compression caused by tension pneumothorax cause a rapid decrease in compliance. Compliance is often less than 25 to 30 ml/cm H_2O in patients with ARDS. Common causes of changes in respiratory system compliance are listed in Box 51-7. Several ventilators report breath-to-breath compliance and resistance values dynamically without the use of pause maneuvers. Monitoring these estimates can indicate impedance problems, and are useful for trending during ventilator setting titration (such as PEEP), but absolute values should be verified by static maneuver calculations.

Box 51-7 Common Causes of Changes in Compliance and Resistance in Mechanically Ventilated Patients

DECREASED COMPLIANCE
↓ Lung compliance (atelectasis, pneumonia, pulmonary edema, ARDS, pneumothorax, fibrosis, bronchial intubation)
↓ Thoracic compliance (obesity, ascites, chest wall deformity)

INCREASED COMPLIANCE
↑ Lung compliance (improvement in any of the above-listed conditions, pulmonary emphysema)
↑ Thoracic compliance (improvement in any of the above-listed conditions; flail chest; position change—sitting patient up)

INCREASED RESISTANCE
Small endotracheal tube, secretions plugging endotracheal tube, biting on endotracheal tube
↑ Bronchospasm, mucosal edema
↑ Secretions
↑ Airway obstruction
High gas flow rate (or ↑ gas flow)

DECREASED RESISTANCE
↓ Improvement in any of the above-listed conditions
↓ Bronchodilator administration
↓ Suctioning and airway care
↓ Use of lower inspiratory gas flow rate

Chest Wall Compliance

In a significant proportion of patients, chest wall compliance can influence the P-V relationship during ventilation. Poor respiratory system compliance may be largely due to external pathologies of the chest wall. Normal chest wall compliance accounts for approximately 20% of the respiratory compliance, but can commonly reach 50% or greater in critically ill patients. Chest wall abnormalities (including the abdomen) may cause an increase in pleural pressure both at rest and during positive pressure ventilation. Direct measurement of pleural pressure at the bedside is highly invasive, and this is why **esophageal balloon pressure** measurement are used as a surrogate (Box 51-8). Chest wall compliance (C_{CW}) by definition using esophageal pressure is as follows:

$$C_{CW} = P_{esinsp} - P_{esexp} / \Delta V$$

where P_{esinp} is the esophageal pressure at end inspiration and P_{esexp} is the esophageal pressure at end exhalation.

Box 51-8 Esophageal Pressure Monitoring

Esophageal pressure is used clinically as a surrogate for pleural pressure. The measurements are used to determine chest wall and lung compliance, measure work of breathing, determine the appropriateness of PEEP, and calculate lung stress. A thin esophageal catheter (approximately 2-mm diameter) is simple to insert, and poses little risk of esophageal perforation. Appropriate placement is achieved by first passing it into the stomach, then inflating the 10-cm long balloon with approximately 0.5 to 1.0 ml of air. The catheter is carefully withdrawn until the final position of the balloon is within the lower third of the esophagus, as verified by the presence of cardiac oscillations within the pressure tracing. In adults this is approximately 35 to 40 cm from the teeth when inserted orally. Proper placement can also be confirmed by occluding the airway (done with an expiratory hold on the ventilator) and measuring the simultaneous deflections in pressure at the airway opening and esophageal pressure either during spontaneous efforts or by a gentle push on the chest or abdomen. The change in pressure in the airway during occlusion should be the same as the pressure change that occurs in the esophageal pressure.

Box 51-9 Common Causes of Elevated Pleural Pressure in ICU Patients

- Obesity
- Intraabdominal hypertension
- Massive fluid resuscitation

Poor chest wall compliance (high chest wall elastance) may buffer the lung-damaging effect of elevated airway pressure by reducing end-inspiratory transpulmonary pressure (Ptp). Higher airway pressures may be required to ventilate these patients, but without the same risk of barotrauma as in patients with low pleural pressure or normal chest wall compliance. One of the most common causes of poor chest wall compliance is intraabdominal hypertension. Regular monitoring of **bladder pressure** can be useful at confirming issues of poor chest wall compliance in the absence of esophageal pressure monitoring. Some causes of elevated pleural pressure (resulting in poor chest wall compliance) are listed in Box 51-9.

Transpulmonary Pressure

Airway pressure as measured by the ventilator does not take into consideration the pleural pressure or chest wall compliance of the patient. True distending pressure of the lung (the pressure that stretches the lung) is the **transpulmonary pressure**. The appropriateness and safety of the airway pressures delivered by the ventilator, both at end-exhalation (PEEP) and end-inspiration (P_{plat}), depends on the resulting trasnspulmonary pressure.[20]

The estimation of transpulmonary pressure is commonly done through the use of esophageal pressure monitoring using the simple equation:

$$P_{airway} - P_{es} = Ptp$$

Where P_{airway} is the airway pressure and P_{es} is the esophageal pressure. Two variations are used in clinical practice, one for end-exhalation and one for end-inspiration. These variations are as follows:

$$P_{PEEP} - P_{esexp} = Ptp_{PEEP}$$
$$P_{plat} - P_{esinsp} = Ptp_{plat}$$

where the first equation is the transpulmonary pressure at end-exhalation and the second equation is the transpulmonary pressure at end-inspiration. Lung compliance (C_L) can be derived from these measurements as follows:

$$C_L = Ptp_{plat} - Ptp_{PEEP}/\Delta V$$

End inspiratory Ptp can be monitored to evaluate global lung stress and the potential for overdistention—usually allowing some liberty in accepting higher P_{plat} to deliver adequate ventilation in patients with elevated pleural pressures (stiff chest walls). Current practice is to limit this end-inspiratory Ptp to less than 20 cm H_2O of pressure. For patients with a large degree of lung inhomogeneity any attempt to maintain an even lower end-inspiratory Ptp should be taken. The monitoring of end-expiratory Ptp has been used more recently as a rationale for setting PEEP.[21] A negative Ptp probably indicates lung closure (dependent lobe) during expiration that can result in lung opening and closing during the ventilatory cycle. Adequate or "optimal" PEEP when measuring Ptp is the PEEP level that avoids a negative Ptp_{PEEP}. (See Chapter 48 for details.)

Resistance

Depending on the **driving pressure** measured, various resistances can be calculated, including airway, pulmonary, chest wall, and total respiratory system resistance. An airway resistance (Raw) can be determined dynamically from simultaneous measurements of airflow and the pressure difference between the airway opening (P_{ao}) and the alveoli (P_{alv}) by Raw = (P_{ao} – P_{alv})/flow. Because resistance changes throughout inspiration and expiration, and expiratory resistance generally is greater than inspiratory resistance, instantaneous measures of resistance are not performed clinically. Inspiratory resistance can be calculated simply during constant flow, volume ventilation. This allows monitoring of airway status over time or after the effects of bronchodilator therapy and is determined by dividing the pressure change by the flow rate:

$$Raw = \Delta P/\Delta F = (P_{peak} - P_{plat})/flow$$

where P_{peak} is peak airway pressure and P_{plat} is plateau pressure. Automated methods of measuring expiratory resistance have been integrated into some ventilators.

In ventilated patients, a significant component of the total flow resistance is from endotracheal tubes.[22] In healthy persons, flow is relatively laminar during tidal ventilation and becomes turbulent only with increasing ventilatory demands. The flow resistance offered by the endotracheal tube increases markedly with increasing flow and varies with the size of the tube. Normal airway resistance is approximately 1 to 2 cm H_2O/L per second;

however, intubated patients receiving mechanical ventilatory support typically have an airway resistance of 5 to 10 cm H_2O/L per second or more. Automated tube compensation modes have been added to mechanical ventilators to deliver flow that accounts for the added resistance of the endotracheal tube. Common causes of changes in airway resistance in mechanically ventilated patients are listed in Box 51-7.

Peak and Plateau Pressures

The maximum value of airway pressure at the airway opening during a ventilatory cycle is routinely monitored in the ICU. Peak airway pressure greater than 50 to 60 cm H_2O is generally discouraged because high values of peak pressure carry increased risk of barotrauma and hypotension.[23] During volume-targeted modes of ventilation, an increase in peak pressure results from increased resistive pressure or increased elastic pressure from decreased lung or chest wall compliance. During pressure-targeted modes of ventilation, increased resistive pressure or increased elastic pressure results in a decrease in delivered tidal volume rather than the increase in peak or plateau pressure. Measurement of end inspiratory P_{plat} helps to differentiate between the resistive and elastic components. The P_{plat} level should be monitored for all ventilated patients. P_{plat} ideally should not exceed 28 cm H_2O because elevated P_{plat} increases the likelihood of developing ventilator-induced lung injury. However, the limit for P_{plat} depends on the resulting lung stress and strain.

Lung Stress and Strain

During mechanical ventilation, the lungs are exposed to positive pressure that exerts more stress and strain on the lungs than experienced during spontaneous ventilation. This **lung stress and strain** may cause injury or extend existing lung injury along the injury/normal tissue border. When positive pressure becomes injurious, it is referred to as *ventilator-induced lung injury*. However, the concepts of stress and strain as applied to the lungs are not clearly defined. The physical definition of stress is a force per unit area. Strain is the deformation of a structure compared with its overall size. Hooke's law associates the two factors by the following relationship: stress = k * strain.

Working definitions for stress and strain applied to the lungs have been studied.[24] *Stress* (Ptp_{plat}) is defined as follows:[20]

$$Ptp_{plat} = Ptp_{PEEP} + E_L \times Vt$$

which can be simplified to:

$$Ptp_{plat} = Ptp_{PEEP} + \Delta Ptp$$

Driving pressure, as previously discussed, may be an alternative measure of stress. However, when chest wall compliance is poor it may be difficult to determine the potential for injury without measuring lung stress. *Strain* has been defined as V_T (the deformation) divided by FRC (the resting size of the lungs). These definitions have been associated as stress = 13.5 * strain, predicting that a stress of 27 cm H_2O (Ptp of 27 cm H_2O) and a strain of 2 (V_T of twice the FRC) approach the limits of safe ventilation.[24] The measurement of lung stress requires placement of an esophageal catheter. To measure strain, automated FRC determinations have become available on some modern ventilators.[25] Stress can also occur at lower pressures if lung units are opening and closing during the ventilator cycle.

Stress Index

Another index involving the dynamic measurement of stress has been reported.[26] The **stress index** is a value derived from the airway pressure-time curve during constant flow delivery of a tidal breath. During constant flow (when resistance is constant), the slope of the pressure-time tracing is analyzed to evaluate the elastic properties of the lungs. The index is calculated by performing a curve fit of the slope of the pressure-time tracing, where pressure = a * time^b + c. Ideally, a slope (b) of 1 indicates normal filling during lung expansion, whereas a slope greater than 1 indicates overdistention, and a slope less than 1 indicates lung recruitment (Figure 51-3). This measure can be calculated for each delivered tidal breath, although an acceptance criterion should be used to exclude analysis of artifacts and factitious breaths. Although the index may not determine a threshold for excessive stress or strain, it may be a useful indicator of lung response to positive pressure. If the chest wall contributes variably to airway pressure, the calculated index can be altered and deceptive.[27]

Driving Pressure

Driving pressure is a measure of the pressure difference between P_{plat} and total PEEP (PEEP plus auto-PEEP). The swing in pressure from end-expiration to end-inspiration may be an independent stress factor on the lungs. Consider driving pressure as the amount of *energy* applied to the lung, the higher the energy applied to the lung, the greater the potential for lung injury. In general, the driving pressure should be kept less than or equal to 15 cm H_2O.

Auto–Positive End Expiratory Pressure (Intrinsic Positive End Expiratory Pressure)

PEEP is the pressure maintained in the airway by the ventilator at end-exhalation. An alveolar pressure that exists above the applied or extrinsic PEEP level at end-exhalation is termed *intrinsic PEEP* or *auto-PEEP*. At the bedside, *total PEEP* is the sum of extrinsic PEEP and intrinsic PEEP. Intrinsic or auto-PEEP is sometimes misunderstood when one considers "trapped" air versus breath-stacking that can occur when a patient is being passively ventilated with insufficient time to exhale. Intrinsic or auto-PEEP is often the result of small airway collapse and can also occur when excessive tidal volume is delivered to a patient with a high ventilatory demand, causing dynamic hyperinflation when the patient has difficulty exhaling all of the excess volume.

Numerous factors, both internal and external to the patient, contribute to the development of auto-PEEP. Expiratory muscle activity can increase auto-PEEP and may interfere with attempts at assessment of auto-PEEP based solely on dynamic hyperinflation. Patients receiving mechanical ventilation for obstructive airways disease have a large degree of inhomogeneity in the

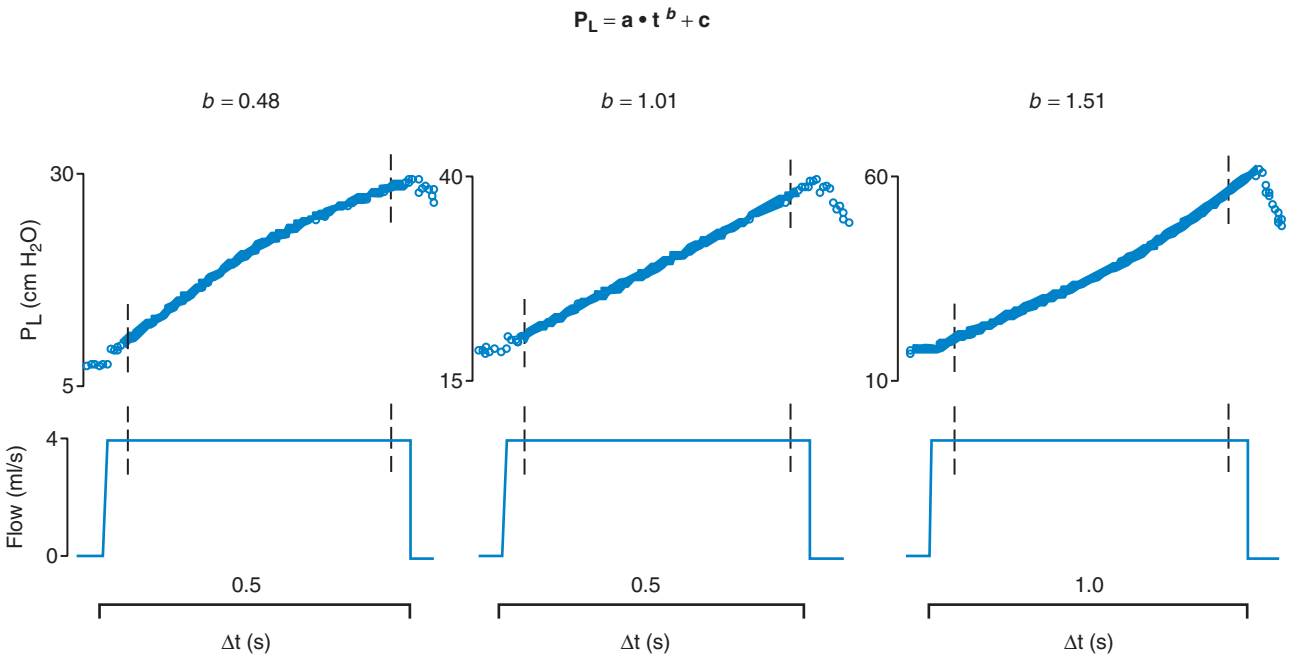

FIGURE 51-3 Conceptional illustration of the dynamic pressure-time (p-t) curve. *Left,* Convex curve indicating recruitment during the breath. *Center,* Linear relationship between pressure and time indicating no recruitment or overdistention. *Right,* Concave curve indicating overdistention. (From Formenti P, Graf J, Santos A, et al: Non-pulmonary factors strongly influence the stress index. Intensive Care Med 37:594–600, 2011.)

emptying of lung units, and auto-PEEP can develop even at relatively low minute ventilation. Auto-PEEP is common in mechanically ventilated patients receiving high minute ventilation and occurs in patients with ARDS.[28] An increase in mean alveolar pressure owing to auto-PEEP may exacerbate the hemodynamic effects of positive pressure ventilation and increase the likelihood of barotrauma in a manner similar to the application of PEEP. In addition, the presence of auto-PEEP makes it more difficult for the patient to trigger a ventilator-assisted breath.

Finally, if unrecognized, auto-PEEP leads to erroneous calculation of static lung compliance by underestimation of total PEEP. Decreasing minute volume can reduce or eliminate auto-PEEP; however, minimal auto-PEEP can be benign. In addition, increasing expiratory time allows more time for airways to empty normally, decreasing auto-PEEP. The use of extrinsic PEEP, when set appropriately, can partially overcome the trigger sensitivity problem seen with auto-PEEP and may provide a "stent" to allow more complete lung emptying and a decrease in patient effort.[29]

Methods for Determining Auto–Positive End Expiratory Pressure. Dynamically, auto-PEEP varies throughout the lungs; however, all measurements of auto-PEEP reflect an average auto-PEEP level throughout the lungs. Assessment of auto-PEEP involves first its detection and then a measurement. Auto-PEEP is suspected if flow continues at end-expiration as seen on ventilator graphics monitoring. In this case, auto-PEEP must be present unless there is active contraction of the expiratory muscles producing end expiratory flow. The following methods are used to estimate auto-PEEP level.

End Expiratory Hold by the Ventilator. Either automated or manual, end expiratory hold by the ventilator closes the expiratory valve at end-exhalation. The hold period must extend until the end expiratory pressure is stabilized or the value is an underestimate of auto-PEEP.

An **esophageal balloon** is used to measure the deflection in the pleural space required to trigger the ventilator. The change in esophageal pressure from baseline to the pressure initiating flow at the airway is equal to the total PEEP that must be overcome to trigger a breath.

Matching Auto–Positive End Expiratory Pressure With Positive End Expiratory Pressure. PEEP can be applied to a level (this is possible in some patients) that results in flow at end-exhalation being closer to zero. The concept involves stenting of the airways by PEEP to allow lung emptying and a better equilibration of end expiratory alveolar pressure with end expiratory ventilatory circuit pressure minimizing the pressure needed to decompress the alveoli and trigger the ventilator.[29] This maneuver is essentially performed by slowly increasing applied PEEP until every patient effort triggers a ventilator breath.

Mean Airway Pressure

MAP represents the average airway pressure over the total ventilatory cycle. Correct measurement of this value requires continuous sampling of airway pressure at the airway opening—this is an automated feature of modern ventilators. MAP is related to mean lung volume, which correlates with oxygenation if perfusion is adequate. When MAP is increased, arterial O_2 levels often improve, but venous return and subsequently arterial pressure can be adversely affected.

In an effort to increase oxygenation while monitoring arterial pressure, the clinician can manage MAP by several means, including V_T, frequency, inspiratory-to-expiratory (I : E) ratio, and PEEP. The management of MAP relates to a concern for improving oxygenation balanced against its detrimental influence on venous return to the chest. Normally, expiratory resistance is greater than (twice) inspiratory resistance, and mean alveolar pressure normally is greater than MAP. For patients with COPD and elevated expiratory resistance, high mean alveolar volume can be significant during mechanical ventilation. For patients with ARDS, airway resistance is more typically low, so MAP and mean alveolar pressures may be similar.

There is an understandable caution while increasing MAP, usually by increasing PEEP, yet two ventilator modes apply dramatic increases in MAP—high-frequency oscillation and airway pressure release ventilation. The marked improvements in oxygenation seen with these modes can be attributed to high MAP. In the case of high-frequency oscillation, the lungs are never allowed to derecruit between breaths. Airway pressure release ventilation is more complicated because the lung deflates to varying unknown alveolar volumes on exhalation. In the use of either mode, end expiratory alveolar lung volume status cannot be easily determined, but oxygenation is often improved.

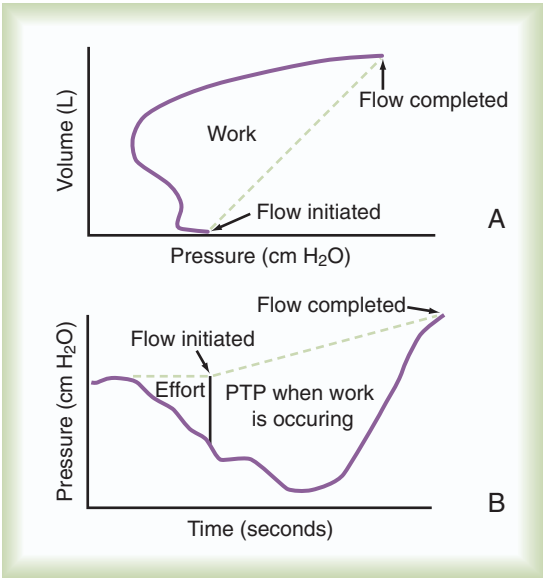

FIGURE 51-4 WOB **(A)** and PTP **(B)** from the same spontaneous breath of a patient receiving ventilatory support. *Dashed lines* represent a tracing of passive inflation by a ventilator-supported breath. Areas of work and PTP are not directly comparable because WOB units (P-V) and PTP units (pressure-time) differ. The area of effort in the total PTP area occurs before (and in addition to) the work measurement.

Monitoring Breathing Effort and Patterns

Work of Breathing

Work of breathing (WOB) is often increased in critically ill patients. Commercially available systems are available for measuring WOB in ventilated patients. For computation of WOB, changes in Ptp must be measured. The procedure requires an assessment of pleural pressure, which is normally estimated by esophageal pressure after placement of an esophageal balloon catheter. The measurement is estimated from the esophageal pressure-versus-volume curve (Figure 51-4).

For healthy persons, average total WOB ranges from 0.030 to 0.050 kg/m/L (0.3 to 0.6 J/L).[30] Patients with severe obstructive or restrictive lung disease "work" at levels two to three times this normal value at rest, with marked increases in work at higher minute ventilation. How much work a patient can tolerate before the ventilatory muscles fatigue is unclear. Maintaining adequate spontaneous ventilation is impossible in many patients when the workload exceeds 0.15 kg/m/L (1.5 J/L).

Monitoring WOB may be valuable in certain situations, such as weaning. Clinicians are expected to assess a patient's WOB continually and to take appropriate action if WOB becomes excessive. Because a direct measurement of WOB requires esophageal manometry, simpler indicators are sought. Monitoring the patient's spontaneous breathing rate, V_T, and **frequency/tidal volume (f/VT) ratio** provides useful surrogates for WOB during ventilator weaning trials. Assessment of the patient's overall clinical presentation also is useful in assessing the WOB. Increased WOB is associated with a rapid shallow breathing pattern, rapid pulse rate, hypertension, and use of accessory muscles of ventilation.

Pressure-Time Product. The **pressure-time product (PTP)** is the area encompassed by the esophageal pressure-time tracing during inspiration as shown in Figure 51-4. PTP is simpler to measure than WOB because it does not require simultaneous measurement of volume. PTP values parallel changes in effort and the O_2 cost of breathing because PTP includes a measure of the "isometric" component of muscle contraction.[31] This index includes work and effort components that may indicate endurance during a weaning trial.

Oxygen Cost of Breathing

The amount of O_2 consumed by the ventilatory muscles ($\dot{V}Q_2R$) is an estimate of respiratory effort at its most basic level. $\dot{V}Q_2R$ can be estimated by measurement of O_2 consumption during active breathing compared with the patient being fully supported in the control mode:

$$\dot{V}O_2R = \dot{V}O_2 \text{ active breathing} - \dot{V}O_2 \text{ apnea}$$

Normal $\dot{V}Q_2R$ is approximately 2% to 5% of total O_2 consumption; however, $\dot{V}Q_2R$ can be 30% of total O_2 consumption during hyperventilation owing to severe dyspnea. Theoretically, $\dot{V}Q_2R$ accounts for all factors that tax the respiratory muscles—that is, the external workload and the efficiency of the conversion between cellular energy and useful work. $\dot{V}Q_2R$ is difficult to measure if the patient's condition is unstable. Other measures of respiratory muscle function are sought to assess the cost of breathing.

Assessing Ventilatory Drive

Until more recently, little attention was paid to measurement of respiratory drive during critical illness. During machine-assisted breathing, ventilatory drive can play an important role in determining the energy expenditure of the patient. One study showed that patients not being weaned from mechanical ventilation often have an elevated drive to breathe and a limited ability to respond to increases in ventilatory load (e.g., increased $PaCO_2$).[32]

A measure that has been used to index drive is $P_{0.1}$. $P_{0.1}$ is the pressure recorded 100 msec after initiation of an inspiratory effort against an occluded airway. $P_{0.1}$ is influenced by muscle strength and lung volume but does not depend on respiratory mechanics. Elevated $P_{0.1}$ (>6 cm H_2O) indicates a continuing need for mechanical ventilation.

In a sophisticated, commercially available system, a direct measure of the neural drive to breathe from the phrenic nerve can be measured by a catheter positioned within the esophagus. This signal is integrated into a feedback circuit in a modern ventilator. As a mode within the ventilator, flow delivery is coordinated and augmented in response to the neural drive to breathe; this is known as *neurally adjusted ventilatory assist*. (See Chapters 45 and 46 for details.)

Rapid Shallow Breathing Index

When muscular strength is limited, patients tend to meet minute ventilation ($\dot{V}_E$) requirements by increasing frequency (f) while decreasing V_T. Although smaller breaths require less effort, rapid shallow breathing increases dead space ventilation causing a need for higher minute ventilation to eliminate CO_2. A very high and continuously increasing frequency (>30 breaths/min) is a sign of ventilatory muscle decompensation and, potentially, impending fatigue.

Considerable attention has been focused on the rapid shallow breathing index (f/V_T ratio), a simple bedside index that indicates whether mechanically ventilated patients can breathe without mechanical assistance.[29] The f/V_T ratio is easy to measure and is independent of the patient's effort and cooperation. Discontinuation of ventilator support is likely to prove successful if the f/V_T ratio is less than 105 breaths/min per L within the first minute of a brief trial of fully spontaneous breathing.[33]

Respiratory Inductive Plethysmography

Respiratory inductive plethysmography is a noninvasive means of monitoring frequency, V_T, fractional duration of inspiration (T_i/T_{tot}), and respiratory muscle coordination. With this technique, loose elastic bands encircle the chest and abdomen. Band expansion and contraction during ventilation (spontaneous or supported) provides a volume-time plot that can also reflect short-term shifts in actual lung volume.

Monitoring Strength and Muscle Endurance

Two values commonly used for bedside assessment of respiratory muscle strength are **vital capacity (VC)** and **maximal inspiratory pressure (MIP)**. A VC maneuver can be performed at the bedside with a simple respirometer connected to the patient's airway. Because VC is effort-dependent, accurate measurements can be obtained only when the patient is conscious and cooperative. Because of an expected variability in bedside VC, three measurements should be obtained, and the best result should be reported. Healthy persons are able to generate a VC of approximately 70 ml/kg. A VC less than 10 to 15 ml/kg indicates considerable muscle weakness, which indicates an inability to breathe spontaneously.

MIP is a more specific measure than VC. MIP provides information based solely on maximum output of the inspiratory muscles. A maximum stimulus is provided by total occlusion of the airway. In contrast to the VC maneuver, the MIP maneuver can be performed on unconscious or uncooperative patients. Measurement of MIP at the bedside requires an aneroid manometer with a maximum value indicator. In an effort to make the measurements more reliable, Marini and colleagues[34] described a modified technique in which a one-way valve is attached to the airway to ensure that inspiratory effort is made at a low lung volume. Maintaining an occlusion for 20 seconds, the values with the one-way valve in place were approximately one-third more negative than values without an occlusion (Figure 51-5).

Endurance: Maximum Voluntary Ventilation

Respiratory muscle fatigue (lack of endurance) may be a cause of respiratory failure. **Maximum voluntary ventilation (MVV)** is a measure used to assess respiratory muscle reserve, endurance, or fatigue. VC is measured to assess the patient's coordinated muscle function from a single breath; MVV is measured to determine the ability of a patient to sustain ventilation over time. Similar to the VC maneuver, the MVV procedure can be performed with a respirometer attached to the patient's airway as the patient is encouraged to breathe as deeply and as fast as possible over a predefined time interval (10 or 15 seconds). The value is extrapolated to a full minute.

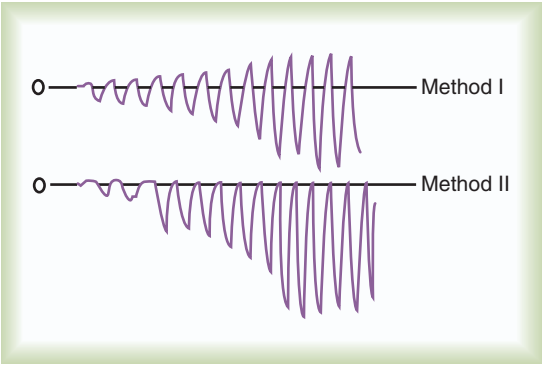

FIGURE 51-5 Measurement of MIP during 25 seconds of airway occlusion. *Method I* is occlusion by sealing the airway to allow no movement of air. *Method II* occludes inspiratory flow but allows expiratory flow through a unidirectional valve.

RULE OF THUMB

To wean from mechanical ventilation, the patient must have adequate gas exchange, respiratory muscle strength and endurance, and WOB that is not excessive. The original cause of respiratory failure must be partially, if not completely, resolved. Although numerous values have been studied to indicate the probability of successful weaning, a frequency-to-V_T ratio less than 105 has been the best index of ability to wean.

Normal MVV values for adults range from 120 to 180 L/min. Values less than twice the spontaneous minute ventilation are associated with difficulty in maintaining spontaneous ventilation without mechanical assistance.[35]

Lung Mapping

The extent of gas-exchange abnormalities is revealed by ABG values and SpO_2, but the location or source of the disorder remains unknown. The source, but not the extent or type of the pathologic process, can be assessed by auscultation. Localization of the disorder within the lungs is more precisely evaluated by static images obtained by radiographic techniques, such as chest x-ray or computed tomography (CT). These assessments are key to directing therapeutic approaches and for tracking changes in pathology (see Chapter 21). However, thorough imaging studies frequently require transportation of the patient to a radiology suite, and transport presents risks to the patient.[36] Also, the imaging is often static, not dynamically obtained throughout the ventilator cycle.

Mapping techniques that can actively locate regions of interest have been developed more recently. Two techniques are available that allow mapping of the lungs during ventilation: **electrical impedance tomography (EIT)** and **acoustic respiratory monitoring (ARM)**. Each technique produces a two-dimensional video or graphic representation of ventilation distribution throughout the lung and allows a regional assessment of the extent of injury. With EIT and ARM, there is an opportunity to perform at the bedside a real-time evaluation of the effects of PEEP, recruitment maneuvers, or other changes in ventilatory support (Figure 51-6).

Electrical Impedance Tomography (EIT)

EIT requires placement of electrodes around the chest (minimum of 16 electrodes). Recent designs utilize an expandable rubber belt (of various sizes) that has built-in electrodes. The belt is connected to a cable which is then connected to the EIT device. Impedance is measured between the electrodes rapidly and in a circular motion, capturing images that are reconstructed into a real-time graphic on the screen. Ventilation is displayed on the screen and various regions can be isolated

for close monitoring of changes during normal ventilation cycles or during adjustment of ventilator parameters. The ability to regionally monitor areas within the lung is of most use with patients presenting with heterogeneous lung disease. Visualizing the effects of ventilator setting adjustment on the various regions of the lung can help balance ventilation and minimize overdistension.[37] Modern EIT devices have the ability to trend lung distribution over time, as well as trend changes in end expiratory lung impedance (EELI). Changes in EELI would represent changes in end expiratory lung volume (EELV), an important trend when titrating PEEP.

Acoustic Respiratory Monitoring (ARM)

ARM involves placement of a series of stethoscopes around the chest. The sounds during ventilation are localized, and, similarly, a map of sounds (ventilation) is reconstructed. Specific characteristics of crackles from interstitial pulmonary fibrosis compared with congestive heart failure have been differentiated by ARM.[38]

Lung Ultrasonography

Ultrasound technology is not as helpful for imaging the lungs because air-filled lung tissue is not penetrated by ultrasound. However, pathologic processes outside the lungs can be seen by ultrasound, such as pleural fluids, air, or lesions. Pneumothorax, empyema, and pleural effusions are most frequently located by **lung ultrasonography**; their extent can be defined and treated with the use of ultrasound. As a diagnostic tool, lung ultrasonography is relatively inexpensive, can be performed in 15 minutes, and does not emit ionizing radiation. There is potential for ultrasonography to evaluate the lung expansion effects on atelectatic lung tissue using recruitment maneuvers.

Monitoring Patient-Ventilator System

Monitoring of a patient during mechanical ventilatory support should include a physical examination (inspection, palpation, percussion, auscultation), assessment of oxygenation and ventilation, and assessment of ventilatory load and capacity. Table 51-1 lists key physiologic monitoring data and acceptable values

TABLE 51-1

Physiologic Monitoring Data (Respiratory Values)

Function Assessed	Description of Value	Symbol/Formula	Acceptable Value
Oxygenation			
Lung Exchange (External)			
Adequacy	Arterial oxygen pressure	PaO_2	60-100 mm Hg
	Arterial oxygen saturation	SaO_2	≥90%
	Oxygen saturation by pulse oximeter	SpO_2	≥90%
	Transcutaneous oxygen partial pressure	$PtcO_2$	60-100 mm Hg
Efficiency	Alveolar to arterial oxygen tension gradient	$P(A-a)O_2$	<350 mm Hg (100% O_2)
	Arterial to alveolar	PaO_2/PAO_2	>0.6
	Respiratory index	$P(A-a)O_2/PaO_2$	<5
	P/F ratio	PaO_2/FiO_2	>300
	Percentage shunt	$\dot{Q}_S/\dot{Q}_T$	<15%-20%
Time exchange (internal)	Mixed venous oxygen content	$C\bar{v}O_2$	>10.0 ml/dl
	Mixed venous oxygen partial pressure	$P\bar{v}O_2$	>30 mm Hg
	Mixed venous oxygen saturation	$S\bar{v}O_2$	>65%
	Arterial-venous oxygen content difference	$C(a-\bar{v}O_2)$	<7 ml/dl
Ventilation			
Adequacy	Minute ventilation	$\dot{V}_E$	5-10 L/min
	Arterial carbon dioxide	$PaCO_2$	35-45 mm Hg (normal pH)
	Transcutaneous carbon dioxide partial pressure	$PtcCO_2$	35-45 mm Hg (normal pH)
	End-tidal carbon dioxide partial pressure	$PETCO_2$	35-43 mm Hg (4.6%-5.6%)
Efficiency	Dead space/tidal volume ratio	V_D/V_T	<0.6
	Minute ventilation vs. carbon dioxide partial pressure	$\dot{V}_E$ vs. $PaCO_2$	$\dot{V}_E$ <10 L/min with normal $PaCO_2$
Ventilatory Load			
Total impedance	Dynamic compliance	$(V_T - V_C)/(PIP - PEEP)$	35-50 ml/cm H_2O
Compliance	Effective compliance	$C_{eff} = \frac{(V_T - V_C)}{P_{plat} - PEEP}$	60-100 ml/cm H_2O
WOB	Work = kg × m/L or J/L	Work = P × V	<0.15 kg × m/L <1.5 J/L
Ventilatory Capacity			
Drive	Occlusion pressure	P0.1	<6 cm H_2O
	Mean inspiratory flow	V_T/T_i	Not established
Strength	Vital capacity	VC	>10-15 mL/kg
	Maximal inspiratory pressure	MIP; PI_{max}	<–20 to –30 cm H_2O
Endurance	Maximum voluntary ventilation	MVV	>20 L/min or 2 × $\dot{V}_E$
	Ratio of minute ventilation to MVV	$\dot{V}_E$/MVV	<1 : 2
	Pressure-time index	$(Pdi/Pmax)*TI/T_{tot}$	<0.15

for patients receiving mechanical ventilation. Monitoring of all aspects of the patient-ventilator system is an important responsibility that must be clearly delineated within the ICU. Monitoring a ventilated patient is the primary responsibility of the RT. Important areas of this responsibility include the following:

- Assessing the integrity of the airway and circuitry, including secretion clearance
- Maintaining the prescribed settings and assessing their appropriateness
- Ensuring acceptable gas-exchange values
- Monitoring of respiratory system mechanics
- Evaluating the comfort and synchrony of breathing of the patient
- Setting of alarms
- Caring for any other safety issues, such as risk of extubation

A system of ensuring and documenting all aspects of safe and appropriate care must be in place. This system usually includes a manual or, more frequently, an electronic recording of all important settings, alarms, and ABG values at regular intervals. This monitoring process has been called *patient-ventilator assessments*. An example of a recording form used for this purpose is shown in Figure 51-7. Increasingly, electronic

transfer of ventilator settings and monitored data is being added to the electronic medical record. The responsibility of the RT is much greater than the task of recording values. This responsibility is care of a critically ill, vulnerable patient with respiratory failure who is being supported with a lifesaving machine. The procedure for performing a patient-ventilator system assessment is outlined in Table 51-2. Although the importance of monitoring the patient-ventilator system has increased, the necessity of entry and transcription of numbers into an assessment sheet is decreasing. The era of electronic transfer of monitored data directly to the patients' charts will soon become the standard. All modern ventilators have the capacity for data transfer, but until standardized transfer protocols, charting formats, and archiving methods are established, electronic monitoring of the patient-ventilator system will continue to be customized to the local setting.

Graphics Monitoring

Monitoring of graphic tracings generated during mechanical ventilation has become widely available and accepted in the ICU. A visual display of pressure, flow, and volume tracings is available on all modern ventilators. Graphic displays are possible through the development of improvements in sensing technology, integrated circuitry, and graphic-user interface. Ventilators measure inspiratory and expiratory flow and circuit pressure with pneumotachometers and transducers. The volume displays are generated through calculation of an integral of the flow tracings. All three values (flow, pressure, and volume)

TABLE 51-2

Performing a Patient-Ventilator System Assessment

Step	Key Points
Gather correct equipment and supplies	Respirometer, O_2 analyzer, stethoscope, and watch with second indicator are needed. *Note:* Most modern ventilators incorporate volume-measuring devices into the system
	Additional auxiliary equipment may include pulse oximeter, cuff pressure manometer, suction and airway equipment, and sterile distilled water
Review patient record	Note patient's admitting diagnosis or problem list, physician orders, medications, vital signs, history and physical examination findings, progress notes, results of laboratory studies, chest radiograph, blood gases, and respiratory care notes
Enter patient area; wash hands and put on gloves	Inattention to proper handwashing and poor aseptic technique are associated with nosocomial infection
Identify the patient	Wristbands sometimes may be attached to the patient's leg or to the foot of the bed
	If there is no attached name band, check with the patient's nurse
Explain what you are doing	Communication with the patient is important; even patients who appear unaware of their surroundings may be able to hear and understand
	Use broad terms, such as "I'm here to assess your breathing"
Observe overall situation and note general patient condition, including level of consciousness, condition of extremities, presence of pallor, skin color, capillary refill, airway patency, circuit connection and patency, and ECG findings	Note general appearance, sensorium, color, and level of activity
	Note equipment in use, including ventilator, circuit, airway type, humidification, manual resuscitation bag, and related equipment and supplies
	Ensure that the patient's condition appears stable and that ventilation is adequate
Drain tubing and service humidifier, if needed	This procedure should be done before the actual ventilator check, if possible
Attend to patient's airway, if necessary	Suctioning and other airway manipulation should be done before actual ventilator check, if possible; after suctioning, note volume and character of secretions
	Note endotracheal or tracheostomy tube stability and position; measure tube cuff pressure and volume to inflate
	If ventilator check is performed first and the patient circuit or airway is disrupted, errors may not be caught, and one of the purposes of ventilator monitoring, patient safety, is defeated
Inspect chest and note accessory muscle use, retractions, jugular vein engorgement, bilateral symmetric chest wall movement, symmetric diaphragm–chest wall movement, respiratory rate and rhythm, and chest wall stability (flail)	Be alert for signs of respiratory distress, increased WOB or patient-ventilatory asynchrony
	Observe patient effort to ensure adequate trigger sensitivity and inspiratory flow rate
Auscultate chest	Always move stethoscope from side to side to compare right and left sides of chest
	Note adventitious breath sounds (crackles, rhonchi, wheezing, bronchovesicular breath sounds)
	Note diminished or absent breath sounds; if breath sounds are absent, attempt to ascertain cause immediately
	Water in the tubing, use of chest tubes, or PEEP may result in adventitious sounds
Percuss chest for dullness, resonance, or hyperresonance	Dullness may be caused by pleural effusion, atelectasis, or consolidation
	Resonance is the percussion note found over normal lung tissue
	Hyperresonance is associated with excess air in the chest (pneumothorax, pulmonary hyperinflation)
Note location of trachea	Tracheal shift is associated with severe atelectasis and tension pneumothorax
Note peak pressure, static or plateau pressure (P_{plat}), baseline pressure (PEEP/CPAP), pressure support level, MAP, and presence of auto-PEEP	Sudden increase in peak airway pressure is associated with pneumothorax, secretions in the airway, bronchospasm, fighting the ventilator, biting the endotracheal tube, occlusion of the airway, and bronchial intubation
	Sudden decrease in peak airway pressure is associated with reversal of any of the above-mentioned conditions, a leak in the system, or patient disconnection
	MAP may be useful in predicting a decrease in CO or barotraumas; the lowest possible MAP needed to achieve adequate ventilation and oxygenation should be used
	P_{plat} >28 cm H_2O is associated with the development of ventilator-induced lung injury; if P_{plat} is ≥28 cm H_2O, consider reducing delivered V_T
Record exhaled volume (ml/kg predicted body weight) and respiratory frequency	Ensure ventilator compensates for compressible volume
	If volume is measured at the exhalation valve, volume loss caused by tubing compliance may be calculated and subtracted from the measured volume

Performing a Patient-Ventilator System Assessment—cont'd

Step	Key Points
If intermittent mandatory ventilation (IMV)/SIMV system is in use, calculate delivered volume per machine breath, spontaneous volume between machine breaths, machine rate, total rate, patient spontaneous rate, and minute ventilation	For IMV/SIMV: $V_{ISP} = \frac{\dot{V}_{Etot} - \dot{V}_{Emech}}{f_{tot} - f_{mach}}$ For assist/control: $\text{Average } V_T = \frac{\dot{V}_{Etot}}{f_{tot}}$
If a ventilator graphics package is in use, observe pressure-time, flow-time, volume-time, and P-V curves	Mode of ventilation, patient trigger, adequacy of machine inspiratory flow, and patient-ventilator synchrony can be evaluated with a ventilator graphics package Slow flow P-V curve can be used to assess lower and upper inflection points Overdistention can be elevated with use of dynamic P-V curve Flow-volume curve may be helpful in assessing effect of bronchodilator
Note delivered FiO_2	FiO_2 should be analyzed
Record other ventilatory values	Ventilatory values include inspiratory flow, inspiratory time, I : E ratio, inspiratory and expiratory positive airway pressures (IPAP and EPAP), sigh volume and rate, airway temperature, compliance and resistance, and alarm settings Many departments chart endotracheal tube size, tube length, cuff pressure or volume, use of minimal occluding volume or minimal leak, ventilator day, circuit change, and other therapy
Record blood gas values and related data, as appropriate	These data may include pH, PaO_2, $PaCO_2$, SaO_2, hemoglobin level, HCO_3^- level, IPAP, base excess, and CaO_2 Blood gas data should be recorded in such a way that the corresponding FiO_2, PEEP, V_T, frequency, mode, and other ventilator settings on which the sample was obtained are noted
Record results of other physiologic monitoring of cardiopulmonary system, as appropriate	These values may include SpO_2, $PETCO_2$, $PtcCO_2$, $PtcO_2$, $\dot{Q}_S/\dot{Q}_T$, and V_D/V_T
Record hemodynamic data, as appropriate	These values may include heart rate, blood pressure, CVP, PAP, PCWP, $\dot{Q}_T$, cardiac index, $S\dot{v}O_2$, $P\dot{v}O_2$, $CaO_2 - C\bar{v}O_2$, pulmonary vascular resistance, and systemic vascular resistance
Record weaning values as appropriate	These values may include spontaneous frequency, V_T, f/V_T ratio, $\dot{v}_E$ VC, and inspiratory force (MIP)
Return all alarm systems to optimal condition. Complete charting using appropriate departmental forms or computer entry systems	Alarms include low pressure, high pressure, disconnection, and volume Apnea values should be reviewed. Apnea values usually are set to deliver an adequate V_T, f_{mach}, and FiO_2 (100%) in the event of apnea development

can be displayed and plotted against time or each other (Figure 51-8).

RULE OF THUMB

Modern mechanical ventilators routinely display tracings of flow, pressure, and volume versus time. Ventilator graphics monitoring is a convenient visual method for monitoring patient-ventilator interaction. The graphic patterns allow rapid determination of mode of ventilation, breathing pattern, auto-PEEP, excessive pressure, secretions in the airway, synchrony, and triggering efforts.

Ventilator manufacturers have developed the graphic displays that allow astute clinicians to base decisions on many more factors than gas-exchange values (Box 51-10). However, the study and verification of features observed in ventilator graphics have not developed at the pace of the technology. Ventilator graphics show many important patient-ventilator interactions, such as presence of auto-PEEP, elevated airway pressure, presence of secretions, and general pattern and dependability of supported ventilation (Figure 51-9). The potential for expanded use of ventilator graphics awaits further investigation of the clinical importance of the graphic displays. For more details, see Chapter 47.

Box 51-10 Purposes of Graphics Monitoring

- Confirm mode functions
- Detect inadequate flow in volume ventilation
- Detect too lengthy an inspiratory time
- Set appropriate rise time and termination criteria in pressure ventilation
- Detect auto-PEEP
- Determine patient-ventilator synchrony
- Assess and adjust trigger levels
- Measure WOB
- Adjust V_T and minimize overdistention
- Assess effect of administration of bronchodilators
- Detect equipment malfunction
- Determine appropriate PEEP level

Monitoring During Lung Protective Ventilation

A lung protective ventilation strategy that reduces the risk of pressure injury to the lungs has evolved from numerous animal studies and several key clinical studies.[39] Meticulous monitoring of the status of patients with ARDS or patients at risk of ARDS is necessary to avoid ventilator-induced lung injury. Three principles have been confirmed: (1) reduce the risk of high-pressure exposure by limiting P_{plat} to less than 28 cm H_2O, (2) reduce V_T ventilation to 4 to 8 ml/kg, and (3) maintain adequate end expiratory lung volume with PEEP to avoid opening/closing injury. The AARC created a clinical practice guideline on patient-ventilator system assessment; excerpts from this guideline appear in Clinical Practice Guideline 51-1.

Other considerations have received attention in monitoring patients with ARDS. Although P-V curves have been automated in ventilator algorithms, the clinical significance of curves determined from PEEP of 0 cm H_2O is questionable. However, current recommendations are to maintain ventilation on the

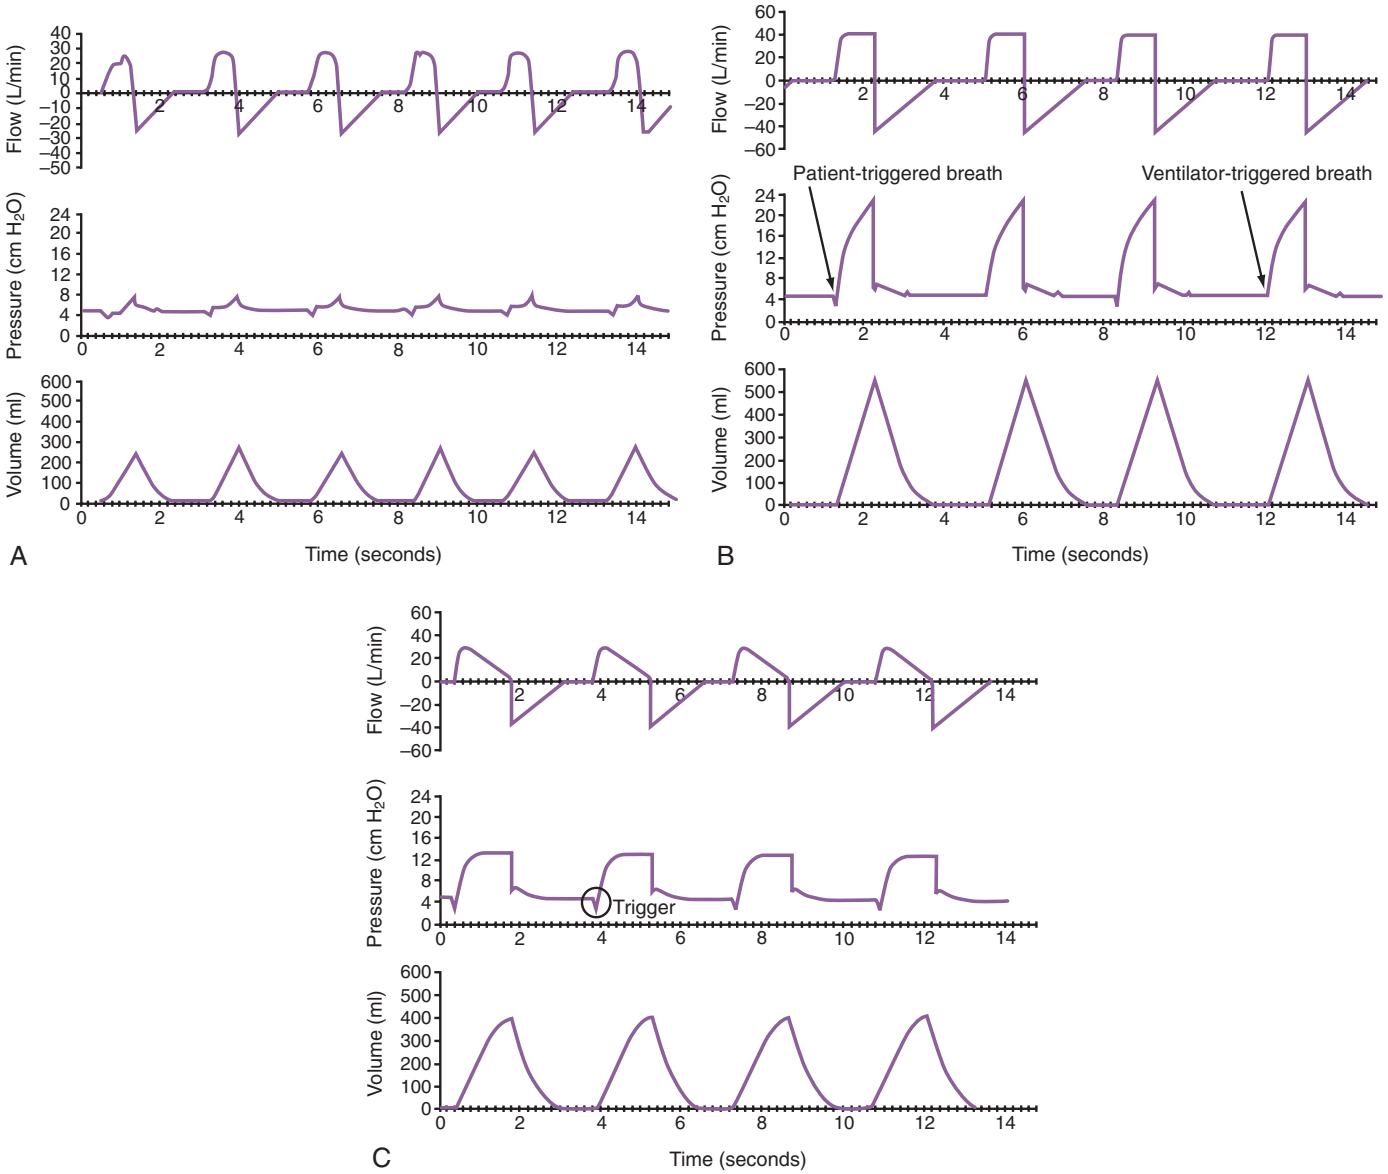

FIGURE 51-8 Ventilator graphics: flow, pressure, and volume tracings. **A,** Spontaneous breathing at an elevated baseline pressure (continuous positive airway pressure [CPAP]). Flow, pressure, and volume curves show spontaneous breathing with a CPAP level of approximately 5 cm H_2O. The flow curve is sinusoidal, the pressure curve fluctuates approximately 1 to 3 cm H_2O around the baseline pressure, and the volume delivered varies. These are typical observations during spontaneous breathing. **B,** Volume ventilation in the assist/control mode. Some breaths are time triggered, and others are patient triggered. There is a square wave flow pattern, and volume is constant, breath to breath. **C,** Pressure support breaths (pressure support ventilation). The patient trigger for each breath is evident. Flow is decelerating, and the pressure waveform approaches a square wave.

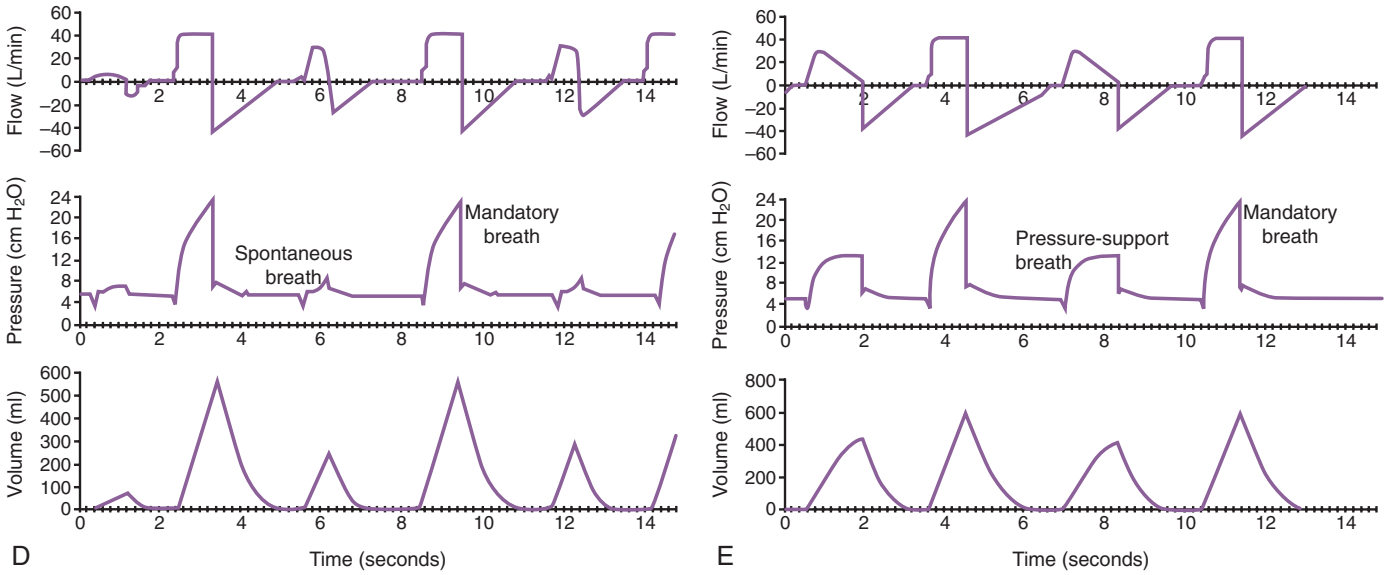

FIGURE 51-8, cont'd **D,** SIMV with an elevated baseline (PEEP). Spontaneous breathing and machine mandatory breaths are interspersed. Spontaneous volume varies, but the SIMV breaths are constant at 600 ml. The square wave flow pattern for mandatory breaths and the sinusoidal flow during spontaneous breathing are evident. The baseline pressure (PEEP) is elevated at approximately 5 cm H_2O. **E,** SIMV with pressure support. Mandatory breaths have a square flow waveform with a constant volume of 600 ml. The pressure support breaths have a decelerating flow waveform and a pressure pattern approaching a square wave. In this example, there is also an elevated baseline of approximately +5 cm H_2O (PEEP).

MINI CLINI

Ventilator Graphics

PROBLEM: The ventilator graphic display of a patient with COPD receiving mechanical ventilation is showing two distinct features: (1) a pressure-time tracing with spikes and dips that is generally irregular and (2) a flow-time tracing that does not reach zero flow at end expiration.

Solution: Graphic displays of pressure and flow allow rapid identification of the presence of secretions, auto-PEEP, and asynchrony. The irregular tracing implies the presence of airway secretions. Auscultation of the lungs should be performed to assess the need for endotracheal suctioning. Without an active expiratory effort, the existence of flow at end expiration confirms the presence of auto-PEEP. Auto-PEEP can be detected in many COPD patients receiving mechanical ventilation. However, intervention to reduce or eliminate auto-PEEP may be unnecessary. Auto-PEEP should be estimated regularly. More important, the effects of auto-PEEP on the ability to trigger the ventilator or on cardiovascular dynamics (caused by reduced venous return) should be monitored. For reduction or elimination of auto-PEEP, adjusting the ventilator settings or bronchodilator therapy may be required. If the patient is unable to trigger every breath because of the auto-PEEP, apply PEEP in steps of 1 to 2 cm H_2O until the patient is able to trigger the ventilator with every inspiratory effort.

upper portion of the deflation limb of the P-V curve to avoid alveolar derecruitment even though this position with the P-V hysteresis curve of a patient may be difficult to determine. A primary concern is to achieve adequate oxygenation in patients with lung injury, but this target can be deceptive if the price of adequate oxygenation is pressure injury to the lungs. An acceptable practice in ventilating these patients is permissive hypercapnia or pressure-protective ventilation that allows $PaCO_2$ to drift upward. This strategy is a higher frequency–lower V_T approach with the predictable effect of decreasing pH (by increasing $PaCO_2$) that requires careful monitoring.

As previously discussed, poor chest wall or abdominal compliance must also be considered during lung protective ventilation. This concern can be significant in obese patients. Essentially, the stiffer the chest wall or abdomen, the greater is the P_{plat} that can be established without inducing lung injury. Meta-analysis of higher versus lower PEEP suggests the use of higher levels of PEEP with patients suffering from moderate to severe ARDS, and high levels of PEEP should be used cautiously when treating mild ARDS.[40] Setting PEEP levels greater than 15 cm H_2O is often necessary in patients with moderate to severe ARDS to maintain oxygenation.[19] Elevated PEEP places greater importance on monitoring cardiovascular performance and development of barotrauma.

CARDIAC AND CARDIOVASCULAR MONITORING

The cardiovascular system is routinely monitored in the critical care setting because patient survival depends on reliable,

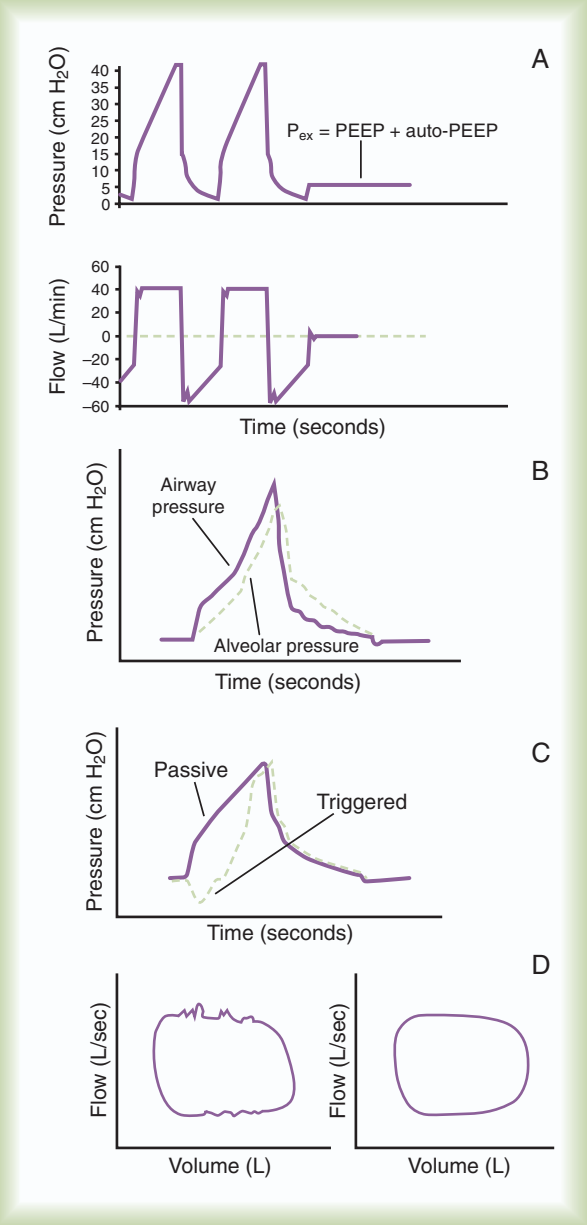

FIGURE 51-9 Patient-ventilator interactions easily identified from tracings of continuous monitoring of pressure, volume, and flow. **A,** Auto-PEEP. Flow and pressure tracings during ventilator-supported breaths and during end expiratory occlusion. The airway pressure during the end expiratory occlusion is an auto-PEEP estimate. **B,** Overdistention. The upper concavity of the airway pressure-time tracing is indicative of overdistention. This example also shows alveolar pressure and its corresponding overdistention. **C,** Patient effort. This is an example of mechanically ventilated passive inflation pressure and the airway pressure-time tracing deformation caused by effort by the patient. **D,** Presence of secretions. P-V tracing of a ventilator-supported breath displays the presence of secretions. The inspiratory and expiratory limbs are irregular (not smooth) when secretions are present. An irregular airflow-time tracing also can indicate the presence of secretions.

competent cardiac and cardiovascular performance. There is little question about the importance of monitoring ECG, a noninvasive, continuous assessment of the performance of the conduction system of the heart. In the care of acutely ill patients, there may be clear justification for continuous monitoring of arterial blood pressure. More controversial has been the assessment of left ventricular function by right heart catheterization with measurement of pulmonary capillary wedge pressure (PCWP) and continuous monitoring of pulmonary artery pressure (PAP) (Figure 51-10). Table 51-3 summarizes cardiovascular monitoring criteria with normal ranges and abnormal values.

Electrocardiography

The conduction system of the heart is monitored in the ICU with a purpose different from that of the standard 12-lead ECG examination (see Chapter 18). The standard 12-lead ECG can be used to analyze disturbances in the conductive pathway that allow location and extent of injury or the source of arrhythmia. The ECG in the ICU is used primarily to detect and manage arrhythmias such as tachycardia, bradycardia, atrioventricular dissociation, ventricular tachycardia, atrial flutter, premature ventricular contractions, and ventricular fibrillation. For this purpose, there is a need for only three electrodes: right arm (or shoulder or right upper chest), left arm (or shoulder or left upper chest), and left lower chest. The deflections usually represent lead II of a standard 12-lead ECG. The direction or amplitude of the waves is of lesser concern than the rhythms being displayed.

When any arrhythmia is detected, therapy or intervention should be considered. The source of the arrhythmia often necessitates management of the underlying cause, such as O_2 therapy for hypoxia or changes or addition to infusion therapy for fluid and electrolyte disturbances. In the ICU, certain interventions may be necessary and must be immediately available. A defibrillator must be available when ventricular fibrillation is detected.

Arterial Blood Pressure Monitoring

Arterial blood pressure is a crucial measurement for assessing the integrity of cardiovascular tone and the probability that O_2 delivery is dependable. Regulation of cardiovascular tone is under the influence of the autonomic nervous system, but there are other factors that affect blood pressure, such as fluid status or the effects of medications. Major concerns include the adequacy of O_2 delivery during hypotension and the risks of hypertension, such as increased hydrostatic pressure or stroke. Continuous monitoring of the actual blood pressure is performed by placement of a catheter usually in the femoral or radial artery. Because fluid is not compressible, the catheter and connecting tubing are filled with saline solution so that the arterial pressure is transmitted to a transducer that allows display of the arterial pressure tracing (Figure 51-11). The transducer must be properly zeroed and calibrated to reflect the true values of the deflections. The arterial line also provides access for obtaining arterial blood for ABG analysis.

51-1 Patient-Ventilator System Assessment

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

A patient-ventilator system assessment must be performed on a scheduled basis, which is institution-specific, for any patient requiring mechanical ventilation for life support. An assessment also should be performed in the following circumstances:

- Before obtaining blood samples for analysis of blood gases and pH
- Before obtaining hemodynamic or bedside pulmonary function data
- After any change in ventilator settings
- As soon as possible after an acute deterioration of the patient's condition
- Any time ventilator performance is questionable

CONTRAINDICATIONS

There are no absolute contraindications to performance of a patient-ventilator system assessment.

ASSESSMENT OF NEED

Because of the complexity of mechanical ventilators and the numerous factors that can adversely affect patient-ventilator interaction, routine assessments of patient-ventilator system performance are mandatory.

ASSESSMENT OF OUTCOME

Routine patient-ventilator system assessments should prevent untoward incidents; warn of impending events; and ensure that proper ventilator settings, according to the physician's orders, are maintained.

FREQUENCY

A patient-ventilator system assessment should be performed at regularly scheduled intervals and in the following circumstances:

- After any change in ventilator settings
- Before obtaining any blood gas samples
- Before obtaining hemodynamic or pulmonary function data
- As soon as possible after an acute deterioration of the patient's condition, in particular, when this occurs after a violation of the ventilator alarm threshold

INFECTION CONTROL ISSUES

- Condensation from the patient circuit should be considered infectious waste and disposed of according to hospital policy.
- Universal precautions should be observed.

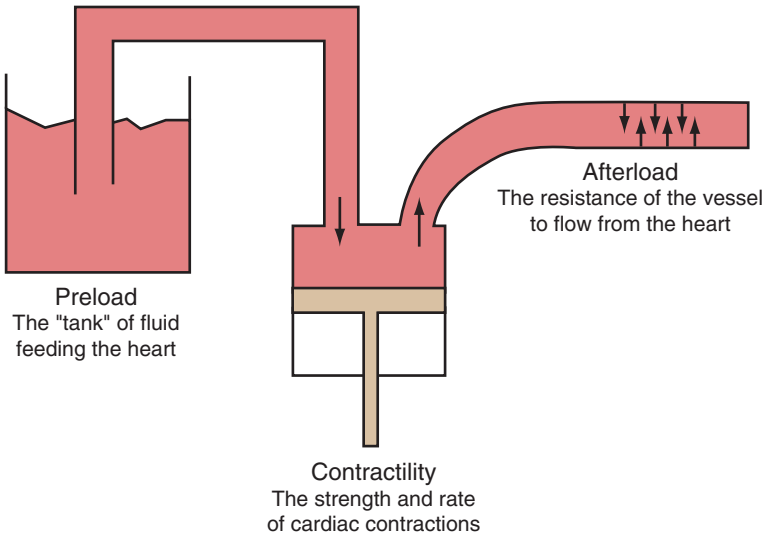

FIGURE 51-10 Preload contractility and afterload.

Central Venous Pressure–Right Atrial Pressure Monitoring

Right atrial pressure or CVP is monitored in the ICU by placement of a central venous catheter. Right atrial pressure normally is the lowest of all the heart chamber pressures, ranging from 2 to 6 mm Hg. Mean right atrial pressure is the same as CVP. CVP is a measure of right atrial preload. Atrial preload is determined by the balance between the capacity of the cardiovascular system, its circulating volume, and the amount of venous return to the heart (see Chapter 10). Right atrial pressure also is a reflection of right ventricular preload under normal circumstances. As a result, abnormally low right atrial pressure suggests inadequate filling of the right ventricle and is common in

TABLE 51-3

Cardiovascular Monitoring Criteria

Criterion	Normal Value (Range)	Abnormal Value
Heart rate (HR)	80 beats/min (60-100 beats/min)	>100 beats/min (tachycardia) <60 beats/min (bradycardia)
Arterial blood pressure (ABP)	120/80 mm Hg (90-140/60-90 mm Hg)	<140/90 mm Hg (hypertension) <90/60 mm Hg (hypotension)
Mean arterial blood pressure ($\overline{MAP}$)	90 mm Hg (80-100 mm Hg)	<80 mm Hg (hypotension) >100 mm Hg (hypertension)
ECG	Normal heart rate and rhythm	PR interval >0.2 sec (tachycardia, bradycardia, heart block [first, second, or third degree], premature ventricular contractions, premature atrial contractions, atrial fibrillation, atrial flutter, elevated ST segment, inverted T wave, ventricular tachycardia, ventricular fibrillation, asystole)
Central venous pressure (CVP)	2-6 mm Hg	>6 mm Hg (fluid overload, right ventricular failure, pulmonary hypertension, valvular stenosis, pulmonary embolus, cardiac tamponade, pneumothorax, positive pressure ventilation, PEEP, left ventricular failure) <2 mm Hg (hypovolemia, blood loss, shock, peripheral vasodilation, cardiovascular collapse)
Pulmonary artery pressure (PAP)	25/10 mm Hg (20-35/5-15 mm Hg)	>35/15 mm Hg (pulmonary hypertension, left ventricular failure, fluid overload) <20/5 mm Hg (pulmonary hypotension, hypovolemia, cardiovascular collapse)
Mean pulmonary artery pressure ($\overline{PAP}$)	15 mm Hg (10-20 mm Hg)	>20 mm Hg (same as ↑ PAP) <10 mm Hg (same as ↓ PAP)
Pulmonary capillary wedge pressure (PCWP)	5-10 mm Hg (<18 mm Hg)	>18 mm Hg (left ventricular failure, fluid overload) >20 mm Hg (interstitial edema) >25 mm Hg (alveolar filling) >30 mm Hg (frank pulmonary edema) <5 mm Hg (hypovolemia, shock, cardiovascular collapse)
Cardiac output ($\dot{Q}_T$ or CO)	5 L/min (4-8 L/min)	>8 L/min (elevated) (see Cardiac index) <4 L/min (decreased) (see Cardiac index)
Cardiac index (CI)	2.5-4 L/min per m^2	>4 L/min per m^2 (elevated owing to stress, septic shock, fever, hypervolemia, or drugs [dobutamine, dopamine, epinephrine, isoproterenol, and digitalis]) <2.5 L/min per m^2 (left ventricular failure, myocardial infarction, pulmonary embolus, high levels of positive pressure ventilation, PEEP, pneumothorax, blood loss, hypovolemia)
Systemic vascular resistance (SVR)	900-1400 dynes-sec/cm^5 (11.25-17.5 mm Hg/L per min)	>1400 dynes-sec/cm^5 (increased owing to vasoconstrictors [dopamine, norepinephrine, and epinephrine], hypovolemia, late septic shock) <900 dynes-sec/cm^5 (decreased owing to vasodilators [nitroglycerin, nitroprusside, and morphine] or early septic shock)
Pulmonary vascular resistance (PVR)	110-250 dynes-sec/cm^5 (1.38-3.13 mm Hg/L per min)	>250 dynes-sec/cm^5 (hypoxemia, ↓ pH, $PaCO_2$, vasopressors, emboli, emphysema, interstitial fibrosis, pneumothorax) <110 dynes-sec/cm^5 (pulmonary vasodilators, nitric oxide, O_2, calcium blockers)

CI = $\dot{Q}_T$ /Body surface area.
SVR = [($\overline{MAP}$ – CVP)/CO] × 80 = dynes-sec/cm^5.
PVR = [($\overline{PAP}$ – PCWP)/CO] – 80 = dynes-sec/cm^5.

hypovolemia. Causes of abnormal right atrial pressure or CVP are summarized in Box 51-11.

Pulmonary Artery Pressure Monitoring

Placement of a right heart/pulmonary artery catheter (**Swan-Ganz catheter**) is invasive and is associated with risk of pneumothorax, hemothorax, and arrhythmias. Placement of the balloon-tipped 7.5F catheter (Figure 51-12) must be performed aseptically by an experienced clinician. The catheter is guided into the pulmonary artery while the clinician visualizes waveforms with a fluid-filled system identical to the arterial pressure monitoring system (Figure 51-13).

Placement of a Swan-Ganz catheter allows determination of CVP, PAP, and PCWP. Data gathered with a Swan-Ganz catheter can be used to calculate thermodilution CO, pulmonary and arterial vascular resistance, and other associated indices (see Table 51-3). PAP monitoring may be helpful in the presence of shock (cardiogenic, hypovolemic, septic), left ventricular failure, myocardial infarction, pulmonary vascular disease, pulmonary edema, and ARDS. The reading and interpretation of Swan-Ganz catheter tracings can be inconsistent. There has been considerable controversy because of the risk-benefit ratio of the procedure.[41] The use of a pulmonary artery catheter in patients without primary cardiovascular disease has decreased markedly in more recent years.

Preload

Preload is defined as the pressure that stretches the ventricular walls at the onset of ventricular contraction. Preload can be approximated by measurement of PCWP. PCWP is an estimate of left atrial pressure, which reflects left ventricular end-diastolic pressure. During left-sided heart failure, preload increases; the increase is reflected in elevated PCWP. Symptoms of congestive heart failure usually can be controlled with diuretic therapy.

Box 51-11 Causes of Increased Right Atrial and Central Venous Pressure

- Right ventricular failure (myocardial infarction, cardiomyopathy)
- Pulmonary valvular stenosis
- Tricuspid stenosis and regurgitation
- Pulmonary hypertension
- Pulmonary embolism
- Volume overload
- Compression around the heart, constrictive pericarditis, cardiac tamponade
- Increased large vessel tone throughout the body, resulting in venoconstriction
- Arteriolar vasodilation, which increases blood supply to the venous system
- Increased intrathoracic pressure (positive pressure breath or pneumothorax)
- Placement of transducer below the patient's right atrial level
- Infusion of solution, especially with pressure infusion pumps, into CVP line
- Left-sided heart failure

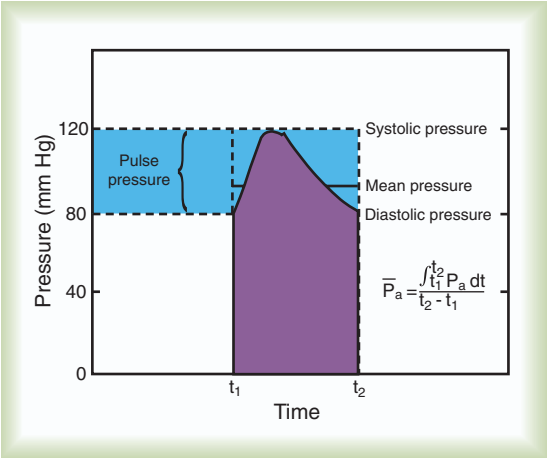

FIGURE 51-11 Arterial pressure wave form systolic pressure, diastolic pressure, MAP, and pulse pressure.

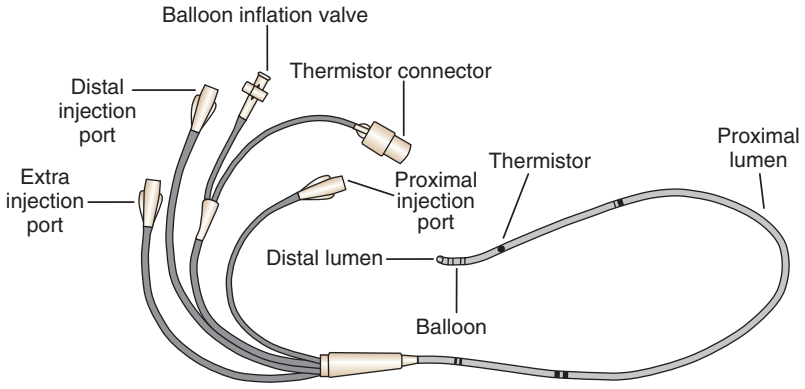

FIGURE 51-12 Quadruple-channel pulmonary artery catheter. The distalmost channel (distal injection port) is for measurement of PAP. Blood can be aspirated from this channel for mixed venous O_2 measurements. A second channel (balloon inflation valve) is used to inflate or deflate the distal balloon. A third channel (proximal injection port), which exits 30 cm from the catheter tip, is used for CVP (right atrial pressure) monitoring and fluid infusion. The fourth channel (extra injection port), which is not present on all catheters, can be used for continuous infusion of hyperalimentation fluid.

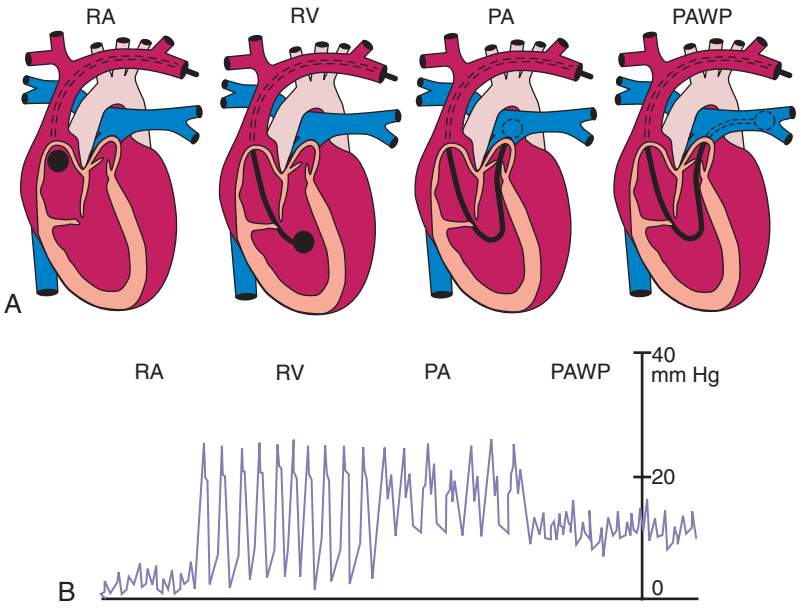

FIGURE 51-13 **A,** Position of pulmonary arterial catheter in the heart. **B,** As monitored by pressure tracings. *PA,* Pressure tracing from pulmonary artery; *PAWP,* pulmonary artery wedge pressure tracing; *RA,* pressure tracing from right atrium; *RV,* pressure tracing from right ventricle.

BP, Blood pressure; *N*, normal or little or no change.

Contractility

Contractility is the forcefulness of the heart muscle contracting under a constant load. Numerous pharmacologic agents are used to cause a modest increase in ejection fraction (contractility) and are associated with improvement in symptoms in patients with congestive heart failure.

Afterload

Afterload usually is defined as the load against which the ventricles must contract. An increase in systemic vascular resistance increases left ventricular afterload. Although increased afterload usually is equated with increased blood pressure, the cause is better understood as the muscle tension required by the left ventricle to generate blood flow. Table 51-4 lists common conditions and associated alterations in hemodynamic variables. Table 51-5 summarizes steps to take in troubleshooting changes in monitored cardiovascular values and vital signs, including possible causes and appropriate corrective action.

Cardiac Output

Cardiac performance is affected by preload, contractility, and afterload and is evaluated by the measurement of CO. The effect

TABLE 51-5

Troubleshooting Changes in Vital Signs

Clue	Possible Problem	Advice
Hypotension	Hypovolemia, pump failure	Evaluate fluid balance and possible need for intravenous fluids or inotropic agents
Hypertension	Anxiety; response to decreased PaO_2, decreased $PaCO_2$ or pain	Reassure, alleviate fear, check patient-ventilatory system; if not easily correctable, obtain and evaluate ABGs
Alteration of blood pressure with breathing	Decreased venous return (caused by changes in intrathoracic pressure)	If systolic/diastolic pressures are less than adequate perfusion levels, evaluate fluid balance; consider intravenous fluids
New arrhythmias, tachycardia, bradycardia	Anxiety	Reassure, alleviate fear
	Decreased PaO_2, decreased $PaCO_2$, increased $PaCO_2$	Check patient-ventilator system; if not quickly correctable, obtain and evaluate ABGs
Large swings in CVP or PCWP	Decreased venous return	Evaluate other hemodynamic values for adequacy of perfusion
Decreased urinary output	Decreased CO	Evaluate other hemodynamic values for adequacy of perfusion
	Hypovolemia	
Fever	Infection	Control infection; review preventive measures
	Atelectasis	Check patient-ventilator system for secretions, plugs, slippage of tube into right main stem bronchus
	Overheated humidifier	Check humidifier heater temperature
Weight gain	Fluid retention	Evaluate hemodynamic values for adequacy of perfusion; consider diuresis
Changes in respiratory rate	Altered settings	Check patient-ventilator settings
	Change in metabolic needs	Evaluate metabolic rate
	Anxiety	Reassure, alleviate fear
	Sleep	Normal; metabolic rate is decreased
Use of accessory muscles or paradoxical breathing	Increased WOB	Increase support level; check and change inspiratory flow
	Patient-ventilator asynchrony	Provide pressure support ventilation Increase sensitivity
	Auto-PEEP	Eliminate auto-PEEP

of cardiac pathology, medications, or mechanical ventilation on CO can be critical monitoring information. An accurate assessment of CO presents a challenge to the clinician. The physical examination (see Chapter 16) can reveal signs and symptoms of impaired cardiac performance, but a composite number provided by CO can provide more direct insight into problem and treatment options.

CO as determined by thermodilution via the use of a Swan-Ganz catheter was the primary method of CO assessment for three decades. The invasiveness of this method and inaccuracies in reading and interpretation led to a decrease in use of the Swan-Ganz catheter. Other methods of CO determination have become available based on algorithms that analyze the arterial pressure waveform and a Fick principle rebreathing method. The waveform analysis methods can be "calibrated" by lithium dilution or by thermodilution. Each technique has been studied and found to be accurate in relatively stable patients.[42-44]

NEUROLOGIC MONITORING

Monitoring of the nervous system is most frequently overlooked in the ICU for several reasons. The first and most important reason is lack of knowledge of proper assessment of the nervous system of a ventilated, restrained, and often sedated patient in the ICU. Neurologic dysfunction is difficult to recognize in a sedated patient. Proper clinical assessment of the nervous system emphasizes neurologic history and examination (Box 51-12).

History

Obtaining a history from a critically ill patient, in particular, a patient with altered state of consciousness, can be difficult. However, attempting to obtain a history by speaking with the patient or family members can provide extremely useful information in the ICU.

Medical conditions with neurologic symptoms can be revealed through history and appropriate clinical tests. A history of an evolving focal deficit occurring over days to weeks before loss of consciousness suggests abscess, tumor, or subdural hematoma, whereas a progression to coma over minutes to hours favors a metabolic cause. Problems such as hypothyroidism, renal failure, cirrhosis, or psychiatric illness suggest greater likelihood of a metabolic cause. Uncontrolled hypertension can induce metabolic (e.g., hypertensive encephalopathy) or structural (e.g., intracerebral hemorrhage) coma.

Box 51-12 Neurologic Monitoring

One of the most important, and frequently overlooked, areas of monitoring is the neurologic examination, which includes the following:

- History
- Assessment of mental status
- Pupillary response
- Eye movement assessment
- Corneal response
- Gag reflex
- Respiratory rate and pattern
- General motor and sensory evaluations

Neurologic Examination

The neurologic examination of a patient in the ICU should address several key issues. In addition to determination of level of consciousness, the primary goal is to determine the presence of focal neurologic signs so that the clinician can localize the lesion anatomically and generate a differential diagnosis and treatment plan.

Mental Status

The mental status examination should determine whether the patient has an altered state of consciousness. Terms such as *lethargy, confusion,* and *disorientation* lack precise definitions. A brief description of the applied stimulus and arousal pattern is preferred. The mental status examination in the ICU varies if the patient is intubated and cannot vocalize responses or speak. The earliest sign of abnormal mental status often is the patient's inability to follow a conversation or complex commands. Subtle changes in mental status often are the earliest signs of central nervous system dysfunction.

Pupillary Response

Pupil size, congruency, and response to light and accommodation should be described. Pupillary light reflexes provide information regarding the status of the brain and of the sympathetic and parasympathetic nervous systems. Pupillary function is controlled by the midbrain. If pupillary function is normal, the cause of coma is either metabolic or a structural lesion located above the midbrain. Small "pinpoint" pupils usually result from pontine hemorrhage or from ingestion of narcotics or organophosphates. Pupillary responses almost always remain intact in metabolic causes of coma. Dilated and fixed (unresponsive to light) pupils are seen in patients who have been given atropine. Midposition and fixed pupils often indicate severe cerebral damage.

Eye Movements

Abnormalities of extraocular movement have prognostic importance in the ICU. Normal movement of the eyes requires an intact pontomedullary-midbrain connection. The resting position of the gaze, the presence of nystagmus, and the response to head movements and cold tympanic membrane stimulation should be identified. Cervical spine stability must be ensured before oculocephalic maneuvers are performed. If rotation of the head (oculocephalic) and vestibular stimulation (calorics) produce no change in eye position, the pons is nonfunctional. If only the eye ipsilateral to the stimulus abducts, a lesion of the medial longitudinal fasciculus should be suspected.

Corneal Responses

The corneal reflex is used to test the afferent fifth and the efferent seventh cranial nerves. This test is performed by lightly touching the cornea with a cotton swab; the patient should blink both eyes in response. The presence of this response implies an intact ipsilateral fifth cranial nerve, intact central pons, and intact bilateral seventh cranial nerve. Testing must be performed bilaterally to evaluate both afferent components of the fifth cranial nerve.

Gag Reflex

The gag reflex is tested by using a tongue blade to stimulate one side of the posterior pharynx of an intubated patient. Each side should be tested separately. A normal response is bilateral movement of the posterior pharyngeal muscles and implies intact ninth and tenth cranial nerves. The ability to cough on suctioning can be tested in an intubated patient and implies an intact tenth cranial nerve. This test should not be attempted on nonintubated patients in the ICU because of the risk of aspiration.

Respiratory Rate and Pattern

The brainstem is the primary site of the central control of respiration. This control occurs at a subconscious level and results in rhythmic contraction and relaxation of the respiratory muscles. The most common abnormal respiratory pattern seen in patients with neurologic disorders is Cheyne-Stokes respiration, which consists of phases of hyperpnea that regularly alternate with episodes of apnea. Breathing waxes in a smooth crescendo and when a peak is reached wanes in an equally smooth decrescendo. Cheyne-Stokes respiration usually has an intracranial cause, although it can be caused by hypoxemia and cardiac failure. Ataxic breathing is a marker of severe brainstem dysfunction. Despite the nonspecificity of most breathing patterns, the respiratory pattern can provide valuable clues to the cause of coma.

Motor Evaluation

A thorough motor evaluation should be performed for all patients. The systematic approach described earlier is key to localization of the site of a pathologic process. The symmetry and pattern of the motor response to noxious stimuli and associated neurologic symptoms should be documented for all patients.

Sensory Evaluation

The assessment of light touch, pinprick, and temperature sensation can be achieved by applying a cotton swab, a clean pin, and a cold or warm object to various parts of the upper and lower extremities. Symmetry of responses between sides and between

upper and lower extremities should be documented and is valuable in localizing the site of a pathologic process.

Intracranial Pressure Monitoring

There are three primary reasons to measure intracranial pressure (ICP): (1) to monitor patients at risk of life-threatening intracranial hypertension, (2) to monitor for evidence of infection, and (3) to assess the effects of therapy aimed at reducing ICP. Mean ICP of a supine patient is normally 10 to 15 mm Hg, and the ICP waveform normally undulates gently in time with the cardiac cycle. Fluctuations of the ICP waveform (>10 mm Hg) suggest a position near the critical inflection point of the cranial P-V curve. Elevations in ICP to 15 to 20 mm Hg compress the capillary bed and compromise microcirculation. At ICP levels of 30 to 35 mm Hg, venous drainage is impeded, and edema develops in uninjured tissue. Even when autoregulatory mechanisms are intact, cerebral perfusion cannot be maintained if ICP increases to within 40 to 50 mm Hg of the mean arterial pressure. When ICP approximates mean arterial pressure, perfusion stops, and the brain dies.

Two categories of ICP monitoring techniques are available at the present time. Fluid-filled systems have external transducers, such as an intraventricular catheter and subarachnoid bolts. Solid-state systems have miniature pressure transducers that can be inserted in the lateral ventricle, brain parenchyma, or subarachnoid or epidural space.

Glasgow Coma Scale Score

The most widely used scoring system for acute neurologic disorders is the **Glasgow Coma Scale (GCS)** (Table 51-6). The GCS score is used to test best motor response, best verbal response, and opening of the eyes. The scale goes from 3 to 15 and can be used for rapid triage. Patients with head injury and GCS scores of 13 to 15 often are admitted to a non-ICU observational unit unless neurologic examination or a CT scan reveals a lesion or abnormality that warrants ICU admission. Scores of 9 to 13 on the GCS signify a significant insult with depressed level of consciousness. Patients with head injury and GCS scores of 8 and less need monitoring of ICP.

TABLE 51-6

Glasgow Coma Scale

Eyes	Open	Spontaneous	4
		To verbal command	3
		To pain	2
		No response	1
Best motor response	To verbal command	Obeys	6
	To painful stimulus	Localized pain	5
		Flexion—withdrawal	4
		Flexion—decorticate	3
		Flexion—decerebrate	2
		No response	1
Best verbal response		Oriented, converses	5
		Disoriented, converses	4
		Inappropriate words	3
		Incomprehensible sounds	2
		No response	1
Total			*3-15*

MONITORING RENAL FUNCTION

The kidney is the main filter of waste products and the principal regulator of the volume and electrolyte composition of body fluid. Because the kidney is the primary excreter of nitrogenous waste, plasma concentrations of blood urea nitrogen (BUN) and creatinine are used to track renal function. As a general guideline, the BUN level increases 10 to 15 mg/dl per day, and the creatinine level increases 1 to 2.5 mg/dl per day after abrupt renal failure. The serum potassium level usually increases 0.5 mEq/L per day, and bicarbonate (HCO_3^-) level decreases approximately 1 mEq/L per day. Under the catabolic stress of burns, trauma, rhabdomyolysis (an acute and sometimes fatal disease in which products of skeletal muscle destruction produce acute renal failure), sepsis, or starvation, the rates of change in these values can double. In contrast to BUN, daily production of creatinine is relatively constant. An increasing creatinine level indicates that the rate of production exceeds clearance by means of glomerular filtration. A stable elevation in creatinine level implies a new steady state has been achieved at a decreased glomerular filtration rate. Until the creatinine level stabilizes, the severity of acute renal dysfunction cannot be assessed reliably. The most common method of estimating glomerular filtration rate (renal function) is measurement of plasma creatinine and creatinine clearance rate. Although calculation of creatinine clearance is more accurate, the procedure entails 24-hour urine collection. The most important factor is whether glomerular filtration rate is changing or stable, and plasma creatinine level is tracked for most patients.

Urine volume usually reflects kidney perfusion. *Polyuria* and *oliguria* refer to a daily urine output of more than 3 L and less than 0.4 L in average-sized adults. *Anuria* is present when urine output is less than 50 ml/day. Polyuria should not be confused with urinary frequency, in which multiple small voidings occur, but total output is less than 3 L/day.

MONITORING LIVER FUNCTION

Adequate liver function is essential for survival of critically ill patients. The liver must detoxify wastes from metabolism and digestion and process poisons. Elevated results of liver function tests reflect the occurrence of liver parenchymal damage. Hepatic dysfunction may precipitate or worsen ARDS.[45] Routine indications for liver function testing in the treatment of critically ill patients include abdominal pain, jaundice, unexplained fever, nausea, malaise, failure to thrive, weight loss, and leukocytosis. Additional indications are facilitation of acuity scoring and definition of the contribution of the liver to multisystem organ failure.

Batteries of biochemical studies are routine in the evaluation of critically ill patients, but they reflect liver function minimally. Acute liver disease can develop in critically ill patients receiving

total parenteral nutrition.[46] Liver disease may manifest as increased liver size and tenderness. When abnormal results of liver function tests have been obtained, it is essential to determine the cause. Elevations in levels of canalicular enzymes and bilirubin necessitate a search for mechanical obstruction and appropriate radiographic investigations. Elevations of transaminase levels are unusual in cholestatic processes, unless there is a superimposed ischemic event—a confounding factor in many critically ill patients. Elevated levels of aspartate aminotransferase and alanine aminotransferase suggest hepatic inflammation. Ischemia, viral hepatitis, and autoimmune hepatitis should be considered in the differential diagnosis.

NUTRITIONAL MONITORING

Assessment and monitoring of nutrition are required in the care of some critically ill patients because nutritional disorders are frequent and important determinants of outcome. Nutritional support is commonly needed by patients who have been critically ill for an extended period and patients with increased metabolic demands and limited nutritional reserve.

Assessment of Nutritional Status

Early detection of malnutrition in critically ill patients, whether preexisting or a result of acute illness, enables prompt and aggressive intervention with supplemental nutrition. No single measurement or assessment tool can adequately characterize nutritional status, and the diagnosis of malnutrition is subjective. However, both functional and biochemical factors should be examined to identify whether a patient is at increased risk of malnutrition and its complications.

Functional Assessment

The functional nutritional assessment consists of the medical history, physical examination, and appraisal of muscle and organ function. Identification of preexisting malnutrition should be attempted by careful attention to the history of present illness, the relevant medical and surgical history, medications, social habits, and a dietary history. Obtaining this information from a critically ill patient frequently is impossible, but the patient's family may be able to provide data on recent dietary habits and weight loss. Historical data should be used to estimate the nutritional consequences of the current hospitalization. Prehospitalization weight should be documented, and any weight changes since hospitalization should be documented and evaluated in the context of diuresis or fluid supplementation. Critically ill patients frequently have volume overload, which makes changes in dry weight difficult to assess.

The physical examination findings may suggest the presence of nutritional and metabolic deficiencies. Temporal muscle wasting, sunken supraclavicular fossae, and decreased adipose stores are easily recognized signs of starvation. Careful inspection of the hair, skin, eyes, mouth, and extremities can reveal protein-calorie malnutrition or vitamin and mineral deficiencies. An assessment of muscle mass and function can provide information about a patient's protein reserves and overall nutritional status. An estimation of muscle mass and fat stores can be obtained from anthropometric measurements such as arm circumference.

The function of the cardiovascular, respiratory, and gastrointestinal systems should be evaluated both for evidence of malnutrition-related dysfunction and because functional deficits may affect the ability of the patient to tolerate nutritional supplementation. The large fluid volumes associated with parenteral nutrition may not be tolerated in the setting of impaired cardiovascular function, and a distended abdomen makes tolerance of enteral supplementation less likely.

Metabolic Assessment

Serum albumin concentration is the most frequently used laboratory measure of nutritional status; a value less than 2.2 g/dl generally reflects severe malnutrition. Although albumin level is popular as an indicator of nutritional status, the reliability of albumin as a marker of visceral protein status is compromised by its long half-life of 14 to 20 days, making it less responsive to acute changes in nutritional status. Serum albumin concentration increases rapidly in response to exogenously administered albumin and is altered regardless of nutritional status in conditions such as dehydration, sepsis, trauma, and liver disease.

Serum chemistry values are important in determining the specifics of nutritional support but do not directly reflect nutritional status. Sodium, potassium, chloride, total CO_2, BUN, glucose, prothrombin time, partial thromboplastin time, iron, magnesium, calcium, and phosphate should be measured at admission and rechecked periodically.

Estimating Nutritional Requirements

The first step in calculating the nutritional prescription is to estimate the energy or caloric needs of the patient. Determining energy needs requires calculating basal energy expenditure (BEE). The BEE is the amount of energy required to perform metabolic functions at rest and is influenced by body size and illness. The BEE classically is estimated with the **Harris-Benedict equation**, as follows:[47]

$$\text{Men: BEE} = 66 + (13.7)(\text{Weight}) + (5)(\text{Height}) - (6.8)(\text{Age})$$
$$\text{Women: BEE} = 65 + (9.6)(\text{Weight}) + (1.8)(\text{Height}) - (4.7)(\text{Age})$$

where weight is expressed in kilograms; height, in centimeters; and age, in years.

The weight in these equations should be the usual or actual weight of a patient without significant weight loss, current weight for a patient with marked weight loss, and ideal body weight for an obese patient. The use of this measurement in the care of a critically ill patient has traditionally involved multiplication by a stress factor of 0.5 to 2.5. The use of the stress factor may result in overfeeding and may predispose the patient to fatty degeneration of the liver (steatosis), hyperglycemia, electrolyte imbalances, respiratory embarrassment owing to increased CO_2 production, and macrophage dysfunction. Use of the baseline Harris-Benedict equation without the stress factor in determining the BEE of critically ill patients yields an average estimate of 25 kcal/kg body weight.

GLOBAL MONITORING INDICES

Organizing the flood of information made available by monitoring instruments is a skill and responsibility of critical care practitioners. In the ICU, the immediate concern is the welfare of the patient. Decisions frequently are based on prognosis with respect to the appropriate tests, treatments, and medications prescribed. Guiding these decisions is the weighing of risks and benefits to the patient and the responsible use of resources. Although the physician makes such decisions with all current information, specific data on the probability of survival can be estimated. In the past 30 years, prognostic indices have been derived from large clinical data sets that provide an indication of the seriousness of the patient's condition. These indices (Acute Physiology and Chronic Health Evaluation [APACHE I, II, III, and IV], Acute Physiology Score, Therapeutic Intervention Scoring System, and Burns Weaning Assessment Program) are determinations of scores from numerous monitored values obtained from isolated observations of the patient's condition, usually during the first 24 hours after hospital admission. A score may be assigned for that patient at that time, and risk of mortality can be calculated (Box 51-13).

The value of severity of illness scoring for individual patients is limited, and the accuracy and usefulness of physiology scoring often are questioned. Imposing a scoring system to judge intent to treat places too much emphasis on the validity of the system. Scoring systems have not been clearly associated with important outcomes such as length of stay or time on mechanical ventilation. At the present time, as a bedside tool in the care of an individual patient, scoring systems have limited value. A specific condition may "score" a 17% risk of death, but a patient has two possible outcomes: life (0%) and death (100%). The decision to withdraw or limit care would rarely be based on a "score" because many other factors are involved in such a decision. Inaccuracies in predicting mortality are frequently reported. Discrepancies are probably due to patient mix differences, hospital factors, admission policies, data collection methods, and differences in quality of care. At the present time, the global indices have limited use in care of individual patients.

Box 51-13 Global Monitoring Indices

Indices (scores) have been developed that take into account several monitored values.

These scoring systems provide an estimate of illness acuity level and an estimate of the risk of mortality.

For clinical studies, scoring systems are required to ensure that the control and experimental groups are similar.

Scoring systems can be useful as a longitudinal monitor of acuity or a means of evaluating the effect of changes in services.

At this time, scoring systems have little value in the care of individual patients. The most commonly used acuity of illness scoring system is APACHE II.

Global monitoring has a definite role in research. Global indices are valuable in the study of the effectiveness of new medications or therapy and the establishment of guidelines for care. When control and experimental (new treatment) groups are compared in a randomized, controlled trial, the severity scores of the groups must be similar, or differences in baseline condition may account for differences in results. As a tracking tool, scoring has significant value; the increasing severity of causes of ICU admissions can be followed over time with severity of illness scoring. The consequences of changes in services or policies or interhospital comparisons can be crudely tracked with the use of expected mortality calculations from APACHE scores. Some institutions calculate severity of illness scores for all patients.

Acute Physiology and Chronic Health Evaluation (APACHE)

The **APACHE scoring system** was developed in 1981 to monitor severity of illness in clinical studies.[48] Studies have referenced a risk of mortality estimate as calculated from APACHE scoring, and the studies can be compared with similar studies in which the APACHE scoring system is used. The APACHE II scoring system assigns points to physiologic variables on the basis of whether the values are high abnormal, low abnormal, or normal. Variables rated include temperature, mean arterial pressure, heart rate, respiratory rate, PaO_2 [or $P(A - a)O_2$], pH, sodium level, potassium level, creatinine level, hematocrit, white blood cell count, and GCS score. Assigned points are added to derive a total APACHE score. There is an imprecision to estimating a risk of mortality. To emphasize the importance of the neurologic examination, the scoring system is weighted toward the importance of the GCS score. Refinements of APACHE are ongoing, although the APACHE II system continues to be used more often than other systems.[49]

TROUBLESHOOTING

Identification and correction of patient-related and ventilator-related problems during mechanical ventilatory support are primary responsibilities of the RT. Under ideal circumstances, potential problems are identified before they occur, or before they can cause harm to the patient. Potential problems with the patient include anxiety, agitation, altered mental status, fighting the ventilator, hypoxemia, hypoventilation, and development of metabolic acidosis. The patient may experience acute changes in respiratory rate, heart rate, blood pressure, and CO.

Other common patient-related problems include excessive secretions, bronchospasm, and other causes of decreased compliance or increased resistance. Recognition of signs of pneumothorax, pneumomediastinum or subcutaneous emphysema, airway malfunction or leaks, and chest tube leaks should lead to prompt attention to the problem.

Problems associated with the ventilator include leaks or malfunctions in the system, inappropriate ventilator settings (including trigger sensitivity and inspiratory flow rate),

Box 51-14 Causes of Sudden Respiratory Distress in a Patient Receiving Ventilatory Support

PATIENT-RELATED CAUSES
- Artificial airway problems
- Movement of endotracheal tube
- Cuff herniation
- Cuff leak
- Kinking of endotracheal tube
- Foreign body
- Transesophageal fistula
- Innominate artery rupture
- Malpositioned nasogastric tube
- Secretions
- Bronchospasm
- Pneumothorax
- Pulmonary edema
- Pulmonary embolism
- Acute hypoxemia
- Blood in endotracheal tube
- Dynamic hyperinflation
- Abnormal respiratory drive
- Alteration in body posture
- Drug-induced problems
- Abdominal distention
- Agitation

VENTILATOR-RELATED CAUSES
- Ventilator malfunction
- Circuit malfunction
- Leaks or disconnects
- Condensate
- In-line nebulizers
- Inadequate ventilatory support
- Patient-ventilator asynchrony

From Tobin MJ, Alex CJ, Fahey PJ: Fighting the ventilator. In Tobin MJ, editor: Principles and practice of mechanical ventilation, New York, 2006, McGraw-Hill.

Box 51-15 Steps for Managing Sudden Distress in a Patient Receiving Ventilatory Support

1. Remove the patient from the ventilator.
2. Initiate manual ventilation with 100% O_2.
3. Patient improvement indicates that the ventilator is the cause of distress.
4. Lack of improvement indicates the problem is within the patient.
5. If death appears imminent, consider and manage the most likely causes, check for airway obstruction (by passing a suction catheter), a dislodged endotracheal tube, or a pneumothorax.
6. If death is not imminent, wait until the patient's condition is stable before attempting a more detailed assessment including a chest radiograph.

Modified from Tobin MJ, Alex CJ, Fahey PJ: Fighting the ventilator. In Tobin MJ, editor: Principles and practice of mechanical ventilation, New York, 2006, McGraw-Hill.

Box 51-16 Pharmacologic Agents Used to Produce Sedation or Paralysis

I. Benzodiazepine tranquilizing agents
   A. Diazepam (Valium)
   B. Lorazepam (Ativan)
   C. Midazolam (Versed)
II. Sedative hypnotics and miscellaneous agents
   A. Sodium thiopental (Pentothal)
   B. Etomidate (Amidate)
   C. Haloperidol (Haldol)
   D. Propofol (Diprivan)
   E. Dexmedetomidine (Precedex)
III. Narcotic analgesics
   A. Morphine
   B. Fentanyl (Sublimaze)
IV. Neuromuscular blocking agents
   A. Nondepolarizing (competitive)
      1. Steroidal agents
         Pancuronium (Pavulon)
         Pipecuronium (Arduan)
         Rocuronium (Zemuron)
         Vecuronium (Norcuron)
      2. Benzylisoquinolinium esters
         Atracurium (Tracrium)
         Cisatracurium (Nimbex)
         Doxacurium (Nuromax)
         Metocurine (Metubine)
         Mivacurium (Mivacron)
         Tubocurarine (Tubarine)
   B. Depolarizing
      1. Succinylcholine (Anectine, Quelicin)
      2. Decamethonium (Syncurine)

development of auto-PEEP, and improper humidification. Box 51-14 lists causes of sudden respiratory distress in patients receiving mechanical ventilatory support. Box 51-15 lists steps for managing sudden respiratory distress. Table 51-7 summarizes troubleshooting of the patient-ventilator system.

If medical and mechanical problems have been excluded and the patient continues to fight the ventilator or exhibit high levels of agitation or distress, sedation should be considered. Agents commonly used for sedation in the ICU include benzodiazepines (lorazepam, midazolam), opiates (fentanyl, morphine), haloperidol, and propofol.

Pharmacologic paralysis should be considered only when no other alternatives are effective. The one exception to this guideline is the patient presenting with severe ARDS (PaO_2/FiO_2 <100 mm Hg). In order to gain control of the patient's physiologic status it is now recommended to paralysis these patients for up to 48 hours. The use of neuromuscular blocking agents can mask other patient problems, and ventilator malfunction or disconnection in the care of a paralyzed patient can be catastrophic. In addition, some patients receiving neuromuscular blocking agents in the ICU may experience prolonged neuropathy. Pharmacologic agents used to produce sedation or paralysis in the ICU are listed in Box 51-16.

TABLE 51-7

Troubleshooting the Patient-Ventilator System

Clue to Problem	Possible Cause	Corrective Action
Decreased minute ventilation or V_T	Leak around endotracheal or chest tube	Check all connections for leaks
	Decreased patient-triggered respiratory rate	Evaluate patient
		Check sensitivity
		Measure auto-PEEP
		Increase set rate
		Change mode
	Decreased lung compliance	Evaluate patient
	Airway secretions	Clear airway of secretions
	Altered settings	Check patient-ventilator system
	Malfunctioning volume monitor	Check with external respirometer
Increased minute ventilation or V_T	Increased patient-triggered respiratory rate	Check respiratory rate
		Check sensitivity
		Change mode
	Altered settings	Check patient-ventilator system
	Hypoxia	Evaluate patient
		Consider ABG and SpO_2 values
	Increased lung compliance	Decrease pressure
		Decrease inspiratory time
	Malfunctioning volume monitor	Check with external respirometer
Change in respiratory rate	Altered setting	Check patient-ventilator system
	Increased metabolic demand	Evaluate patient
	Hypoxia	Evaluate patient
		Consider ABG and SpO_2 values
Sudden increase in peak airway pressure	Coughing	Alleviate uncontrolled coughing
	Airway secretions or plugs	Clear airway secretions
	Ventilator tubing kinked or filled with water	Check for kinks and water
	Changes in patient position	Consider repositioning patient
	Endotracheal tube in right main stem bronchus	Verify position
	Patient-ventilator asynchrony	Correct asynchrony
		Check for adequate peak flow
		Verify with waveforms
	Bronchospasm	Identify cause and treat
	Pneumothorax	Insert chest tubes
Gradual increase in peak airway pressure	Diffuse, reactive, or obstructive process	Evaluate for problems, such as atelectasis, increasing lung water, bronchospasm
Sudden decrease in peak airway pressure	Volume loss from leaks in the system	Check patient-ventilator systems for leaks
		Verify with waveforms
		Check for active inspirations
		Evaluate patient
FiO_2 drift	O_2 analyzer error	Calibrate analyzer
		Change O_2 sensor
	Blender piping failure	Correct failure
	O_2 source failure	Correct failure
	O_2 reservoir leak	Check ventilator reservoir
I : E ratio too high or too low	Altered inspiratory flow	Check flow setting and correct
	Alteration in other settings that control I : E ratio	Check settings and correct
	Alteration in sensitivity setting	Check setting and correct
	Airway secretions (pressure ventilator)	Clear airway of secretions
	Subtle leaks	Measure minute ventilation
Inspired gas temperature too high	Addition of cool water to humidifier	Wait
	Altered settings	Correct temperature control setting
	Adding cool gas by small-volume nebulizer treatment	Turn off heater during treatment
	Thermostat failure	Replace heater
Changes in PEEP	Change in V_T	Adjust PEEP level
	Change in compliance	Adjust PEEP level
	Altered settings	Check settings and correct
Changes in static pressure	Changes in lung compliance	Evaluate patient and correct if possible
Changes in ventilator setting	Changes in these settings resulting from deliberate or accidental adjustment of dials or knobs	Determine whether current settings are the intended ones

Modified from Martz K, Joiner JW, Shepherd RM: Management of the patient-ventilator system: a team approach, ed 2, St. Louis, 1994, Mosby.

SUMMARY CHECKLIST

- Caregivers must be experienced at filtering the noise from the changes in monitored variables that require attention. Caregivers need to recognize false alarms. They also need to discriminate real pathophysiologic changes from normal physiologic variations and from variations inherent in the data.
- Because only caregivers can make choices about altering care, caregivers continue to be the most important monitors.
- Monitoring of the respiratory system includes assessment of ventilation, gas exchange, and respiratory system mechanics and function.
- Ventilation is monitored by measurement of V_T, respiratory rate, and minute ventilation and by assessment of dead space and alveolar ventilation.
- Gas exchange is routinely monitored with ABG analysis and pulse oximetry. Derived values such as V_D/V_T, $P(A - a)O_2$ difference, PaO_2/FiO_2 ratio, shunt, and lung injury score can clarify the nature and severity of gas-exchange abnormality. Arterial $PaCO_2$ is the best index of alveolar ventilation.
- Respiratory system mechanics are routinely monitored by tracking peak pressure, P_{plat}, auto-PEEP, compliance, and resistance.
- When mechanically ventilating any patient, ideally, the tidal volume should be 4 to 8 ml/kg PBW and the plateau pressure should be less than 28 cm H_2O.
- Monitoring of transpulmonary pressure is becoming increasingly important in the management of patients with decreased chest wall compliance and patients with severe ARDS requiring high PEEP levels.
- Factors such as WOB, f/V_T, VC, MIP, and MVV can be extremely helpful in assessing the need to increase ventilatory support or in assessing the potential for weaning.
- Advanced monitoring techniques include EIT, ARM, lung stress and strain, stress index, and esophageal pressure monitoring.
- The most important responsibility of the RT in the ICU is monitoring of the patient-ventilator system.
- Monitoring of the patient-ventilator system includes overall assurance of the integrity and safety of the system. Monitoring requires complete knowledge of the ventilator settings; all aspects of ventilator function; the circuitry; airway status; gas exchange; ventilator graphics; lung mechanics; alarms; and the overall care, safety, and comfort of the patient.
- Acute changes in cardiac performance, cardiovascular status, or impulse conduction (ECG) can be life-threatening; some form of monitoring of the heart, vascular system, and ECG is necessary in the care of nearly all patients in the ICU.
- Hemodynamic monitoring requires the use of invasive pulmonary arterial, central venous, and arterial catheters. Values obtained with these monitoring lines must be carefully interpreted by experienced caregivers. All ICU patients should receive ECG monitoring.
- Monitoring of changes in neurologic status is extremely important and is more often overlooked than monitoring of other organ systems.
- The neurologic examination includes assessment of mental status, pupillary response, eye movements, corneal response, gag reflex, and respiratory rate and pattern and a general motor and sensory evaluation. ICP monitoring may be needed to detect or manage elevated ICP.
- Global index monitoring is calculation of an illness level score that is an estimate of the risk of mortality from numerous monitoring values. Illness scores are not used in the care plan for an individual patient, but scoring systems are widely used in clinical studies. The APACHE II system is among the most popular of these estimates.
- Troubleshooting the patient-ventilator system is aimed at identifying and correcting problems before they harm the patient.

CHAPTER 52

Discontinuing Ventilatory Support

ROBERT M. KACMAREK

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the relationship between ventilatory demand and ventilatory capacity as well as their relationship with ventilator discontinuance.
- List the factors associated with ventilator dependence.
- Explain how to evaluate a patient before attempting ventilator discontinuation or weaning.
- List acceptable values for specific weaning indices used to predict a patient's readiness for discontinuation of ventilatory support.
- Describe factors that should be optimized before an attempt is made at ventilator discontinuation or weaning.
- Describe techniques used in ventilator weaning, including daily spontaneous breathing trials, synchronized intermittent mandatory ventilation, pressure support ventilation, and other newer methods.
- Contrast the advantages and disadvantages associated with various weaning methods and techniques.
- Describe how to assess a patient for extubation.
- List the primary reasons why patients fail a ventilator discontinuance trial.
- Explain why some patients cannot be successfully weaned from ventilatory support.

CHAPTER OUTLINE

KEY TERMS

adaptive support ventilation (ASV)
airway occlusion pressure
automatic tube compensation (ATC)
continuous positive airway pressure (CPAP)
Intellivent
mandatory minute volume ventilation (MMV)
pressure support ventilation (PSV)
prolonged mechanical ventilation (PMV)
rapid, shallow breathing index (f/V_T)
spontaneous awaking trial (SAT)
spontaneous breathing trial (SBT)
synchronized intermittent mandatory ventilation (SIMV)

The purpose of mechanical ventilation is to support the patient until the disease state or condition that caused the need for support is alleviated or resolved. Ventilatory support can sustain life, but it cannot cure disease. Further, many complications and hazards are associated with mechanical ventilation. Consequently, ventilatory support should be withdrawn as soon as the patient is able to adequately resume spontaneous breathing.[1] All patients who are mechanically ventilated should be evaluated on a daily basis, beginning with the day of intubation, for their ability to wean from ventilatory support.[2,3] Frequently this evaluation is very quick, but it should be performed daily regardless of the patient's status.

After the problem or condition that caused the need for mechanical ventilation is resolved, most patients can be quickly and easily removed from ventilatory support. For example, for most patients who need mechanical ventilation as a result of drug overdose or severe asthma, for those who are recovering from postoperative anesthesia, and for those who have received ventilation for 72 hours or less, one may simply discontinue ventilation when the precipitating condition has resolved.[1,4] However, some patients require mechanical ventilation for longer periods. The term *ventilator dependent* is usually reserved for patients who need ventilatory support for lengthy periods (i.e., 2 weeks or more) or who have not responded to attempts at ventilator discontinuation. For these patients, a more prolonged ventilator discontinuation process is required.[1]

Ventilator discontinuation should be carefully timed. Premature removal from the ventilator may severely stress the cardiopulmonary system and delay the patient's recovery.[4] Premature discontinuation also exposes the patient to the hazards of reintubation. However, delays in discontinuing ventilation expose the patient to an increased risk of complications, including nosocomial pneumonia, myocardial infarction, and death.[4]

There are three basic methods for discontinuing ventilatory support[1]:

1. **Spontaneous breathing trials (SBTs)** alternating with mechanical ventilation
2. **Synchronized intermittent mandatory ventilation (SIMV)**
3. **Pressure support ventilation (PSV)**

Other techniques that may facilitate ventilator discontinuation include the use of volume-support ventilation (VSV); **adaptive support ventilation (ASV)/Intellivent**; automatic tube compensation (ATC); proportional assist ventilation (PAV), which is also known as *proportional pressure support* (PPS); neurally adjusted ventilatory assist (NAVA); and **continuous positive airway pressure (CPAP)**. However, little data exist that support the use of any of these techniques except for CPAP, which seems potentially beneficial during the ventilator discontinuation process.

Techniques for predicting when patients are ready for ventilator discontinuation and weaning have been studied extensively.[4] Many weaning indices designed to predict successful ventilatory discontinuation have been proposed. Despite this, there are no universally applicable indices for predicting success. Of all of the methods studied, SBTs and PSV have been shown to be the most effective methods for ventilator discontinuation and weaning. Evidence-based reviews recommend the use of at least daily SBTs.[1] Protocols for ventilator discontinuation administered by an interdisciplinary team of respiratory therapists, nurses, and physicians can be highly effective, and have been recommended.[1,4,5-9] Regardless of the method used, success is unlikely unless the precipitating problems that caused the ventilator dependency have been resolved.[1,4,9] After these problems are resolved, an organized plan or protocol should be followed, and variations should be based on each patient's response.[1,4,5]

Some patients cannot be successfully removed from mechanical ventilatory support. This group of ventilator-dependent patients poses clinical, economic, and ethical concerns.[10,11]

The term *weaning* has been used as a general term to refer to the process of discontinuing ventilatory support, regardless of the time frame or method involved. The term has also been used to refer to reductions in fractional inspired oxygen concentration (FiO_2), PEEP, and CPAP. Alternatively, the term

ventilator discontinuation has been used to refer to the process of disconnecting a patient from mechanical ventilatory support. For the purposes of this chapter, the term *weaning* is defined as a gradual reduction in the level of ventilatory support, whereas *discontinuing ventilatory support* refers to the overall process of removing the patient from the ventilator, regardless of the method used. In general, patients who are being considered for removal from ventilatory support fall into one of five categories:

1. Those for whom removal is quick and routine, which is normally the vast majority of ventilated patients
2. Those who need a more systematic approach to discontinuing ventilatory support, which is normally about 15% to 20% of ventilated patients
3. Those who require days to weeks to wean from ventilatory support, which is usually less than 5% of ventilated patients
4. Those ventilator-dependent or "unweanable" patients, who compose less than 1% of patients who require ventilatory support
5. Those who have no chance for survival in whom the ventilator is discontinued while comfort measures are provided, normally referred to as terminal weaning.[12]

REASONS FOR VENTILATOR DEPENDENCE

Patients may require mechanical ventilation because of apnea, acute or impending ventilatory failure, or severe oxygenation problems that necessitate high levels of PEEP or CPAP. Regardless of the reason for initiating mechanical ventilation, patients remain dependent on the ventilator because of respiratory, cardiovascular, neurologic, or psychologic factors.[1]

Ventilatory Workload and Demand

Patients who need mechanical ventilation often have a ventilatory workload and demand that exceeds their ventilatory capacity. This is the most common cause of ventilator dependence.[1,4] The term *ventilatory workload* refers to the amount of work that the respiratory muscles are asked to perform to provide an appropriate level of ventilation. A patient's total ventilatory workload is primarily determined by the following: (1) the level of ventilation needed, (2) the compliance of the lungs and thorax, (3) the resistance to gas flow through the airways, and (4) any imposed work of breathing (WOB_I) due to ventilatory system mechanical factors.[1,4]

The level of ventilation required is determined by the following: (1) the metabolic rate; (2) the central nervous system (CNS) drive; and (3) the ventilatory dead space. Common causes of an increased demand for ventilation include increased carbon dioxide production (i.e., fever, shivering, agitation, trauma, or sepsis) and increased dead space (i.e., pulmonary emboli or chronic obstructive pulmonary disease [COPD]). Other common causes of increased ventilatory demand include metabolic acidosis, severe hypoxemia, pain, and anxiety.

Compliance is determined by the elastic nature of the lung–thorax system. Resistance is largely related to the nature of the conducting airways. Common causes of decreased lung compliance include atelectasis, pneumonia, pulmonary edema, acute lung injury, and acute respiratory distress syndrome. Thoracic compliance may be reduced because of obesity, ascites, or abdominal distention. Airway resistance increases with bronchospasm, excessive secretions, and mucosal edema.

Mechanical factors that can increase the work of breathing include artificial airways (i.e., endotracheal and tracheotomy tubes), partial obstruction of the airway, ventilator circuits, demand flow systems, auto-PEEP, and inappropriate ventilator flow and sensitivity settings. Factors that may increase ventilatory workload are summarized in Box 52-1.

Ventilatory Capacity

Ventilatory capacity is determined by CNS drive, ventilatory muscle strength, and ventilatory muscle endurance. Most patients who are being withdrawn from ventilatory support have a normal or an increased drive to breathe. Patients with neuromuscular disorders and those who are receiving sedatives, narcotics, or neuromuscular blocking agents may have a reduced drive to breathe or impaired neuromuscular transmission. Patients with metabolic alkalosis, hypothyroidism, and sleep deprivation also may have reduced ventilatory drive. Box 52-2 summarizes the factors that may reduce ventilatory drive.

Muscle strength is influenced by age, sex, muscle bulk, and overall health. Malnutrition, starvation, and electrolyte imbalances (especially involving calcium, magnesium, potassium, and phosphate) can lead to ventilatory muscle weakness. Critical illness myopathy, critical illness polyneuropathy, and the

Box 52-1 Factors That May Increase Ventilatory Workload

INCREASED VENTILATORY DEMAND: INCREASED LEVEL OF VENTILATION REQUIRED

- Increased CNS drive: hypoxia, acidosis, pain, fear, anxiety, and stimulation of J receptors (e.g., pulmonary edema)
- Increased metabolic rate: increased carbon dioxide production, fever, shivering, agitation, trauma, infection, and sepsis
- Increased dead space: COPD and pulmonary embolus

DECREASED COMPLIANCE

- Decreased lung compliance: atelectasis, pneumonia, fibrosis, pulmonary edema, and acute respiratory distress syndrome
- Decreased thoracic compliance: obesity, ascites, abdominal distention, and pregnancy

INCREASED RESISTANCE

- Increased airway resistance: bronchospasm, mucosal edema, and secretions
- Artificial airways: endotracheal tubes, tracheostomy tubes, and partial obstruction of the artificial airway or the patients airway
- Other mechanical factors: ventilator circuits, demand flow systems, and inappropriate ventilator flow or sensitivity settings

Box 52-2 Factors That May Reduce Ventilatory Drive

- Decreased $PaCO_2$ (respiratory alkalosis)
- Metabolic alkalosis
- Pain (visceral)
- Electrolyte imbalance
- Pharmacologic depressants (narcotics, sedatives)
- Fatigue
- Decreased metabolic rate
- Increased $PaCO_2$ associated with chronic carbon dioxide retention
- Neurologic or neuromuscular disease

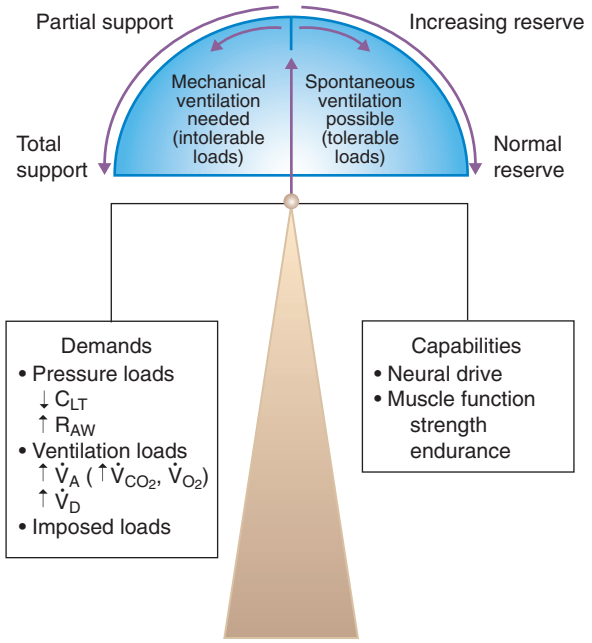

FIGURE 52-1 Ventilatory failure and the need for ventilatory support depend on the balance between ventilatory muscle demands (i.e., loads) and ventilatory muscle capabilities. C_{LT}, Lung–thorax compliance; *RAW,* airway resistance, $\dot{V}$, minute alveolar ventilation; $\dot{V}$, minute dead space ventilation. (Modified from MacIntyre NR: Respiratory factors in weaning from mechanical ventilatory support. Respir Care 40:244–259, 1995.)

prolonged use of neuromuscular blocking agents are major causes of the development of ventilatory muscle weakness in the intensive care unit (ICU).[13] Controlled ventilation for prolonged periods can result in ventilatory muscle discoordination and atrophy. Ventilatory muscle endurance is a function of energy supply versus demand. Energy supply is related to nutrition, perfusion, and cell use, whereas demand is related to the amount of work performed and is a function of minute ventilation, compliance, and resistance. Figure 52-1 summarizes the relationship between ventilatory demands and capabilities.

Global Criteria for Discontinuing Ventilatory Support

Success with the discontinuation of ventilatory support is related to the patient's condition in four main areas[1,2,3,4]:

1. Ventilatory workload versus ventilatory capacity
2. Oxygenation status
3. Cardiovascular function
4. Psychologic factors

Simply put, when ventilatory workload or demand exceeds ventilatory capacity, successful ventilator discontinuation is unlikely. Excessive ventilatory workload may lead to ventilatory muscle fatigue. When the ventilatory muscles fatigue, they must be rested for at least 24 hours to recover.[14] Ventilatory workload increases with decreased compliance, increased airway resistance, or an increased requirement for ventilation. Ventilatory capacity can be reduced by ventilatory muscle fatigue and by a loss of muscle strength and endurance.

Other factors that may contribute to ventilator dependence include inadequate arterial oxygenation, poor tissue oxygen delivery, myocardial ischemia, arrhythmias, low cardiac output, and cardiovascular instability. Neurologic problems that may contribute to ventilator dependence include decreased central drive to breathe and impaired peripheral nerve transmission. Psychologic issues that may contribute to ventilatory dependence include the fear of removal of the life-support system, anxiety, stress, depression, and sleep deprivation. Box 52-3 summarizes the major factors that contribute to ventilator dependence.

PATIENT EVALUATION

Careful patient assessment is required to determine which patients are ready to be removed from ventilatory support quickly, which patients may need a prolonged ventilator discontinuation phase, and which patients are not yet ready for the discontinuation of ventilatory support.

An important factor to consider as part of this assessment is the length of time that the patient has been receiving mechanical ventilation. In general, those who receive support for 72 hours or less often can be removed quickly from the ventilator.[15,16] Those who need a longer period of support may need a more prolonged approach. Current guidelines recommend that patients who need mechanical ventilation for more than 48 to 72 hours be carefully assessed to determine all of the possible causes of ventilator dependence.[1,4] These include the respiratory, cardiovascular, neurologic, and psychologic causes of ventilator dependence that are listed in Box 52-3. This recommendation is especially important for the care of patients who have had unsuccessful attempts at the discontinuation of ventilation.[1,4] Factors associated with readiness for the discontinuation of ventilatory support are summarized in Box 52-4.

The Most Important Criterion

The single most important criterion to consider when evaluating a patient for ventilator discontinuation or weaning is whether there has been significant alleviation or reversal of the disease state or condition that necessitated use of the ventilator in the first place.[1,4,9] The clinician should determine whether the patient's condition is improving, whether the initial reason for providing ventilatory support is improved or resolved, and

Box 52-3 Factors That Contribute to Ventilator Dependence

RESPIRATORY FACTORS

- Ventilatory workload exceeds ventilatory capacity
- Decreased compliance: lung or chest wall
- Increased resistance: artificial airways, bronchospasm, mucosal edema, secretions, and mechanical demand flow systems
- Increased dead space: pulmonary embolus and COPD
- Ventilatory muscle weakness or fatigue
- Oxygenation problems
  - ↓ $\dot{V}/\dot{Q}$
  - Increased shunt
  - ↓ DO_2
  - ↓ Oxygen extraction ratio

NONRESPIRATORY FACTORS

- Cardiovascular factors
- Myocardial ischemia
- Heart failure
- Hemodynamic instability, hypotension, and arrhythmias
- Neurologic factors
- Decreased or increased central drive to breathe
- Decreased peripheral nerve transmission
- Psychologic factors
- Fear and anxiety
- Stress
- Confusion or altered mental status
- Depression
- Poor nutrition
- Multiple-system organ failure
- Equipment shortcomings

Data from MacIntyre N: Respiratory factors in weaning from mechanical ventilatory support. Respir Care 40:244, 1995; Slutsky AS: Mechanical ventilation. American College of Chest Physicians' Consensus Conference. Chest 104:1833–1859, 1993; Pierson DJ: Nonrespiratory aspects of weaning from mechanical ventilation. Respir Care 40:263–270, 1995; MacIntyre NR, Cook DJ, Ely EW Jr, et al; American College of Chest Physicians; American Association for Respiratory Care; American College of Critical Care Medicine: Evidence-based guidelines for weaning and discontinuing ventilatory support: a collective task force facilitated by the American College of Chest Physicians; the American Association for Respiratory Care; and the American College of Critical Care Medicine. Chest 120(6 Suppl):375S–395S, 2001.

Box 52-4 Factors Associated With Readiness for the Discontinuation of Ventilatory Support

- Reversal or partial reversal of reason for instituting mechanical ventilation
- Good baseline functional status
- Ventilatory capacity that is capable of meeting ventilatory workload
- Good oxygenation status
- Good cardiovascular performance
- Good functional status of other organs and systems
- Short duration of the critical illness
- Short duration of mechanical ventilation
- No psychologic factors affecting current status

Modified from Pierson DJ: Nonrespiratory aspects of weaning from mechanical ventilation. Respir Care 40:263–270, 1995.

whether the patient's clinical condition is stable. The following specific questions for patient evaluation have been suggested[1]:

1. Is there evidence of improvement or reversal of the disease state or condition that caused the need for mechanical ventilation?
2. Is the patient's oxygenation status adequate? Specific criteria may include the following: PaO_2 of 60 mm Hg or more, FiO_2 of less than 0.40 to 0.50, PEEP of less than 5 to 8 cm H_2O; PaO_2/FiO_2 of 150 to 200 or more; and pH of 7.25 or more.
3. Is the patient medically and hemodynamically stable? Specific criteria may include the absence of acute myocardial ischemia or marked hypotension. Patients should have adequate blood pressure without vasopressor therapy or with only low-dose vasopressor therapy (i.e., less than 5 μg/kg/min of dopamine or dobutamine).
4. Can the patient breathe spontaneously? The patient must be able to breathe spontaneously and have a sufficient drive to breathe if ventilator discontinuation is being considered.

If the patient's condition is improving, if the alleviation or reversal of the precipitating disease state or condition has occurred, if the patient is capable of spontaneous breathing, and if the oxygenation status and hemodynamic values are stable, then ventilator discontinuation should be attempted.[1]

Weaning Indices

Mechanical ventilation is hazardous, and unnecessary delays in ventilator discontinuation increase the associated complication rate. Unfortunately, premature ventilator discontinuation may also cause serious problems, including difficulty with reestablishing the artificial airway and serious compromise of the patient's clinical status. Clinical judgment has been found to be a poor guide to determining whether a patient is ready for ventilator discontinuation, and more specific indicators have been sought. Specific indicators or weaning indices that clearly show whether a patient is ready to have the ventilator removed and help to avoid inappropriate ventilator discontinuation have been sought. Unfortunately, none of the current weaning indices are capable of predicting readiness for ventilator discontinuance with a high level of accuracy.[1,4]

Traditional discontinuation indices include the PaO_2/FiO_2 ratio, the alveolar-to-arterial partial pressure of oxygen difference [$P(A - a)O_2$], the maximum inspiratory pressure (MIP), the vital capacity (VC), the spontaneous minute ventilation (V_{Esp}), and the maximum voluntary ventilation (MVV).[3,17] Newer indices include the **rapid, shallow breathing index (f/VT)**, **airway occlusion pressure** ($P_{0.1}$), and measures of WOB.[1,4] Although all of these values can be useful, there are enormous discrepancies in the literature regarding their accuracy with regard to the prediction of "weanability."[1,4] With respect to the more traditional discontinuation indices, vital capacity and MIP can be highly variable, whereas minute ventilation, respiratory rate (f), and f/V_T tend to be more reliable.[1,4] However, these measures may not correlate well with

discontinuation success among all patients and especially among those receiving long-term ventilatory support, the elderly, and those with major pulmonary abnormalities.[1,4,18]

A comprehensive evidence-based review identified a possible role for 66 specific measurements as predictors of weaning success.[4] Of these, eight values were found to be the most useful for the prediction of successful ventilator discontinuation.[1,4] Useful predictive measures included spontaneous respiratory rate, spontaneous tidal volume, f/V_T, minute ventilation, MIP, $P_{0.1}$, $P_{0.1}$/MIP, and a combined index called the *CROP score* that included compliance, respiratory rate, oxygenation, and MIP.[1,4] Unfortunately, these measures all have limitations and relatively high false-positive predictions in specific settings.

It is doubtful that a single index will be found that can be used for consistent discrimination between discontinuation success and failure. Moreover, none of these traditional indicators alone has proved useful for the prediction of improvements in patient outcome or in the selection of a particular discontinuation method.[5] The likely explanation for this failure to identify any consistently powerful discontinuation predictor is that patients' conditions vary greatly and, for research purposes, clinicians already fully consider information from predictors when choosing patients for trials of the reduction or discontinuation of ventilatory support.[5,18]

Notwithstanding these limitations, the measurement of discontinuation indices in the difficult-to-wean patient may provide guidance with regard to the reasons that patients fail discontinuation trials. Many find it useful to trend these data on a daily basis for those patients who require lengthy weaning times.[10,15] Specific values for respiratory indices that are used to predict the successful discontinuation of ventilatory support are found in Table 52-1.

TABLE 52-1

Indices That Are Used to Predict the Success of Weaning and Ventilator Discontinuation

Measurement	Criterion
Oxygenation	
FiO_2	≤0.40 to 0.50
PEEP (cm H_2O)	≤5 to 8
PaO_2 (mm Hg)	≥60
SaO_2 (%)	≥90
SvO_2 (%)	≥60
PaO_2/PAO_2 ratio	≥0.35
PaO_2/FiO_2 ratio	>150 to 200
$P(A\text{-}a)O_2$ (mm Hg)	<350
$\dot{Q}_s\dot{Q}_T$ (% shunt)	<15% to 20%
No lactic acidosis, adequate $\dot{Q}_s\dot{Q}_T$, blood pressure	
Ventilation	
$PaCO_2$ (mm Hg)	<50
pH	≥7.35
Ventilatory Mechanics	
Respiratory rate (f) (breaths/min)	12 to 30
Tidal volume (V_T) (ml/kg)	>5
Vital capacity (VC) (ml/kg)	>10 to 15
Static compliance (ml/cm H_2O)	>25
f/V_T	<105
Respiratory Muscle Strength	
Maximum inspiratory force (MIF) (cm H_2O)	<–20 to –30
Ventilatory Drive (Demand)	
Minute ventilation ($\dot{V}_E$) for	
Normal PCO_2 (L/min)	<10
V_{DS}/V_T	<0.55 to 0.60
$P_{0.1}$ (cm H_2O)	<6
$P_{0.1}$/MIP	<0.30
Work of Breathing	
Spontaneous work of breathing	<1.6 kg·m/min (<0.14 kg·m/L)
Pressure-time index	<0.15 to 0.18
Ventilatory Reserve	
Maximum voluntary ventilation (MVV) (L/min)	>20; more than twice the $\dot{V}_E$

Data from MacIntyre NR, Cook DJ, Ely EW, et al: Evidence-based guidelines for weaning and discontinuing ventilator support: a collective task force facilitated by the American College of Chest Physicians, the American Association for Respiratory Care, and the American College of Critical Care Medicine. Chest 120:375S-395S, 2001; AHRQ publication no. 01-E010, Rockville, MD, 2000, Agency for Healthcare Research and Quality; American College of Chest Physicians: Chest 104:1833, 1993; Burns SM et al: Am J Crit Care 4:4, 1995; Sharar S: Resp Care 40:239, 1995; Bassili HR, Deitel M: JPEN J Parenter Enteral Nutr 5:161, 1981.

Ventilation

Increased thoracic cage movement during spontaneous breathing and asynchronous chest-wall-to-diaphragm movement are related to an increased workload that may lead to ventilatory muscle fatigue and failure. Tachypnea (i.e., more than 30 to 35 breaths/min in adults) is a sensitive marker of respiratory distress, but it can prolong intubation if it is used as an exclusive criterion. Irregular spontaneous breathing or periods of apnea indicate that the patient is at risk for weaning failure. Asynchronous and rapid, shallow breathing patterns—although not definitive—suggest respiratory decompensation.[18] However, decreased ventilatory variability over time (rate, V_T, minute ventilation) has been clearly shown to identify patients who will failure an SBT.[19,20]

The evaluation of patients for the presence of palpable scalene muscle use during inspiration, an irregular ventilatory pattern, palpable abdominal muscle tensing during expiration, and the inability to alter the ventilatory pattern on command can be helpful for the assessment of the potential for prolonged spontaneous ventilation. Patients with none of these signs have a very high probability of successful ventilator discontinuance. Patients with one or two of these signs usually need continued support. The presence of three or more of these signs can mean that the patient's condition is unstable and that the patient has a poor prognosis for ventilator removal.[21]

$P_{0.1}$ is the inspiratory pressure that is measured 100 milliseconds after airway occlusion.[1,4] The $P_{0.1}$ is effort independent, and it correlates well with central respiratory drive. Ventilator-dependent patients with COPD who have a $P_{0.1}$ of more than 6 cm H_2O tend to be difficult to wean.[1,4]

The f/V_T is the ratio of spontaneous breathing frequency (breaths/min) to tidal volume (liters), and it has been found to

be a good predictor of discontinuation success for many patients who need mechanical ventilation.[1,4,18] The f/V_T has less predictive ability for patients who need ventilatory support for longer than 8 days, and it may be less useful for predicting discontinuation success among elderly patients.[1,4] Despite these limitations, an f/V_T of less than 105 can be an accurate and early predictor of weaning outcome, and an f/V_T of 80 is associated with an almost 95% probability of successful discontinuation.[18] The ratio must be calculated during 1 minute of unsupported spontaneous breathing, and the addition of pressure support during measurement significantly reduces the predictive value of the ratio.[18]

RULE OF THUMB

Adult patients with spontaneous respiratory rates in excess of 35 breaths/min and tidal volumes of less than 5 ml/kg PBW are difficult to wean.

The $P_{0.1}$/MIP ratio has been found to be a good early predictor of discontinuation success,[1,4] and it may be more useful than the MIP by itself. The f/V_T also has been found to be a better predictor of discontinuation success than the MIP alone.[1,4] However, even with f/V_T of less than 105, as many as 20% of patients have false-positive results (i.e., they cannot be discontinued from ventilation despite a favorable index) as a result of unpredictable factors such as congestive heart failure, aspiration, other comorbidities or the development of a new pulmonary lesion. In addition, some patients can be successfully discontinued from ventilatory support despite poor f/V_T values (>105).

MINI CLINI

Calculating and Interpreting the Rapid, Shallow Breathing Index

PROBLEM: You measure the following spontaneous breathing values for two patients who are being considered for weaning from mechanical ventilation:

Patient	Rate (f) (breaths/min)	V_T (L)
A	32	0.28
B	28	0.42

For which patient is successful weaning least likely?

Solution: First, compute the rapid, shallow breathing index for each patient as follows:

Patient	Rate (f) (breaths/min)	V_T (L)	f/V_T
A	32	0.28	114
B	28	0.42	67

Patient A clearly exceeds the threshold criterion of 105 breaths/min per liter, whereas patient B falls well below this criterion. All else being equal, patient A is least likely to be successfully weaned.

WOB would seem to be an excellent way to gauge spontaneous ventilatory workload. Successful weaning has been found to be less likely among patients with spontaneous WOB levels of more than 1.6 kg/m/min (16 J/min) or 0.14 kg/m/L (1.4 J/L).[1,4] However, WOB may not be predictive of weaning success for specific patients.[1,4] This may be because WOB does not take into account ventilatory muscle capacity or fatigue. Consequently, WOB may be less accurate than other conventional discontinuation indices, and it is very difficult to measure at the bedside.

Oxygen cost of breathing (OCB) is the difference between oxygen consumption during spontaneous breathing and oxygen consumption during apnea (i.e., during full ventilatory support), which is determined as follows:

$$OCB = VO_{2sp} - VO_2 \text{ (controlled ventilation)}$$

After the OCB has been estimated, the relative proportion of oxygen consumed by the respiratory muscles as compared with the body as a whole can be calculated as follows:

$$\%VO_2\,(\text{Resp}) = (OCB/VO_{2sp}) \times 100$$

Both OCB and $\%VO_2$ have been correlated with the number of days required to wean patients. Patients with an OCB of 15% or less of the total VO_2 may be more likely to achieve discontinuation success.[1,4]

Pressure–time product (i.e., the area under the inspiratory pressure–time curve) and pressure–time index (PTI) may be the best measures of ventilatory workload of patients who are receiving mechanical support.[1] The PTI can be calculated as follows:

$$PTI = (\text{Mean inspiratory pressure}/MIP) \times T_i/T_{tot}$$

where MIP is maximum inspiratory pressure, T_i is the inspiratory time in seconds, and T_{tot} is the total respiratory cycle. The T_{tot} can be calculated by dividing 60 by the respiratory rate (f) (i.e., 60/f). A PTI of more than 0.15 to 0.18 has been associated with diaphragmatic fatigue, and a PTI of more than 0.15 cannot be sustained indefinitely.[1,4] There is currently no well accepted and reliable way to measure ventilatory muscle fatigue in patients who are receiving mechanical ventilation.

Oxygenation

Poor oxygenation status is associated with weaning failure. Arterial blood gas (ABG) analysis, pulse oximetry, and continuous mixed venous oximetry have been used to monitor and assess the oxygenation status of patients before and during a discontinuation trial. In general, a PaO_2 of more than 60 mm Hg (or of more than 55 mm Hg for patients with COPD with carbon dioxide retention) with an FiO_2 of less than 0.40 to 0.50 and a PEEP of 5 to 8 cm H_2O or less should be adequate for ventilator discontinuation. The PaO_2/FiO_2 ratio should be 150 to 200 mm Hg or more. With these values, a normal hemoglobin level, a normal oxygen saturation (SaO_2), and adequate cardiac output and tissue perfusion are assumed. Specific indices used to assess oxygenation status are found in Table 52-1.

Acid-Base Balance

Ideally the patient should have a normal acid-base balance (i.e., a pH of 7.35 to 7.45), and abnormalities in acid-base status have been corrected, if possible, before weaning. Patients with metabolic acidosis often have an increased ventilatory drive that can make weaning difficult. Patients who have metabolic alkalosis or those who have been mechanically hyperventilated for several days may have a reduced ventilatory drive. In these cases, a gradual method of discontinuing ventilatory support may be necessary.

Metabolic Factors

Metabolic factors primarily affect discontinuation in those patients who require long-term ventilatory support. Although nutritional factors are important for all patients, they are unlikely to affect discontinuation in those who only require short-term ventilatory support. Nutrition should be adequate to maintain respiratory muscle mass and contractile force. Feeding should be adjusted according to individual patient needs; most patients need 1.5 to 2.0 times their resting energy expenditure. In addition, protein intake should be between 1 and 1.5 g/kg per day. Excessive carbohydrate feeding can increase carbon dioxide production and may precipitate acute hypercapnic respiratory failure. Parenteral nutrition solutions that contain amino acid formulations (e.g., arginine/lysine) can cause metabolic acidosis and thus increase ventilatory demand. Metabolic rate can increase as a result of fever or sepsis. Increased WOB, shivering, seizures, and agitation can also increase oxygen demand and should be evaluated (see Chapter 23).

Renal Function and Electrolytes

Adequate renal function is required to maintain acid-base homeostasis, electrolyte concentrations, and fluid balance. The patient ideally should have an adequate urine output (i.e., more than 1000 ml/day), and there should be no inappropriate weight gain or edema.

Renal insufficiency can lead to metabolic acidosis, which increases respiratory drive. Electrolyte disorders can impair ventilatory muscle function. Key electrolytes should be normal (see Chapter 17 for details). Fluid overload can lead to congestive heart failure and pulmonary edema, which may impair pulmonary gas exchange.

Cardiovascular Function

Adequate cardiovascular function is needed to provide sufficient oxygen delivery to the tissues. Cardiac rate and rhythm and blood pressure should be evaluated. Tachycardia (i.e., a heart rate of more than 100 beats/min) and bradycardia (i.e., a heart rate of less than 60 beats/min) should be controlled. The presence of arrhythmias, hypotension (i.e., a blood pressure of less than 90/60 mm Hg), and severe hypertension (i.e., a blood pressure of more than 180/110 mm Hg) should be evaluated carefully before the discontinuation of ventilatory support is considered.

TABLE 52-2

Criteria for Confirming Cardiovascular Stability

Criterion	Normal Value	Values That May Be Inconsistent With Weaning
Heart rate (beats/min)	60 to 100	<60, >120
Blood pressure (mm Hg)	90/60 to 150/90	<90/60, >180/110
$\dot{Q}_t$ (L/min)	4 to 8	<4, >8
Cardiac index ($L/min^{-1} \cdot m^2$)	2.5 to 4	<2.1
Cardiac rhythm	No major arrhythmias present	Tachycardia, bradycardia, multiple premature ventricular contractions, heart block
Hemoglobin (g/dl)	12 to 15	Anemia, <8
Hematocrit	40% to 50%	<35%
No angina present		
No lactic acidosis		

Cardiac output and index measurements as well as central venous pressure measurements may be helpful for the evaluation of cardiovascular function. Left ventricular dysfunction, myocardial ischemia, and cardiovascular instability are associated with decreased discontinuation success.[1,4] Table 52-2 provides criteria for confirming cardiovascular stability.

Psychologic Factors and Central Nervous System Assessment

Adequate CNS function is needed to ensure stable ventilatory drive, adequate secretion clearance (i.e., coughing and deep breathing), and the protection of the airway (i.e., gag reflex and swallow). In addition, the level of consciousness, dyspnea, anxiety, depression, and motivation can affect discontinuation success.[1,4]

The patient ideally is awake and alert, free of seizures, and able to follow instructions. Patients should have an intact central drive to breathe and peripheral nerve function. Brainstem strokes, electrolyte disturbances, sedation, neuromuscular blocking agents, and narcotic drugs can impair the central neurologic control of ventilation. Mental status is a good predictor of discontinuation success, and patients who are not alert are at risk for upper airway obstruction, aspiration, and secretion retention. Obtunded patients should, at a minimum, have an adequate gag reflex and cough. Decreased levels of consciousness are associated with aspiration after extubation. The level of consciousness is affected by the use of narcotic, sedative, and analgesic drugs. Drugs with CNS depressant effects should be discontinued, if possible, before the withdrawal of ventilatory support and extubation. Protocols to reduce sedation and the daily cessation of sedative drugs may reduce weaning time[7,22,23] (see the section on Spontaneous Awaking Trials). Neuromuscular blocking agents to allow for controlled ventilation should only be administered when absolutely necessary to insure

patient-ventilator interaction and for the shortest period possible.[24]

Psychologic factors may be among the most important nonrespiratory contributing factors that lead to ventilator dependence.[1,4] Fear, anxiety, pain, and stress should be minimized, and frequent communication among the staff, the patient, and the patient's family can be helpful. Box 52-5 summarizes nonrespiratory factors that affect discontinuation success.

Integrated Indices

Many factors are associated with discontinuation success. Integrated indices improve prediction by combining several measures of ability to breathe without ventilatory support. Current examples of integrated indices include the CROP score, the Adverse Factor/Ventilator Score, the weaning index, and the Burns Weaning Assessment Program.[1,4] The CROP score combines measures of ventilatory load, respiratory muscle strength, and gas exchange.

The Adverse Factor/Ventilator Score combines ratings of 15 adverse factors, including hemodynamic values, infection, nutrition, and neurologic/psychiatric state, with ratings of six ventilator factors, including FiO_2, compliance, minute ventilation, and rate.[1,4] The weaning index combines measures of ventilatory strength, endurance, and efficiency of gas exchange. A weaning index of less than 4 suggests successful discontinuation from mechanical ventilation. The Burns Weaning Assessment Program is a 26-item assessment that combines 12 general and 14 respiratory factors into a single score.[1,4] Although integrated indices appear promising, none of these indices has emerged as superior for use in diverse patient populations. Despite the success of these integrated indices in very specific settings, the best approach to determining if a patient can be successfully discontinued from ventilatory support is the patient's performance on a spontaneous breathing trial. All patients should be assessed daily, and their ability to breathe spontaneously should be the primary variable to determine if the ventilator can be discontinued.

Box 52-5 Nonrespiratory Factors That Affect Weaning

- Acid-base status
- Metabolic alkalosis: decreased ventilatory drive
- Metabolic acidosis: increased ventilatory demand
- Mineral and electrolyte balance
- Hypophosphatemia: ventilatory muscle weakness
- Hypomagnesemia: ventilatory muscle weakness
- Hypokalemia: ventilatory muscle weakness
- Hypothyroidism: decreased ventilatory drive and impaired muscle function
- Stability of other organs and systems
- Cardiac: excessive preload (e.g., overall volume overload, increased preload on discontinuation of positive pressure ventilation) and impaired contractility
- Renal: renal insufficiency and metabolic acidosis
- Hepatic: encephalopathy and protein synthesis
- Gastrointestinal: stress-related hemorrhage and ability to take enteral nutrition
- Neurologic: level of consciousness, ability to protect the airway, and clear secretions
- Effects of drugs: narcotics, benzodiazepines, other sedatives and hypnotics, muscle relaxants, and aminoglycosides
- Nutritional status
- Ventilatory muscle function
- Ventilatory drive
- Immune defense system
- Psychologic and motivational factors

Modified from Pierson DJ: Nonrespiratory aspects of weaning from mechanical ventilation. Respir Care 40:289, 1995.

MINI CLINI

Assessment of Readiness for a Spontaneous Breathing Trial

PROBLEM: A 64-year-old man who underwent a lung resection and who has a long history of COPD is now 24 hours postoperative, and he is being evaluated for readiness for an SBT. The data currently available for this patient include the following:

- Ventilator settings:
  - Mode pressure support 10 cm H_2O
  - Average V_T 450 ml (6.5 ml/kg ideal body weight)
- Respiratory rate of 28 breaths/min
- FiO_2 of 0.40
- PEEP of 5 cm H_2O

The patient is alert and cooperative.

The patient is not receiving any vasoactive drugs, and he is only receiving intermittent sedatives and narcotics.

Should this patient be placed on an SBT?

Solution: By 24 hours, the patient should have initially recovered from the effects of the surgical procedure. The patient's ventilator settings are offering minimal support. Because the patient is alert and able to breathe spontaneously and because he requires only intermittent sedatives or narcotics, it is very appropriate to perform an SBT on this patient at this time.

Evaluation of the Airway

The ability to maintain a patent natural airway and the likelihood of aspiration should be evaluated as a part of the process of discontinuing ventilatory support. It is important for the clinician to separate the decision to discontinue ventilatory support from the decision to extubate. The clinician must also be aware that most weaning indices do not evaluate airway patency or protection (see the section on Extubation). The inability to protect or maintain the natural airway is a clear contraindication to extubation. Some patients who can be successfully removed from a ventilator should not be extubated. Although controversial, evaluating if gas moves freely around the ETT with the cuff deflated may identify an increased likelihood of postextubation airway obstruction. If auscultation of the lateral neck does not identify gas flow around the EET, extubation should be delayed until airway edema is properly

treated with steroids. Tracheotomy may be considered for patients who need artificial airways for an extended period.

Tracheotomy may improve patient comfort, allow for more effective suctioning, decrease airway resistance, enhance mobility, and allow the patient to eat and speak. Some patients also need high levels of sedation to tolerate the endotracheal tube. Consequently, tracheotomy should be considered for the care of patients who are likely to benefit and for those who need prolonged mechanical ventilatory support. See Chapter 36 for details about airway management and extubation.

Other patients with good airway patency and protection may be unable to maintain spontaneous breathing for prolonged periods without assistance.[29] These patients may be candidates for noninvasive ventilation (NIV) after extubation; see Chapter 49 for details.[25,26]

PREPARING THE PATIENT

Optimizing the Patient's Medical Condition

Before the removal of ventilatory support is attempted, the patient's oxygenation status, ventilation, cardiovascular status, and overall medical condition should be optimized. Disease-imposed ventilatory load is minimized with the management of infection, bronchospasm, and airway edema. Bronchodilator therapy should be maximized and the appropriate use of anti-inflammatory agents considered. Techniques to facilitate secretion clearance (e.g., suctioning, adequate humidification, bronchial hygiene techniques), good nutrition, and optimal positioning should be used. The patient should be rested and not fatigued or sleep deprived, which can be common in the ICU. The patient should be allowed to sleep at night while maintained on a level of ventilatory support that ensures ventilatory muscle rest.[27] Intrinsic PEEP during mechanical ventilation may increase trigger work, and small amounts of PEEP or CPAP can help to overcome this problem.[1,2] Box 52-6 lists factors that should be optimized before ventilatory support is discontinued.

Patients' Psychologic and Communication Needs

As many as 47% of patients who spend more than 5 days in an ICU may experience psychologic disturbances.[27] The cause may be the stress of critical illness, the interruption of nighttime sleep, or the use of sedatives, tranquilizers, hypnotics, narcotics, and other drugs that affect the CNS.[27] The patient's environment should be optimized, anxiety and depression should be evaluated, and communication should be maximized.

Environmental considerations that may improve the patient's sense of well-being and outlook include reducing extraneous noise and providing clocks, calendars, pictures, a radio, a television, and, if possible, a room with windows. Daily mobility should be considered, including getting the patient up in a chair or placing the patient in the hall in a chair. Patients whose condition has been stable can sometimes even be helped to walk

Box 52-6 Factors That Should Be Optimized Before the Discontinuation of Ventilatory Support Is Attempted

- Oxygenation
- PaO_2 and SaO_2
- Anemia, if present
- Atelectasis, pneumonia, and acute pulmonary disease
- Ventilation
- Humidification
- Secretion clearance (e.g., bronchial hygiene, suctioning)
- Bronchodilator therapy
- Respiratory alkalosis
- Imposed WOB
- Respiratory muscle fatigue or atrophy
- Acid-base balance and electrolytes
- Metabolic acidosis (e.g., lactic acidosis, ketoacidosis)
- Metabolic alkalosis (e.g., decreased serum potassium or chloride ions, nasogastric tube, vomiting)
- Low phosphate level
- Low magnesium level
- Cardiac and cardiovascular status
- Blood pressure and cardiac output
- Arrhythmias, if present
- Myocardial ischemia
- Left ventricular function
- Renal factors
- Kidney function
- Fluid balance
- Fever, infection, or sepsis
- Pain (i.e., minimize without oversedation)
- Sleep deprivation
- Drugs (narcotics, sedatives, tranquilizers, hypnotics, aminoglycosides, and neuromuscular blocking agents can depress or block the ventilatory drive)
- Psychologic status
- Level of consciousness (e.g., delirium, coma)
- Agitation
- Motivation
- Fear and anxiety
- Psychologic dependence on the ventilator
- Depression
- ICU psychosis
- Hypothyroidism
- Nutritional factors
- Overfeeding (i.e., increased carbon dioxide production)
- Malnutrition or protein loss
- Consider a high-fat, low-carbohydrate diet to minimize the production of carbon dioxide
- Gastrointestinal bleeding or obstruction
- Abdominal distention or ascites
- Time of day (avoid evenings, nights, and shift changes)
- Adequate staffing
- Interruptions and disruptions
- Technical factors

Modified from Hess DR, Kacmarek RM: Essentials of mechanical ventilation, ed 2, New York, 2003, McGraw Hill; Kacmarek RM, Mack CW, Dimus S: Essentials of respiratory care, ed 4, St. Louis, 2005, Mosby; and Tobin MJ: Principles and practice of mechanical ventilation, ed 2, McGraw Hill, 2006, New York.

with the use of an E cylinder for oxygen, a transport ventilator or ICU ventilator with appropriate battery support, and two or more health care workers for support.

A method for the patient to communicate with staff and visitors should be devised, if possible. Writing tablets, picture boards, and alphabet boards have been used effectively by patients to communicate with staff and visitors.

Anxiety and agitation should be minimized, and communication and encouragement may be helpful. The patient should be told what is planned and be given some control over the situation. Patients should be asked to participate and help in the weaning process. Depression or a lack of motivation may increase weaning time. If depression is present, assessment and treatment by an appropriate health care provider should be considered.

CAREGIVER PREPARATION

Just like careful patient preparation, caregiver preparation should occur before the onset on an SBT, the respiratory therapist needs to be properly prepared to perform the SBT. The orders should be checked and equipment should be gathered. Specifically, oxygen therapy, NIV, and reintubation equipment should be gathered and readied for use. The patient should be carefully assessed, the ventilator alarms properly set, and the patient emotionally prepared for the SBT. Patients should be aware that the SBT is a trial and that they may fail the trial. The patient should NOT consider a failed trial as a step backwards but as a part of a process to become independent of the ventilator and should know that a number of SBTs are commonly necessary before the ventilator is discontinued.

METHODS

There are three basic methods of discontinuing ventilatory support[1,4]:

1. Spontaneous breathing trials (via the mechanical ventilator or with a T-piece) alternating with mechanical ventilatory support
2. SIMV
3. PSV

Box 52-7 summarizes evidence-based criteria and related conclusions regarding methods for ventilator discontinuation.

Box 52-7 Agency for Healthcare Research and Quality Summary of Evidence for Criteria for Weaning from Mechanical Ventilation

- Differences in clinicians' intuitive thresholds for the reduction or discontinuation of ventilatory support have a far greater impact on the failure of SBTs and on reintubation than do modes of discontinuation. When clinicians set a high threshold, many patients who could tolerate weaning remain on mechanical support longer than is necessary.
- There may be an interaction between the threshold and the mode of discontinuation; in other words, one mode may be superior when the threshold is high, whereas another may be superior when the threshold is low.
- Research to date suggests that the best answer to the question of when to start discontinuation trials is to develop a protocol that can be implemented by nurses and respiratory therapists that begins testing for the opportunity to reduce support immediately after intubation and reduces support at every opportunity.
- For stepwise reductions in mechanical support, pressure support mode or multiple daily spontaneous breathing trials are superior to SIMV.
- For trials of unassisted breathing, low levels of pressure support may be beneficial in select patients.
- There may be substantial benefits to the use of noninvasive positive pressure ventilation immediately following discontinuation and extubation.
- After cardiac surgery, early extubation is achieved with a variety of interventions and ICU protocols.
- Although steroids can reduce postextubation stridor in children, the impact of steroids on reintubation in children and adults remains uncertain.
- Most theoretically plausible predictors of discontinuation and extubation success have no predictive power. Those with some predictive power include the rapid, shallow breathing index, which has been most intensively studied, the $P_{0.1}$/MIP ratio, and the CROP index. However, these are relatively weak predictors of discontinuation success.
- Tests are rarely useful for increasing the probability of discontinuation success; on occasion, the results can lead to moderate increases in the probability of success.
- In general, discontinuation predictors are probably found to perform poorly because physicians have already considered the results when they select patients for studies.

Modified from the Agency for Healthcare Research and Quality: Evidence report/technology assessment Number 23 (AHRQ Publication No. 01-E010), Rockville, Md, 2000, Agency for Healthcare Research and Quality.

Rapid Ventilator Discontinuation

When the precipitating disease state or condition that necessitates support has been significantly alleviated or reversed, most patients can be rapidly removed from mechanical ventilation.[1,4] These patients typically have acceptable blood gas levels with mechanical ventilation, adequate myocardial function, and no underlying cardiovascular, pulmonary, neurologic, or neuromuscular disorders. After a careful evaluation, patients in stable condition who have been treated with a ventilator for less than 72 hours and who have a good spontaneous respiratory rate and minute ventilation may undergo an SBT on the ventilator or with a T-piece for 30 to 120 minutes.[1,4,28] If the patient does well, the endotracheal tube can then be removed if there is no reason to maintain an artificial airway.

Today, most SBTs are performed with the patient attached to a ventilator that is set on zero PSV and zero CPAP. This allows for a stable FiO_2 and ongoing monitoring. Others have recommended treating the patient with a low level of PSV (i.e., 5 to 7 cm H_2O) to overcome the resistance caused by the ventilator circuit, the demand flow system, and the artificial airway.[1,4] Others may prefer simply using CPAP (i.e., 5 to 7 cm H_2O). These methods have the advantage of allowing the clinician to maintain ventilator alarm settings that can provide a margin of

safety in the event of apnea or severe hypoventilation. Low levels of CPAP may be useful for maintaining lung volumes and overcoming intrinsic PEEP. Some experts recommend PSV in combination with PEEP or CPAP.[2] However, the most widely accepted guidelines recommend a simple spontaneous breathing trial for the first SBT using the ventilator at zero CPAP and zero PEEP or a T-piece.[1,4]

Patients Who Need Progressive Weaning of Ventilatory Support

Patients who have been receiving mechanical ventilation for more than 72 hours and those with marginal oxygenation, ventilatory, cardiovascular, or medical statuses may need a more prolonged period for ventilator discontinuation.[1,4] The most common method for accomplishing this is SBTs interspersed with continued ventilatory support.

Spontaneous Breathing Trials

The oldest discontinuation method is an SBT via either the ventilator or T-piece, which allows for spontaneous breathing several times per day interspersed with periods of mechanical ventilatory support. For gradual weaning, initial SBTs may last only 5 to 10 minutes. Full ventilatory support is resumed for a 1- to 4-hour rest period in the assist/control or pressure-support mode. The time off of the ventilator is gradually increased until the patient is able to stay off of the ventilator for an extended period. SBTs can progress rapidly to ventilator removal.

When weaning is very difficult, the process can last days or even weeks. When a T-piece is used instead of the ventilator, the patient must be more carefully monitored, because none of the ventilator alarms are active during the SBT. If distress occurs, mechanical ventilation is resumed. In no case should the patient be overstressed during the SBT, because exhaustion can delay weaning.[2,8] An example of an SBT is presented in Box 52-8.

Box 52-8 Steps for Spontaneous Breathing Trials

1. Prepare the patient psychologically.
2. Set the ventilator at zero PSV and zero CPAP.
3. Maintain the FiO_2 at the baseline FiO_2 that the patient is receiving.
4. Monitor the patient's appearance, pulse, oxygen saturation measured by pulse oximeter, and blood pressure; observe the cardiac monitor for arrhythmia. Use the ventilator to monitor respiratory rate, tidal volume, and minute ventilation.
5. If the patient tolerates the SBT for 30 to 120 minutes, consider extubation.
6. If the patient does not tolerate the SBT for at least 30 minutes, reestablish the ventilator settings, and allow the patient to rest for at least a few hours before reattempting another SBT.
7. If repeated SBTs over multiple days are needed, individualize the patient's schedule, depending on his or her condition. In general, the weaning schedule should be stopped during the night so that the patient can rest and sleep.

Advantages of SBTs include the early and frequent testing of the patient's ability to breathe spontaneously without support. The use of SBTs several times per day has become unpopular, because it requires a great deal of time on the part of ICU staff, and a single daily SBT seems to be just as effective for most patients.[1,4] PSV and CPAP are sometimes used during the SBT, and patients who tolerate spontaneous breathing with a low level of PSV (i.e., 7 cm H_2O or less) should be able to tolerate extubation.[29] Current recommendations suggest a single daily trial of spontaneous breathing may be preferable to other methods of weaning.[1,4] Results of randomized, controlled studies have shown SBTs to be faster than SIMV and at least as effective as PSV.[5,28,30] Furthermore, performing an SBT one time per day is as effective as performing SBTs several times per day, and 30-minute trials are as effective as 120-minute trials.[1,4]

A collective task force representing the American College of Chest Physicians, the American Association for Respiratory Care, and the American College of Critical Care Medicine published evidence-based guidelines for weaning and discontinuing ventilatory support.[1] These guidelines were based in part on a comprehensive review of the evidence collected under the direction of the U.S. Agency for Health Care Policy and Research.[4]

The task force made 12 specific recommendations (Box 52-9). These include the regular use of formal and carefully monitored SBTs to guide clinical decision making regarding the discontinuation of ventilatory support.[1] Specifically, the task force recommended that, for the care of patients who need mechanical ventilation for more than 24 hours, a search for all possible causes of ventilatory dependence should be conducted and an attempt should be made to reverse or optimize each condition. Spontaneously breathing patients with evidence of reversal of the underlying condition that necessitated the ventilatory support, adequate oxygenation, and hemodynamic stability should be assessed with an SBT. Table 52-3 lists criteria to be used when determining whether patients who are receiving high levels of ventilatory support can be considered for SBTs.

A daily screen that includes the assessment of oxygenation, PEEP, and the use of vasopressors and sedatives should be conducted. A PaO_2/FiO_2 ratio of more than 150 to 200, a PEEP value of less than 5 to 8 cm H_2O, and a lack of a continuous infusion of vasopressors or sedatives (i.e., less than 5 mg/kg/min of dopamine) were good predictors of successful extubation and survival.[31]

The formal SBT may be performed in combination with low levels of PSV (i.e., 5 to 7 cm H_2O), CPAP (i.e., 5 cm H_2O or less), or automatic tube compensation applied to just offset the imposed WOB caused by the endotracheal tube.[1] During the SBT, the patient is carefully observed for breathing comfort, anxiety, agitation, dyspnea, or diaphoresis. Respiratory rate, heart rate, blood pressure, and SpO_2 are monitored. The SBT is terminated if signs of distress are observed, including the following:

- Agitation, anxiety, diaphoresis, or a change in mental status
- A sustained respiratory rate of more than 35 breaths/min
- A sustained SpO_2 of less than 90%

Box 52-9 Evidence-Based Guidelines for Weaning and Discontinuing Ventilatory Support

Recommendation 1: For patients who need mechanical ventilation for more than 24 hours, a search for all of the causes that may be contributing to ventilatory dependence should be undertaken. This is particularly true for the patient who has failed attempts at withdrawing the mechanical ventilator. Reversing all possible ventilatory and nonventilatory issues should be an integral part of the ventilatory discontinuation process.

Recommendation 2: Patients who are receiving mechanical ventilation for respiratory failure should undergo a formal assessment of discontinuation potential if the following criteria are satisfied:

1. Evidence for some reversal of the underlying cause for respiratory failure;
2. Adequate oxygenation (e.g., PaO_2/FiO_2 ratio of more than 150 to 200; requiring PEEP of no more than 5 to 8 cm H_2O; FiO_2 of no more than 0.4 to 0.5) and pH of more than 7.25;
3. Hemodynamic stability as defined by the absence of active myocardial ischemia and the absence of clinically significant hypotension (i.e., a condition that necessitates no vasopressor therapy or therapy with only low-dose vasopressors such as dopamine or dobutamine [less than 5 μg/kg/min]); and
4. The capability to initiate an inspiratory effort. The decision to use these criteria must be individualized. Some patients who are not satisfying all of these criteria (e.g., patients with chronic hypoxemia values of less than the thresholds cited) may be ready for attempts at the discontinuation of mechanical ventilation.

Recommendation 3: Formal discontinuation assessments for patients who are receiving mechanical ventilation for respiratory failure should be performed during spontaneous breathing rather than while the patient is still receiving substantial ventilatory support. An initial brief period of spontaneous breathing can be used to assess the capability of continuing onto a formal SBT. The criteria with which to assess patient tolerance during SBTs are the respiratory pattern, the adequacy of gas exchange, hemodynamic stability, and subjective comfort. The tolerance of SBTs that last 30 to 120 minutes should prompt consideration for permanent ventilatory discontinuation.

Recommendation 4: The removal of the artificial airway from a patient who has successfully been discontinued from ventilatory support should be based on assessments of airway patency and the ability of the patient to protect the airway.

Recommendation 5: Patients who are receiving mechanical ventilation for respiratory failure who fail an SBT should have the cause of the failed SBT determined. After any reversible causes of failure are corrected and if the patient still meets the criteria listed in Table 52-3, subsequent SBTs should be performed every 24 hours.

Recommendation 6: Patients who are receiving mechanical ventilation for respiratory failure who fail an SBT should receive a stable, nonfatiguing, and comfortable form of ventilatory support.

Recommendation 7: Anesthesia and sedation strategies and ventilatory management that are aimed at early extubation should be used for postsurgical patients.

Recommendation 8: Weaning and discontinuation protocols that are designed for nonphysician health care professionals should be developed and implemented by ICUs. Protocols that are aimed at optimizing sedation should also be developed and implemented.

Recommendation 9: Tracheotomy should be considered after an initial period of stabilization on the ventilator when it becomes apparent that the patient needs prolonged ventilatory assistance. Tracheotomy should then be performed when the patient appears to be likely to gain one or more of the benefits ascribed to the procedure. Patients who may derive particular benefit from early tracheotomy include the following:

- Those who need high levels of sedation to tolerate translaryngeal tubes;
- Those with marginal respiratory mechanics (often manifested as tachypnea) in whom a tracheostomy tube with lower resistance may reduce the risk of muscle overload;
- Those who may derive psychological benefit from the ability to eat orally, communicate by articulated speech, and experience enhanced mobility; and
- Those in whom enhanced mobility may assist with physical therapy efforts.

Recommendation 10: Unless there is evidence for clearly irreversible disease (e.g., high spinal cord injury, advanced amyotrophic lateral sclerosis), a patient who requires prolonged mechanical ventilatory support for respiratory failure should not be considered permanently ventilator dependent until 3 months of weaning attempts have failed.

Recommendation 11: Critical care practitioners should familiarize themselves with facilities in their communities or units in hospitals that are staffed with individuals that specialize in managing patients who have prolonged dependence on mechanical ventilation. Such familiarization should include reviewing published peer-reviewed data from those units, if available. When they are medically stable for transfer, patients who have failed ventilatory discontinuation attempts in the ICU should be transferred to those facilities that have demonstrated success and safety with accomplishing ventilator discontinuation.

Recommendation 12: Weaning strategies in the patient who requires prolonged mechanical ventilation should be slow paced and should include gradually lengthening self-breathing trials.

Modified from MacIntyre NR, Cook DJ, Ely EW, Jr, et al; American College of Chest Physicians; American Association for Respiratory Care; American College of Critical Care Medicine: Evidence-based guidelines for weaning and discontinuing ventilatory support: a collective task force facilitated by the American College of Chest Physicians; the American Association for Respiratory Care; and the American College of Critical Care Medicine. Chest 120 (6 Suppl):375S–395S, 2001.

TABLE 52-3

Criteria Used to Determine Whether Patients Who Are Receiving Ventilatory Support Can Be Considered for Spontaneous Breathing Trials

Criteria	Description
Objective measurements	Adequate oxygenation (e.g., PO_2 of ≥60 mm Hg with an FiO_2 of ≤0.40 to 0.50; PEEP of ≤5 to 8 cm H_2O; PO_2/FiO_2 ratio of ≥150 to 200)
	Stable cardiovascular system (e.g., heart rate ≤100 beats/min; stable blood pressure; no [or minimal] pressors)
	Afebrile (i.e., temperature about 37° C)
	No significant respiratory acidosis
	Adequate hemoglobin (e.g., ≥8 to 10 g/dl)
	Adequate mentation (e.g., arousable, Glasgow coma score of ≥13, no continuous sedative infusions)
	Stable metabolic status (e.g., acceptable electrolyte levels)
Subjective clinical assessments	Resolution of acute phase of disease; physician believes discontinuation is possible; adequate cough

Modified from MacIntyre NR, Cook DJ, Ely EW, et al: Evidence-based guidelines for weaning and discontinuing ventilator support: a collective task force facilitated by the American College of Chest Physicians, the American Association for Respiratory Care, and the American College of Critical Care Medicine. Chest 120:375S–395S, 2001.

- A more than 20% increase or decrease in heart rate or a heart rate of more than 120 to 140 beats/min
- A systolic blood pressure of more than 180 mm Hg or of less than 90 mm Hg

Patients with unsuccessful results of an SBT are returned to full ventilatory support for 24 hours to allow the ventilatory muscles to recover. During this period, the causes of failure are identified and corrected, if possible, and the patient is then reevaluated. If the criteria listed in Table 52-3 continue to be met, SBTs are repeated every 24 hours.[3] Patients who tolerate the formal SBT for 30 to 120 minutes remain off of the ventilator, and extubation is considered. Box 52-10 is a sample protocol for an SBT for the discontinuation of ventilatory support.

Continuous Positive Airway Pressure

CPAP is used during an SBT in many facilities. CPAP has the advantages of maintaining the lung volume during the weaning phase and thus of improving the patient's oxygenation status. Minimal levels of CPAP may be useful for reducing WOB and compensating for auto-PEEP, particularly in patients with obstructive lung disease.[1,4] CPAP is usually provided through the use of the CPAP mode that is available on most mechanical ventilators. By using the ventilator in the CPAP mode, the clinician can take advantage of the alarm systems that are available. In fact, most institutions use the CPAP mode with zero CPAP level to take advantage of the ventilator alarms during weaning. This always provides an improved margin of safety as compared with the use of a T-piece and should be the standard approach to an SBT.

Box 52-10 Weaning Protocol for a Spontaneous Breathing Trial

1. Verify that the patient is a candidate for ventilator discontinuation.
   a. Is there evidence of the reversal or alleviation of the disease state or condition that required mechanical ventilatory support?
   b. Is the patient able to breathe spontaneously?
   c. Has the patient's medical condition been optimized (i.e., afebrile, adequate hemoglobin, and acceptable electrolyte levels)?
   d. Are oxygenation, ventilation, and blood gas values adequate?
      - PaO_2 of at least 60 mm Hg with FiO_2 of no more than 0.40 to 0.50 with PEEP/CPAP of no more than 5 to 8 cm H_2O
      - PaO_2/FiO_2 ratio of 150 to 200 mm Hg or more
      - pH of 7.25 or more
   e. Is the patient awake and alert, free of seizures, and able to follow instructions?
   f. Is there evidence of hemodynamic stability? Are vasopressors only administered intermittently?
2. Prepare the patient for the SBT.
   a. Be sure that adequate personnel are present.
   b. Ensure that there are no other ongoing procedures or other major activities.
   c. Eliminate or minimize respiratory depressants (e.g., sedatives, narcotics).
   d. Suction the airway, as needed.
   e. Sit the patient up in bed, if possible.
3. Set the ventilator at zero CPAP and zero pressure support.
4. Continuously monitor the patient.
5. If any of the following occurs and are sustained, return the patient to mechanical ventilatory support:
   a. Respiratory rate of at least 35 breaths/min
   b. Oxygen saturation measured by pulse oximeter of less than 90%
   c. 20% increase or decrease in heart rate or heart rate of more than120 beats/min
   d. Systolic blood pressure of more than 180 mm Hg or of less than 90 mm Hg
   e. Agitation, diaphoresis, or anxiety
6. Continue the trial for at least 30 minutes but not more than 2 hours. If no signs of intolerance develop (see step 5), consider extubation.

Chest 120(6 Suppl):375S–395S, 2001.

Synchronized Intermittent Mandatory Ventilation

SIMV can be used to provide full or partial ventilatory support. Weaning from SIMV involves the gradual reduction of the machine rate on the basis of the results of ABG analysis and patient assessment. Early claims that SIMV allowed for faster weaning times[8] have not been substantiated by subsequent studies.[28,29,30]

Patients who are receiving ventilation in the SIMV mode uncouple their breathing efforts from the support provided by the machine.[1,4] They continue to make spontaneous breathing efforts during the delivery of a "mandatory breath." Evidence also suggests that, once the machine cycling rate is reduced to approximately 50% of the full ventilatory support value, the patient breathes approximately as hard per cycle as when ventilatory support is completely withdrawn.[32,33] This additional work can be overcome with the use of pressure support (i.e., 5 to 10 cm H_2O). However, the addition of pressure support further complicates the weaning process. For initial ventilator setup, the SIMV rate and the tidal volume usually are set at values that are equivalent to those used during volume control-continuous mandatory ventilation (VC-CMV) or pressure control-continuous mandatory ventilation (PC-CMV). When the patient's condition has been stabilized, one of two approaches can be used. Some clinicians prefer to continue at these settings until the patient's precipitating disease state or condition has improved considerably. At that point, the rate is reduced in a stepwise manner until complete spontaneous breathing can be achieved. Other clinicians prefer to immediately reduce the level of mechanical ventilation to an SIMV rate of 4 to 8 per minute, thereby forcing the patient to perform additional WOB. From the beginning, attempts are made to reduce the SIMV rate, and the patient is challenged to provide a portion of the required ventilation. Unfortunately, research indicates that SIMV prolongs ventilatory support and that it is the least effective method of weaning from ventilatory support as compared with either SBT or PSV.[1,4,28,29,30]

Pressure Support Ventilation

PSV is a mode of ventilatory support that allows the patient to have significant control over the process of ventilatory support. The only gas-delivery variable directly controlled by the ventilator is peak airway pressure; see Chapters 45 and 48 for details.

For initial ventilator setup in the PSV mode, the beginning pressure level can be adjusted to deliver an appropriate tidal volume, which is usually approximately 4 to 8 ml/kg of the ideal body weight based on the patient's condition and the desired tidal volume. PSV is then gradually reduced to a minimal value that only compensates for the WOB imposed by the artificial airway.[28,29,30] Generally this is about 5 to 8 cm H_2O. After this reduction is accomplished, extubation can be performed directly from the low level pressure support, or an SBT may be conducted for 30 to 120 minutes.[1,4]

PSV allows the clinician to manipulate the level of patient work, but the benefit of this to weaning is questionable.[1,4] In general, patients who can spontaneously breathe comfortably at 5 to 8 cm H_2O of PSV can be extubated without problems. However, if upper airway edema is present, WOB after extubation may be about the same as that caused by the endotracheal tube. In these cases, low levels of pressure support may give a false impression about the patient's ability to tolerate extubation[1,4] (Box 52-11).

Box 52-11 Protocol for Pressure Support Weaning

1. Verify that the patient is a candidate for ventilator discontinuation:
   - Evidence of alleviation or reversal of the disease state or condition that necessitated ventilatory support
   - Stable, spontaneous breathing pattern without irregular breathing or periods of apnea
   - Optimization of the patient's medical condition
   - Adequate oxygenation, ventilation, and acid-base balance
2. Begin with a PSV level that achieves a tidal volume of 4 to 8 ml/kg of the ideal body weight. A PSV of more than 20 cm H_2O rarely is needed. The need for a high level of PSV indicates that the patient may not be ready for ventilator discontinuation.
3. Reduce the PSV 2 to 4 cm H_2O as tolerated, ideally at least twice daily, and reassess the patient for signs of intolerance:
   - Rate of at least 25 to 30 breaths/min
   - 20% or greater increase in heart rate or a heart rate of more than 120 beats/min
   - 20% or greater increase in systolic blood pressure or systolic blood pressure of more than 180 mm Hg or of less than 90 mm Hg
   - Agitation, anxiety, and diaphoresis
4. If the patient does not tolerate a reduction in PSV, return to the previous value, and reassess.
5. Continue to reduce PSV as tolerated at least twice per day and more frequently if the patient does not have signs of distress.
6. Consider extubation when the patient is able to tolerate a PSV of 5 to 8 cm H_2O for 2 hours with no apparent distress.

Modified from Esteban A, Frutos F, Tobin M, et al: A comparison of four methods of weaning patients from mechanical ventilation. Spanish Lung Failure Collaborative Group, N Engl J Med 332:345-350, 1995; and Brochard L, Rauss A, Benito S, et al: Comparison of three methods of gradual withdrawal from ventilatory support during weaning from mechanical ventilation. Am J Respir Crit Care Med 150:896–903, 1994.

Synchronized Intermittent Mandatory Ventilation With Pressure Support Ventilation

With SIMV, the addition of pressure support can overcome the WOB imposed during "spontaneous" breaths because of the presence of endotracheal and tracheostomy tubes, demand flow systems, and ventilator circuits. In this setting, pressure support is set to achieve the desired tidal volume during the spontaneous breaths (i.e., 4 to 8 ml/kg of the ideal body weight).

Although it is clear that the addition of PSV during SIMV can reduce or eliminate imposed work caused by mechanical factors, it has not been shown how this affects weaning. In one study, SIMV with PSV increased tidal volume and reduced respiratory rate but did not significantly reduce weaning time or success as compared with SIMV alone.[34] On the basis of all of the weaning trials, it can be concluded that this approach to weaning can only increase the length of ventilatory support. Current guidelines recommend the use of SBT to rapidly wean patients from ventilatory support.[1,4]

MINI CLINI

Setting Pressure Support Levels

PROBLEM: An intubated patient is receiving mechanical ventilation in the SIMV mode with the following settings:

- V_T = 400 ml
- Rate = 12 breaths/min
- Peak inspiratory pressure = 40 cm H_2O
- Plateau pressure (P_{plat}) = 20 cm H_2O
- Ventilator inspiratory flow ($\dot{V}$) = 60 L/min (1 L/s)

The patient is breathing spontaneously with a spontaneous rate of 12 breaths/min and a spontaneous peak inspiratory flow of 30 L/min (0.5 L/s). Find the level of PSV that is needed to overcome the imposed WOB.

Solution:

$$PSV = \left(\left[PIP - P_{plat}\right]/\dot{V}_{mach}\right) \times \dot{V}_{Imax}$$

$$PSV = \left(\left[40\ cm\ H_2O - 20\ cm\ H_2O\right]/1\ L/s\right) \times 0.5\ L/s$$

$$= 10\ cm\ H_2O$$

The calculated PSV level to overcome the imposed WOB for this patient is 10 cm.

Spontaneous Awaking Trials

Concern regarding the use of sedation in critically ill patients has increased markedly during the last few years. This concern has focused on the issue of delirium.[35] The indiscriminate use of sedatives in the ICU is considered inappropriate patient management. In general, sedatives should always be considered last when trying to handle an agitated patient (Chapter 47). Something has caused the patient's agitation, and it should be addressed and corrected, if possible, before sedation is administered. In addition, it is becoming clearer that the use of excessive sedation lengthens the time of mechanical ventilation. The use of **spontaneous awaking trials (SAT)** along with daily SBT results in the faster weaning of patients from ventilatory support as well as a decrease in mortality.[36] The decrease in mortality is attributed to patients being exposed for a shorter time to the complications of mechanical ventilation. Throughout the course of mechanical ventilation, sedation should be kept to the bare minimum necessary; patient sedation should be periodically carefully assessed before additional sedation is given.[36,37] In general, one of the currently available systems to rate the level of sedation should be in use on all mechanically ventilated patients (Riker/Sedation Agitation Scale (SAS), Ramsay Sedation Scale, or Richmond Agitation Scale (RASS).

NEWER TECHNIQUES FOR FACILITATING VENTILATOR DISCONTINUANCE

Mandatory Minute Volume Ventilation

Mandatory minute volume ventilation (MMV) was described and introduced in 1977.[38] With this mode of ventilation, the total minute volume is set, and the patient may elect to inspire all of the minute volume, part of the minute volume, or none of the minute volume spontaneously. The ventilator would automatically provide a clinician-set remainder of the minute volume. It was originally assumed that, as the patient's status improved, he or she would assume a greater and greater percentage of the set minute volume, eventually inspiring it all spontaneously. However, this did not occur; patients generally settled into a ventilator pattern where the overall WOB was shared between the patient and the ventilator, and the patient never assumed a greater percentage of the work.[39] There is no data to support the use of MMV over SBT or PSV to wean patients from ventilatory support.

Adaptive Support Ventilation/Intellivent

ASV is a newer mode of ventilation that maintains a minimum minute ventilation with an optimal breathing pattern (tidal volume and rate) that is based on the work of Otis;[40,41] see Chapters 45 and 48 for details. ASV automatically adjusts inspiratory pressure and ventilator breath rate to achieve the target minute volume set. As the patient's status improves, the target minute volume is reduced, and the level of pressure required each breath diminishes. When a minimal level is reached, the patient is considered weaned from ventilatory support and ready for extubation.

Preliminary studies of ASV for the care of patients who are recovering from cardiac surgery show a reduction in the duration of mechanical ventilation as compared with an SIMV weaning protocol.[41,42] Additional data about ASV indicates that it works very well for patients who are under controlled ventilation,[43] but data from large heterogeneous groups of patients will be necessary to determine if ASV truly improves the speed of ventilator discontinuation.

A recent upgrade of ASV is referred to as Intellivent.[44] With this modification the ventilator becomes a total closed loop controller of not only ventilation but also oxygenation. Incorporated into the management algorithm are the ARDSnet PEEP/F_IO_2 tables. Thus, all aspects of gas delivery are controlled. As with ASV, Intellivent works well on patients under control ventilation and those requiring simple postoperative ventilation, and has shown the ability to wean patients from ventilatory support.[45] However, no comparison to SBT is currently available. Intellivent use in the complex patient spontaneously triggering the ventilator is still controversial. However, one can expect this type of closed loop control of ventilation will begin to appear on other mechanical ventilators.

Computer-Based Weaning

Current versions of MMV and ASV/Intellivent are examples of computer-controlled mechanical ventilation. Several more complex systems have been developed, including Ventilation Manager, VQ-attending, ESTER, Continuous Respiratory Evaluator (CORE), KUSIVAR, and WEAN-PRO.[46] The desire to develop computer-based weaning protocols is based on two factors. First, weaning is a time-consuming and labor-intensive

process. If computer control can expedite or simplify this process, considerable time and money can be saved. Second, because most weaning decisions are based on objective data, computer-based weaning protocols are relatively easy to develop.[46]

The most successful computerized application for weaning is the Smart Care approach.[47,48] The system adjusts pressure support on the basis of the patient's tidal volume, respiratory rate, and end-tidal carbon dioxide level. When the pressure support has been decreased to a predefined level, the ventilator automatically begins an SBT. If the patient fails the SBT, which is determined by changes in the patient's respiratory rate, tidal volume, and end-tidal carbon dioxide level, then the ventilator automatically reassumes ventilatory support. If the patient passes the SBT, the ventilator also returns to baseline ventilatory support but notifies the clinician that the patient is ready for ventilator discontinuation. Two randomized comparisons of SmartCare to clinician-controlled SBT have demonstrated that patients wean faster and both the total number of days that patients are maintained in the ICU and the need for postextubation NIV are reduced with SmartCare.[47,48] One criticism of this study was that the clinician-applied SBTs were not always performed consistently. However, this is clinical reality—in the ICU there is always good intention to do an SBT but emergencies, new admissions, and other distractions prevent clinicians from always performing the SBT in a timely manner. With SmartCare, if the patient meets criteria the SBT is performed regardless of the activity in the ICU. It should be noted that at least at the time of this revision the FDA only allows Smart Care in the United States to notify clinicians of the readiness for an SBT and the patient's status during the SBT. The clinician must adjust the ventilator into and out of the SBT. In the rest of the world this is performed automatically be the ventilator. It can be expected that automated weaning systems will increasingly have a place in the care of critically ill patients.

Automatic Tube Compensation

Automatic tube compensation (ATC) is an option on newer mechanical ventilators that compensates for the flow-dependent pressure decrease across the endotracheal tube during both inspiration and expiration; see Chapters 45 and 48 for details. ATC reduces WOB and may improve patient comfort.[49] Because it compensates for the imposed WOB caused by the artificial airway, ATC has been referred to as *electronic extubation.* Patients who are able to breathe adequately with the addition of ATC at low peak airway pressure (i.e., less than 8 cm H_2O) should tolerate extubation. ATC is similar to pressure support in that an inspiratory pressure is used to compensate for imposed WOB; however, ATC varies the pressure, depending on the size of the endotracheal tube and the patient's inspiratory flow rate. Alternatively, PSV delivers a preset inspiratory pressure that may overcompensate or undercompensate imposed WOB at any given point in time. However, no data are available to indicate that ATC weans patients faster than SBTs or PSV.

MINI CLINI

Response to a Spontaneous Breathing Trial

PROBLEM: A 70-year-old woman with a long history of congestive heart failure has been mechanically ventilated for 6 days. She has failed three previous SBTs, but today, at the end of a 45-minute SBT, her clinical presentation was as follows:

- Respiratory rate of 24 breaths/min
- Tidal volume of 300 ml (6 ml/kg ideal body weight)
- Pulse of 98 beats/min
- Blood pressure of 138/86 mm Hg

The patient did not appear to be short of breath, and she did not demonstrate excessive use of her accessory muscles of ventilation to breathe during the trial.

Should this patient's ventilatory support be discontinued?

Solution: On the basis of the given data, this patient passed her SBT and should be discontinued from ventilatory support and extubated if there is no reason for her to remain intubated. However, because of her age, history of congestive heart failure, and multiple failures of SBT, she should ideally be placed on NIV immediately after she is extubated and slowly transitioned to independent spontaneous breathing over the next 12 to 48 hours. See the following discussion below and Chapter 49.

Volume Support

VC is a newer mode of ventilation that combines pressure support and volume ventilation by allowing the level of pressure support to be automatically adjusted to maintain a target tidal volume. In the VC mode, inspiration is initiated by the patient. During the inspiratory phase, the pressure level is regulated to a value that is based on the previous breath's pressure-volume relationship as compared with a target tidal volume. The pressure-support level is automatically adjusted in a stepwise manner by up to ±3 cm H_2O from one breath to the next to maintain the target tidal volume.

A major problem with VC is the excessive reduction of airway pressure in the presence of high ventilatory demand, thereby increasing patient effort.[50] With most ventilators offering this mode, no lower limit to ventilating airway pressure is set, and inspiratory airway pressure can decrease all the way to the PEEP level. Volume support may offer a sort of automatic weaning from pressure support. As the patient's spontaneous tidal volume improves, the level of pressure support is automatically reduced. However, clinical trials indicate no benefit to the use of VC to wean patients.[51]

Proportional Assist Ventilation and Neurally Adjusted Ventilatory Assist

Proportional assist ventilation (PAV) and neurally adjusted ventilatory assist (NAVA) are two of the newest modes of ventilatory support.[52] These modes differ from all other modes of ventilation since they do NOT force a ventilatory pattern. Instead they follow the ventilatory pattern desired by the patient.

As a result, patient-ventilatory synchrony is greater with these modes than with any of the other ventilatory modes.[53,54,55] Unfortunately, there are no data regarding the use of these modes to facilitate ventilator discontinuation. At this time, regardless of how these modes improve patient-ventilator interaction, the decision to discontinue ventilatory support should be made based on performance of an SBT. Future research should be able to define if these modes have a greater role in discontinuation process.

Noninvasive Ventilation

A number of groups have studied the use of NIV as an adjunct to ventilator discontinuance. Essentially, NIV has been used in this setting in three different manners:

1. Transitioning patients with COPD who failed SBTs from invasive ventilation to spontaneous breathing[56-58]
2. Supporting patients who passed SBTs but who were considered to be at high risk for failing the extubation[25-26,59]
3. Supporting patients who developed hypoxemic respiratory failure after extubation[60,61]

The literature strongly supports the first two indications but does not support the third application. Refer to Chapter 49 for details regarding the application of NIV during weaning and the use of NIV in general.

Role of Mobility

If you do not move it, you lose it! This has become increasingly clear when it comes to patients in the process of weaning from ventilatory support. Mobilization of the mechanically ventilated patient should begin as soon as the patient is stabilized, requires minimal sedation, and is capable of interacting with the ventilator.[62,63] Mobilization may begin simply by sitting the mechanically ventilated patient at the side of the bed. However, in many cases it may mean that the patient is walked in the hallway while receiving ventilatory support. Of course this requires the cooperation of respiratory therapy, nursing, and physical therapy, and the use of equipment that facilitates mobilization: transport ventilator, portable suction, and walker/chair that maintains support of the patient but also allows the patient to sit and rest. Mobilization is increasingly important the longer the patient requires ventilatory support.

Respiratory-Therapist–Driven Protocols

A number of randomized, controlled clinical trials have demonstrated that patients are weaned faster with the use of protocols than with individual physician orders.[64-67] In all of these studies, the therapists, nurses, and physicians who normally manage patients in the unit developed the protocol. In addition, in the individual physician order group, the physicians who wrote the protocol also wrote the individual weaning orders. In all of these trials, patients who were randomized to the protocol group weaned faster and with fewer complications then the patients randomized to the individual physician group.[64-67]

What these results do not mean is that therapists wean patients better than physicians. However, what they do mean is that, when an evidence-based approach to patient management is developed and followed precisely, care is generally better than with individual physician orders. The reason for this is that protocols empower the clinician at the bedside to advance care when the patient meets specific criteria without waiting for the physician to come and write an order. In many community hospitals, the wait for the physician could be an hour or a whole shift or more. Thus, with protocols, care proceeds rapidly on the agreed-upon course. In addition, the individual bias of the caregiver does not affect the manner in which care is provided. Thus, the approach does not change from day to day depending on which physician is at the bedside. An example of a respiratory-therapist–directed ventilatory discontinuance protocol is presented in Box 52-12.

Box 52-12 Respiratory-Therapist–Directed Weaning Protocol

- The physician's written order identifies the patient as being eligible for the respiratory-therapist–directed weaning protocol.
- The timing of weaning initiation is defined as part of the protocol.
- All patients must undergo continuous oxyhemoglobin saturation monitoring by pulse oximetry.
- When the patient meets weaning criteria, the ventilator is set to zero CPAP and zero PEEP.
- The SBT continues for a minimum of 30 minutes to a maximum of 120 minutes if none of the following weaning failure conditions are present:
  - SaO_2 of less than 90% or diaphoresis
  - Spontaneous respiratory rate of at least 35 breaths/min that is sustained for at least 5 minutes
  - Agitation or a decreased level of consciousness
  - A heart rate increase of at least 20%
  - A blood pressure change of at least 20%
  - A cardiac output reduction of at least 30% or ventricular arrhythmia
- Results of the SBT are discussed with the unit physician
- If the SBT is well tolerated and there is no reason not to extubate the patient, the patient is extubated.

SELECTING AN APPROACH

Current evidence suggests that, for ventilator discontinuance and progressive weaning from mechanical support, it may be best to avoid SIMV.[1,4] It has also been suggested, regardless of approach used, that protocols administered by respiratory therapists and other health care workers be developed.[3,6,10] These protocols should be designed to begin testing for the opportunity to reduce support very soon after intubation and to reduce the level of ventilatory support at every opportunity.[1,66] The approach to weaning that seems to wean patients most rapidly is the SBT. This should be the approach that is used to identify readiness for ventilator discontinuance in the vast majority of patients.[1] In addition, NIV should be considered as part of the total ventilator discontinuance process.[65]

One area that requires additional research is the role of ventilatory muscle conditioning in patients who require long-term

ventilatory support. Endurance conditioning of the ventilatory muscles can be achieved by the continuous repetition of low levels of ventilatory work. Strength conditioning can be achieved by maximal ventilatory effort for short periods. In theory, PSV would allow for improving ventilatory muscle endurance, whereas intermittent SBTs would favor the development of muscle strength. Inspiratory resistive training to improve ventilatory muscle strength has been tried as an adjunct to weaning for the care of patients undergoing long-term ventilation.[13] Unfortunately, the role of ventilatory muscle rest and load in the care of difficult-to-wean patients has not been established.[13]

In summary, a single daily SBT that lasts from 30 minutes to 2 hours has been recommended as the primary approach to weaning.[1,4] If the trial is successful, extubation is considered. If the trial is unsuccessful, a period of rest is provided before another trial is attempted.[1] There are advantages and disadvantages to each of the methods used to conduct ventilator weaning. Table 52-4 compares SBT, SIMV, and PSV as weaning techniques. The best approach currently supported by the literature is an SBT, but it may alternatively be the approach with which a given clinician is most familiar. It should be based on knowledge of the patient's condition, a sound rationale, and good clinical experience. The method chosen should include careful patient assessment, and the patient's condition should be optimized before weaning. For the vast majority of patients, a protocolized approach to ventilator discontinuance is most efficient.

MONITORING THE PATIENT DURING WEANING

Ventilatory Status

Respiratory rate and pattern are easy to monitor and may be the most reliable indicators of patient progress during weaning.[1,4] Weaning may proceed as quickly as the patient's respiratory rate and subjective tolerance allow. However, in no case should patients be pushed beyond their physiologic limits; to do so may result in diaphragmatic dysfunction and further delay the weaning process. If the patient is allowed to fatigue during a weaning trial, it will require at least 24 hours for the muscles to recover.[68,69] Dyspnea should be monitored during weaning and may be quantified with a visual analog scale or a modified Borg scale[70] (Table 52-5). The onset or worsening of discomfort, respiratory distress, fatigue, sweating, signs of increased WOB (e.g., accessory muscle use, abdominal paradox), deterioration in vital signs, or changes in mental status (e.g., agitation, anxiety, somnolence, coma) may be signs of intolerance of a weaning trial.[1]

The single best index of ventilation remains the measurement of $PaCO_2$. However, the assessment of a patient's tolerance of an SBT should be based on clinical presentation rather than $PaCO_2$. A patient with a $PaCO_2$ of 40 mm Hg but a clinical presentation defined by a rapid, shallow breathing pattern with abdominal paradox, tachycardia, and hypertension has not

TABLE 52-4
Comparison of Available Weaning Methods

Method	Advantages	Disadvantages
SBT	Tests patient's spontaneous breathing ability Allows periods of work and rest Weans faster than SIMV A single daily SBT may be as effective as multiple trials May be performed with 5 cm H_2O CPAP, 5 cm H_2O PSV, or both	More staff time Abrupt transition may be difficult for some patients May overstress the patient if not monitored carefully Requires careful supervision
SIMV	Less staff time Gradual transition Easy to use Minimum minute ventilation guaranteed Sophisticated alarm systems may be used May be used in combination with PSV or CPAP	Patient-ventilator asynchrony Prolongs weaning May worsen fatigue
PSV	Less staff time Gradual transition Prevents fatigue Maintains activity of diaphragm Increased patient comfort Weans faster than SIMV Overcomes resistive WOB caused by the following: Endotracheal and tracheostomy tubes Ventilator circuits Demand flow systems Patient can control cycle length, rate, and inspiratory flow Every breath is supported	Large changes in minute ventilation can occur Increased mean airway pressure as compared with SBT Tidal volume not guaranteed; low tidal volumes possible May prolong weaning

TABLE 52-5
Modified Borg Scale for Dyspnea

Grade	Degree of Dyspnea
0	None
0.5	Very, very slight (just noticeable)
1	Very slight
2	Slight
3	Moderate
4	Somewhat severe
5	Severe
6	Very severe
7	
8	
9	Very, very severe (almost maximal)
10	Maximal

Modified from Mahler DA: Dyspnea, Mt. Kisco, NY, 1990, Futura.

passed an SBT. The results of capnography should not be used to guide the weaning of patients. End-tidal PCO_2 values can be highly misleading as an estimate of effective ventilation in sick patients.[71] Gastric pH has been used as a predictor of patient status, and gastrointestinal acidosis may be an early sign of weaning failure.[72]

Oxygenation

During the SBT, FiO_2 should be the same as during ventilatory support or 10% higher. Continuous pulse oximetric (SpO_2) monitoring can provide a sensitive indicator of oxygenation status during weaning.[1] Arterial blood gas analysis for PaO_2 and SaO_2 and the calculation of the oxygen content of the arterial blood (CaO_2) may be performed after the patient has been considered a weaning failure to determine the extent of the failure. Success, however, can be based on the SpO_2 only. SpO_2 monitoring during the SBT is generally the standard of care.

Cardiovascular Status

Pulse, blood pressure, and cardiac rhythm should be monitored, and arrhythmias should be assessed to determine whether weaning should be continued. Tachycardia, bradycardia, and abnormalities in blood pressure should be promptly evaluated and the patient returned to ventilatory support or a higher level of support, if indicated. Silent myocardial ischemia may occur frequently in some postoperative patients during weaning.[73] Table 52-6 summarizes changes that may occur during the withdrawal of ventilatory support.

TABLE 52-6

Changes During the Withdrawal of Ventilatory Support

Expected Change	Deleterious Change
Respiratory	
Respiratory rate minimally increased	Respiratory rate of ≥35 breaths/min
Stable $\dot{V}$	Large increase or decrease in $\dot{V}_E$
SpO_2 ≥90%	Decrease in SpO_2 to ≤90%
5 to 10 mm Hg swing in PaO_2	PaO_2 of <60 mm Hg
5 to 10 mm Hg swing in $PaCO_2$	An increase of >10 mm Hg in $PaCO_2$
pH of >7.30 and <7.50	pH of <7.30
Minimal use of accessory muscles	Increased use of accessory muscles
No paradoxical breathing	Paradoxical breathing
	Diaphoresis
	Dyspnea
Cardiovascular	
Heart rate increased by 15 to 20 beats/min	Persistent tachycardia of ≥120 to 140 beats/min
Blood pressure increased 10 to 15 mm Hg	Hypotension (blood pressure of <90/60 mm Hg)
	Hypertension (systolic blood pressure of >180 mm Hg)
Increased cardiac index	Decreased cardiac index
Increased stroke volume	Decreased stroke volume
	Angina
	New arrhythmias
Other	
Mental status good (i.e., awake, alert, responsive)	Anxiety, agitation, somnolence, coma

EXTUBATION

Artificial Airways and Weaning

The effect on a patient of a properly sized artificial airway on WOB is controversial.[74] However, many endotracheal tubes are partially obstructed and as a result impose a significant increase in WOB. Removing the endotracheal tube may markedly improve the patient's clinical status. There is little difference in the airway resistance of healthy adults with low minute ventilation (i.e., <8 L/min) breathing through endotracheal tubes with an internal diameter (ID) of 7, 8, or 9 mm.[75] However, in critically ill patients decreases in ID and increases in minute ventilation increase WOB. Adults have a critical increase in workload when the tube has an ID of less than 7 mm.[75] It is thought that the added work due to the presence of an artificial airway may contribute to ventilator dependency among patients with borderline pulmonary function or ventilatory muscle weakness.[76]

Biofilm buildup on the inside of the endotracheal tube can cause dramatic increases in airway resistance, especially among infants and children.[77,78] Taking care to provide adequate humidification and careful suctioning can help to avoid this problem.

Tracheotomy may substantially reduce the WOB of patients who need mechanical ventilatory support. The short length of tracheotomy tubes results in an overall decrease in resistance as compared with the resistance of an endotracheal tube, even though the curvature of the tracheotomy tube is greater.[1] It appears that the performance of a tracheotomy improves airway resistance and reduces the load of the ventilatory muscles. It may be the ability to avoid secretions/biofilm buildup on the inside of the trachestomy tube that makes the difference.

Weaning and extubation should be separate decisions. Weaning indices are not predictive of the adequacy of airway patency or the need for the protection of the airway. The reintubation rate among patients with prolonged postoperative ventilation as a result of respiratory failure can range from 5% to 20%.[1,4]

Patients who have been successfully extubated generally have the following characteristics: (1) the resolution of the disease state or condition; (2) hemodynamic stability; (3) the absence of sepsis; (4) adequate oxygenation status with a decreased FiO_2 and decreased PEEP or CPAP; and (5) adequate ventilatory status and $PaCO_2$. The decision to extubate should be based on the assessment of upper airway patency and protection. No one indicator is 100% sensitive and specific with regard to the prediction of successful extubation. Practical guidelines for extubation are presented in Box 52-13. Regardless of the weaning technique used, an SBT is recommended before extubation to ensure that the patient can sustain spontaneous unsupported ventilation.[1]

Some patients may be successfully extubated even if extubation criteria are not met. If the patient is at risk, trained personnel who are able to perform reintubation must be immediately available before extubation is attempted. At a minimum, those who perform the extubation must be prepared to provide an airway and ventilatory support in the event that problems develop immediately after extubation. Extubation should be postponed when myocardial ischemia is present, when the patient has upper gastrointestinal hemorrhage, or when a procedure that necessitates reintubation is impending. If difficult reintubation is anticipated, trained personnel should be immediately available.

Many patients report hoarseness and sore throat after extubation, and patients should be advised that these symptoms may occur. Other common problems after extubation include airway obstruction, increased risk of aspiration, and difficulty with secretion clearance. Patients with neurologic or neuromuscular disorders and those with excessive secretions are at increased risk after extubation. The compression of the airway as a result of a traumatic or postoperative hematoma of the neck, infectious masses or abscesses, and malignant tumors or compression after major head or neck surgery can lead to upper airway obstruction after extubation. The cuff leak test may detect airway obstruction before extubation; however, results of studies addressing this are controversial.[79,80] An air leak of less than 11% to 12% or 110 to 130 ml has been shown to be predictive of stridor.[79,80] Box 52-13 provides a protocolized guide for extubation.

Box 52-13 Practical Guidelines for Extubation

- There is no immediate need for mechanical ventilation or intubation.
- The medical course does not suggest impending respiratory failure or other indications for mechanical ventilation.
- Procedures that require intubation and general anesthesia are not immediately planned.
- There is adequate oxygenation and ventilation with spontaneous ventilation.
- The patient's FiO_2 requirement can be achieved with a mask or a nasal cannula.
- The patient no longer needs mechanical ventilatory assistance.
- Weaning is successful.
- There is a minimal risk of upper airway obstruction.
- The patient has minimal edema or mass encroachment of the oropharynx and upper airway.
- There is adequate airway protection and a minimal risk of aspiration.
- The level of consciousness and neuromuscular function ensures a gag reflex and an adequate cough.
- Gastric contents are minimized by the discontinuation of tube feedings for 4 to 6 hours before extubation.
- A positive gag reflex is present.
- There is adequate clearance of pulmonary secretions.
- The level of consciousness and muscular strength allow for an effective cough.
- Secretion volume and thickness are not worsening.

After extubation, glottic edema can result in partial airway obstruction, which can cause mild to severe stridor. Postextubation stridor occurs in 2% to 16% of patients in the ICU and should be viewed with concern.[81] Severe edema after extubation can lead to complete airway obstruction. Children, patients with epiglottitis or angioedema (i.e., dermal, subcutaneous, or submucosal edema of the face or larynx), and patients who have sustained smoke inhalation are at greater risk. Postextubation edema occurs in as many as 47% of children with trauma injuries or burns.[1,4] See Chapter 36 for detailed information about airway management and postextubation care.

VENTILATOR DISCONTINUANCE FAILURE

As many as 25% of patients who have been removed from ventilatory support experience respiratory distress that is severe enough to necessitate the reinstitution of mechanical ventilation. In patients who are unlikely to be successfully weaned, rapid, shallow breathing begins almost immediately after the ventilator is disconnected. As spontaneous breathing continues, respiratory mechanics worsen in these patients for reasons that are not clearly understood. Approximately half of patients who have poor results after the discontinuation of ventilation experience marked hypercapnia as a result of rapid, shallow breathing. An unsuccessful SBT also causes considerable cardiovascular stress. Myocardial ischemia may occur frequently among ventilator-dependent patients, and it has been associated with weaning failure.[82] Critical illness polyneuropathy has been cited as a frequent cause of neuromuscular weaning failure among critically ill patients.[83] Unsuspected neuromuscular disease may be an important factor in ventilator dependency.

Inability to wean can sometimes be attributed to psychologic dependence, poor oxygenation status, or cardiovascular instability (i.e., congestive heart failure or ischemia).[1,4] However, the most common cause of the inability to wean is an imbalance between ventilatory capability and ventilatory demand. Inability to wean is usually caused by a concurrent pathologic process that necessitates treatment. Common causes of weaning failure are summarized in Box 52-14.

PROLONGED MECHANICAL VENTILATION

Prolonged mechanical ventilation (PMV) may be required for 3% to 7% of patients who are receiving mechanical ventilation.[1,4] Patients who require a lengthy course of ventilatory support after the acute phase of their disease has resolved may be suffering from some of the items listed in Table 52-7. Any patient who is repeatedly failing SBTs should undergo a complete review of all systems to determine if something has been overlooked that may add to the patient's workload, thereby preventing them from weaning. In many patients, their pulmonary mechanics have not been optimized and thus they are

Box 52-14 Common Causes of Weaning Failure

- Poor respiratory mechanics or wheezing
- Untreated cardiac disease
- Electrolyte imbalances
- Anxiety
- Secretions
- Aspiration
- Alkalosis
- Neuromuscular weakness
- Sepsis
- Excessive sedation
- Inadequate nutrition
- Opiates
- Obesity
- Thyroid disease

MINI CLINI

Patient Who Requires Long-Term Weaning

PROBLEM: A 68-year-old man with a history of COPD was hospitalized after a motor vehicle accident. Over the course of the next 2 weeks, the patient became septic and developed acute respiratory distress syndrome. For the last week, the patient has met the criteria for an SBT, but he has failed every attempt. How should this patient's ventilator care progress from this point forward?

Solution: This patient should be classified as a difficult-to-wean patient who would benefit from a program that has been designed specifically for patients who are failing to wean. This program should systematically evaluate all systems to determine the cause of weaning failure and include the assistance of other health care providers, specifically physical therapy, occupational therapy, and speech and language pathology; he may also benefit from the efforts of social services. Ideally, this should take place in a unit that has been specifically designed for the difficult-to-wean patient.

unable to assume the workload required of spontaneous breathing. In others, underlying cardiac disease may not have been properly treated. Always a concern is the patient's acid-base status. If a patient had baseline compensated respiratory acidosis, then he or she will not be able to wean if the compensation has been eliminated. Every time these patients are trialed on an SBT, their carbon dioxide levels will rise, and they will develop respiratory failure. If this is the problem, the baseline acid-base status must be slowly reestablished if these patients are to wean. In other patients, sedation, opiates, nutritional status, electrolytes, and other underlying issues many be the concern. The more carefully all systems are reviewed, the greater the likelihood that the problem will be identified and the patient weaned from ventilatory support.

Box 52-15 Goals for Weaning After Long-Term Mechanical Ventilation

- Reduce the amount of support.
- Decrease the invasiveness of any support.
- Increase independence from mechanical devices.
- Preserve function.
- Maintain medical stability.

From Pierson DJ: Nonrespiratory aspects of weaning from mechanical ventilation. Respir Care 40:289, 1995.

CHRONICALLY VENTILATOR-DEPENDENT PATIENTS

Chronically ventilator-dependent patients (i.e., less than 1% of those requiring ventilatory support) present ethical, economic, and practical problems.[84] From an economic point of view, the long-term care of ventilator-dependent patients in an ICU is prohibitively expensive. Often these patients are transferred to subacute or long-term care facilities, where they can be cared for in an environment that is less intrusive and more like home (see Chapter 56).[84] For cases in which the family has adequate resources, the patient may be cared for in the home. Regional weaning centers have been developed and have reported success with weaning most patients who are undergoing long-term mechanical ventilation.[1,84] Current guidelines suggest that, unless there is clear evidence of an irreversible cause of ventilator dependency (e.g., a high spinal cord injury, amyotrophic lateral sclerosis), patients should not be considered permanently ventilator dependent until 3 months of weaning attempts have failed. If the patient is unweanable, the goal should be to restore the patient to the highest level of independent function possible. For example, portable wheelchair-mounted ventilators have been effective for providing a surprising level of mobility and independence to persons who are quadriplegic. Table 52-7 describes the management of common problems among difficult-to-wean patients. Box 52-15 lists the goals for weaning of patients who are receiving long-term ventilation.

TERMINAL WEANING

The term *terminal weaning* has been used to refer to the discontinuation of mechanical ventilatory support in the face of a catastrophic and irreversible illness.[85] The decision to proceed with disconnecting the ventilator when such an act is likely to cause the death of a patient is fraught with ethical, emotional, and practical problems. The decision should be made by the family in consultation with the patient's physician and in accordance with established ethical and legal guidelines.[85] Determinants of the decision to withdraw ventilation include the patient's desire to not continue with life support, the predictions of a low chance of survival in the ICU (i.e., less than 10%), the likelihood that future cognitive function would be severely impaired, and the continuous need for inotropes or vasopressors to maintain blood pressure.[85] After the decision has been

TABLE 52-7

Management of Problems Among Difficult-to-Wean Patients

Problem	Management Strategy
Anemia	Transfuse when hemoglobin level is ≤10 g/dl and hematocrit level is ≤30% if these are thought to be factors in decreased tissue oxygenation.
Increased WOB	1. Tube related a. Apply pressure support or ATC. b. Change the size of the small endotracheal tube. c. Deflate the cuff if all breathing is spontaneous and the risk of aspiration is minimal. d. Consider tracheotomy. 2. Secretion related (see later) 3. Bronchospasm related a. Administer bronchodilators. • β_2-agonists • Anticholinergics • Steroids b. Apply CPAP to reduce auto-PEEP. c. Manage the cause. 4. Ventilator related a. Assure synchrony for machine breaths. b. Eliminate auto-PEEP. c. Use flow-by or flow-trigger ventilation with or without pressure support.
Secretions, atelectasis, or plugging	1. Systemically hydrate. 2. Provide adequate humidity (i.e., humidifier temperature 35° C to 37° C at airway connection). 3. Maximally bronchodilate when necessary. 4. Suction.
Dyspnea	1. Use positioning (i.e., out of bed, dangling, and leaning forward). 2. Reassure and communicate with the patient. 3. Increase endurance, alternate weaning with rest to promote endurance. 4. Provide distraction.
Malposition	1. Position the patient to maximize diaphragmatic excursion and to improve lung volume and gas exchange (i.e., sitting or dangling). 2. Use a rocking chair. 3. Follow $\dot{V}_E$, V_T, rate, values for optimum positioning.
Respiratory muscle fatigue	1. Direct management at the cause. 2. Ensure adequate oxygen transport and cardiac output. 3. Nourish the patient. 4. Replace depleted electrolytes. 5. Decrease the WOB. a. Administer supplemental oxygen. b. Clear secretions. c. Decrease airway resistance.
Hemodynamic and fluid problems	1. Administer volume replacement and drugs to increase contractility, increase or decrease preload, and decrease afterload. 2. Delay weaning until the patient's cardiovascular status is stable. 3. Use techniques and the mode of ventilation to decrease the mean airway pressure.
Infection	1. Identify potential sites of infection. 2. Remove lines early, or replace them periodically. 3. Control infection. 4. Nourish the patient.
Metabolic problems	1. Control the cause and postpone weaning if the patient has acidosis. 2. Keep the carbon dioxide level at baseline if the patient has COPD, or allow progressive renal compensation during long-term weaning. 3. Provide moderate carbohydrate loading with total parenteral nutrition.
Low magnesium level High magnesium level Low calcium level Low phosphate level	4. Give supplements. 5. Provide dialysis or calcium chloride. 6. Control the cause before weaning. 7. Replace phosphate before weaning.
Nutrition	1. Assess weight, albumin, and total lymphocyte count at admission. 2. Label the degree of malnutrition, and calculate protein needs. 3. Nourish the patient.

TABLE 52-7

Management of Problems Among Difficult-to-Wean Patients—cont'd

Problem	Management Strategy
Exercise	1. Provide exercise therapy to increase muscle function, prevent contracture, and maintain joint integrity (i.e., passive-to-active range of motion and sitting to walking). 2. Increase strength during activities of daily living. 3. Secure a physiotherapy consultation. 4. Consider the use of an exercise bicycle. 5. Encourage wheelchair rides or walks with a portable ventilator. 6. Provide breathing retraining.
Psychologic problems	1. Secure early psychiatric consultation. 2. Allow for patient control. 3. Demonstrate staff accountability and honesty. 4. Provide a communication method. 5. Decrease environmental stress. 6. Teach relaxation methods. 7. Provide mental stimulation. 8. Provide recreation. 9. Provide rewards for reaching short-term goals. 10. Encourage self-care. 11. Allow other patients to visit. 12. Provide flexible visiting hours 13. Take the patient out of the ICU environment.
Sleep disturbances	1. Provide a quiet environment (i.e., dim lights), reposition the patient, give a back rub, and administer sedation. 2. Provide for uninterrupted sleep. 3. Avoid weaning at night. 4. Provide relaxation method (e.g., hypnosis, biofeedback, progressive muscle relaxation). 5. Prescribe short-acting sedative hypnotics.
Pain	1. Administer minimal analgesia.

Modified from Norton LC, Neureuter A: Weaning the long-term ventilator-dependent patient: common problems and management. Crit Care Nurse 9:42–52, 1989.

made, the process is generally one of ventilator disconnection rather than weaning. The method of terminal weaning should be as humane and as comfortable as possible and should not be done in a way that further burdens the family.[86]

SUMMARY CHECKLIST

- The most common cause of ventilator dependence is a ventilatory workload that exceeds the patient's ventilatory capabilities.
- Other common causes of ventilator dependence include oxygenation problems, cardiovascular instability, and psychologic factors.
- The most important criterion for determining whether a patient is ready for ventilator discontinuation or weaning is a significant improvement or reversal of the disease state or condition that caused the patient to need ventilatory support.
- Factors that should be optimized before weaning include oxygenation, ventilation, acid-base balance and electrolyte levels, cardiovascular status, kidney function and fluid balance, sleep deprivation, psychologic status, nutrition, and overall medical condition.
- Weaning techniques include spontaneous breathing trials, PSV, and SIMV.
- Spontaneous breathing trials and PSV result in faster discontinuation of ventilatory support as compared with SIMV.
- The ideal approach to weaning the vast majority of patients is a therapist-driven protocol that makes use of an SBT.
- The monitoring of the patient during weaning should include SpO_2, respiratory rate and pattern, dyspnea, cardiac rate and rhythm, and blood pressure assessments.
- The use of daily SATs or the maintenance of minimal sedation not only improves the speed of weaning but has also been shown to improve mortality.
- Before extubation, patients should be assessed for the ability to maintain and protect their airway and for the presence of upper airway edema.
- Common causes of weaning failure include an excessive ventilatory workload in the presence of ventilatory muscle weakness or fatigue, oxygenation problems, cardiovascular instability, the inability to clear secretions, poor mental status, and the presence of an underlying concurrent pathologic condition that necessitates treatment.
- The goals of the weaning of long-term ventilator-dependent patients include reducing the amount of support, reducing the invasiveness of support, and increasing the patient's level of independent function.
- Only <1.0% of patients that require mechanical ventilation end up long-term ventilator-dependent patients.
- The decision to terminally wean a patient should be made by the family in consultation with the patient's medical team and in accordance with established ethical and legal guidelines.

CHAPTER 53

Neonatal and Pediatric Respiratory Care

DANIEL W. CHIPMAN

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the correct approach to assessment of the fetus and newborn infant.
- Discuss the use of oxygen therapy, bronchial hygiene therapy, aerosol drug therapy, airway management, and resuscitation approaches in the care of infants and children.
- List the components of an Apgar Score.
- Identify the different S_PO_2 target ranges for preterm and full term infants and those with primary pulmonary hypertension.
- Describe the correct approach to assessment of the pediatric patient.
- Discuss the use of high flow nasal cannulas in infants and children.
- Discuss the use of continuous positive airway pressure and the basics of mechanical ventilation including high-frequency ventilation in the care of infants and children.
- Discuss the use of noninvasive ventilation in infants and children.
- List clinical situations where nitric oxide is used, and discuss its basic application.
- Explain the correct approach to ventilator management for a patient in status asthmaticus.
- Discuss the use of heliox for a patient with asthma.
- Discuss the steps to ventilator discontinuance for infants and children including a safety screen and assessment of ability to breathe spontaneously.

CHAPTER OUTLINE

KEY TERMS

Apgar score
appropriate for gestational age (AGA)
continuous positive airway pressure (CPAP)
extremely low birth weight (ELBW)
grunting, flaring, and retracting
high-frequency ventilation (HFV)
inhaled nitric oxide (INO)
large for gestational age (LGA)
meconium
patent ductus arteriosus (PDA)
primary pulmonary hypertension of the newborn (PPHN)
retinopathy of prematurity (ROP)
small for gestational age (SGA)
surfactant
very low birth weight (VLBW)

Caring for infants and children is one of the most challenging and rewarding aspects of respiratory care. Competent clinical practice in this area requires knowledge of the many pathophysiologic differences among infants, children, and adults. Understanding the unique pathophysiology involved in neonatal and pediatric respiratory disorders (see Chapter 34) can assist the respiratory therapist (RT) in providing quality care to infants and children. A thorough understanding of how the respiratory system develops in the fetus is the first step toward acquiring the specialized knowledge needed to practice neonatal respiratory care (see Chapter 9). This chapter begins with an overview of neonatal and pediatric patient assessment and then describes respiratory care modalities used to treat these patients.

ASSESSMENT OF THE NEWBORN

Assessment of the newborn begins before birth with assessment of the maternal history, the maternal condition, and the status of the fetus.

Maternal Factors

Maternal risk factors include many medical, physical, and social conditions. Maternal health and individual physiology, pregnancy complications, and maternal behaviors affect the health of the fetus. Any condition that causes an interference with placental blood flow or the transfer of oxygen (O_2) to the fetus can result in an adverse outcome. The clinician must be prepared for the possibility of resuscitation at delivery. This possibility is best anticipated by identifying risk factors that relate to neonatal compromise. Table 53-1 lists maternal risks and related outcomes of which the team preparing to receive the infant should be aware when the infant is delivered.

Fetal Assessment

Fetal assessment is performed with ultrasonography, amniocentesis, fetal heart rate monitoring, and fetal blood gas analysis. Ultrasonography uses high-frequency sound waves to obtain an image of the infant in utero. This image allows the physician to view the position of the fetus and placenta, measure fetal growth, identify possible anatomic anomalies, and assess the amniotic fluid qualitatively.

Amniocentesis involves direct sampling and quantitative assessment of amniotic fluid. Amniotic fluid may be inspected for **meconium** (fetal bowel contents) or blood. In addition, sloughed fetal cells can be analyzed for genetic normality. Lung maturation can be assessed with amniocentesis. The lecithin-to-sphingomyelin ratio (L:S ratio) involves measurement of two phospholipids, lecithin and sphingomyelin, synthesized by the fetus in utero. As shown in Figure 53-1, the L:S ratio increases with increasing gestational age. At approximately 34 to 35 weeks' gestation, this ratio abruptly increases to greater

TABLE 53-1
Maternal Condition and Neonatal Outcomes

Maternal Condition	Fetal or Neonatal Outcome
Previous pregnancy complication	Same outcome as previous fetus
Diabetes mellitus	LGA, congenital malformations, RDS, hypoglycemia
Pregnancy-induced hypertension	Prematurity, SGA (preeclampsia)
Maternal age <17 years	Low birth weight, prematurity
Maternal age >35 years	Prematurity, chromosomal defects
Placenta previa	Prematurity, bleeding, SGA
Abruptio placentae	Fetal asphyxia, bleeding
Alcohol consumption	SGA, CNS dysfunction, mental retardation, facial dysmorphology
Smoking	SGA, prematurity, mental retardation, SIDS
Drug use	Placental abruption, IUGR, prematurity, CNS abnormalities, withdrawal disorders

IUGR, Intrauterine growth restriction; *RDS,* respiratory distress syndrome; *SIDS,* sudden infant death syndrome.

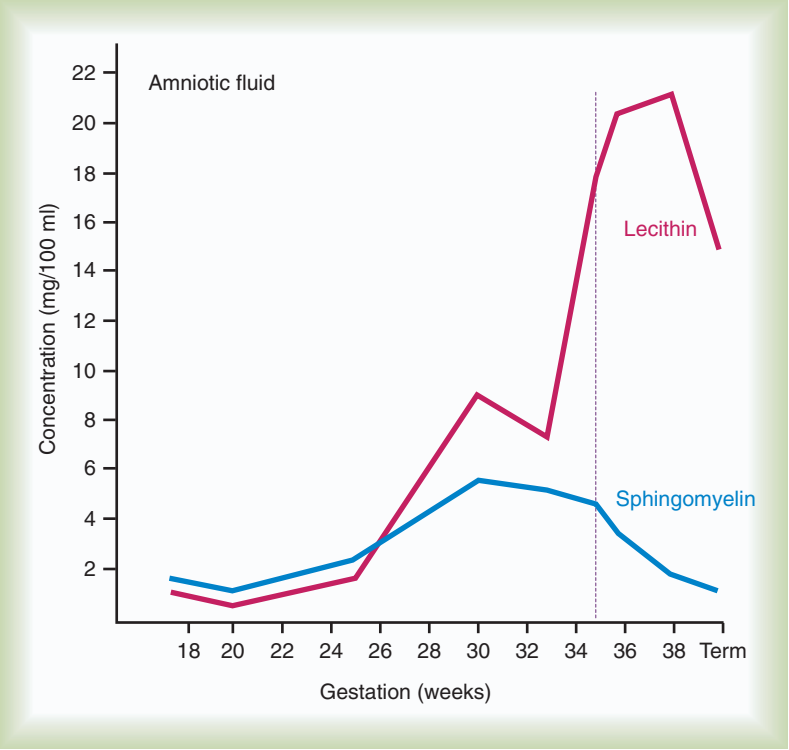

FIGURE 53-1 Lecithin *(red line)* and sphingomyelin *(blue line)* concentrations plotted against gestational age. L:S ratio rises to 1.2 at 28 weeks and to 2 or more at 35 weeks, indicating maturation of the fetal lung. (Modified from Gluck L, et al: Am J Obstet Gynecol 109:440, 1971.)

than 2:1. An L:S ratio greater than 2:1 indicates stable **surfactant** production and mature lungs.[1] Phosphatidylglycerol is another lipid found in the amniotic fluid that is used to assess fetal lung maturity. Phosphatidylglycerol first appears at approximately 35 to 36 weeks' gestation. If phosphatidylglycerol is more than 1% of the total phospholipids, the risk of respiratory distress syndrome is less than 1%.[2] Fetal heart rate monitoring includes the measurement of fetal heart rate and uterine contractions during labor. Examination of fetal heart rate changes related to uterine contractions identifies a fetus in distress. Fetal well-being is obtained by examining the variability and reactivity of the fetal heart rate. A normal fetal heart rate ranges from 120 to 160 beats/min. Fetal tachycardia can be a sign of fetal hypoxemia or could be related to other factors, such as prematurity or maternal fever. Temporary declines in fetal heart rate are called *decelerations* and can be mild (<15 beats/min), moderate (15 to 45 beats/min), or severe (>45 beats/min). Decelerations are classified by their occurrence in the uterine contraction cycle.

Figure 53-2 illustrates the three common patterns of early decelerations, late decelerations, and variable decelerations. Early decelerations occur when the fetal heart rate decreases in the beginning of a contraction. This type of deceleration is benign and in most cases is caused by a vagal response related to compression of the fetal head in the birth canal. A late deceleration occurs when the heart rate decreases 10 to 30 seconds after the onset of contractions. A late deceleration pattern indicates impaired maternal-placental blood flow, or uteroplacental insufficiency. With variable decelerations, there is no clear relationship between contractions and heart rate. This pattern is the most common of the three and probably related to umbilical cord compression. Short periods of cord compression are generally benign, but prolonged periods of compression result in impaired umbilical blood flow and can lead to fetal distress. Fetal heart rate variability is the beat-to-beat variation in rate that occurs because of normal sympathetic or parasympathetic influences. A completely monotonous heart rate tracing may be indicative of fetal asphyxia. Fetal heart rate reactivity is the ability of the fetal heart rate to increase in response to movement or external stimuli. A healthy fetus has two accelerations within a 20-minute period.

In utero, the fetus receives its blood supply from the placenta. Only a small portion of the blood that enters the fetal right heart flows through the lungs. This is a result of fetal pulmonary blood vessels being constricted with a high resistance to blood flow. There are two openings in the fetal heart through which most fetal blood flows. These normal anatomic shunts in the fetus are called *patent foramen ovale* and *patent ductus arteriosus (PDA)*. Blood flows through these openings and into the umbilical vessels before returning to the mother. Pressure in the umbilical vessels is low. During the transition from fetal life to newborn life, the umbilical cord is clamped, and the infant's systemic blood pressure is increased. The infant begins to breathe, and O_2 enters the infant's blood. Oxygenated blood

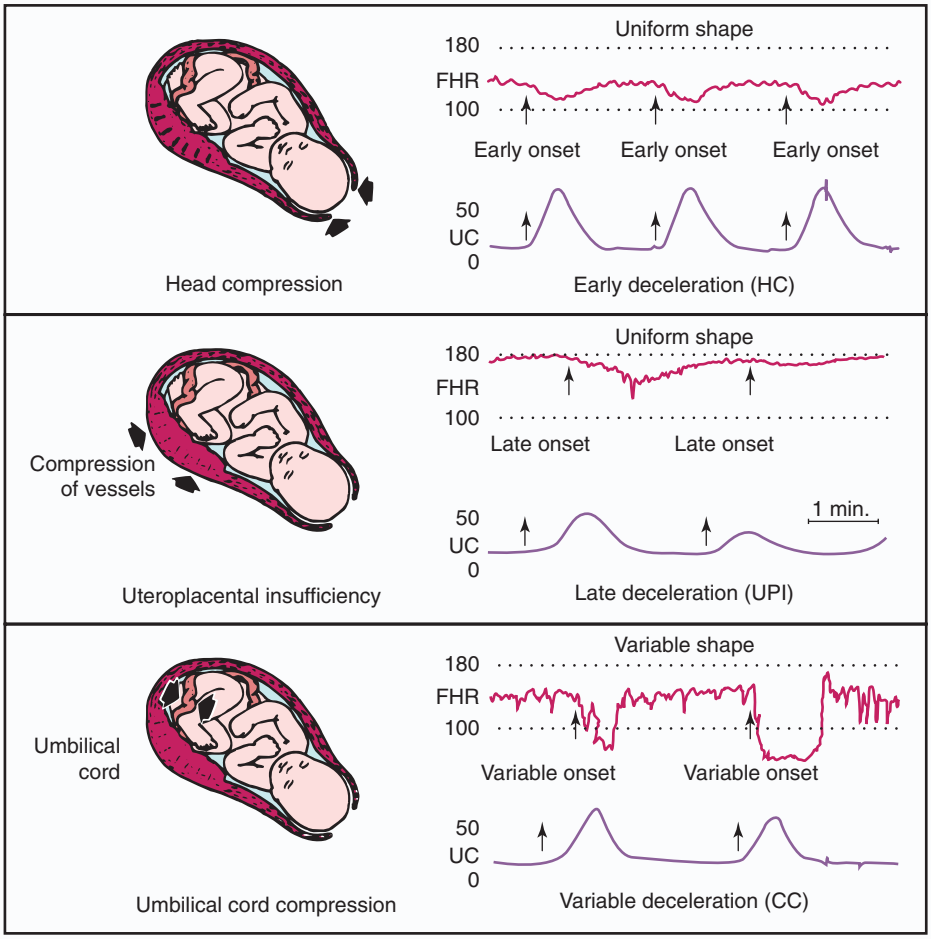

FIGURE 53-2 Fetal heart rate patterns. (Modified from Avery GB, editor: Neonatology: pathophysiology and management of the newborn, ed 2, Philadelphia, 1981, JB Lippincott.)

entering the pulmonary vessels causes the vessels to dilate and decreases pulmonary resistance. With higher systemic resistance and lower pulmonary resistance, less blood flows through the anatomic openings, and these openings begin to close. Evidence of normal transitional circulation is noted as the infant's skin turns from a bluish hue to pink over the first several minutes of life.

RULE OF THUMB

Infants presenting with a monotonous heart rate or a fetal scalp pH less than 7.2 may be experiencing asphyxia.

Fetal Blood Gas Analysis

When other factors indicate potential problems during labor and delivery, fetal blood pH can be used to determine severity. Normally, fetal blood is obtained from a capillary sample taken from the presenting body part, usually the scalp. Normal fetal capillary pH ranges from 7.35 to 7.25, with the lower values occurring late in labor. A pH less than 7.20 may indicate that the fetus is experiencing asphyxia. There is no direct correlation between fetal scalp and arterial blood pH; scalp pH should be used only to assist in interpreting clinical signs of fetal distress.

Evaluation of the Newborn

All newborns should be assessed immediately on delivery. Most newborns (>90%) do not need intervention when transitioning

from intrauterine to extrauterine life. The two categories of newborns most likely to need intervention are infants born with evidence of meconium in their airway and premature infants. The need for intervention is determined by assessing for the presence of meconium, breathing or crying, muscle tone, color, and gestational age.

Meconium is the medical term for the infant's first stool. It is a sticky green-black substance that if inhaled by the infant can cause significant respiratory problems. It is more likely to be present in a term or postterm newborn than one born prematurely. Term infants delivered without evidence of meconium who are crying or breathing and have good tone should not routinely be separated from the mother. They should be dried, covered, and given to the mother and observed for breathing, activity, and color. If meconium is present and the infant is vigorous, pharyngeal suctioning with a bulb suction is appropriate. Simultaneously the infant should be dried and placed under a warmer and assessed for signs of respiratory distress.

If meconium is present in a nonvigorous infant, stimulation should be avoided. Immediate endotracheal intubation before beginning positive pressure ventilation (PPV) is indicated as a means to clear meconium from the airway. The endotracheal tube should be attached to a meconium aspirator, and a suction device should be regulated for −70 to −100 mm Hg. As soon as the endotracheal tube is inserted, suction should be applied to the tube, and then the endotracheal tube is withdrawn. Reintubation and repeat suctioning may be necessary if meconium is still visible in the airway. Frequent assessment of the heart rate is indicated during this process, and if the heart rate is less than 100 beats per minute, bag-mask ventilation should be performed.

Preterm infants frequently need intervention. The more preterm the infant, the more likely the infant will need some level of resuscitation. If an infant is preterm, is not breathing, is not vigorous, or does not have good tone, resuscitation efforts should be initiated. Efforts are directed at warming the infant because cold stress may increase O_2 consumption and impair all subsequent resuscitation efforts.

After the infant is dried and warmed, the infant is positioned supine, with the head in a neutral position or slightly extended. A bulb syringe or 8F to 10F suction catheter may be used for secretion removal; however, in the absence of blood or meconium, catheter suctioning should be limited because aggressive pharyngeal suctioning may cause laryngospasm or bradycardia. Suction pressure should not exceed −100 mm Hg. Once the infant is suctioned, dried, and warmed, if apnea or inadequate respirations are present, tactile stimulation may be used to encourage spontaneous breathing. Many infants respond to stimulation and need no further resuscitative efforts. If after 30 seconds the infant has a heart rate of less than 100 beats/min or is apneic, bag-mask ventilation at a rate of 40 to 60 beats/min should be initiated.

The *most* important and effective action in neonatal resuscitation is effective ventilation. Recommendations from the American Academy of Pediatrics are to attach a pulse oximeter to the infant, begin resuscitation efforts using room air, and assess carefully the amount of O_2 needed.[3] Effective PPV usually results in rapid improvement of heart rate. Initial ventilating pressures of 30 to 40 cm H_2O may be necessary to achieve noticeable chest movement, particularly in a preterm newborn with surfactant deficiency. Continuous assessment of the lowest pressure needed to observe the chest rise is essential throughout the resuscitation. After application of PPV for 30 seconds, the heart rate is reassessed. If the heart rate is less than 60 beats/min, chest compressions are begun, and PPV is maintained. If the heart rate remains less than 60 beats/min after adequate ventilation with 100% O_2 and chest compressions for 30 seconds, appropriate medications are given. As soon as the heart rate is noted to be greater than 100 beats/min, compressions are discontinued. If spontaneous breathing is present, PPV may be gradually reduced and then discontinued. If spontaneous breathing remains inadequate or if heart rate remains less than 100 beats/min, assisted ventilation is continued via bag-mask or endotracheal tube. Figure 53-3 outlines a newborn resuscitation algorithm and includes the targeted saturation levels for the first 10 minutes of life.

RULE OF THUMB

The most important and effective action in neonatal resuscitation is to ventilate.

Apgar Score

An Apgar score is assigned at 1 minute and 5 minutes of life. The **Apgar score** is an objective scoring system used to evaluate a newborn rapidly. As shown in Table 53-2, the score has five components: heart rate, respiratory effort, muscle tone, reflex irritability, and skin color. Each component is rated according to standard definitions, resulting in a composite assessment score. Generally, infants scoring 7 or higher at 1 minute are responding normally. An infant with a score of 7 may require supportive care, such as O_2 or stimulation to breathe. Infants

TABLE 53-2

Apgar Scoring System for Newborn Assessment

	SCORE		
Sign	**0**	**1**	**2**
Heart rate	Absent	<100/min	>100/min
Respirations	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion	Active motion
Reflex irritability (catheter in nares, tactile stimulation)	No response	Grimace	Cough, sneeze, cry
Color	Blue or pale	Pink body with completely blue extremities	Pink

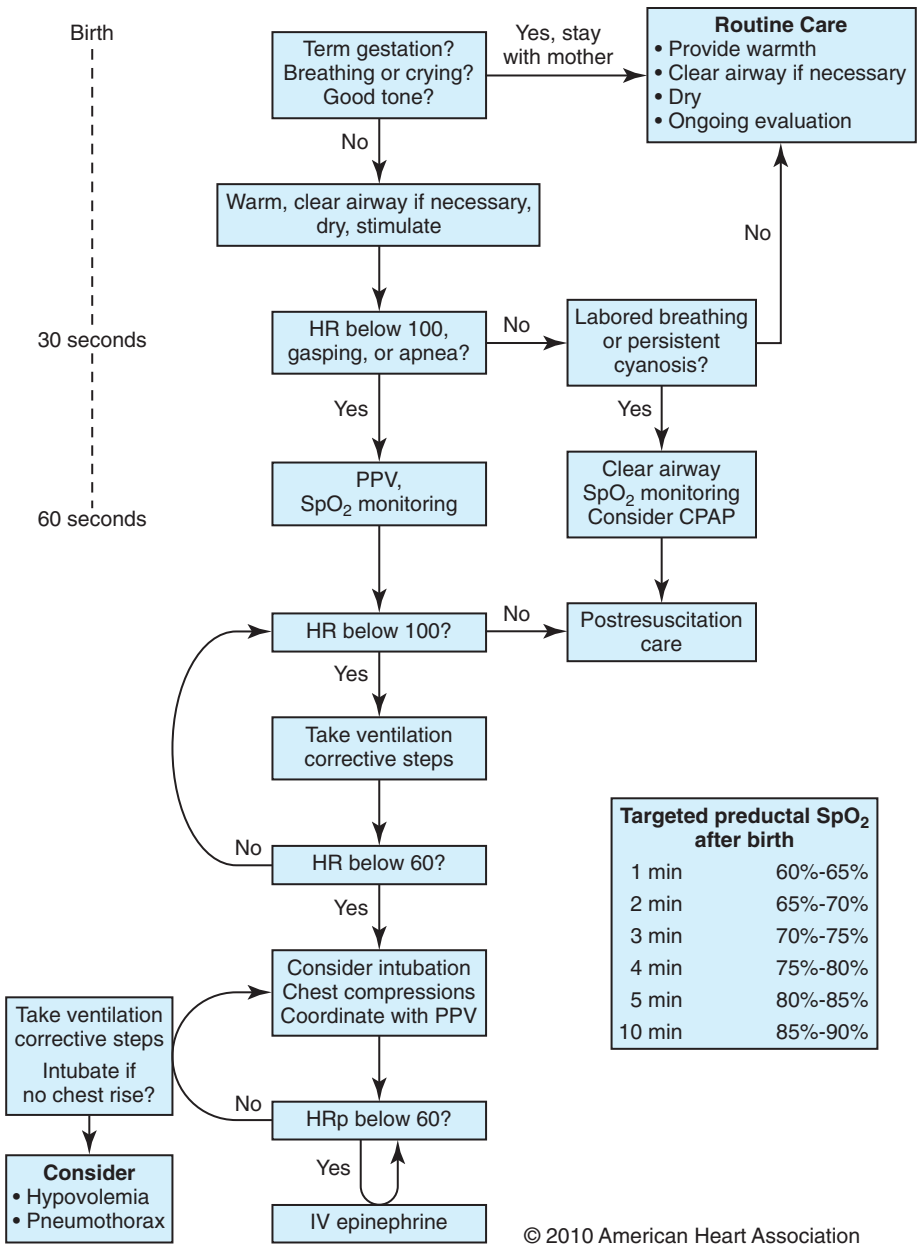

FIGURE 53-3 Neonatal resuscitation algorithm. Neonatal Resuscitation: 2010. American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. © 2010 American Heart Association, Inc.

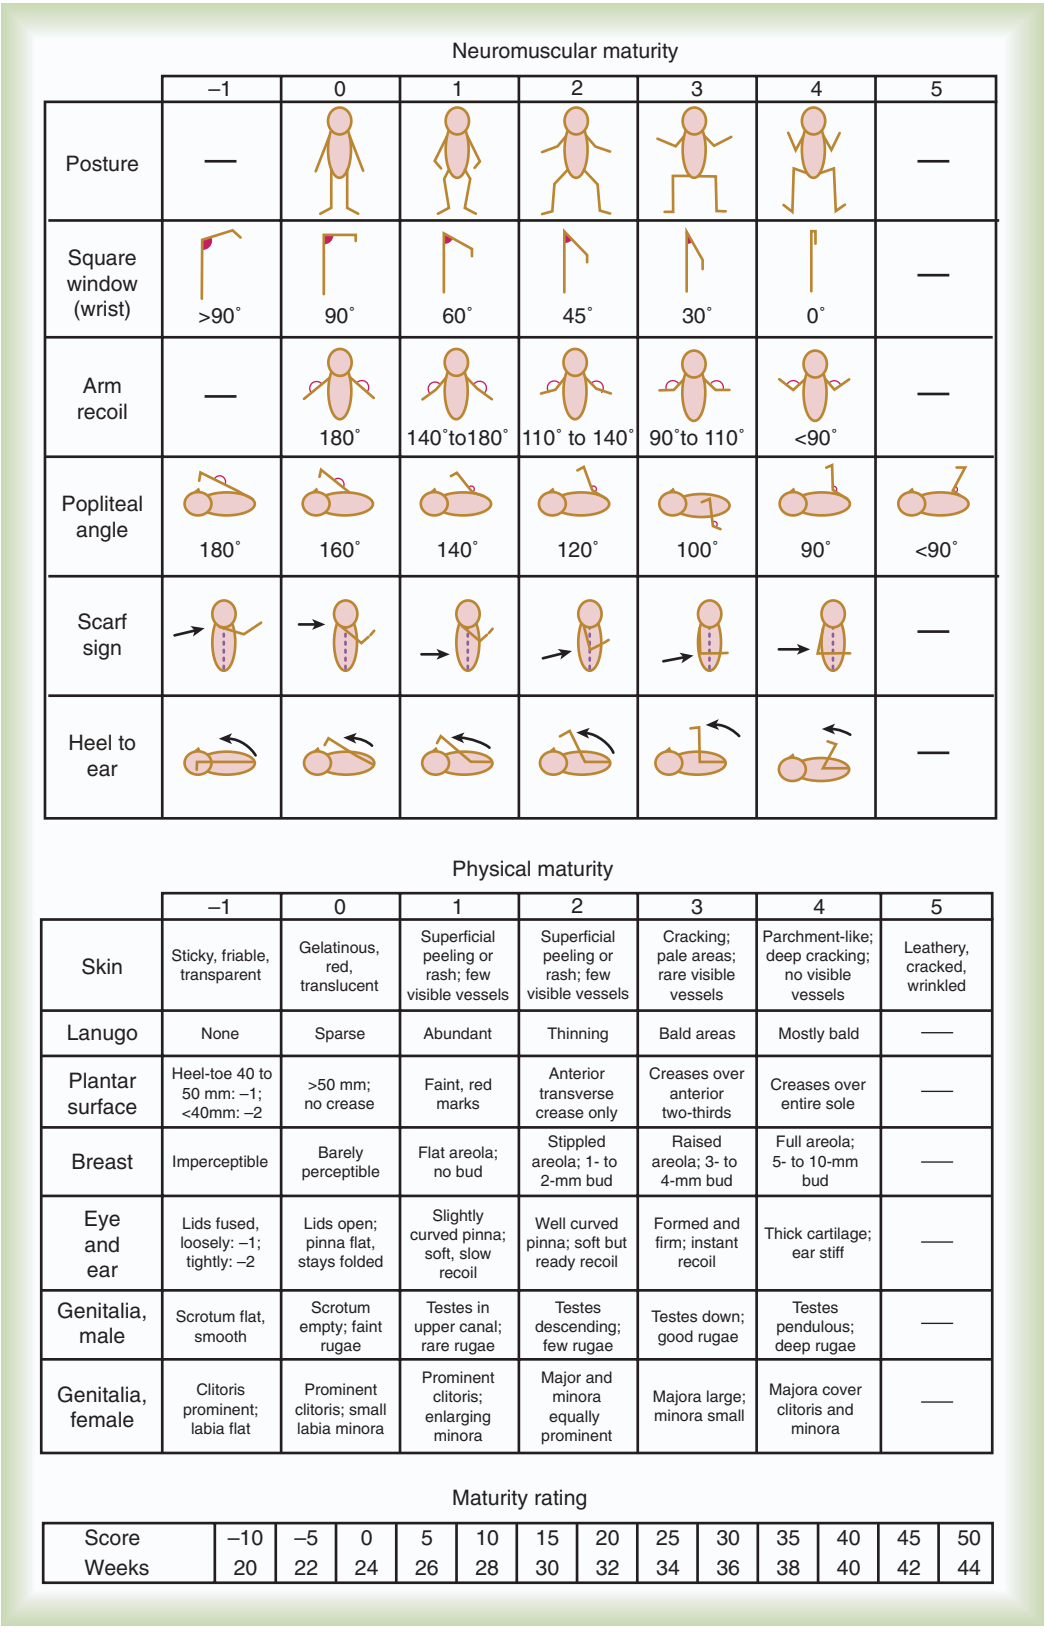
with a 1-minute Apgar score of 6 or lower may require more aggressive support.

Assessment of Gestational Age

Gestational age assessment and assessment of relationship of weight to gestational age are performed shortly after delivery. Determination of gestational age involves assessment of multiple physical characteristics and neurologic signs. Two common systems are used to determine gestational age: the Dubowitz scales and the Ballard scales. The Dubowitz scales involve assessment of 11 physical and 10 neurologic signs.[4] Physical criteria include assessment of skin texture, skin color, and genitalia. Neurologic criteria include posture and arm and leg recoil. The Ballard scales are a simplified version of the Dubowitz scales and include six physical and six neurologic signs as illustrated in Figure 53-4. Soon after delivery, the newborn is stabilized and weighed, followed by determination of gestational age. Infants born between 38 weeks and 42 weeks are considered term gestation. Infants born before 38 weeks are preterm. Infants born after 42 weeks are postterm.

All newborns weighing less than 2500 g are considered low birth weight. Newborns weighing less than 1500 g are considered **very low birth weight (VLBW)** Newborns weighing less than 1000 g are considered **extremely low birth weight (ELBW)** A newborn with a weight that is either too large or too small or who has been born preterm or postterm has a higher risk of



Neuromuscular maturity

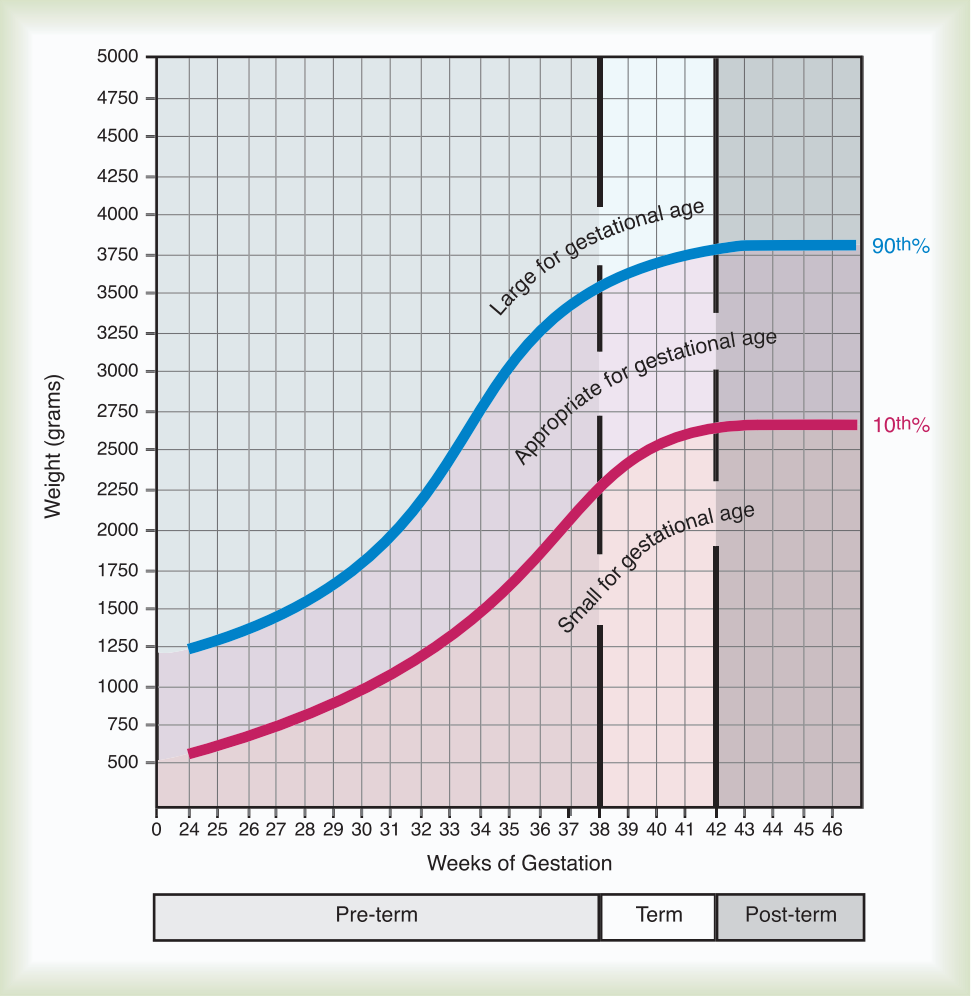

FIGURE 53-5 Colorado intrauterine growth chart. (Modified from Avery GB, editor: Neonatology: pathophysiology and management of the newborn, ed 4, Philadelphia, 1994, JB Lippincott.)

morbidity and mortality. As shown in Figure 53-5, by plotting the infant's gestational age against weight, the newborn's relative developmental status can be classified. Infants whose weight falls between the 10th and 90th percentiles are **appropriate for gestational age (AGA)** Infants whose weight is above the 90th percentile are **large for gestational age (LGA)** Infants whose weight is below the 10th percentile are **small for gestational age (SGA)**.

RULE OF THUMB

Infants weighing less than 2500 g are normally considered low birth weight neonates. Infants weighing less than 1500 g are considered VLBW neonates, and neonates weighing less than 1000 g are considered ELBW neonates.

By classifying infants into one of the combined categories, such as "preterm, AGA," the clinician can help identify infants at highest risk and predict the nature of the risks involved and the likely mortality rate. Small, preterm infants are at highest risk. Compared with term infants, the lungs of these infants are not yet fully prepared for gas exchange. In addition, their digestive tracts cannot normally absorb fat, and their immune systems are not yet capable of warding off infection. Small, preterm infants also have a very large surface area-to-body weight ratio; this increases heat loss and impairs thermoregulation. Finally, the vasculature of these small infants is underdeveloped, increasing the likelihood of hemorrhage (especially in the ventricles of the brain).

RULE OF THUMB

Infants born before 38 weeks' gestation are considered preterm.

Respiratory Assessment of the Infant

Not all respiratory problems occur at birth; many respiratory disorders develop after birth and may develop slowly or suddenly. RTs are commonly called on to help assess and treat infants who develop respiratory distress after birth.

Physical Assessment

Physical assessment of the infant begins with measurement of vital signs. A normal newborn respiratory rate is 40 to 60 breaths/min. The lower the gestational age, the higher the normal respiratory rate will be. A 28-week gestational age infant may normally breathe 60 times a minute, whereas the rate more typical of a term newborn is 40 breaths/min. Tachypnea (>60 breaths/min) can occur because of hypoxemia, acidosis, anxiety, or pain. Respiratory rates less than 40 breaths/min should be interpreted with previous trends of the newborn's respiratory rate. A baseline respiratory rate of 36 breaths/min in a term newborn is within normal limits; however, a respiratory rate of 36 breaths/min in a preterm newborn previously breathing at 70 breaths/min may indicate compromise. Causes of slow respiratory rates include medications, hypothermia, or neurologic impairment.

Normal infant heart rates rang from 100 to 160 beats/min. Heart rate can be assessed by auscultation of the apical pulse, normally located at the fifth intercostal space, midclavicular line. Alternatively, the brachial and femoral pulses may be used. Weak pulses indicate hypotension, shock, or vasoconstriction. Bounding peripheral pulses occur with major left-to-right shunting through a **patent ductus arteriosus (PDA)**.[5] A strong brachial pulse in the presence of a weak femoral pulse suggests either PDA or coarctation of the aorta. Table 53-3 lists normal ranges of blood pressure for neonates of different sizes.

RULE OF THUMB

The normal respiratory rate for a full-term infant is 40 to 60 breaths/min.

Chest examination in an infant is more difficult to perform and interpret than in an adult because of the small chest size and the ease of sound transmission through the infant chest. Thorough observation of the infant greatly enhances the assessment data obtained. Infants in respiratory distress typically exhibit one or more key physical signs: nasal flaring, cyanosis, expiratory grunting, tachypnea, retractions, and paradoxical breathing. Nasal flaring is seen as dilation of the ala nasi on inspiration. The extent of flaring varies according to facial structure of the infant. Nasal flaring coincides with an increase in the work of breathing. In concept, nasal flaring decreases the resistance to airflow. It also may help stabilize the upper airway by minimizing negative pharyngeal pressure during inspiration.[6] Cyanosis may be absent in infants with anemia, even when arterial partial pressure of oxygen (PaO_2) levels are decreased. In addition, infants with elevated fetal hemoglobin levels may not become cyanotic until PaO_2 decreases to less than 30 mm Hg. Hyperbilirubinemia, common among newborns, may mask cyanosis. Grunting occurs when infants exhale against a partially closed glottis. By increasing airway pressure during expiration, grunting helps prevent airway closure and alveolar collapse. Grunting is most common in infants with respiratory distress syndrome, but it is also seen in other respiratory disorders associated with alveolar collapse. Figure 53-6 illustrates the Silverman score, which is a system of grading severity of lung disease.

TABLE 53-3

Normal Neonatal Blood Pressures

Weight (g)	Systolic (mm Hg)	Diastolic (mm Hg)

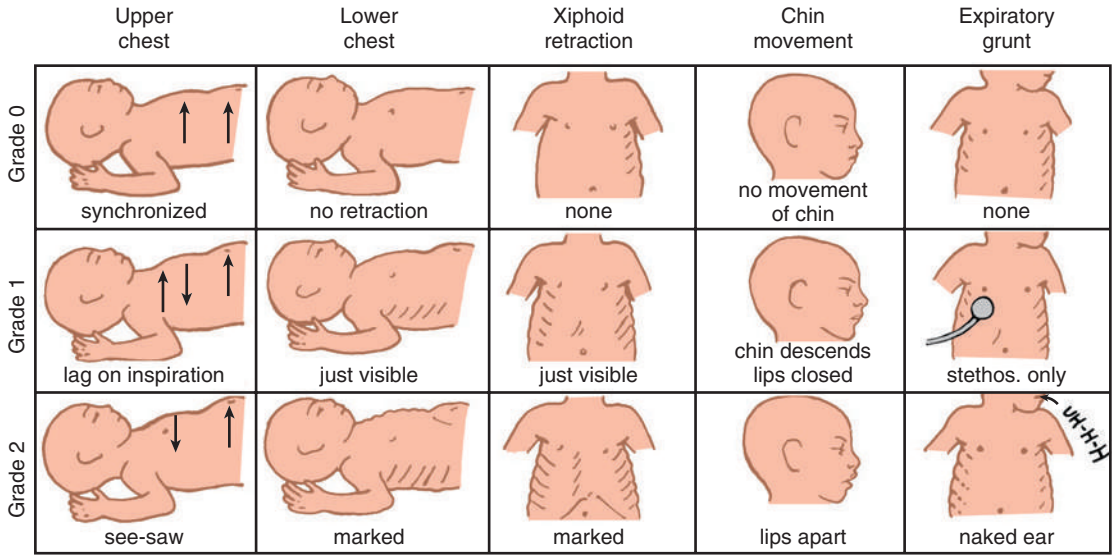

FIGURE 53-6 Silverman score—a system for grading severity of underlying lung disease. (Modified from Silverman WA, Anderson DH: Pediatrics 17:1, 1956.)

Retractions refer to the drawing in of chest wall skin between bony structures. Retractions can occur in the suprasternal, substernal, and intercostal regions. Retractions indicate an increase in the work of breathing, especially because of decreased pulmonary compliance. Paradoxical breathing in infants differs from paradoxical breathing normally seen in adults. Instead of drawing the abdomen in during inspiration, an infant with paradoxical breathing tends to draw in the chest wall. This inward movement of the chest wall may range in severity. As with retractions, paradoxical breathing indicates an increase in ventilatory work. Applying continuous positive airway pressure (CPAP) to a newborn exhibiting signs of respiratory distress including **grunting, flaring, and retracting** may help to increase lung volume by preventing alveolar collapse and improve gas exchange. The benefits of CPAP in children are discussed in more detail later.

Surfactant

Surfactant production begins around the 24th week of gestation and continues through gestation. Surfactant contributes to the stability of the alveolar sacs by reducing the surface tension of the fluids that coat the alveoli. Surfactant deficiency places an infant at increased risk for respiratory distress. By about 34 weeks' gestation, most infants have produced enough surfactant to keep the alveoli from collapsing. There are two specific approaches to preventing and treating surfactant deficiency. Surfactant deficiency is due to lung immaturity. When a premature delivery is anticipated, steroids are given to the mother to help promote lung maturation. In addition, infants born before 35 weeks' gestation, especially infants born very prematurely (<30 weeks), should be assessed clinically for the need to receive exogenous surfactant. The need for surfactant is determined by assessing the infant's lung volume on chest x-ray, evaluating the inspired O_2 concentration to maintain O_2 saturations greater than approximately 88%, and clinically assessing the infant's work of breathing.

Recent evidence supports early surfactant replacement, immediately following delivery, for infants less than 27 weeks' gestation. Infants 27 to 30 weeks' gestation should be placed on CPAP and evaluated clinically for the need to receive surfactant.[7-9]

Surfactant administration has also been shown to be useful in conditions in which surfactant structure and/or function has been altered. These conditions include meconium aspiration, neonatal pneumonia, pulmonary hemorrhage, and primary surfactant deficiency. Administration of surfactant requires intubation. It is essential to ensure the endotracheal tube is properly positioned, approximately 0.5 to 1 cm above the carina, before delivering surfactant. The dose depends on the specific brand of surfactant being administered. Close monitoring of the infant's vital signs, O_2 saturation, and compliance is necessary during and after surfactant administration. Soon after surfactant is delivered, the infant's compliance should begin to increase resulting in improved gas exchange. Ventilating pressures and fractional concentration of inspired oxygen (FiO_2) need to be decreased to avoid lung injury and excessive partial pressure of O_2. The ventilating pressure should be decreased to the level that maintains a tidal volume (V_T) of 5 to 7 ml/kg. FiO_2 should be decreased to maintain an oxygen saturation level (SpO_2) of approximately 89% to 94% in preterm infants and to the lowest FiO_2 possible to maintain SpO_2 >92% in term or postterm infants. Those with primary pulmonary hypertension should have SpO_2 >95% (see Clinical Practice Guideline 53-1).

Blood Gas and Pulse Oximetry Analysis

Blood gas analysis is helpful in assessing respiratory distress in an infant. Many noninvasive techniques, such as transcutaneous partial pressure of oxygen ($PtcO_2$), transcutaneous partial pressure of carbon dioxide ($PtcCO_2$), end-tidal carbon dioxide (CO_2), and pulse oximetry (SpO_2), are used to obtain comparable data, although blood gas analysis is more precise when results are critical. An infant blood gas sample can be obtained from an artery or capillary. Chapter 19 summarizes the advantages, disadvantages, and complications of these sampling methods. Care must be taken in assessing the results of capillary sampling. Capillary blood gases provide only information regarding ventilation and acid-base status, and accuracy is highly dependent on technique.[10] Normal values for infant blood gases are listed in Table 53-4.

Monitoring O_2 saturation using a pulse oximeter is a standard of care for sick newborns. Saturation probes must be carefully placed on the newborn; the most common sites are the wrist, the medial surface of the palm, or the foot. Sufficient cardiac output and skin blood flow are essential to provide an accurate saturation value. The pulse rate indicated on the oximeter should correlate with the infant's actual pulse before any conclusions regarding saturation can be drawn. Intracardiac shunting and intrapulmonary shunting are causes of decreased saturation in sick infants. When interpreting saturation levels in a newborn, it is important to consider where the saturation is being monitored. Saturation probes placed on the right hand assess preductal saturations. Probes placed on other extremities indicate postductal saturation levels. Infants at risk for pulmonary hypertension should have saturation probes placed to monitor preductal and postductal saturations. A large difference (>5%) between the two readings should prompt the clinician to consider pulmonary hypertension as a potential concern. Conditions that prevent the closing of the ductus arteriosus and foramen ovale result in decreased saturation. Many congenital heart defects result in significant intracardiac shunting. Interpreting adequate saturation for a newborn requires knowledge of any cardiac defect along with the infant's pulmonary condition.

Respiratory Assessment of the Pediatric Patient

Normal breathing in children is evidenced by quiet inspiration and passive expiration at an age-appropriate rate. Respiratory rates are rapid in neonates and decrease in toddlers and older children. Table 53-5 lists normal respiratory rates. The initial assessment of a pediatric patient starts with evaluating airway

53-1 Surfactant Replacement Therapy

AARC Clinical Practice Guideline (Excerpts)

INDICATIONS

- Prophylactic surfactant administration is indicated in (1) infants at high risk of developing respiratory distress syndrome (RDS) because of short gestation (<32 weeks) or low birth weight (<1300 g) and (2) infants with known surfactant deficiency
- Rescue therapy is indicated in preterm or full-term infants who (1) require intubation and mechanical ventilation secondary to increased work of breathing and O_2 requirements and (2) have clinical evidence of RDS

CONTRAINDICATIONS

Relative contraindications to surfactant administration are the following:

- Presence of congenital anomalies incompatible with life beyond the neonatal period
- Respiratory distress in infants with laboratory evidence of lung maturity

HAZARDS AND COMPLICATIONS

- Procedural complications resulting from the administration of surfactant
  - Plugging of endotracheal tube by surfactant
  - Administration of surfactant to only one lung
  - Hemoglobin desaturation or need for extra O_2
  - Drug dosing errors
  - Bradycardia secondary to hypoxia
  - Tachycardia secondary to agitation, with reflux of surfactant into endotracheal tube
  - Pharyngeal deposition of surfactant
- Physiologic complications of surfactant replacement therapy
  - Apnea
  - Increased necessity for treatment for PDA
  - Pulmonary hemorrhage
  - Marginal increase in ROP
  - Mucous plugs
  - Barotrauma with increased lung compliance

ASSESSMENT OF NEED

Determine that valid indications are present:

- Assess lung immaturity before prophylactic administration of surfactant (see Contraindications)
- Establish the diagnosis of RDS in the presence of short gestation or low birth weight

ASSESSMENT OF OUTCOME

- Reduction of FiO_2 requirement or work of breathing or both
- Improvement in lung volumes and lung fields as indicated by chest radiograph
- Improvement in pulmonary mechanics (e.g., compliance, airway resistance, V_T, VE, FRC, transpulmonary pressure)
- Reduction in ventilator requirements (PIP, PEEP, Paw)
- Improvement in ratio of arterial to alveolar PO_2 (a/A PO_2), oxygenation index

MONITORING

The following should be monitored as part of surfactant replacement therapy:

- Variables to be monitored during surfactant administration
  - Proper placement of delivery device
  - Position of patient (i.e., head direction)
  - FiO_2 and ventilator settings
  - Chest wall movement
  - Reflux of surfactant into endotracheal tube
  - O_2 saturation by pulse oximetry
  - Heart and respiratory rate, chest expansion, skin color, and vigor
- Variables to be monitored after surfactant administration
  - Arterial blood gases
  - Pulmonary mechanics and volumes
  - Chest radiography
  - Breath sounds
  - Ventilator PIP, PEEP, Paw, FiO_2
  - Blood pressure
  - Heart and respiratory rate, chest expansion, skin color, and vigor

For complete guideline, see American Association for Respiratory Care: Clinical practice guideline: surfactant replacement therapy. Respir Care 39:824, 1994.

MINI CLINI

Neonatal Ventilation

PROBLEM: A 1.8-kg, 28-week newborn is transported from the delivery room to the neonatal ICU. The patient was apneic and bradycardic at birth and failed to respond to initial stimulation and resuscitation. He was intubated with a 3.0 uncuffed endotracheal tube. His heart rate increased to 120 and he has been manually ventilated with a T-piece resuscitator at a PIP of 25 cm H_2O and PEEP of 5 cm H_2O during transport. When the neonate is admitted to the neonatal ICU, the RT is asked to recommend appropriate ventilator settings.

Solution:

- Mode—A/C pressure ventilation
- PIP—20 cm H_2O
- PEEP—5 cm H_2O
- Set respiratory rate—40 breaths/min
- Inspiratory time—0.3 sec
- FiO_2—0.4

Because the patient was manually ventilated during transport, it is unclear what V_T has been delivered. Initial PIP of 20 cm H_2O and PEEP of 5 cm H_2O are safe and common settings. Immediate observation of the chest would allow the RT to evaluate chest expansion and adjust PIP as required. Over the next several minutes if V_T monitoring is available, targeting V_T of 6 to 8 ml/kg would guide subsequent settings.

Set respiratory rate of 40 breaths/min is at the lower end of the normal range for this patient; however, use of the A/C mode with a time-cycled, pressure-limited breath and appropriately set trigger sensitivity would allow the patient to establish a more comfortable respiratory rate. Adjustment of the inspiratory time may also be necessary to increase patient comfort and improve patient-ventilator synchrony. Further adjustments may be guided by $PaCO_2$. Because this patient was born prematurely, rapid assessment of SpO_2 is essential, and FiO_2 should be adjusted to maintain SpO_2 between 88% and 92%.

This patient should receive surfactant replacement therapy. The clinician may consider volume-targeted, pressure-limited ventilation (e.g., pressure-regulated volume control, volume guarantee) during and immediately after surfactant delivery. This modality may help prevent lung overdistention until compliance has stabilized.[11,12]

TABLE 53-5

Normal Respiratory and Heart Rates by Age

Age	Breaths/Minute	Heart Rates
Infants (<1 yr)	30-60	90-120
Toddler (1-3 yr)	24-40	80-100
Preschooler (4-5 yr)	22-34	70-90
School age (6-12 yr)	18-30	70-90
Adolescent (13-18 yr)	16-22	60-80

patency. Normal heart rates are higher in younger children and decrease with age. In assessing a pediatric patient, establishing if the airway is patent or has any obstructive component is essential. Signs that suggest upper airway obstruction include increased inspiratory effort with retractions or inspiratory efforts with no airway or breath sounds.

The clinician observes for movement of the chest or abdomen. The clinician listens for breath sounds focusing on both inspiratory sounds and expiratory sounds. Chest or abdominal movement without breath sounds may indicate total airway obstruction, and basic life-support maneuvers are indicated. High-pitched sounds heard on inspiration (stridor) are often indicative of upper airway conditions, whereas expiratory noises are more often associated with lower airway obstruction.

Causes of stridor in children can be infections, such as croup; foreign body aspiration, particularly in a small child; congenital or acquired airway abnormalities; allergic reactions; or edema after a procedure. Inhaled epinephrine via nebulizer and intravenous steroids are commonly used to treat stridor. Common causes of lower airway obstruction are bronchiolitis and asthma. When wheezing is noted, inhaled bronchodilators are indicated. If the patient is able to use a metered dose inhaler (MDI), repeated inhalations can act quickly to improve aeration. When the patient is unable to use the MDI appropriately or when severe symptoms are present, delivering a bronchodilator with a nebulizer can bring relief. More than one nebulizer treatment often is necessary to relieve airway inflammation. A common approach is to deliver three consecutive treatments. If the patient continues to be symptomatic, continuous bronchodilator therapy may be delivered with a nebulizer attached to an infusion pump set to administer a bronchodilator continuously. Tachycardia secondary to the beta-1 effect of inhaled bronchodilators may occur. Frequent reassessment of any patient receiving continuous bronchodilator therapy is essential. Heliox, an inhaled mixture of helium and O_2 (described in the section on specialty gases), has been shown to be beneficial in cases of some airways conditions in children.

As noted in the section describing newborn assessment, use of accessory muscles, grunting, flaring, and retracting all can be signs of respiratory distress. Head bobbing, noted by chin up and neck extended during inspiration with chin falling during expiration, and seesaw respirations, indicated by the chest retracting and the abdomen expanding during inspiration, are signs of impending respiratory failure. Assessing the child's level of alertness is essential. Levels of alertness range from fully awake, agitated, minimally responsive, to unresponsive. A child's ability to protect his or her airway should be questioned in a minimally responsive or unresponsive child.

RESPIRATORY CARE

Respiratory care of infants and children incorporates approaches taken from adult practice. Important physiologic and age-related differences between adults and children require variations in the provision of respiratory care. This section

focuses on neonatal and pediatric O_2 therapy, bronchial hygiene, humidity and aerosol therapy, airway management, and resuscitation.

Oxygen Therapy

Goals and Indications

O_2 should be administered as any other drug, using the lowest dose necessary to achieve the intended goal. The goal of O_2 therapy is to provide adequate tissue oxygenation. However, O_2 therapy is most frequently adjusted according to O_2 saturation levels. A clear understanding of the limitation of O_2 saturation is needed to interpret the saturation reading and make appropriate decisions. Infants and children receiving O_2 therapy have variable O_2 saturation target ranges depending on age and underlying condition.

Lower saturation levels are targeted in infants less than 32 weeks' gestation. There is evidence that exposure to supplemental O_2 in a premature infant is a risk factor for the development of **retinopathy of prematurity (ROP)** ROP is caused by an abnormal vascularization of the retina, which in the most severe cases leads to retinal detachment. Preterm neonates weighing less than 1500 g are most susceptible. Hyperoxia is not the only factor associated with ROP, but close monitoring and adjusting of O_2 therapy to avoid hyperoxia is crucial to decrease the risk of ROP. A specific saturation goal of 88% to 94% should be established for this age group, and O_2 should be adjusted to maintain the intended target. Avoiding very high or very low saturation levels is critical. Adjusting the delivered O_2 concentration by small increments avoids large swings in saturation levels.[13-17]

In a term infant with **primary pulmonary hypertension of the newborn (PPHN)** a higher targeted saturation level is desired to avoid further pulmonary constriction associated with hypoxemia. The position of the saturation probe needs to be considered when interpreting saturation. Intracardiac shunting can occur in the presence of PPHN. One saturation probe positioned on the upper right extremity represents preductal saturations and is indicative of the saturation of blood being delivered to the brain. O_2 saturation measured on other extremities is considered postductal and represents saturation to other parts of the body.

Newborns with certain cardiac anomalies are dependent on their intracardiac shunt through the ductus arteriosus to survive. An increased saturation in newborns promotes constriction of the ductus arteriosus. Although this constriction is normally a positive response, it may cause premature closure of the ductus arteriosus in infants with ductal-dependent congenital heart defects. An infant born with hypoplastic left heart syndrome, a defect in which the left-sided heart structures are poorly developed, relies on the patency of the ductus arteriosus for systemic blood supply. In addition, hyperoxia can increase aortic pressures and systemic vascular resistance, decreasing the cardiac index and O_2 transport in children with acyanotic congenital heart disease. The emphasis for O_2 therapy for all newborns should be to provide only as much O_2 as indicated by the infant's condition. O_2 therapy should be administered using a written care plan with specified clinical outcomes (e.g., titrate flow/FiO_2 to maintain SpO_2 88% to 92%, notify physician if FiO_2 is >0.40).

Methods of Administration

The effectiveness of O_2 devices depends on the performance characteristics of the device (delivered FiO_2, flow rate, relative humidity), the interface of the device, and the tolerance of the patient for using the device. Children are often frightened and combative, making it impractical to use some O_2 administration devices. Selection of an O_2 device must be based on the degree of hypoxemia and the emotional and physical needs of the child and family. O_2 can be administered to infants and children by mask, cannula, high-flow nasal cannula, or oxyhood. Table 53-6 compares the advantages and disadvantages of standard O_2 delivery methods.

TABLE 53-6

Oxygen Delivery Devices

Device	Age	FDO_2	Advantages	Disadvantages
Air entrainment mask	≥3 yr	High flow; 0.24-1	Precise FiO_2; good for transport; ease of application	Low relative humidity; pressure necrosis to face; difficult to fit and maintain on active child, not recommended for infants; risk of aspiration
Nasal cannula	Premature infants to adult	Low flow; 25 ml/min-6.0 L/min	Tolerated well by all ages	Inaccurate FiO_2; low relative humidity; excessive flows may cause inadvertent CPAP in infants; precise FiO_2 may be achieved with O_2 blender
Incubator	Newborns ≤28 days	<0.40 FiO_2, combine use with cannula or hood for precise FiO_2	Low FiO_2 for stable infants; neutral thermal environment for premature infants	Varying FiO_2; long stabilization time; limits access to child for patient care
Oxyhood	Premature infants to ≤6 mo	0.21-1 FiO_2 with O_2 blender maintained at 30°C to 34°C	Warmed and humidified gas at stable FiO_2 during routine patient care	Overheating may cause apnea and dehydration; underheating may cause O_2 consumption; inadequate flow causes CO_2 buildup; noise produced by humidification device may cause hearing loss

FDO_2, Delivered oxygen concentration.

Secretion Clearance Techniques

Secretion clearance techniques that can be applied to infants and children include chest physiotherapy, positive expiratory pressure therapy, autogenic drainage, flutter therapy, and mechanical insufflation-exsufflation.[18,19] Secretion clearance techniques are considered when accumulated secretions impair pulmonary function and an infiltrate is visible on a chest radiograph. Secretion retention is common in children who have pneumonia, bronchopulmonary dysplasia, cystic fibrosis, bronchiectasis, and some neuromuscular diseases. Figure 53-7 shows postural drainage and percussion positions for infants and children.

Methods

Infants and young children cannot cough on command. For this reason, secretions often must be removed by suctioning. For older children with excessive secretions, directed deep breathing and coughing may help improve pulmonary clearance. The use of mechanical insufflation-exsufflation in children with neuromuscular disease can be helpful in clearing secretions. Adjunctive therapy devices such as positive expiratory pressure, flutter, or intermittent percussive ventilation therapy have been effective in secretion clearance in patients with cystic fibrosis.[20]

Monitoring

Given the instability of most critically ill infants and children, a thorough initial assessment and ongoing patient evaluation during and after treatment are mandatory. Traditional assessment of vital signs, blood pressure, color, and breath sounds before, during, and after treatment should be supplemented with pulse oximetry monitoring if hypoxemia is suspected.

Humidity and Aerosol Therapy

Key differences in humidity and aerosol therapy in infants and children include assessment of patient response to therapy, age-related physiologic changes, and equipment application.

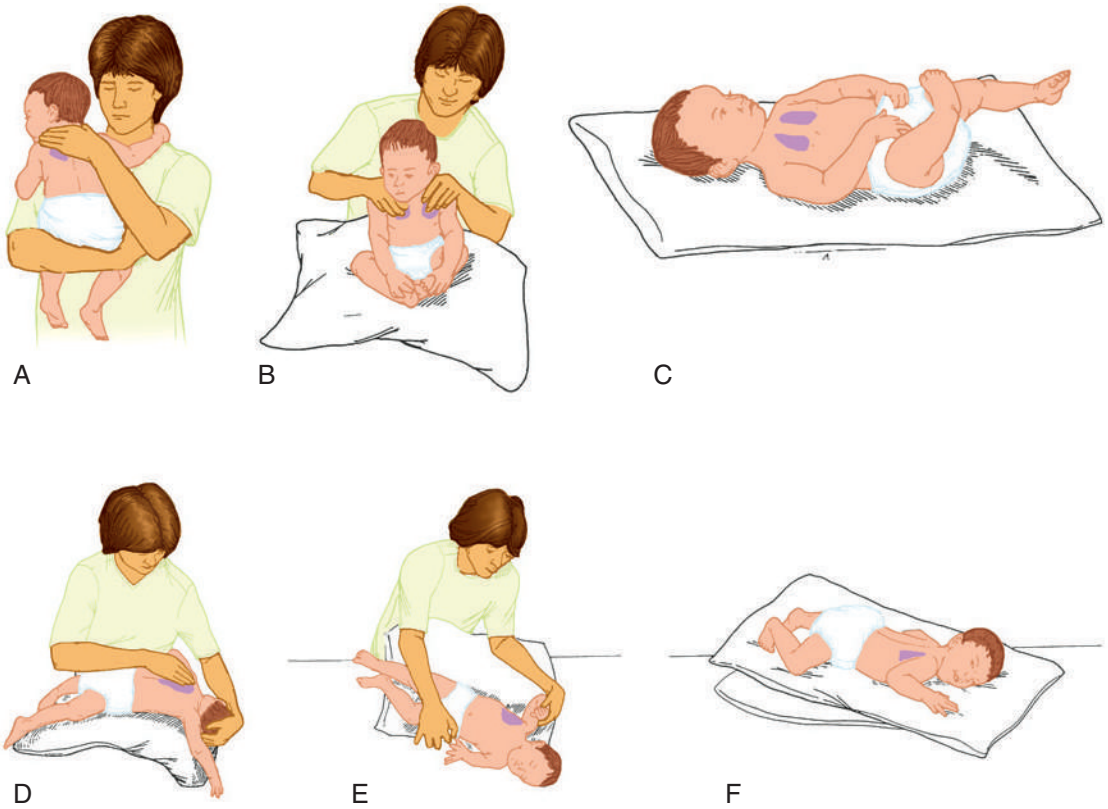

FIGURE 53-7 Postural drainage and percussion positions for infant and child. Angles of drainage for infant are not as obtuse as those for child. **A,** Posterior segments of right and left upper lobes are drained with patient in upright position at 30-degree angle forward. Percuss over upper posterior thorax. **B,** Apical segments of right and left upper lobes are drained with patient in upright position, leaning forward 30 degrees. Percuss over area between clavicle and tip of scapula on each side. **C,** Anterior segments of right and left upper lobes are drained with patient in flat, supine position. Percuss anterior side of chest directly under clavicles to around nipple area *(shaded).* Avoid direct pressure on sternum. **D,** Right and left lateral basal segments of lower lobes are drained at 30 degrees Trendelenburg. Patient lies on appropriate side, rotated 30 degrees forward. Percuss over uppermost portions of lower ribs. **E,** Right and left anterior basal segments of lower lobes are drained at 30 degrees Trendelenburg. Patient lies on appropriate side with a 20-degree turn backward. Percuss above anterior lower margin of ribs. **F,** Right and left superior segments of lower lobes are drained at 15 degrees Trendelenburg, with patient in prone position. Percuss below scapula in midback area.

Humidity Therapy

In children with an intact upper airway, O_2 therapy devices, such as low-flow nasal cannulas, do not routinely need to be humidified. However, any time the upper airway is bypassed by intubation, supplemental humidification must be provided using a heated humidifier. Humidification of inspired gases for infants and children receiving mechanical ventilation is commonly provided by a servo-controlled humidifier. Ideal features for these systems include the following: (1) low internal volume and constant water level to minimize compressed volume loss; (2) closed, continuous feed water supply to avoid contamination; (3) distal airway temperature sensor and high/low alarms. Common problems with humidifier systems include condensation in the tubing, inadequate humidification, and hazards associated with the heating coil.[21,22] Using heated wire circuits can also reduce condensation in the circuit. Frequent evaluation of the humidification system is necessary to increase the potential of adequate humidity delivered to the airway. Inadequate humidification occurs in nonheated circuits when the humidifier temperature probe is placed too far upstream from the airway connector. Variable humidification problems occur when ventilator circuits pass through an environment and then into a warmed enclosure, such as an incubator or radiant warmer.

Aerosol Drug Therapy

Drug action in infants and children differs significantly from drug action in adults because of differences in physiology, which may include immature enzyme systems, immature receptors, and variable gastrointestinal absorption. Dosing may be imprecise, and systemic effects may be hard to predict. Table 53-7 lists aerosolized medications commonly used in children.

Small volume nebulizers (SVNs), vibrating mesh nebulizers, MDIs, and dry powder inhalers (DPIs) can be used to deliver aerosolized drugs via mouthpiece or face mask to infants and children.[23] Continuous aerosol drug therapy is also used for patients unresponsive to intermittent SVN treatments. Aerosol drug administration to intubated infants and children is challenging because of the decreased deposition from baffling of small endotracheal tubes in these patients, which prevents approximately 90% of the drug from entering the lungs, regardless of delivery system. In addition, careful adjustments must be made to the ventilator so that nebulizer flows do not alter delivered V_T and inspiratory pressure and interfere with triggering efforts.[24] Newer vibrating mesh type nebulizers provide a more stable particle size and do not add additional flow to the breathing circuit. As a result, there is no change in the delivered tidal volume and patient triggering is not affected.

Airway Management

Airway management methods in infants and children are unique because of the anatomic differences between neonates and adults. Specifically, equipment and technique must be tailored to each child according to his or her size, weight, and postpartum age. Masks, resuscitation bags, oral airways, suction catheters, laryngoscope blades, and endotracheal tubes in a wide selection of infant and child sizes are needed to account for variations in patient age and weight. Table 53-8 provides recommendations regarding endotracheal tube and suction catheter sizes for infants and children.

Box 53-1 Complications and Hazards of Endotracheal Intubation in Infants and Children

- Palatal grooving (neonates)
- Incisal enamel hypoplasia (neonates)
- Accidental extubation
- Tube blockage
- Tracheal stenosis
- Esophageal perforation
- Tracheal perforation

Intubation

Endotracheal intubation is a generally safe method of airway management in infants and children, even when used for extended periods.[25,26] Complications and hazards associated with intubation in these age groups are listed in Box 53-1. The infant's age or weight can be used to estimate proper endotracheal tube size and depth of insertion. If the tube is too small in diameter, a leak may result, decreasing delivered minute ventilation. Small endotracheal tubes have high resistance, increasing the spontaneous work of breathing for the child. An inappropriately large endotracheal tube can cause mucosal and laryngeal damage that is evident after extubation, resulting in upper airway obstruction.[27]

Most neonatal and pediatric endotracheal tubes are uncuffed. The narrowest point of the airway in an infant and small child is the cricoid cartilage. When an appropriately sized uncuffed tube is positioned in the airway, the fit of the tube in the airway "seals" the airway enough so that adequate ventilation can usually be maintained. Cuffed endotracheal tubes are an option if a large leak persists around the tube and stable ventilation cannot be maintained. Similar to adults when a cuffed tube is used, careful attention to the pressure of the cuff on the tracheal wall is essential. Because the tongue is large and the epiglottis is anatomically high in infants and small children, practitioners generally find the Miller (straight) laryngoscope blade best for intubation. Infant endotracheal tubes are small and can be easily kinked or obstructed. In addition, slight changes in the position of the endotracheal tube in movement can result in bronchial intubation.[28]

Once a tube is inserted, immediate securing of the tube to the infant's face and ongoing evaluation of the security of the tube are essential. Proper head positioning and avoidance of cumbersome connecting apparatus help reduce the potential of accidental extubation. Estimates of the distance the tube should be inserted into the airway based on patient weight are provided in Table 53-9. Further confirmation of correct tube position should be evaluated with a chest x-ray. Noting the infant's head position when the chest x-ray is obtained is helpful in assessing appropriate tube position in the airway. Slight changes in head

TABLE 53-7

Commonly Used Aerosolized Medications

Medication Name	Dosage Form	Usual Child Dose	Comments
Bronchodilators			
Beta-2 Agonists			
Albuterol (Proventil, Ventolin)	MDI (90 mcg/puff)	1-2 puffs MDI q 15 min to q 6 hr ± PRN	May be used 15 min before exercise to prevent exercise-induced bronchospasm; should be used as a rescue medication
	Nebs (0.5%, 5 mg/ml)	0.01-0.05 ml/kg/dose (maximum 1 ml/dose) neb q 15 min to q 6 hr ± PRN	
	Rotohaler (200 mcg caps)	1-2 caps inhaled q 15 min to q 6 hr ± PRN	
Levalbuterol (Xopenex)	Nebs (0.63 mg/3 ml, 1.25 mg/3 ml)	0.32-1.25 mg neb q 6-8 hr ± PRN	May still cause extrapulmonary side effects including tachycardia and hypokalemia
Salmeterol (Serevent)	MDI (21 mcg/puff)	2 puffs inhalation q 12 hr	Not to be used as a rescue medication; long-acting beta-2 agonist; QT_C prolongation has occurred in overdose
	DPI-Diskus (50 mcg/inhalation)	1 inhalation q 12 hr	
Anticholinergic			
Ipratropium (Atrovent)	MDI (18 mcg/puff)	2 puffs inhalation q 4-6 hr ± PRN	MDI is contraindicated in patients with peanut allergy; for neonates, use 25 mcg/kg/dose neb tid; may cause mydriasis if aerosolized drug gets into the eye
	Nebs (0.02%)	0.25-0.5 mg neb q 4-6 hr ± PRN	
Antiinflammatory Agents			
Corticosteroids			
Beclomethasone (Beclovent, Vanceril)	MDI (42 mcg/puff)	1-2 puffs inhalation qid or 2-4 puffs inhalation bid	Start at lower end of dosing range if patient not previously on steroids; titrate to lowest dose that is effective; always rinse mouth after each treatment
	MDI double strength (84 mcg/puff)	2 puffs inhalation bid	
Budesonide (Pulmicort)	DPI-Turbuhaler (200 mcg/inhalation)	1-2 puffs inhalation bid	May take several weeks to see benefit; not to be used as a rescue medication
	Nebs-Respules (0.25 mg/2 ml, 0.5 mg/2 ml)	0.25-0.5 mg neb bid *or* 0.5-1 mg neb qd	
Flunisolide (Aerobid, Aerobid-M)	MDI (250 mcg/puff)	2-3 puffs inhalation bid	
Fluticasone (Flovent)	MDI (44 mcg/puff, 110 mcg/puff, 220 mcg/puff)	2 puffs inhalation bid (maximum 880 mcg/day)	
	Rotadisk (50 mcg/blister)	50-100 mcg inhalation bid	
Triamcinolone (Azmacort)	MDI (100 mcg/puff)	1-2 puffs inhal qid	
Mast Cell Stabilizers			
Cromolyn (Intal)	MDI (800 mcg/puff)	2 puffs inhalation qid	May take several weeks to see benefit; not to be used as a rescue medication
	Nebs (20 mg/2 ml)	20 mg neb qid	
Nedocromil (Tilade)	MDI (1.75 mg/puff)	2 puffs inhalation qid	
Mucolytics			
N-acetylcysteine (Mucomyst)	Nebs (20%, 200 mg/ml)	3-5 ml neb qid	Consider pretreatment with albuterol 15 min before *N*-acetylcysteine secondary to bronchospasm
Dornase alfa (Pulmozyme)	Nebs (2.5 mg/2.5 ml)	2.5 mg neb qid-bid	May cause hemoptysis
Antiinfectives			
Pentamidine (Pentam)	Nebs (300 mg)	8 mg/kg/dose (maximum 300 mg/dose) neb q month	Used for PCP prophylaxis
Ribavirin (Virazole)	Powder (6 g vial)	2 g over 2 hr neb q 8 hr × 3-7 days *or* 6 g over 12-18 hr neb q 24 hr × 3-7 days	Used for RSV treatment; mutagenic, teratogenic

position can result in the tube position sitting too high or too low in the airway. In very small infants, slight flexion of the head can move the tube into the right main stem bronchus.

Breath sounds may be of limited value in infants and small children for evaluation of tube position. Portable end-tidal CO_2 monitoring devices may be used to help assess tracheal versus esophageal intubation, although they should be used only as additional assessment tools with recognition of their limitations. Factors associated with accidental extubation of infants include tension on the tube from the ventilator circuit, patient agitation, suctioning, head turning, chest physiotherapy, too short a tube distance between lip and adapter, moving the patient during procedures, and inadequately taped endotracheal tube.[23,29] Recently, infant-sized endotracheal tube holders have become available.

Laryngeal mask airways (LMAs) are available as an alternative to intubation. LMAs are typically used in children when a short-term airway is indicated, such as during some surgical procedures or when endotracheal intubation cannot be accomplished and an airway needs to be established. Table 53-10 outlines appropriate sizes and maximum cuff volumes of LMAs for varying weights.

Box 53-2 Indications for Suctioning

ABSOLUTE INDICATIONS
- Secretions visible in endotracheal tube
- Aspiration of gastrointestinal or oropharyngeal contents
- Inadvertent water aspiration from ventilator circuit

RELATIVE INDICATIONS
- Rhonchi noted during auscultation raising suspicion of retained secretions
- Change in compliance (↓ V_T at same peak pressure or ↑ pressure for same V_T)
- ↑ Work of breathing
- ↓ SpO_2 with same or ↑ FiO_2

Suctioning Intubated Pediatric Patients

The goal of suctioning is to remove secretions from large airways and stimulate a cough. Although suctioning can be beneficial, significant risks are associated with the procedure, including lung derecruitment, hypoxia, hypertension, increased intracranial pressure, tracheal trauma, and infection. Absolute and relative indications for suctioning are listed in Box 53-2.

Additional considerations include the use of closed suction catheters for all mechanically ventilated patients. The closed suctioning technique helps to minimize derecruitment, which is more likely to occur during ventilator disconnections. An increase in O_2 concentration after suctioning may be necessary but should be evaluated for each patient. To reduce the risk of tracheal trauma, suction catheters should not be inserted further than 1 cm beyond the tip of the endotracheal tube or tracheostomy tube. Routine instillation of normal saline is not recommended. Increasing ventilator support to regain volume lost during the procedure may be necessary but should be assessed each time the patient is suctioned. Because of the risks associated with suctioning, the procedure should be performed only when a clinical indication exists, not on a fixed interval.

Suctioning. Nasopharyngeal and tracheal suctioning helps minimize aspiration, prevents endotracheal tube occlusion, and reduces airway resistance in infants and children.[2,30] Suctioning

Box 53-3 Complications and Hazards of Tracheal Suctioning in Infants and Small Children

- Infection
- Lung derecruitment
- Accidental extubation
- Atelectasis
- Blood pressure instability
- Increased intracranial pressure
- Cerebral vasodilation or increased blood volume
- Arterial hypoxemia
- Cerebral hypoxemia
- Hypercapnia
- Bradycardia
- Pneumothorax
- Mucosal damage

is a hazardous procedure, and complications can occur. Box 53-3 lists the common complications and hazards associated with tracheal suctioning of infants and children. Tracheal suctioning of preterm infants and neonates should be performed only when clinical signs indicate a need.[25,31,32]

Oral and pharyngeal suctioning of infants can be done with a bulb syringe. A DeLee trap or a mechanical vacuum source with catheter may be used for nasopharyngeal and nasotracheal suctioning of neonates. Equipment for suctioning larger infants and children is similar to the equipment used with adults with modifications in vacuum pressure and catheter size. Recommended suction pressures for neonates range from approximately −60 to −80 mm Hg. With large infants and children, pressures in the range of −80 to −100 mm Hg are generally safe and effective. Catheter sizes are chosen according to the age of the patient and the size of the tracheal airway (see Table 53-8). Other techniques for averting hypoxemia include use of endotracheal tube adapters that allow preoxygenation and suctioning without disconnection of the ventilator and use of closed tracheal suction systems.[27,33,34]

CONTINUOUS POSITIVE AIRWAY PRESSURE

Spontaneous breathing can be supported with **continuous positive airway pressure (CPAP)** a breathing mode that maintains a constant pressure above baseline throughout inspiration and expiration. Newborn infants have increased chest wall compliance along with decreased lung compliance, which makes them prone to developing atelectasis. CPAP maintains inspiratory and expiratory pressures above ambient, which improves functional residual capacity (FRC) and static lung compliance.[35] It is essential that the patient is able to maintain adequate minute volume while breathing spontaneously because ventilatory support is not provided.

CPAP is indicated when arterial oxygenation is inadequate despite elevated FiO_2. This condition is usually accompanied by certain signs of respiratory distress. CPAP is commonly used

Box 53-4 Indications for Continuous Positive Airway Pressure in Children

RESPIRATORY DISTRESS
- Tachypnea
- Retractions or accessory muscle use
- Grunting
- Nasal flaring
- Head bobbing

ABNORMAL BREATHING PATTERNS
- Apnea of prematurity
- Obstructive sleep apnea

LUNG DISEASE
- Decreased lung volumes on chest radiograph
- Pneumonia
- Tracheomalacia
- Pulmonary edema
- PaO_2 <50 mm Hg with FiO_2 ≥0.60

OTHER
- Postextubation failure

when PaO_2 is less than 50 mm Hg while the infant is breathing an FiO_2 of 0.60 or greater, provided that the $PaCO_2$ is less than or equal to 50 mm Hg and the pH is greater than 7.25. The indications for CPAP are described in Box 53-4.

Methods of Administration

The application of CPAP is most commonly accomplished noninvasively. In preterm and term neonates, short nasal prongs or oronasal masks are preferred over nasopharyngeal tubes which were traditionally used. Continued improvement of interface devices has led to more consistent CPAP delivery, better patient comfort, and reduced incidence of pressure ulcers (Figure 53-8). These interfaces include nasal masks, soft, pliable nasal CPAP cannulas, and the RAM cannula, all of which provide a comfortable interface without applying excessive pressure to maintain an effective seal. The American Association for Respiratory Care (AARC) has published Clinical Practice Guideline: Application of CPAP to Neonates via Nasal Prongs, Nasopharyngeal Tube, or Nasal Mask. Excerpts from this guideline appear in Clinical Practice Guideline 53-2.

For larger children, nasal masks, oronasal masks, nasal pillows, and other interfaces similar to interfaces used in adults may be used. In all patients, it is important to assess the patient-device interface at regular intervals to allow prevention or early detection and intervention in the event of pressure ulcers.

CPAP may be delivered using a mechanical ventilator in the CPAP mode, a CPAP driver, or continuous flow system with an underwater seal, also referred to as bubble CPAP. Mechanical ventilators provide better patient monitoring and may be connected to a central alarm system. CPAP drivers have the capability of adjusting flow to maintain set CPAP in the presence of a leak and/or increased patient inspiratory demand, and typically have some type of built in disconnect alarm. The continuous flow bubble CPAP systems are the simplest and least expensive

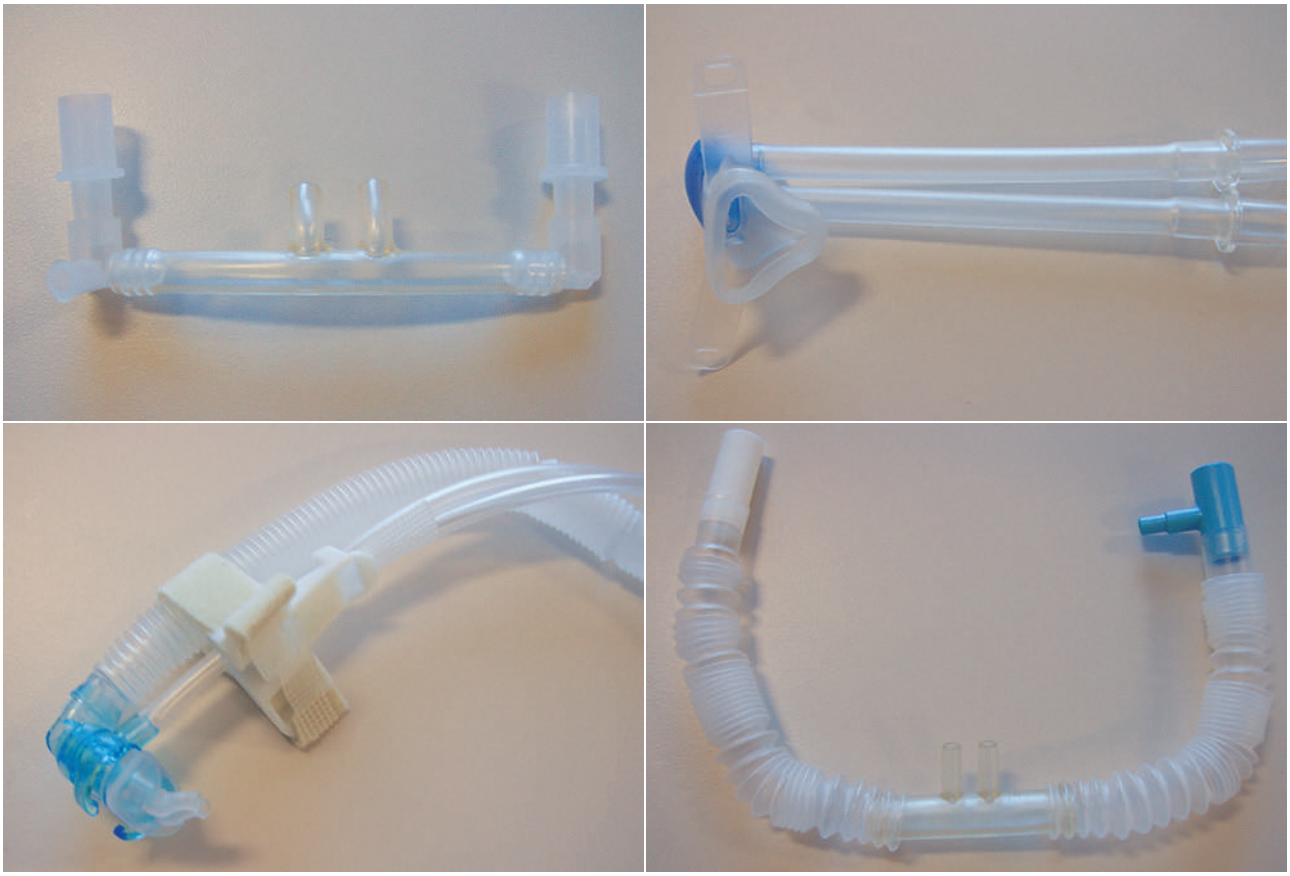

FIGURE 53-8 Patient interfaces for CPAP or NPPV.

of all the devices, but generally lack the ability to automatically adjust flow and do not have an integrated alarm system in the event of a patient disconnect. All are equally effective as long as the interface is appropriately sized and fitted to the patient. The choice of one device over another is often based on equipment availability or user or institutional bias.

CPAP levels are selected based on clinical observation. Initial CPAP levels are usually 5 to 7 cm H_2O and are adjusted in increments of 1 to 2 cm H_2O. The patient's SpO_2, respiratory rate, work of breathing, breath sounds, and blood pressure are monitored. The appropriate CPAP level is achieved when the respiratory rate decreases to near-normal ranges, signs of respiratory distress are lessened, and SpO_2 increases while O_2 requirements are reduced. Arterial and capillary blood gas analysis may provide additional information in determining the effectiveness of CPAP, and chest radiographs are obtained to determine the degree of lung inflation.

Weaning and eventually discontinuing CPAP is considered when oxygenation is adequate at FiO_2 less than 0.30 to 0.40, there is a sustained reduction in work of breathing, and chest radiograph and clinical assessment indicate resolution of the underlying disorder. The use of CPAP for prolonged periods in preterm infants helps reduce the work of breathing and prevent intubation. Long-term and intermittent use of CPAP is indicated in children with obstructive airway problems, chronic lung disease, and neuromuscular disorders.

High-Flow Nasal Cannula

Supplemental O_2 administration by nasal cannula is the most comfortable and simplest means of providing O_2 for infants and children. Evidence in preterm and term neonates indicates that using a nasal cannula at flow rates of 2 to 8 L/min may be as effective as and is easier to apply than a nasal CPAP system.[36-39]

Specially designed humidification systems have been developed and allow the use of nasal cannulas at flow rates of 2 to 30 L/min.[38] These devices maximize humidification and minimize condensation accumulating in the small-diameter supply tubing. The gas should always be conditioned (warmed and humidified) for approximately 5 to 10 minutes before it is connected to the patient. High-flow nasal cannula systems have been used successfully in neonates for the same indications that CPAP has been used. Instead of titrating levels of CPAP, the flow rate is incrementally adjusted. However, the amount of positive pressure that the high-flow nasal cannula potentially produces cannot be measured, and inadvertent high levels may occur, particularly if the nasal cannula fits snugly in the nares.[33,40-42] To prevent inadvertent high levels of CPAP from developing, the nasal prongs should not occupy more than 50% of the patient's nares.

High-flow nasal cannula systems have the potential for maximizing supplemental O_2 administration because the O_2

53-2 Application of Continuous Positive Airway Pressure to Neonates via Nasal Prongs, Nasopharyngeal Tube, or Nasal Mask

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

- Abnormalities on physical examination—tachypnea, substernal and suprasternal retractions, grunting, and nasal flaring; the presence of pale or cyanotic skin color; agitation
- Inadequate oxygenation (PaO_2 <50 mm Hg with FiO_2 ≤0.60, provided that VE is adequate as indicated by $PaCO_2$ ≤50 mm Hg and pH ≥7.25)
- Presence of poorly expanded or infiltrated lung fields on chest radiograph
- Presence of a condition thought to be responsive to CPAP, including:
  - Respiratory distress syndrome
  - Recent extubation
  - Pulmonary edema
  - Transient tachypnea of the newborn
  - Atelectasis
  - Apnea of prematurity
  - Tracheomalacia or other similar abnormality of the lower airways

CONTRAINDICATIONS

- Although nasal CPAP has been used in bronchiolitis, this application may be contraindicated
- Need for intubation or mechanical ventilation or both as evidenced by the presence of:
  - Upper airway abnormalities that contraindicate nasal CPAP (e.g., choanal atresia, tracheoesophageal fistula)
  - Severe cardiovascular instability and impending arrest
  - Unstable respiratory drive with frequent apneic episodes resulting in desaturation or bradycardia or both
  - Ventilatory failure as indicated by the inability to maintain $PaCO_2$ <60 mm Hg and pH >7.25
  - Application of nasal CPAP to patients with untreated congenital diaphragmatic hernia may lead to gastric distention and further compromise of thoracic organs

HAZARDS AND COMPLICATIONS

Hazards and complications associated with equipment include the following:

- Obstruction of nasal prongs from mucous plugging or kinking may interfere with delivery of CPAP and result in a decrease in FiO_2 through entrainment of room air via opposite naris or mouth.
- Inactivation of airway pressure alarms
  - High resistance through nasal appliances can maintain pressure in the system even after decannulation; this can result in failure of low airway pressure or disconnect alarms to respond
  - Complete obstruction of nasal prongs and nasopharyngeal tubes results in continued pressurization of CPAP system without activation of low or high airway pressure alarms
- Activation of a manual breath (commonly available on infant ventilators) may cause gastric insufflation and patient discomfort, particularly if the peak pressure is set inappropriately high

Hazards and complications associated with the patient's clinical condition include the following:

- Lung overdistention causing barotrauma, $\dot{V}/\dot{Q}$ mismatch, hypercapnia, including work of breathing
- Impedance of pulmonary blood flow (increased pulmonary vascular resistance, decreased cardiac output)
- Gastric insufflation and abdominal distention potentially leading to aspiration
- Nasal irritation with septal distortion
- Skin irritation and pressure necrosis
- Nasal mucosal damage owing to inadequate humidification

ASSESSMENT OF OUTCOME

CPAP is initiated at levels of 4 to 5 cm H_2O and may be gradually increased up to 10 cm H_2O to provide the following:

- Stabilization of FiO_2 requirement ≤0.60 with PaO_2 levels >50 mm Hg or the presence of clinically acceptable noninvasive monitoring of O_2 ($PtcO_2$), while maintaining an adequate VE as indicated by $PaCO_2$ of ≤50 to 60 mm Hg and pH ≥7.25
- Reduced work of breathing as indicated by decreased respiratory rate, retractions, grunting, nasal flaring
- Improvement in lung volumes and appearance of lung as indicated by chest radiograph
- Improvement in patient comfort as assessed by bedside caregiver

MONITORING

Patient-ventilator system assessments should be performed at least every 2 to 4 hours and should include documentation of ventilator settings and patient assessments:

- O_2 and CO_2 monitoring, including periodic sampling of ABG values and continuous noninvasive monitoring (e.g., transcutaneous O_2 and CO_2 monitoring, pulse oximetry)
- Continuous monitoring of electrocardiogram and respiratory rate
- Continuous monitoring of proximal airway pressure, PEEP, and $\bar{P}aw$
- Continuous monitoring of FiO_2
- Periodic physical assessment of breath sounds and signs of increased work of breathing
- Periodic evaluation of chest radiographs

**For complete guideline, see American Association for Respiratory Care: Clinical practice guideline: application of continuous positive airway pressure to neonates via nasal prongs, nasopharyngeal tune, nasal mask: 2004 revision and update. Respir Care 49:1100, 2004.*

VE, *Minute ventilation.*

concentration delivered to the patient should approximate the set FiO_2. This approximation occurs because the anatomic reservoir of the upper airway is continuously flushed, greatly reducing the entrainment of room air. High-flow nasal cannula systems may be beneficial in stabilizing acute respiratory failure caused by hypoxemia, which may reduce the need for noninvasive or invasive assisted ventilation, such as in the case of a pulmonary exacerbation in a patient with bronchiolitis, cystic fibrosis or congestive heart failure.

RULE OF THUMB

When using a high-flow nasal cannula, the nasal prong should not occupy greater than 50% of the opening to patient's nares.

MECHANICAL VENTILATION

Early attempts to provide assisted ventilation to infants and children were largely derived from the experiences gained in adults, including the type of ventilators used and the associated techniques. Recognition of the physiologic differences of neonates and children led to further advances in ventilator design and modes and a wider range of capabilities. Although the classic "infant ventilator" is still used in some centers, modern microprocessor ventilators offer an ever-evolving array of options capable of supporting the full range of patient sizes and physiologic conditions.[43] Respiratory therapists caring for infants and children need to be familiar with their physiologic differences to select and modify the appropriate ventilatory strategy.[44-46]

Basic Principles

Conventional mechanical ventilation is the delivery of a bulk flow of humidified gas into and out of the lungs. The removal of CO_2, typically measured by PCO_2, is directly related to alveolar ventilation (frequency $\times V_T$). Gas moves from the ventilator across an artificial airway in response to a change in pressure or pressure gradient. The magnitude of pressure required to move a particular amount of volume is derived from the compliance of the pulmonary system and the resistance of the airways.

Compliance is a measure of the distensibility of the lungs and is expressed as the volume change per unit of pressure change ($C = \Delta V/\Delta P$). *Resistance* is the tendency for airflow across the tracheobronchial tree to be impeded at a particular pressure per unit of gas flow ($R = \Delta P/\text{flow}$). The product of compliance and resistance is the respiratory time constant, or the measure of time necessary for the equilibration of a change in airway pressure ($TC = C \times R$). A patient with stiff or noncompliant lungs, such as a preterm infant with surfactant deficiency, has short time constants, meaning less time is required for equilibration, and filling and emptying of lungs occur faster, requiring shorter inspiratory and expiratory times. A patient with a disease characterized by impaired airflow or high resistance, such as a child with asthma, has longer time constants, in which more time is required for filling and emptying, thus longer inspiratory and expiratory times are needed.

Goals of Mechanical Ventilation

The basic goals of mechanical ventilation are to improve O_2 delivery to meet metabolic demand and eliminate CO_2, while reducing the work of breathing. The basic aim of assisted ventilation is to meet the goals while minimizing the associated deleterious effects. One approach to mechanical ventilation begins with the selection of an appropriate breath type, either pressure-controlled or volume-controlled, and a mode that best meets the physiologic needs of the patient's condition.[47] Box 53-5 lists the indications for mechanical ventilation in infants and children.

Modes of Ventilation and Breath Delivery Types

Historically, the most common mode of ventilation used in neonates and children was intermittent mandatory ventilation. Because early infant ventilators were unable to respond to the small triggering efforts of these patients, mandatory timed breaths were superimposed over a continuous flow of gas. These asynchronous, mandatory breaths provided most of the ventilation, while the patient was allowed to breathe spontaneously from the continuous gas source. Eventually, technologic improvements resulted in triggering devices that provided synchronization of the mandatory breaths with patient effort (synchronized intermittent mandatory ventilation [SIMV]) followed by the ability to provide assist/control (A/C) and pressure support ventilation (PSV). Despite evidence that SIMV is more likely to result in patient-ventilator asynchrony,[48,49] most

Box 53-5 Indications for Mechanical Ventilation

POSTSURGERY
- Thoracic surgery

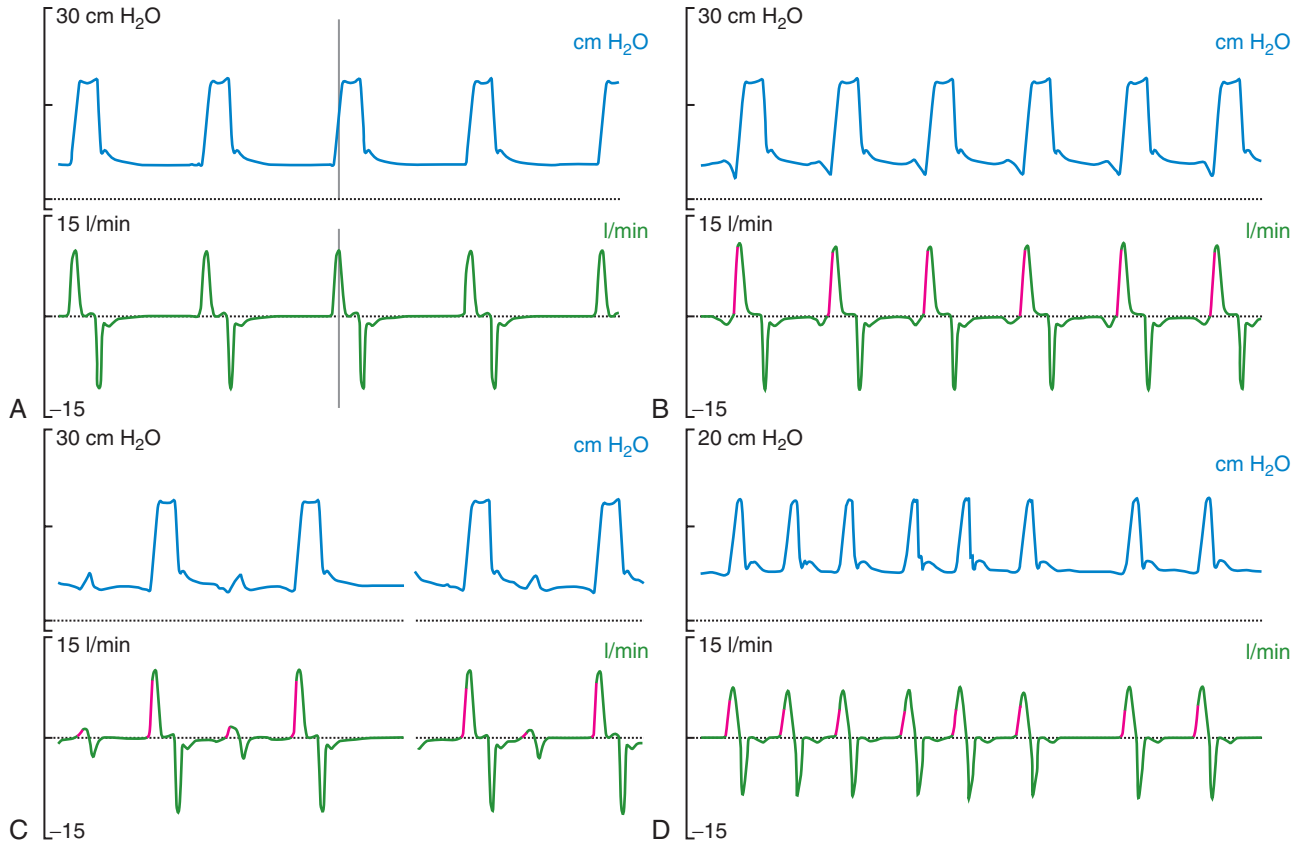

FIGURE 53-9 Airway graphics. **A,** Patient is apneic. Regardless of SIMV or A/C mode all breaths are mandatory at set rate. **B,** A/C mode. Total respiratory rate is determined by patient's spontaneous rate. **C,** SIMV mode. Mechanical breaths are delivered at a set rate. Patient is allowed to breathe spontaneously in between mandatory breaths. **D,** PSV mode. There are no set mandatory breaths. All breaths are pressure supported at patient's spontaneous rate.

neonatal and pediatric patients are managed by using one of these three modes or a combination (i.e., SIMV + PSV). The most common triggering device for infant ventilators is a pneumotachygraph placed in the ventilator circuit, often proximal to the airway, which in many cases also serves as a monitoring device. The pneumotachygraph allows for the integration of a flow signal, which can be displayed as inhaled and exhaled V_T and minute ventilation. Figure 53-9 displays graphic representations of A/C, SIMV, and PSV. Another mode of ventilation increasingly used in neonates and small children is called *neurologically adjusted ventilatory assist* (NAVA) in which the ventilator responds to electrical activity of the diaphragm (Eadi). This requires use of a special gastric tube with electrodes that sense Eadi. In this highly responsive mode ventilation is provided by adjusting the amount of airway pressure applied per 1 microvolt change in Eadi.

In almost all cases of neonatal ventilation, the mechanical breaths delivered during SIMV and A/C are time-cycled, pressure-limited breaths.[50] Inspiration is initiated by patient effort or as a result of the set respiratory rate (whichever comes first). Based on the available flow—continuous, demand, or both—the set inspiratory pressure is reached early in the inspiratory phase and maintained throughout the remainder of the inspiratory time, after which the ventilator cycles to expiration. In many cases, appropriate setting of the *inspiratory rise time* (the speed in which gas flow is delivered controlling how rapidly set airway pressure is achieved) improves patient-ventilator synchrony. Most current-generation ventilators are capable of providing volume-targeted, pressure-limited ventilation, often referred to as *pressure-regulated volume control* or *volume guarantee*. In this dual mode of ventilation, the inspiratory V_T is compared with a preset target V_T, and the inspiratory pressure on the next breath is adjusted up or down in an attempt to meet the target volume. True volume-controlled breaths are rarely used for ventilating neonatal patients. (See Chapter 45 for details.)

RULE OF THUMB

When ventilating neonates, choose time-cycled, pressure-limited mechanical breaths.

Pediatric patients may be ventilated with either volume-controlled or pressure-controlled breaths. The choice may be based on health care team or institutional preference, prior experience, and equipment availability or may be evidence-based for specific diseases (e.g., asthma).

MINI CLINI

Pediatric Ventilation

PROBLEM: A 12-year-old girl with asthma is admitted to the emergency department. She was intubated in the field by paramedics and is currently ventilated with a transport ventilator at the following settings:

- Mode—SIMV
- V_T—10 ml/kg
- PIP—90 cm H_2O
- PEEP—0 cm H_2O
- Set respiratory rate—16 breaths/min
- Total respiratory rate—20 breaths/min
- Inspiratory time—0.25 sec
- FiO_2—1.0

The paramedics inform the RT that since the patient has been placed on the mechanical ventilator, PIP has steadily increased, blood pressure has begun to decrease, and breaths sounds consisting of bilateral inspiratory and expiratory wheezes have become increasingly diminished. What should the RT recommend?

Solution: The ventilator circuit should be immediately disconnected from the endotracheal tube allowing the patient to exhale fully. This patient should be fully sedated and possibly paralyzed to allow the RT to set and control ventilation. The ventilator settings should be set as follows:

- Mode—A/C
- Breath delivery type—volume controlled
- V_T—4 to 6 ml/kg
- Plateau pressure—maintain at ≤30 cm H_2O
- Respiratory rate—set at whatever rate allows ventilation without an increase in auto-PEEP or increased plateau pressure or both
- Inspiratory time—1.0 sec
- PEEP—5 cm H_2O
- FiO_2—1.0

Patients with severe status asthmaticus are among the most challenging patients to ventilate. The pulmonary time constants are increased such that it is equally difficult to inflate the lungs as it is for the patient to exhale. The inspiratory flow rate must be controlled by the clinician by means of volume-controlled ventilation, and sufficient time must be provided to allow the lungs to inflate. Expiratory time must be sufficient to allow exhalation, preventing the accumulation of trapped gas or auto-PEEP. The result is a decrease in minute ventilation, which leads to permissive hypercapnia as a lung protective strategy. $PaCO_2$ should be allowed to increase as long as the pH is greater than or equal to 7.10.

The inspiratory time must be increased (up to 1 second for this patient and longer in older teenagers) to allow inspiratory gas flow to the patient. Although this increase in inspiratory time may seem counterintuitive in a patient with prolonged expiratory time constants, it is necessary to deliver gas on inspiration. Decreasing the inspiratory time to less than 1 second does little to prevent the development of auto-PEEP and frequently markedly decreases the level of ventilation.

In the presence of an elevated $PaCO_2$ and decreased pH, a higher FiO_2 is required to maintain SpO_2 greater than 90% owing to shifting of the oxyhemoglobin dissociation curve. FiO_2 should be set initially at 1.0 and titrated to maintain SpO_2 within acceptable range.

Ventilator Settings and Parameters

After the mode of ventilation is selected, the respiratory therapist begins to adjust the various settings associated with the mode, while keeping in mind the goals of ventilation and the patient's weight, underlying problem, and reason for mechanical ventilation. The RT often can get a sense of the patient's compliance by manually ventilating the patient and observing the pressure needed to make the chest rise.

Peak Inspiratory Pressure

For time-cycled, pressure-limited breaths, the peak inspiratory pressure (PIP) is set according to predetermined criteria (e.g., 20 to 25 cm H_2O) or by observing the pressure required to move the chest during manual ventilation with a flow inflating bag or T-piece resuscitator. The delivered V_T is monitored, and adjustments may be made. Increasing the PIP normally results in an increase in V_T, whereas a decrease in PIP results in decreased V_T. In the absence of V_T monitoring, PIP may be adjusted based on subjective assessment of chest movement and auscultation of breath sounds. Efforts should be made to maintain the lowest possible PIP that delivers the target V_T because PIP greater than 28 cm H_2O in time-cycled, pressuresimited (pressure controlled) breaths has been shown to increase the likelihood of ventilator-induced lung injury.

RULE OF THUMB

Always strive to maintain PIP less than or equal to 28 cm H_2O.

Positive End Expiratory Pressure

Positive end expiratory pressure (PEEP), referred to as the *baseline pressure,* is used to prevent alveolar collapse at end-expiration. PEEP results in improved oxygenation for a given O_2 concentration. If the PEEP is set too low, alveolar collapse may occur, resulting in decreased FRC, altered ventilation/perfusion ($\dot{V}/\dot{Q}$ matching), and hypoxemia. If the PEEP is set too high, overdistention may occur, increasing the likelihood of lung injury. Typically, PEEP is set between 5 cm H_2O and 6 cm H_2O, although higher levels may be used if necessary. PEEP is set in conjunction with PIP, and the difference between the two is often referred to as the delta P *or driving pressure*. As the delta P is increased, either by increasing PIP or decreasing PEEP, the V_T will most likely increase as well (unless overdistention occurs). Conversely, decreasing the delta P results in lower V_T. Ideally the delta pressure or driving pressure should not be greater than 15 cm H_2O.

Tidal Volume

When selecting V_T, the clinician must consider a volume that provides adequate lung inflation without overstretching the alveoli. Setting V_T that is too high most likely would result in lung injury. V_T of 6 to 8 ml/kg is generally considered safe in most patients. However, in some patients with extremely low lung compliance, such as patients with severe acute respiratory distress syndrome (ARDS), it may be necessary to reduce V_T to 4 to 5 ml/kg.

If the clinician chooses to deliver volume-controlled breaths, V_T is set as a control variable. Every mechanical breath delivers an identical V_T at either a preset inspiratory time or a preset flow rate. Set V_T, inspiratory time, and flow all are interrelated. If V_T is set at 300 ml, and flow rate is 30 L/min (0.5 L/sec), the inspiratory time is 0.6 second. See formulas in Box 53-6.

When ventilating patients with pressure-controlled breaths, V_T is not set, but it should be monitored. The clinician must compare the monitored V_T with a predetermined target and adjust the delta P to meet that target.

Regardless of whether the clinician chooses volume-controlled or pressure-controlled breaths, he or she must recognize that some of the V_T is compressed in the circuit and not delivered to the patient; this is referred to as *compressible volume loss*. Most current-generation ventilators automatically compensate for compressible volume loss and adjust the delivered and displayed (monitored) V_T accordingly. With older ventilators and current, less sophisticated ventilators, such as those used for transport, during volume-controlled breaths, the clinician must calculate the compressible volume loss and increase the set V_T to deliver the desired volume to the patient. During both volume-controlled and pressure-controlled breaths, the calculated compressible volume loss must be subtracted from the ventilator displayed exhaled V_T. See Box 53-7 for calculation of compressible volume loss.

Box 53-6 Interrelationship of Tidal Volume, Flow, and Time

V_T = Flow in L/sec × Inspiratory time
Inspiratory time = V_T/Flow rate

Box 53-7 Determining Effective or Corrected Tidal Volume

Effective V_T = Delivered V_T – Compressible volume
Compressible volume = Compressible factor × (PIP – PEEP)

Example: A 12-year-old child weighing 28 kg requires assisted ventilation. V_T is set at 240 ml, PIP is 25 cm H_2O, and PEEP is 5 cm H_2O. The compressible factor for the ventilator is 2 ml/cm H_2O.

Compressible volume = (2 ml/cm H_2O) × (25 – 5 cm H_2O)
= 40 ml
Effective V_T = 240 ml – 40 ml = 200 ml
Effective V_T/kg = 200 ml ÷ 28 kg = 7.1 ml/kg

RULE OF THUMB

Large V_T (>8 ml/kg) is likely to overstretch the lung, resulting in acute lung injury, and should be avoided. Patients with severe ARDS may require even lower V_T (4 to 5 ml/kg). In addition, PIP and/or plateau pressure should be maintained <28 cm H_2O and delta P ≤15 cm H_2O.

MINI CLINI

Pediatric Ventilation

PROBLEM: A 10-year-old boy with a complex medical history including history of trisomy 21, intractable infantile spasms, seizure disorder, and developmental delay (nonverbal), is admitted with increased difficulty breathing. His temperature on admission is 101° F, and a chest x-ray shows a left lower lobe infiltrate consistent with pneumonia. His home regimen includes nocturnal NIV via nasal mask with an inspiratory pressure of 8 cm H_2O, 3 cm PEEP, and 2 L/min of O_2 added to the breathing circuit. On admission, the patient complains of shortness of breath. His respiratory rate is 40 breaths/min, and SpO_2 is 88% on a nonrebreathing mask. What should the RT suggest?

Solution:

- NIV—consider beginning NIV via oronasal mask
- PIP—10 to 12 cm H_2O
- PEEP—3 to 5 cm H_2O
- Set respiratory rate—12 breaths/min
- FiO_2—1.0

Although this patient receives NIV for nocturnal support when stable, he currently has an acute infection superimposed on chronic restrictive lung disease. Beginning NIV now may provide sufficient support to prevent intubation during this acute condition. Initial PIP of 10 to 12 cm H_2O titrated to patient comfort may provide additional support, increasing V_T and allowing respiratory rate to return to baseline. Choosing an oronasal mask may prove to be a more efficient interface than the patient's usual nasal mask at this time. The set respiratory rate of 12 breaths/min is intended to be a backup rate because this patient is spontaneously breathing and should be allowed to establish his own breathing pattern. FiO_2 should be adjusted to maintain an acceptable SpO_2.

Ventilator Rate

The ventilator rate is the set number of breaths delivered in 1 minute. During A/C ventilation, the set respiratory rate is the minimum number of breaths the patient will receive and is increased if the patient triggers the ventilator at a respiratory rate faster than that which is set. The actual or total respiratory rate multiplied by V_T determines the minute ventilation, which is directly related to alveolar ventilation and PCO_2. Because V_T is usually set according to the patient's ideal or calculated body weight, adjusting minute ventilation is most often accomplished by changing the respiratory rate. The clinician must be aware of the total respiratory rate when making changes to adjust

minute ventilation. If the set respiratory rate is 16, but the total respiratory rate is 22 because of patient triggering, decreasing the set rate to 12 or increasing the set rate to 18 would have no effect on minute ventilation.

Inspiratory Time

The inspiratory time is often defined as the time required to deliver V_T; however, this may be misleading. As described earlier, with volume-controlled breaths, the inspiratory time is determined by V_T and inspiratory flow rate and is the time required to deliver the preset V_T at the preset flow rate. However, with pressure-controlled breaths, the inspiratory time is set by the clinician and may be shorter, longer, or equal to the time required to deliver the breath. In the case of increased airway resistance, such as a patient with asthma, if the inspiratory time is not set long enough, flow delivery to the patient may not decelerate to zero by the end of the set inspiratory time. Under these circumstances, increasing inspiratory time would result in an increase in delivered V_T. Conversely, under the same conditions, shortening the inspiratory time would result in a decrease in delivered V_T. In the case of decreased compliance, as in pneumonia, increasing inspiratory time beyond the time necessary to allow full flow deceleration would result in an inspiratory pause or breath-hold, which may not be tolerated by the patient.

RULE OF THUMB

Inspiratory time is usually set between 0.2 second and 0.4 second for neonates and up to 1.0 second in teenagers. With patients who are awake and have spontaneous breathing efforts, inspiratory time must be set at a level that matches patient demand to avoid patient-ventilator asynchrony.

Oxygen Concentration

The O_2 concentration or FiO_2 is kept as low as possible to avoid the risk of O_2 toxicity. Although the precise mechanisms are not understood, the best approach is to maintain the lowest FiO_2 possible. The immature lung is particularly susceptible to O_2 toxicity, which can result in the development of bronchopulmonary dysplasia. In a preterm infant, FiO_2 is titrated to a narrow SpO_2 range (e.g., 88% to 94%) so that retinal damage (ROP), which is caused by elevated PO_2, does not develop.[17]

RULE OF THUMB

O_2 is considered a drug and should be used appropriately. High O_2 concentrations are potentially injurious and may cause O_2 toxicity in the immature lung and retinal damage in preterm infants.

Mean Airway Pressure

Mean airway pressure ($\bar{P}aw$) is the average airway pressure during a 1-minute period. It is affected by changes in PIP, PEEP, inspiratory time, and respiratory rate. An increase in $\bar{P}aw$ is often associated with improved oxygenation but is not without hazards. Increasing PEEP would result in increased $\bar{P}aw$ and potentially increased oxygenation. However, if the PEEP is set too high, the alveoli may become overinflated resulting in worsening $\dot{V}/\dot{Q}$ matching, and lung injury may occur.

Noninvasive Ventilation

Noninvasive ventilation (NIV), also known as *noninvasive positive pressure ventilation,* has become more popular recently in neonatal patients. In the past, use of NIV was limited by the lack of available interfaces; however, these are becoming more readily available. Figure 53-8 shows various interfaces that may be used for NIV (or CPAP) in neonates. NIV for neonates has been used successfully for premature infants in the delivery room and as an accepted mode of ventilation in the NICU where it has been used to prevent initial intubation or secondarily to prevent reintubation in the setting of extubation failure. NIV has also been used as a primary mode of ventilation for patients with acute respiratory failure.[51-53] However, there is scant evidence to support the use of NIV over CPAP or as a method of reducing the incidence of bronchopulmonary dysplasia. Patient triggering may be problematic given the large leaks that may occur with most patient interfaces, even with some current ventilators' "Noninvasive Modes," which generally include various forms of sophisticated leak compensation. However, there is ample evidence to support the use of both synchronized and nonsynchronized NIV in the NICU.[54,55]

Outside the NICU, NIV has been used extensively in patients of all ages, including pediatric patients.[56-59] Indications may include short-term support of hypoxemic respiratory failure, such as that seen with pulmonary edema associated with left-sided heart failure; prevention of intubation; postextubation support; and long-term support of patients with neuromuscular disease. Some limitation of available interfaces persists, particularly in smaller patients; however, most patients can be fitted without too much difficulty. As with CPAP and other noninvasive interface devices, care must be taken to prevent or minimize patient injury owing to iatrogenic pressure ulcers from a tight or poorly fitted device.

NIV may be provided with simple, single-limb devices such as bilevel positive airway pressure generators, or sophisticated ICU ventilators. Care must be taken whenever a single-limb circuit is employed to provide sufficient PEEP in the system to prevent rebreathing of gases (see Chapter 51).

Monitoring Mechanical Ventilation

The RT should develop a systematic approach to monitoring the effects of mechanical ventilation. Components of a ventilator assessment should include an evaluation of the artificial airway, physical examination, assessment of patient-ventilator interaction,[60] analysis of laboratory and radiographic data, adjunct ventilator monitoring, and a systematic ventilator safety assessment including alarm function and assessment of humidification. Alarms should be connected to a central monitoring system to alert clinicians away from the bedside of a change the patient's condition.

A flow sheet is used to prompt the user and guide the clinician through the process of assessing the patient, while serving as documentation of the ventilator settings and outputs. In the past, these flow sheets were paper and were maintained as part of the patient's medical record. Currently, most flow sheets are integrated into an electronic medical record that is readily available to the entire patient care team. Although many elements of the patient-ventilator assessment may be automatically entered via an electronic interface and require validation only by the clinician, some data must still be entered by hand. As standardization improves and these systems become more sophisticated and interchangeable, all of the data, including ventilator information, laboratory values, and radiographic and other imaging data, should automatically download, eliminating transcription errors, providing a more comprehensive assessment, and allowing the clinician to focus on the patient and patient-ventilator interaction.

MINI CLINI

Pediatric Mechanical Ventilation

PROBLEM: A 14-month-old child, who weighs 13 kg and has a history of chronic lung disease (bronchopulmonary dysplasia), requires mechanical ventilation after surgery for correction of gastric reflux. The surgeon requests that the RT select ventilator parameters and develop a weaning plan for this child. The child has an uncuffed 4.5 oral endotracheal tube in place. SpO_2 is 100% with manual ventilation and 100% O_2. Sedation is prescribed to keep the child comfortable but allow spontaneous breathing.

This child needs a ventilatory strategy that takes into account his age, disease process, amount of sedation, and current ventilation needs. What would be the appropriate choices for his initial ventilator management in terms of mode, V_T, set rate, FiO_2, and PEEP level?

Solution:

- Mode—Pressure A/C
- Pressure level set to ensure V_T 6 to 8 ml/kg or 100 to 130 ml
- Respiratory rate—20 to 30 breaths/minute
- FiO_2—1.0 then titrated to an acceptable SpO_2
- PEEP—5 cm H_2O

If this child had previously been mechanically ventilated, reviewing the presurgery settings may be helpful in deciding a ventilator plan. If not, a rationale for the suggested parameters follows.

By using the Pressure A/C mode, patient-ventilator synchrony can be more easily achieved; this reduces the need for sedation later, after the pain of surgery has dissipated. The initial V_T is based on current recommendations. The ventilator rate is determined by the normal respiratory rate for the age of the child, the desired PCO_2 level, and the number of assisted or triggered breaths the child is having. Because this child has chronic lung disease, a higher PCO_2 may be optimal at this time. A younger child with a higher PCO_2 and with a decreased respiratory rate may have a higher set rate. Initial FiO_2 is usually reflective of the amount currently being delivered with hand ventilation but quickly titrated to maintain normal SpO_2. FiO_2 of 0.40 after surgery would not be unusual in the child. In addition, plateau pressure should not be greater than 28 cm H_2O and the delta P should not be higher than 15 cm H_2O.

Physical Examination

Examination of the patient can yield quick and useful information. The chest is examined for adequacy of chest rise, the presence of asymmetric movement and deformities, and signs of increased work of breathing such as retractions. Breath sounds are helpful in gauging the degree of air entry, verifying bilateral aeration, and identifying airflow problems and areas of diminished aeration. Skin appearance can also give the clinician a sense of the patient's perfusion—an indirect measure of cardiac output. A mottled appearance, poor capillary refill, and pale or gray color indicate poor perfusion.

Patient-Ventilator Interaction

The patient-ventilator interaction is the assessment used to determine the ease with which the patient can trigger and interact with the ventilator throughout the complete ventilatory cycle. This assessment is made by simultaneously observing the trigger indicator, waveforms, and the patient. Refinements in the trigger threshold may need to be made if there is a leak present or the work to trigger or initiate a breath is too great. Most ventilators may be flow triggered or pressure triggered. There is little difference between the two as long as they are set correctly. The trigger sensitivity should be set as sensitive as possible without auto-triggering. The manner in which the breath is terminated is also assessed. Pressure-supported breaths are flow cycled based on the patient's spontaneous inspiratory time and flow demand. Mechanical breaths are time cycled. Theoretically, flow-cycled, pressure-supported breaths should be more comfortable and promote improved patient-ventilator synchrony because the patient has more control over the breath than with mechanical breaths. Together, patient synchrony and comfort are determined. Patient-ventilator asynchrony occurs when the patient's efforts to breathe are unmatched with the preselected ventilator support. Airway graphics are also helpful in identifying nuances and refining ventilator settings.[61] Airway graphics routinely displayed are scalar waveforms of flow, airway pressure, and volume. Additionally, each of these parameters can be plotted against the others. Pressure-volume and flow-volume loops can be particularly helpful in assessing alterations in work of breathing, overdistention of the lung, and compliance. See Chapter 47 for more detail on patient-ventilator interaction.

Additional Monitoring

The use of noninvasive monitors, particularly measurements of end-tidal CO_2 and SpO_2, has become routine. Periodic blood gas analysis is a useful tool to quantify acid-base status and to refine ventilator settings further. Other laboratory data, such as electrolytes and hematologic information, are also assessed.

Periodic chest radiographs are obtained to identify suspected problems and to assess the progress of lung disease.

Patient-Ventilator Periodic Assessment

A systematic patient-ventilator assessment should be conducted periodically.[61] Prescribed ventilator settings are confirmed and documented along with verification of ventilator outputs. Measurements of mandatory and spontaneous V_T values are made and expressed per the patient's weight to determine if targets are being achieved. Alarms must be set and tested and should minimally detect loss of pressure, high pressure, and patient disconnection. Additional alarms should alert the clinician to changes in tidal volume, minute ventilation, respiratory rate, and PEEP.

The humidification system is evaluated including airway temperature and the presence of condensation in the ventilator circuit. Some visible condensation or "rain-out" is important because a completely dry circuit may be a sign of inadequate humidification, which results in thickened secretions and possible airway obstruction.

RULE OF THUMB

Routine monitoring of ventilated patients is essential and should include an assessment of the patient's physiologic status including vital signs and a systematic assessment of the patient-ventilator interaction.

Weaning from Mechanical Ventilation

Weaning or, more appropriately, liberation from mechanical ventilation is a topic that that has become more standardized over the past several years in pediatric patients.[62-64] Clear guidelines for "assessment of readiness to extubate" and "spontaneous breathing trials" have become standard practice.[65] However, some controversy remains and this assessment has not yet become standard practice in neonatal patients even though there is considerable literature available to guide clinicians in this area.[66-68] Considerable variation in practice exists among institutions and even among clinicians within institutions. Nevertheless, these patients should be assessed daily to determine their readiness for liberation from mechanical ventilation. Some general considerations for extubation are presented in Box 53-8. Once it is agreed that a patient may be ready for extubation, a systematic coordinated approach should be undertaken. This includes a safety screen followed by some agreed-upon evaluation of the patient's ability to breathe spontaneously without ventilatory assistance. Box 53-9. If a spontaneous breathing trial is attempted, it should be coordinated with a reduction in the level of sedation, often referred to as a *spontaneous awakening trial*. However, in some cases this may not be feasible as a reduction in sedation may result in the

Box 53-8 Considerations for Extubation

- Spontaneous respiratory rate appropriate for age and weight
- Presence of apnea or periodic breathing
- FiO_2 requirement ≤0.4
- Ability to protect airway
- Normal work of breathing
- Acceptable amount and consistency of respiratory secretions
- Normal vital signs
- Minimal sedation needs
- SpO_2 >90%
- Spontaneous V_T >4-5 ml/kg

Box 53-9 Pediatric/Neonatal Ventilator Discontinuance Protocol

STEP 1

Safety Screen (lack of the following)

- Brain death, ICP >15 mm Hg, suspected high ICP, or difficult to control ICP
- Neuromuscular blockade
- Significant hemoptysis (significant amounts of blood from endotracheal tube or tracheostomy)
- Hemodynamic instability
- Unstable airway
- FiO_2 >0.6
- PEEP ≥8 cm H_2O
- Lack of ICU team consensus
- Extracorporeal life support
- Chronic disease requiring ventilation

Issues to Address Before Extubation

- Fluid overload
- Secretions
- Neurologic impairment
- Medication requirement precludes safe extubation
- NPO time insufficient
- Unstable, unsafe, swollen airway
- Imminent procedure
- Psychosocial factors (e.g., unclear code status, assent)
- Imminent return to home hospital

STEP 2

If none of the above conditions exist, the pediatric ICU team discusses the feasibility of extubation.

Consider the Following

- Stage of ventilation
  I—initial or acute stage (escalation)
  II—ventilator management stage (plateau)
  III—discontinuance stage (deescalation)
- Immediate extubation (may include reversal of sedation)
- Spontaneous breathing trial (may include some level of pressure support)
- Reduction of ventilator settings

If Spontaneous Breathing Trial Is Performed, Stop Trial At Any Point for the Following

- Tachypnea, bradypnea, apnea (age appropriate)
- Excessive use of accessory muscles, nasal flaring present, subjective dyspnea (consider baseline)
- Significant, unresolved change in agitation or anxiety
- Significant tachycardia or bradycardia
- Hemodynamic changes
- Unacceptable decrease in SpO_2

STEP 3

Critical care team discusses extubation plan.

ICP, Intracranial pressure; *NPO,* nothing per mouth.

patient pulling the endotracheal tube (and intravenous lines, etc.) and unplanned extubation may occur. Whenever a patient is extubated, either planned or unplanned, there should be appropriate supplies, equipment, and personnel immediately available to reintubate if necessary. (See Chapter 52 for details on weaning.)

High-Frequency Ventilation

High-frequency ventilation (HFV) is a form of invasive mechanical ventilation that uses small V_T values (less than dead space) at rapid frequencies, up to 900 breaths/min (15 Hz). The primary goal of HFV is to provide adequate ventilation and oxygenation, while limiting the incidence of lung injury. HFV has been used as a primary mode of ventilation as well as a rescue therapy for patients determined to be failing conventional mechanical ventilation. Although early studies showed a beneficial effect on gas exchange compared with conventional ventilation, there has been no demonstrated improvement in outcome compared with current lung protective strategies.[69-75] In fact, recent studies have shown a trend toward increased mortality in patients treated with high-frequency ventilation.[76,77] Despite the lack of evidence supporting its use, HFV remains a controversial mode of ventilation for pediatric and neonatal patients but should be used only by clinicians expert in its clinical application and knowledgeable about its physiologic effects.

There are three basic types of HFV: high-frequency oscillatory ventilation, high-frequency jet ventilation, and high-frequency percussive ventilation. High-frequency oscillatory ventilation is the most common form of HFV. Oxygenation is achieved by inflating the patient's lungs to a high resting level, or FRC, by establishing a high mean airway pressure, similar to CPAP, at levels typically ranging from 16 to 30 cm H_2O. This "recruitment" improves the $\dot{V}/\dot{Q}$ ratio by opening previously collapsed alveoli. Ventilation is provided by the to-and-fro movement of a large piston in the ventilator circuit that results in high-frequency oscillations in the patient's airways. Gas exchange results from a combination of six mechanisms: bulk flow of gas, longitudinal dispersion, pendelluft, asymmetric velocity profiles, cardiogenic mixing, and molecular diffusion.

Gas exchange during high-frequency jet ventilation is believed to occur via two mechanisms—convection and diffusion. Fresh gas is injected into the endotracheal tube at a high velocity and travels down the mid-portion of the airways, reducing dead space. Bidirectional flow occurs as gas simultaneously travels up the outer lumen of the airways. Diffusion occurs in the lower airways as cross-sectional area increases and velocity decreases, similar to conventional ventilation.

During high-frequency percussive ventilation, a series of small, rapid breaths accompanied by air trapping are delivered that result in a steady increase in airway pressure, similar to a conventional breath. This is followed by a release phase to allow exhalation. The rapid "percussive" breaths are maintained through the entire breathing cycle, which facilitates gas exchange and simultaneously promotes movement of secretions to larger airways and eventually the trachea where they may be more easily removed.

Cardiovascular Effects

The cardiovascular effects of HFV vary with the strategy employed. Using the high lung volume strategy, lung volume is recruited, and $\bar{P}aw$ can be slowly reduced while maintaining alveolar ventilation. This strategy limits the adverse side effects of PPV on cardiovascular performance and may result in increased systemic blood flow. However, if $\bar{P}aw$ greater than that used during conventional ventilation is required during HFV, cardiovascular compromise may occur. Increases in intravascular volume and use of vasoactive drugs help support mean arterial blood pressure, cardiac output, and O_2 delivery. Increases in central venous pressure or decreases in mean arterial pressure indicate decreases in systemic blood flow as a result of overdistention of the lung and inappropriately high $\bar{P}aw$ after adequate intravascular volume has been established.

Weaning from High-Frequency Ventilation

When FiO_2 is equal to or less than 0.6, $\bar{P}aw$ is weaned slowly. When $\bar{P}aw$ is less than 15 to 18 cm H_2O, the patient may be trialed off or transitioned to conventional ventilation. Alternatively, the patient may be extubated directly from HFV once the mean airway pressure and F_IO_2 have been reduced to 8 to 9 cm H_2O and 0.3 respectively.

Complications of Mechanical Ventilation

Box 53-10 summarizes the most common complications associated with mechanical ventilation in newborns and other pediatric patients.

SPECIALTY GASES

Inhaled Nitric Oxide

Inhaled nitric oxide (INO) is a selective pulmonary vasodilator used to treat newborns who require mechanical ventilation for hypoxic respiratory failure.[78,79] INO improves oxygenation and reduces the need for extracorporeal membrane oxygenation (ECMO). See Chapter 50 for details. The approved indications for INO are listed in Box 53-11. INO also has been studied in preterm infants with the aim to reduce the incidence of chronic lung disease. These clinical investigations showed a modest improvement in pulmonary outcomes, but other problems associated with prematurity, such as intracranial hemorrhage, were unchanged. At the present time, INO is not routinely used in the management of respiratory failure associated with prematurity.

INO is administered in conjunction with mechanical ventilation via a specially designed delivery and monitoring system that provides precision drug dosing and safety features (Figure 53-10). The recommended INO dose is 20 parts per million (ppm) with an optimal response achieved when lung inflation is maximized.[80,81] When a response has been achieved and

Box 53-10 Complications of Mechanical Ventilation in Infants and Children

- Ventilator-induced injuries
- Air leak syndromes
- Pneumothorax
- Pneumomediastinum
- Pneumopericardium
- Pneumoperitoneum
- Pulmonary interstitial emphysema
- Subcutaneous emphysema
- Parenchymal lung damage
- Bronchopulmonary dysplasia
- Cardiovascular complications
- Decreased venous return
- Decreased cardiac output
- Increased pulmonary vascular resistance
- Increased intracranial pressure
- Increased incidence of intraventricular hemorrhage
- O_2-induced injuries
- O_2 toxicity
- ROP
- Airway complications
- Accidental extubation
- Atelectasis
- Inadequate humidification
- Endobronchial intubation
- Equipment contamination
- Postintubation stridor
- Endotracheal tube plugging or kinking
- Tracheal lesions
- Infection
- Ventilator-associated pneumonia

sustained, the INO dose is gradually reduced, typically by 50% each step, to a final dose of 1 ppm, at which point the drug is discontinued. During withdrawal of INO, FiO_2 is increased to minimize any recurrence of pulmonary hypertension.[82]

During INO therapy, concentrations of nitric oxide and O_2 are continuously monitored. The combined exposure of nitric oxide and O_2 leads to the formation of nitrogen dioxide, which is potentially toxic and is continuously monitored. INO doses typically used are considered to be very low and have a good safety profile. A metabolite of INO is the formation of methemoglobin as the nitric oxide molecule is bound to hemoglobin. During INO administration, the patient's ability to metabolize methemoglobin is assessed by periodically monitoring methemoglobin levels.[83]

INO should be available in any hospital that has a level III intensive care nursery. INO should be an integral part of any high-risk transport team, and it is important that non-ECMO centers have a plan for treatment failure that takes into account the distance to an ECMO center.[84] INO therapy has also been used for diagnosing and treating certain congenital heart diseases; although used in the management of ARDS, it has no effect on outcome and the oxygenation benefit is normally lost within 48 hrs.[85] The AARC has published a clinical practice guideline on INO therapy. Excerpts from this guideline appear in Clinical Practice Guideline 53-3.[86]

Heliox

Heliox is a gas mixture of O_2 and helium. Typical concentration of a tank of heliox is 80%/20% or 70%/30% (helium/oxygen). Helium is less dense than air. Inhaling a less-dense gas can reduce the pressure needed to overcome airway resistance and results in decreased work of breathing. In patients with a high O_2 requirement, helium is less effective. Heliox has been used in conjunction with other therapies in the treatment of partial large airway obstruction and asthma where airway resistance is high. It may be used to deliver bronchodilators but due to its lower density is not as efficient as air or oxygen so a higher flow rate should be employed. Heliox may serve as a temporizing measure while steroids are administered to reduce airway swelling. When high O_2 concentrations are necessary, heliox is not likely to be effective as the amount of inspired helium is diminished. Signs of decreased work of breathing, decreased use of accessory muscles, improved aeration, and decreased respiratory rate after initiating heliox are indications of its effectiveness.

NEONATAL AND PEDIATRIC TRANSPORT

Treatment of a critically ill infant or child is usually provided at a tertiary care facility. Many of these facilities have established transport teams that go to the referring facility, initiate ICU-type support, and transport the patient back to the tertiary care center. The composition of transport teams varies from one institution to another; however, typical team members include some combination of registered nurse, RT, paramedic, nurse

53-3 Inhaled Nitric Oxide Therapy

AARC Clinical Practice Guideline (Excerpts)*

1. A trial of INO is recommended in newborns (>34 weeks' gestation, 14 days of age) with PaO_2 100 mm Hg on FiO_2 1.0 or an oxygenation index >25, or both. (Grade 1A)
2. It is recommended that INO therapy be instituted early in the disease course, which potentially reduces the length of mechanical ventilation, O_2 requirement, and stay within the ICU. (Grade 1A)
3. INO should not be used routinely in newborns with congenital diaphragmatic hernia. (Grade 1A)
4. INO therapy should not be used routinely in newborns with cardiac anomalies dependent on right-to-left shunts, congestive heart failure, and lethal congenital anomalies. (Grade 2C)
5. There are insufficient data to support the routine use of INO therapy in postoperative management of hypoxic term or near-term infants with congenital heart disease. (Grade 2C)
6. The recommended starting dose for INO is 20 ppm. (Grade 1A)
7. Response to a short trial (30-60 minutes) of INO should be judged by an improvement in PaO_2 or oxygenation index; if there is no response, INO should be discontinued. (Grade 1A)
8. For a newborn with parenchymal lung disease, optimal alveolar recruitment should be established before initiation of INO therapy. (Grade 1A)
9. For newborns with a response to INO therapy, the dose should be weaned to the lowest dose that maintains that response. (Grade 1A)
10. It is recommended that INO should not be discontinued until there is an appreciable clinical improvement, that the INO dose should be weaned to 1 ppm before an attempt is made to discontinue, and that FiO_2 should be increased before discontinuation of INO therapy. (Grade 1A)
11. INO delivery systems approved by the U.S. Food and Drug Administration should be used to ensure consistent and safe gas delivery during therapy. (Grade 1C)
12. During conventional mechanical ventilation, the INO gas injector module should be placed on the dry side of the humidifier. (Grade 2C)
13. During conventional ventilation, the sampling port should be placed in the inspiratory limb of the ventilator, downstream from the site of injection, no greater than 15 cm proximal to the patient connection/interface. (Grade 2C)
14. FiO_2 should be measured downstream from the injection of INO into the circuit. (Grade 2C)
15. The patient-ventilator system should be continuously monitored for changes in ventilation parameters, with adjustments to maintain desired settings during INO therapy. (Grade 2C)
16. The lowest effective doses of INO and O_2 should be used to avoid excessive exposure to nitric oxide, nitrogen dioxide (NO_2), and methemoglobinemia. (Grade 2C)
17. The INO delivery system should be properly purged before use to minimize inadvertent exposure to NO_2. (Grade 2C)
18. The high NO_2 alarm should be set at 2 ppm on the delivery system to prevent toxic gas exposure to the lungs. (Grade 2C)
19. Methemoglobin should be monitored approximately 8 hours and 24 hours after therapy initiation and daily thereafter. (Grade 2C)
20. The INO dose should be weaned or discontinued if methemoglobin increases to >5%. (Grade 2C)
21. It is suggested that continuous pulse oximetry and hemodynamic monitoring be used to assess patient response to INO therapy. (Grade 2C)
22. Scavenging of exhaled and unused gases during INO therapy is *not* necessary. (Grade 2C)

**For complete guideline, see DiBlasi RM, Myers TR, Hess DR: Evidence based clinical practice guideline: inhaled nitric oxide for neonates with acute hypoxic respiratory failure. Respir Care 55:1741, 2010.*

practitioner, and physician. Regardless of the composition of the team, there are some characteristics that all transport teams should have in common.[87] All members should have exquisite assessment and critical thinking skills. They should be technically adept and have good communication skills. Each team develops minimum criteria that a team member must possess. Many teams cross-train multiple disciplines to perform certain technical tasks. Establishing proficiency and maintaining proficiency with all skills is a must for team members.

The team essentially functions as an extension of the ICU. To do this, much of the same equipment used in the ICU is taken to the referring hospital. Establishing responsibility for assessing function and maintaining appropriate inventory is essential. Many centers use elaborate checklists to be certain not to be without necessary equipment, disposables, or medications. Teams generally prepare for the worst. Many times when the team arrives at the referring facility, the patient's condition is not the same as when the initial call for help was made. Being prepared for the worst helps in stabilizing the patient for transport. The American Academy of Pediatrics has guidelines for all ages and common conditions requiring transport to a tertiary facility. Box 53-12 lists the basic equipment and supplies needed to provide respiratory care during neonatal and pediatric transport.

Box 53-12 Equipment and Supplies Needed to Provide Respiratory Care During Neonatal and Pediatric Transport

EQUIPMENT

- Adequate supply of O_2 and compressed air
- Air-O_2 blender
- Mechanical ventilator with circuit
- Manual resuscitator capable of giving 100% O_2 with PEEP
- Noninvasive O_2 monitor (SpO_2 or $PtcO_2$)
- O_2 analyzer
- Airway pressure monitor (electronic or mechanical)
- Electrocardiograph monitor
- Portable suction apparatus
- Laryngoscope handle
- Laryngoscope blades (sizes newborn to adult)
- Extra laryngoscope bulbs and batteries
- Stethoscope

SUPPLIES

- Resuscitation masks (sizes 0, 1, 2, 3, 4)
- Feeding tubes (sizes 6F, 8F, and 10F)
- Disposable O_2 hood
- O_2 connecting tubing
- Disposable hand-held nebulizer with tubing (for bronchodilators)
- Cloth adhesive tape for taping endotracheal tubes
- Tincture of benzoin for taping endotracheal tubes
- Pulse oximeter probes (at least two, in case one fails)
- Endotracheal tubes (sizes 2.5-7)
- Stylet
- Forceps
- Suction apparatus

RULE OF THUMB

A high-risk transport team must be prepared to provide the same level of care and highly trained personnel as would be available in the ICUs they are transporting patients to and from.

SUMMARY CHECKLIST

- Neonatal and pediatric care is one of the most sophisticated specialty areas in the field of respiratory care. Competent practice in this area requires a firm understanding of the many anatomic and physiologic differences between infants, children, and adults.
- A critical component in the respiratory management of infants and children is thorough clinical assessment. Because of the significant anatomic and physiologic differences between adults and infants, many of the assessment techniques useful with adults do not apply to infants.
- General assessment of the infant begins before birth and involves the maternal history and the fetal and newborn status. As a child grows and develops, more of the assessment methods used with adults become applicable.
- Respiratory care plan development is based on accurate patient information, detailed knowledge of the disease process, and current treatment guidelines and recommendations.
- Respiratory care modalities provided to pediatric and neonatal patients enclude: O_2, aerosol and humidity, airway care, and mechanical ventilation.
- CPAP is commonly used to overcome atelectasis and oxygenation problems.
- Using high-flow nasal cannulas has become common practice; however, care must be taken to prevent the delivery of higher than expected levels of CPAP.
- Noninvasive ventilation has become an acceptable choice of ventilation.
- Improved design of nasal masks and nasal prongs should help prevent the development of pressure ulcers during CPAP and noninvasive ventilation.
- For mechanically ventilated patients, plateau pressure or PIP during pressure-targeted ventilation should not exceed 28 cm H_2O and delta P should not exceed 15 cm H_2O.
- V_T should be maintained between 4 ml/kg and 8 ml/kg.
- Compressible volume loss may account for a significant portion of the small V_T used for infants and small children.
- Infants and children can be effectively managed with conventional ventilation. The use of HFV has become increasingly controversial. Mechanically ventilated infants and children should be assessed daily for readiness for liberation from mechanical ventilation.
- Nitric oxide is now considered standard therapy for the management of term infants who present with PPHN and should be available in all level III neonatal ICUs.
- Surfactant replacement has become the standard of care for preterm (gestation <32 weeks) or low birth weight infants (<1300 g) and infants with known surfactant deficiency.
- Highly specialized transport teams are available to transport newborn and pediatric patients to tertiary care facilities.

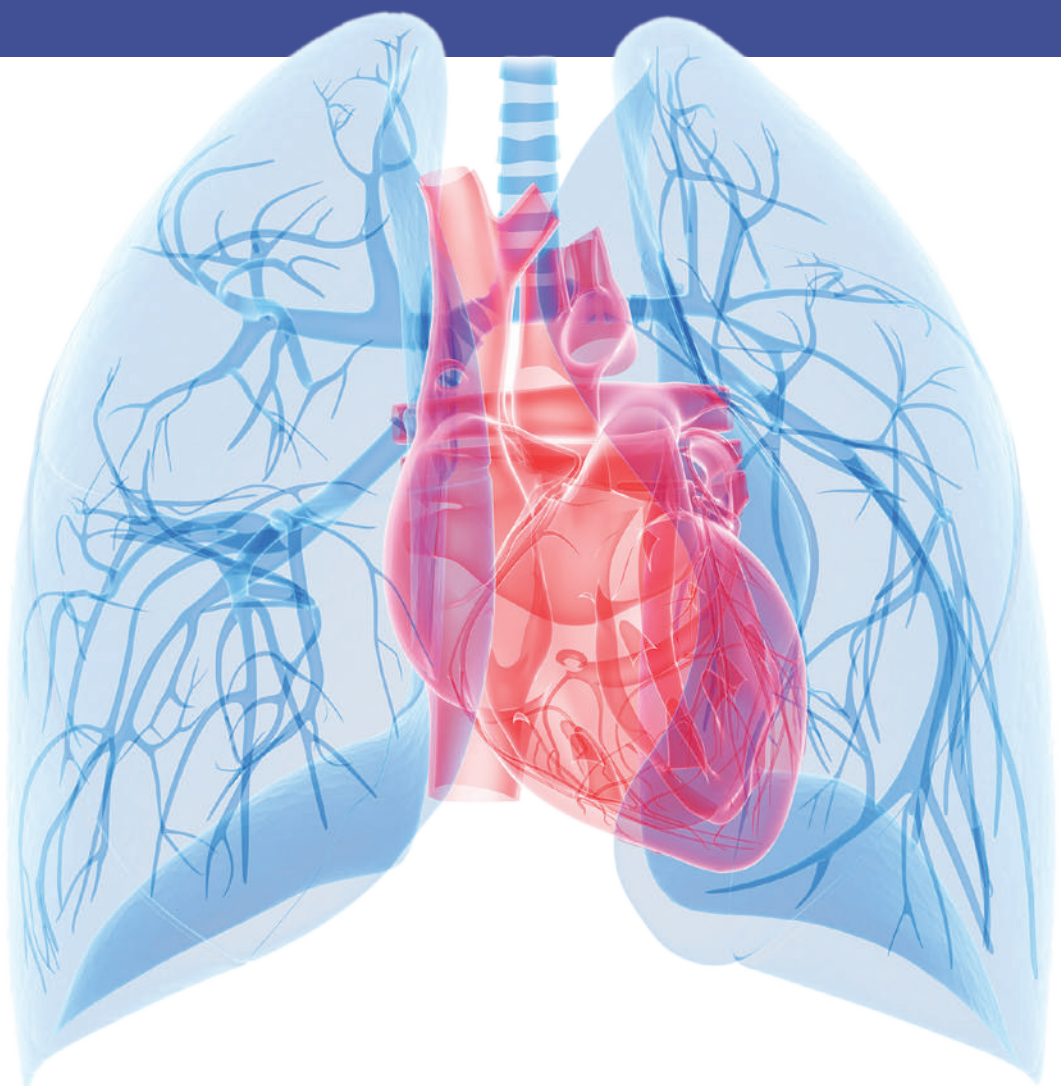
SECTION VII

PATIENT EDUCATION AND LONG-TERM CARE



CHAPTER 54

Patient Education and Health Promotion

DONNA D. GARDNER

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Write learning objectives in the cognitive, affective, and psychomotor domains.
- Compare and contrast how adults and children learn.
- Describe the methods that are used to evaluate patient education.
- Explain the importance of health education.
- Identify the settings that are appropriate for the implementation of health promotion activities.
- Describe the respiratory therapist's role in a disease management program.

CHAPTER OUTLINE

KEY TERMS

affective domain
cognitive domain
disease management
health education
health promotion
psychomotor domain
health literacy

Effective health education is invaluable to the health care of society. Respiratory therapists (RTs) educate patients by providing information about disease processes, medications, and treatment procedures. They teach patients how to perform diagnostic tests like basic spirometry, and they educate patients about health promotion issues such as tobacco cessation. RTs educate patients in all age groups, including geriatric, adult, adolescent, and pediatric patients. In certain situations, RTs educate the parents or the spouse of the patient in the home-care setting. RTs are also frequently called on to provide educational programs to patients with pulmonary diseases such as COPD, asthma and cystic fibrosis.

For these reasons, this chapter reviews important issues related to patient education, disease management, and health promotion.

The top three causes of death in the United States are heart disease, cancer, and chronic lower respiratory system disease, and the most deadly is chronic obstructive lung disease (i.e.,

bronchitis and emphysema).[1] Public education about risk factors is the key to the prevention of these diseases and probably has the greatest potential for making an impact on health care in this country. Therefore, the emphasis in health care should be on health promotion and disease prevention. RTs will need to play a greater role in health promotion and prevention in the future.

PATIENT EDUCATION

If we think of patient care as customer service—which it indeed is—then we cannot ignore education as a crucial component of that service. Whether we buy a car or a television set, we expect the salesperson to educate us about the essential aspects of our purchase. We also expect this information to be provided in writing. Likewise, education is an essential component of patient care. For patients to assume or resume control of their health, they must be educated. Because they rely on the health care practitioner to provide this education, every respiratory care education program should include instruction regarding patient education.

Cultural Diversity and Health Literacy

Culture refers to patterns of beliefs and behaviors shared by members of a population. Patients use their culture in the way they view health and the need for health care interventions. Successful respiratory therapy patient teaching must include patient cultural values that are appreciated and respected to better understand the patient's behaviors.

Some cultures do not recognize illness when symptoms are not present, such as with a chronic illness. Therefore, the ongoing need for care is a challenge when teaching patients whose symptoms have subsided. This occurs with asthma disease management. When asthma is under control the patient may not have symptoms and therefore the patient may stop taking his or her medication. There is risk associated with patients misunderstanding therapy or medications. This is not related to patients' ability to read; it is about patients' culture and their ability to comprehend information well enough to follow the instructions to take a medication, know when to reorder a medication, and how to complete a therapy necessary for lung disease.

Health literacy is the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions.[2] Health care information such as medication instruction is complex and often requires critical thinking skills. Health literacy encompasses educational, social, and cultural factors that influence an individual.

Respiratory therapists must understand where the patient is coming from in regards to the patient's beliefs, values, and cultural norms to influence the education provided. Low health literacy affects patient safety and the ability for the patient to participate in care, and results in poor health outcomes.

Respiratory patients will not be able to be self-directed and navigate the health care system if they do not have the ability to follow the educational programs and instructions provided. Reading and comprehension may not always go hand in hand. Patients often will not voluntarily admit that they do not understand to avoid embarrassment. Therefore, to determine whether or not a patient understands, it is important to look for the following clues that indicate reading or writing is a concern and to be sensitive to prevent any feelings of shame.

- Patient repeatedly is noncompliant
- Patient uses the excuse of being too busy, tired, or sick to maintain attention when given instruction
- Claims that the patient did not feel like reading the information, gave the information to a family member, or lost or forgot their glasses
- Insistence on taking the information home to read
- Demonstrates nervousness and stress, confused about the materials
- Talks about something else and not on topic
- Returns documents that are not complete or illegible

Respiratory therapy patient educators must assess readiness to learn from the patient's point of view to ensure patient compliance. Patients must believe the change in behavior is possible and beneficial before they will make a behavior change.

Performance Objectives

Initially it is helpful for the RT to develop learning objectives that are appropriate for the specific patient education topic to be addressed. These learning objectives will help to clarify the teaching strategies that are needed for patient education sessions. Objectives should be stated in measurable terms so that the RT and the patient can recognize when the objective has been accomplished. Clear objectives describe what is to be accomplished and how evaluation will occur.

The format for writing an objective is as follows:

1. Begin with the phrase, "At the end of the lesson, the patient will.…"
2. Write the action verb (e.g., "list," "describe," "demonstrate").
3. Write a condition, if needed (e.g., with or without the use of notes).
4. Write a standard, if needed (e.g., how fast, how accurate).

For example: At the end of the session, the patient will be given a metered-dose inhaler and spacer and be able to demonstrate the correct technique for using it without error.

Action verb: "demonstrate" (from the psychomotor domain; the relevant domains are discussed later in this chapter)

Condition: "given a metered-dose inhaler and spacer"

Standard: "without error "

Learning Domains

Learning occurs in three domains: **cognitive**, **psychomotor**, and **affective**. Some learning sessions will involve only one domain, whereas others may involve all three. The cognitive domain is very important, because it will address the knowledge that a patient needs regarding his or her illness and how to manage it. The psychomotor domain addresses the skills that the patient will need to acquire to perform specific treatment

modalities (e.g., the use of metered-dose inhalers). The affective domain involves teaching patients about the necessary attitudes and motivations for successfully living with their diseases.

MINI CLINI

Developing Learning Objectives for the Use of an Albuterol Metered-Dose Inhaler

PROBLEM: Your 31-year-old patient is newly diagnosed with asthma, and she is being discharged tomorrow. She requires instruction regarding how to properly use her controller medication, Advair diskus, and the reliever medication albuterol metered-dose inhaler. Develop learning objectives for her, and address each learning domain.

Solution: Use a variety of learning objectives, including the following:

Cognitive domain: Describe the action of albuterol on the bronchial smooth muscle; recognize when it is necessary to seek medical attention.

Affective domain: Agree that it is important not to skip a dose; verbalize willingness to use the Advair diskus daily; feel satisfaction by controlling the disease.

Psychomotor domain: Demonstrate the ability to assemble the metered-dose inhaler and spacer; inhale slowly and deeply with an inspiratory hold.

Cognitive Domain

The cognitive domain is probably the easiest to translate into learning objectives because it involves the facts and concepts that the RT wants the patient to know and apply by the end of the education session. Objectives for the cognitive domain might include the following:

1. List the indications for oxygen therapy.
2. Discuss the importance of using the prescribed liter flow.
3. Explain the relationship between oxygen and combustion.

Any factual information that you expect the patient to understand and apply falls under the cognitive domain. Action verbs for the cognitive domain are included in Table 54-1.[3]

Psychomotor Domain

Repetition and active involvement are important when teaching a psychomotor skill. RTs who teach new skills to patients need to provide plenty of opportunity for the patient to practice the activity. Simple demonstration of the skill to the patient is not enough. To confirm performance in the psychomotor domain, have your patients provide a return demonstration. Be sure to provide help and encouragement as needed. Be patient; not everyone develops skills at the same rate.

Examples of action verbs for the psychomotor domain are included in Table 54-2.[3]

TABLE 54-1

Verbs for the Cognitive Domain

Purpose	Example Verbs
Knowledge	Cite, define, read, identify, list, label, name, outline, recognize, select, state
Comprehension	Convert, describe, defend, explain, illustrate, interpret, give examples of, predict, paraphrase, summarize, translate
Application	Apply, compute, construct, demonstrate, change, calculate, use, estimate, modify, present, prepare, solve, proceed, relate, utilize
Analysis	Analyze, associate, compare, contrast, determine, diagram, differentiate, discriminate, distinguish, outline, illustrate, separate
Synthesis	Categorize, combine, compile, compose, create, design, develop, devise, integrate, modify, organize, plan, propose, rearrange, reorganize, revise, rewrite, translate, write
Evaluation	Appraise, assess, compare, conclude, contrast, critique, discriminate, make a decision, support, evaluate, judge, weigh

Modified from French D, Olrech N, Hale C, et al: Blended learning: an ongoing process for Internet integration, Victoria, Canada, 2003, Trafford Publishing.

TABLE 54-2

Verbs for the Psychomotor Domain

Purpose	Example Verbs
Perception: prepares and recognizes sensory cues to want to respond	Detect, distinguish, differentiate, identify, isolate, relate, recognize, observe, perceive, see, watch
Ready to act and respond	Begin, explain, move, react, show, state, establish a body position, place, posture, assume a stance, sit, stand, position
Guided response: imitate and practice; rough sequencing of events	Copy, duplicate, imitate, manipulate, operate, try, practice, dismantle
Efficiency: smooth sequencing of events	Assemble, calibrate, construct, display, fasten, fix, grind, manipulate, measure, mix, sketch, demonstrate, execute, increase speed, improve, make, show dexterity, pace, produce
Perform alone: modifies, responds as needed	Act habitually, advance confidently, control, excel, guide, manage, master, organize, perform quickly and more accurately
Creates a new or original model	Adapt, alter, rearrange, reorganize, revise

Modified from French D, Olrech N, Hale C, et al: Blended learning: an ongoing process for Internet integration, Victoria, Canada, 2003, Trafford Publishing.

RULE OF THUMB

People learn by doing. Get the learner involved.

Affective Domain

The patient's attitudes and motivations influence his or her ability to learn. It is important to remember that, with patient education, timing is everything. Patients who have recently been given a poor prognosis or who are in pain are not in an optimal position to learn. Maslow suggested a hierarchy of needs, and he identified physiologic needs as the most basic of human needs, followed by safety, love, esteem, and self-actualization.[4] Lower-level needs must first be satisfied before moving on to higher-level needs. For example, if a patient is dyspneic or in pain, he or she will probably not be receptive to learning the steps that are involved in cleaning a small-volume nebulizer. It is important for RTs to assess a patient's readiness to learn by talking with the patient and his or her family and by listening to the patient's concerns. It is important to develop a relationship of trust and to be empathetic with the patient.

The RT should begin with easy-to-master facts and skills. After the patient conquers these, motivation should increase, and the patient will have a feeling of accomplishment. Motivation is also enhanced by presenting material clearly with the use of a variety of teaching methods and by relating the facts and skills to practical applications. Getting patients to see how these skills will benefit them is the key to motivation. Communicating to the patient that there is something that he or she can do to maintain or improve his or her health and sense of well-being is important.

Objectives in the affective domain—using the oxygen therapy example mentioned earlier—might include the following:

1. Express genuine concern for yourself by using your oxygen therapy correctly.
2. Commit to learn by being an active participant in the program.

Affective domain action verbs are included in Table 54-3.[3]

Teaching Tips

Following is a list of time-honored suggestions for improving patient education:

- Address the patient's immediate concerns first.
- Create an optimal learning environment. Teach in a quiet and relaxed setting.
- Have patients use as many of their senses as possible during their learning session. Whenever possible, include hearing, seeing, smelling, speaking, touching, and doing.
- Keep sessions short. If the material is complex, break it down into brief segments.
- Repeat, repeat, repeat!
- Provide many opportunities for the patient to practice psychomotor skills.
- Be prepared.
- Be organized. People learn more quickly when they are presented with information that is well organized.
- Demonstrate enthusiasm for what you are doing. The learner can always sense your level of motivation.
- Evaluate in a nonthreatening manner, and provide helpful feedback. Use evaluation as a learning tool.

TABLE 54-3

Verbs for the Affective Domain

Purpose	Example Verbs
Receive: becoming aware of	Accept, acknowledge, alert, choose, give, attend, notice, perceive, tolerate, select
Respond: interested in or doing something about something	Agree, assist with, aid, answer, assist, comply, conform, communicate, consent, label, obey, cooperate, follow, read, report, visit, volunteer, study
Value: concerned about, developing an attitude	Adopt, assume, behave, choose, demonstrate, commit, desire, initiate, join, exhibit, express, prefer, seek, share
Organize: arranging systematically, confirming	Adapt, adjust, arrange, classify, conceptualize, group, rank, validate, verify, strengthen, substantiate, corroborate, confirm
Characterize: internalizing a set of values, championing	Demonstrate a change in lifestyle, discriminate, defend, influence, invite, listen, preach, qualify, question, serve, act upon, advocate, devote, expose, justify, support

Modified from French D, Olrech N, Hale C, et al: Blended learning: an ongoing process for Internet integration, Victoria, Canada, 2003, Trafford Publishing.

Teaching Children as Compared With Teaching Adults

Teaching children is often very different than teaching adults. Children are more motivated by external factors (e.g., prizes) as compared with adults, who tend to have internal motivating factors. This suggests that adults will learn quicker if they can easily see the intrinsic value of knowing more about their illness. Alternatively, children may need a more obvious reward system in place before learning can take place. Adults, however, are more independent, and they do not like being dependent on others. This suggests that adults should be more involved in setting program goals and that they will readily learn skills that make them more independent. Other important issues related to differences between children and adult learners are listed in Box 54-1, and allocated time for teaching is given by age in Box 54-2.[5]

Evaluation of Patient Education

The critical question that remains when all of the patient education sessions are complete is, "Has the patient learned?" Evaluation is the process that answers that question. The method used to evaluate learning is determined by the measurable learning objectives (i.e., cognitive, affective, or psychomotor). Cognitive objectives are often evaluated with the use of a written examination. Objectives in the affective and psychomotor domains are evaluated with the use of performance checklists.

Informal evaluation should occur during the educational process. The RT can ask simple questions along the way to identify whether the patient has comprehended the information. If the patient provides an answer that is not correct, the RT should view this as an opportunity to repeat previous

Box 54-1 Learning Differences Between Children and Adults

CHILD
- Motivated by external factors like grades
- Directed by others
- Learning is a big part of his or her life
- Trusts teacher
- Has limited experience
- Learns for the future
- Learns quickly
- Tends to learn in accordance with his or her developmental stage
- Has no problem with a slow pace of learning
- Subject oriented

ADULT
- Motivated internally
- Is self-directed
- Learning is only one part of his or her life
- Questions the teacher
- Has rich life experiences
- Learns for the present
- May learn more slowly
- Varies with regard to learning ability
- Dislikes a slow pace of learning
- Problem oriented

Box 54-2 Attention Spans for Different Ages

- Toddlers: about 2 to 3 minutes
- School-aged children: about 10 to 15 minutes
- Adolescents and adults: about 20 to 30 minutes

discussions or to present the material with a new approach. The RT must never convey disappointment or frustration when patients are having trouble learning new material.

RULE OF THUMB

Evaluation results reflect the quality of instruction as much as the degree of learning.

HEALTH EDUCATION

Health education may have been the earliest form of organized health promotion in the United States. Health programs in schools is a result of Lemuel Shattuck's report in 1850 to the Sanitary Commission of Massachusetts, which described the value of schools helping to contain communicable diseases. However, it was not until 1875 that health education became widespread. During that year, the Women's Christian Temperance Union lobbied for alcohol education in the schools. As a result of these efforts, 38 states passed legislation to require this education, which later turned into tobacco, alcohol, and drug education. From that time, health education has been enhanced and expanded in schools. There are public health agencies at the local, state, national, and international levels that provide health education and care for those who would otherwise have none.

MINI CLINI

Metered-Dose Inhaler Instruction for a Pediatric Patient

PROBLEM: How would you change the approach to the metered-dose inhaler situation described in the previous Mini Clini if your patient was a 7-year-old boy with asthma?

Solution: Although the learning objectives may remain the same, the methods may be different. You may compare the slow, deep inspiration to getting ready to blow out the candles on a birthday cake. You may use swimming under water as an image to encourage breath holding. Use simple diagrams to show how the medication will act on the patient's lungs. If he likes sports, tell him about athletes who compete well despite having asthma (you may also use this illustration to stress the importance of controlling asthma). An abundance of resource materials are available for children with asthma; make use of them. Many local, state, and national lung associations (www.ala.org) offer such learning aids as age-appropriate books, coloring books, and puppets to make the learning process more fun for children.

Health education is a process of planned learning that is designed to enable individuals to make informed decisions and to take responsible actions regarding their health. The primary goal of health education is behavior change, and it is designed to promote, maintain, and improve both individual and community health. Health education covers the continuum between health and disease and between prevention and treatment.

Health promotion helps people change their lifestyles in a variety of settings, from the home or school to the workplace or the health care agency or institution. To be effective, health education must be combined with strategies for health promotion; the two are strongly linked. The American Association for Respiratory Care has created a statement for health promotion and disease prevention (Box 54-3).[7]

Although individuals must ultimately assume responsibility for their own health, promoting healthy behaviors through education is an important part of being an RT. In this capacity, the RT should serve as a role model for the public. Unless health care professionals model healthy behaviors, successful health outcomes cannot be expected from the public. To this end, the American Association for Respiratory Care has created a role-model statement to encourage RTs to set a positive example for the public (Box 54-4).[7]

Providing a good example is not enough to ensure successful health education programming. For the desired outcomes to be achieved, certain conditions must first be met. The components are remarkably similar to patient education requirements. The essential components of effective health education are as follows:

1. Program participants must be actively engaged in the learning process.

54-1 AARC Clinical Practice Guideline (Excerpts)*

Providing Patient and Caregiver Training

American Association for Respiratory Care Clinical Practice Guideline (Excerpts)* updated June of 2010. www.rcjournal.com/cpgs/pdf/06.10.0765.pdf.

INDICATIONS

Patients who need to increase knowledge and understanding of health status and therapy; improve skills needed for safe and effective health care; and develop a positive attitude, strong motivation, and increased compliance. Patients need to know the answers to "Ask Me 3": What is my main problem? What do I need to do? Why is it important for me to do this?

CONTRAINDICATIONS

None.

COMPLICATIONS

Omission of essential steps concerning care, presentation of inconsistent information, or failure to validate the learning process can lead to unfavorable results. Lack of cultural competence, and information appropriate in the language other than English will result in less than desirable outcomes. Lack of trust.

LIMITATIONS

- For the patient: Lack of motivation; impairment (physical, mental, or emotional); inability to understand instruction; illiteracy; language barriers; religious and/or cultural beliefs that are at odds with the material presented. Lack of health literacy, despite educational completed and conflicts of religious and/or cultural practices.
- For the RT: Lack of a positive attitude or flexibility; limited knowledge of skill being taught; inadequate assessment of patient's readiness to learn; cultural or religious practices that may affect learning; inability to personalize the material; insufficient time; inadequate communication skills, and inadequate knowledge of cultural or religious practice.
- For the system: Hospital stay too brief; lack of interdisciplinary communication and/or cooperation; inconsistent information presented; lack of an interpreter.
- Other factors: Lack of support system for the patient; reimbursement issues; interruptions, distractions, or noise; inadequate lighting, heat, or space; poorly chosen resources including inappropriate reading level and vocabulary.

ASSESSMENT OF NEED

Determine the knowledge gap between what the patient knows and what he or she needs to know. Apply this to cognitive, psychomotor, and affective domains.

ASSESSMENT OF OUTCOME

Evaluate knowledge gained, skills mastered, patient should return demonstration without assistance, reassess patient outlook, attitude and life style changes.

RESOURCES

Access trained interpreters, ensure the written materials are readable at a fifth or sixth grade level, materials should be available in a variety of formats (audio and visual), use demonstration models, reevaluate the skills.

MONITORING

The monitoring of the training processes should include awareness of the patient's verbal and nonverbal responses, including eye contact, listening skills, and participation in discussion.

**For the complete guideline, see the American Association for Respiratory Care: AARC Clinical Practice Guidelines. Providing patient and caregiver training 2010. Respir Care 55(6):765–769, 2010.*

2. Activities must incorporate the values and beliefs of the learner. Familial, cultural, societal, and economic factors must be considered.
3. The role of the health educator is to facilitate behavioral change. Thus, the learning process should be approached together by both the learner and the educator.
4. The process of predisposing an individual toward improved health as well as enabling and reinforcing health attitudes requires effort, which will only reap results over time.
5. The health care educator must be willing to listen nonjudgmentally to the concerns of the learners. Empathy and understanding are necessary to foster a trusting relationship.
6. The level of the learners' self-esteem and self-concept may either enhance or inhibit their ability to make decisions about their own health. The health care educator should be willing to provide emotional support as necessary.
7. The health care educator's personal characteristics have a direct impact on the outcome of the educational program. Generally, successful outcomes occur as a result of a confident and professional approach.

For RTs to assist patients, caregivers, or the public with regard to the development of healthier lifestyles, greater emphasis must be placed on health promotion and disease prevention strategies.

HEALTH PROMOTION AND DISEASE PREVENTION

In 2012, the United States spent $2.8 trillion, or $8,915 per person, on health care.[9] The top three causes of death in the United States are heart disease, cancer, and chronic obstructive pulmonary disease (COPD). All three lead to chronic

54-2 AARC Clinical Practice Guideline (Excerpts)*

Training of the Health Care Professional (HCP) for the Role of Patient and Caregiver Educator

American Association for Respiratory Care Clinical Practice Guideline (Excerpts)*

INDICATIONS

- HCPs who must educate patients and caregivers about knowledge, skills, and motivation necessary to effectively participate in health care.
- Evidence that HCPs lack the knowledge about educational principles and practices needed to:
  - Assess educational needs
  - Prepare educational objectives tailored to individuals or groups
  - Accomplish learning objectives
  - Prepare educational materials
  - Supervise practice of skills
  - Give feedback and assess outcomes
  - Modify educational efforts according to individual or group response

CONTRAINDICATIONS

None.

COMPLICATIONS

Inadequate training of the HCP may cause harm to the patient or inhibit the patient's ability to participate in the management of his or her own health.

LIMITATIONS

- Of the HCP: Lack of educational preparation; unreceptive or inept; lack of interdisciplinary cooperation; inability to modify learning objectives based on age, culture, or religion; inability to communicate effectively
- Of the system: Inadequate time, space, or financial resources; insufficient faculty for training program; inconsistent information provided to the HCP
- Of the patient or caregiver: Negative attitude; lack of basic education; presence of a language barrier or perception of cultural conflict

ASSESSMENT OF NEED

HCPs who provide education should be periodically assessed for adequate knowledge and skills by observation in a patient education setting and by a specialist.

ASSESSMENT OF OUTCOME

Evaluate verbally and in writing; observe HCP in teaching setting; evaluate whether goals set concerning knowledge, skills, compliance, and attitude have been met; evaluate long-term through institutional quality improvement indicators.

MONITORING

HCP training should include evidence of classes and in-service training; availability of written and audiovisual resources; and evaluation of training effectiveness.

**For complete guideline, see Training the health care professional for the role of patient and caregiver educator. Respir Care 41(7):654–657, 1996; or www.rcjournal.com/cpgs/thcpcpg.html.*

conditions and might be preventable by avoiding tobacco use, poor diet, and physical inactivity.

Current medical practice is designed to respond to the acute problems of patients; its focus is on diagnosing and treating the presenting symptoms rather than focusing on the prevention of disease by identifying risk factors and providing methods for behavioral changes. Only focusing on the acute or episodic health problems creates a discrepancy when using this model of care to care for chronic conditions that may be prevented or managed. Preventative health care is very different from chronic care.

With this in mind, a quote from Rufus Howe is appropriate: "What a rare privilege it is to be in a position to improve the lives of others."

A patient with asthma goes to the emergency department and is treated effectively and efficiently. The patient received good quality care, and, in many people's minds, the patient was "fixed." However, asthma is manageable to the point that the patient should not have to be in the emergency department. There are excellent national guidelines (www.NAEPP.org) that outline how to manage asthma, and there are medications that control asthma and keep the patient out of this situation. Usually the reason for the emergency visit is that the patient's asthma is not in control; this may occur because the patient is not using inhaled steroids, because he or she has a poor understanding of the disease and how to manage it, because the national guidelines are not being used, or because of a combination of all of these issues. Either way, this chronic disease can be self-managed by a patient with the proper multidisciplinary education and follow up.

However, the public health model attempts to reduce disease in the nation as a whole through mass education campaigns. Examples include education about the hazards of drinking and driving, tobacco use (both smokeless and smoking) education, and food labeling to indicate fat and cholesterol content. This is known as *health promotion and disease prevention.*[10] By participating in public education programs, RTs have the potential to affect the health of individuals and of the population as a whole.

Recent efforts such as Healthy People 2020 have attempted to place the focus on the health of the population rather than on that of the individual.[11] The four broad goals of the Healthy

Box 54-3 American Association for Respiratory Care Health Promotion and Disease Prevention Statement

HEALTH PROMOTION AND DISEASE PREVENTION

- The AARC acknowledges that respiratory therapists in both the civilian and uniformed/military services are integral members of the health care team, in hospitals, home health care settings, pulmonary laboratories, rehabilitation programs and all other environments (including ICUs and critical care transport) where respiratory care is practiced.
- The AARC recognizes that education and training of the respiratory therapist is the best method by which to instill the ability to improve the patient's quality and longevity of life, and that such information should be included in their formal education and training in CoARC accredited programs.
- The AARC recognizes the respiratory therapist's responsibility to participate in pulmonary disease teaching, smoking cessation programs, pulmonary function studies for the public, air pollution alerts, allergy warnings, and sulfite warnings in restaurants, as well as research in those and other areas where efforts could promote improved health and disease prevention. Furthermore, the respiratory therapist is in a unique position to provide leadership in determining health promotion and disease prevention activities for students, faculty, practitioners, patients, and the general public in both civilian and uniformed service environments.
- The AARC recognizes the need to 1) provide and promote consumer education related to the prevention and control of pulmonary disease; 2) establish a strong working relationship with other health agencies, educational institutions, Federal and state government, businesses, military and other community organizations; and 3) monitor such activities. Furthermore, the AARC supports efforts to develop personal and professional wellness models and action plans that will inspire and encourage all respiratory therapists to cooperate on health promotion and cardiorespiratory disease prevention.

Effective 1985.
Revised 2000.

Box 54-4 American Association for Respiratory Care Role Model Statement

- As health care professionals engaged in the performance of cardiopulmonary care, RTs must strive to maintain the highest personal and professional standards.
- In addition to upholding the code of ethics, the RT shall serve as a leader and advocate of public health.
- The RT shall participate in activities leading to awareness of the causes and prevention of pulmonary disease and the problems associated with the cardiopulmonary system. The RT shall support the development and promotion of pulmonary disease awareness programs, to include smoking cessation programs, pulmonary function screenings, air pollution monitoring, allergy warnings, and other public education programs.
- The RT shall support research to improve health and prevent disease.
- The RT shall provide leadership in determining health promotion and disease prevention activities for students, faculty, practitioners, patients, and the general public.
- The RT shall serve as a physical example of cardiopulmonary health by abstaining from tobacco use and shall make a special personal effort to eliminate smoking and the use of other tobacco products from the home and work environment.
- The RT shall strive to be a model for all members of the health care team by demonstrating responsibility and cooperating with other health care professionals to meet the health needs of the public.

Effective 3/90.
Revised 3/00.
From the American Association for Respiratory Care: Position statement (website): www.aarc.org/resources/position_statements/rms.html.

People 2020 program are as follows: (1) to promote quality of life, healthy development, and healthy behaviors across all life stages; (2) to achieve health equity, eliminate disparities, and improve the health of all groups; (3) to attain high-quality, longer lives free of preventable disease, disability, injury, and premature death; and (4) to create social and physical environments that promote good heatlh for all.[11] These goals encompass the essential elements of health promotion and disease prevention, which are the prevention of premature death, disease, and disability as well as the improvement of the quality of life.

The recognition that allied health professionals such as RTs play vital roles in these activities prompted professional organizations to develop policy statements about health promotion and disease prevention. The American Association for Respiratory Care policy statement appears in Box 54-5.[6]

RTs can take an active role in the development of educational materials to assist both the public and other health professionals with regard to health promotion activities. Many medical manufacturers have also developed asthma education kits of various types that include peak flow meters, spacers, and educational materials. These kits are generally developed with input from the medical community and in particular from RTs. An example of an asthma program is given in Table 54-4.[12] Respiratory care educational programs need to be diligent when incorporating health promotion and disease prevention activities into all learning domains as part of their curricula.

Another specific area of health promotion that receives much attention in both hospital and public health settings is nicotine intervention. Hospitalized patients are more motivated to try to quit smoking for two reasons: the illness that resulted in the patient being in the hospital may have been made worse due to tobacco use, and hospitals have smoke-free environments. Therefore, RTs should use this opportunity to promote nicotine treatments.

Nicotine intervention is a progressive, comprehensive program that incorporates a series of steps from risk identification to maintenance support. Smoking is the leading cause of preventable disease and death in the US. January 11, 2014

Box 54-5 Health Promotion and Disease Prevention

- The AARC submits this paper to identify and illustrate the involvement of the RT in the promotion of health and prevention of disease and supports these activities. The AARC realizes that RTs are integral members of the health care team, in hospitals, home health care settings, pulmonary laboratories, rehabilitation programs, and all other environments where respiratory care is practiced.
- The AARC recognizes that education and training of the RT is the best method by which to instill the ability to improve the patient's quality and longevity of life, and that such information should be included in their formal education and training.
- The AARC recognizes the RT responsibility to participate in pulmonary disease teaching, smoking cessation programs, pulmonary function studies for the public, air pollution alerts, allergy warnings, and sulfite warnings in restaurants, as well as research in those and other areas where efforts could promote improved health and disease prevention. Furthermore, the RT is in a unique position to provide leadership in determining health promotion and disease prevention activities for students, faculty, practitioners, patients, and the general public.
- The AARC recognizes the need to provide and promote consumer education related to the prevention and control of pulmonary disease and to establish a strong working relationship with other health agencies, educational institutions, federal and state government, businesses and other community organizations and to monitor such. Furthermore, the AARC supports efforts to develop personal and professional wellness models and action plans that will inspire and encourage all RT to cooperate on health promotion and disease prevention.

Effective 7/85.
Revised 3/00.
From the American Association for Respiratory Care: Position statement (website): www.aarc.org/resources/position_statements/hpdp.html.

marked the fiftieth anniversary of the first Surgeon General Report on smoking and health that linked smoking with lung cancer and heart disease and the thirty-second Surgeon General Report,"The Health Consequences of Smoking— 50 years of progress: A report of the Surgeon General," which presents new data on the consequences of smoking.[13] The Affordable Care Act's (ACA) Public Health and Prevention Fund expanded access to smoking cessation services through most insurance companies to include Medicaid. The ACA supports community-based programs and public education campaigns promoting prevention and helping people to quit; 1.6 million smokers have made an attempt to quit.[13] Safe and effective tobacco treatment enhances the success for quitting. Nicotine replacement therapies (NRT) such as nicotine gum, lozenges, or patches are available over the counter. NRT combined with behavioral therapy is more effective for tobacco cessation. Varenicline tartrate (Chantix) and bupropirion (Zyban) do not contain nicotine. They are both available by prescription only.[14] Chantix interacts at the sites in the brain that are influenced by nicotine.

National, state, and local agencies such as the American Cancer Society, the American Lung Association, and the American Heart Association offer educational materials and behavioral counseling. The educational materials that these agencies offer are available via mail, telephone, and the Internet. In 2004, the U.S. Department of Health and Human Services established a nationwide toll-free number (800-QUIT-NOW [800-784-8669]) to serve as an access point for smokers who are seeking assistance with quitting. Components of the Office of Surgeon General's tobacco cessation program are included in Tables 54-5 and 54-6.[15]

DISEASE MANAGEMENT

The most recent data show that more than 145 million people—which is approximately half of all Americans—live with chronic disease.[16] Half of those with chronic illness have more than one chronic condition or comorbidity. The prevalence of chronic disease has increased due to tobacco use, physical inactivity, poor nutrition choices, obesity, and the aging of the population during the same time the cost of care has markedly risen. These chronic diseases are extremely expensive and lead to unnecessary admissions and readmissions (recidivism). Chronic care models have been used since the 1990s. A chronic care model is patient centered; it encourages multidisciplinary focus on self-management and continuous quality control. Wagner originally presented the chronic care model that is illustrated in Figure 54-1.[17]

Wagner explains the model as follows: "Patients and families who struggle with chronic illness require planned, regular interactions with their caregivers, with a focus on function and prevention of exacerbations. This interaction includes systematic assessments, attention to treatment guidelines, and behaviorally sophisticated support for the patient's role as a self manager. These interactions must be linked through time by clinically relevant information and continuing follow-up."[17]

As with **disease management**, which is a method of applying the best health care practices to a population with a chronic illness one person at a time,[10] the goals of this type of program include improving the health of the person, improving patient satisfaction, reducing mortality, improving quality of life, and eliminating unnecessary medical treatment to reduce the cost of health care.[10] There is no one definition of disease management. However, the Care Continuum Alliance defines disease management as a coordinated system of interventions for people who have conditions that require significant self-care.[18] Disease management is measured by its impact on costs, clinical outcomes, and quality of life. The programs have similar components, including a coordinated comprehensive interdisciplinary care team with a process for measuring improvement. Health insurance companies, pharmaceutical companies, and the federal government all pay for disease management programs.[10] Most programs have the following attributes:

- The provision of interdisciplinary comprehensive care (i.e., health promotion, prevention, and acute care involving

TABLE 54-4

Components of an Asthma Disease Management Program

Component 1: Assessment and monitoring	Assessment: • Detailed patient history • Thorough physical examination • Spirometry to document the reversibility of airflow obstruction Monitoring: Periodic assessment and ongoing monitoring of asthma to determine if goals are being met • Minimal or no chronic and troublesome symptoms, day or night • Normal or near-normal pulmonary function • No limitations on activities • Minimal or no recurrent exacerbations of asthma • Optimal medications with minimal or no adverse side effects • Satisfaction with asthma care
Component 2: Control of the factors that contribute to asthma	Identify the allergens and irritants • House dust mites, cockroach feces, molds, and animal dander • Tobacco smoke, emissions from wood-burning stoves, strong odors and sprays such as perfume and hairspray • Nitrogen dioxide and sulfur dioxide • Rhinitis and sinusitis • Gastroesophageal reflux disease • Viral respiratory infections • Aspirin • Sulfites Reduce exposure to the allergens and irritants, and provide medications or immunotherapy
Component 3: Pharmacologic therapy: managing asthma for the long term	Classify the asthma severity into one of the four levels on the basis of the severity of recurrent symptoms and lung function Prescribe medications for the level of asthma • All patients with asthma need a quick-relief medication (i.e., short-acting β2-agonists) • Those with persistent asthma need daily long-term control medications to achieve control (e.g., an inhaled corticosteroid) • Start treatment in a stepwise approach (i.e., begin at a higher level to achieve rapid control; when control is achieved and sustained, cautiously step down treatment)

Component 4: Patient education for a partnership in asthma care	Patient education begins at the time of diagnosis.
	• Provide basic facts about asthma
	• Identify the roles of the medications
	• Skills: correct use of the medication delivery devices, the peak flow meter, and the symptom diary
	• Discuss environmental control measures
	• Discuss when and how to take rescue actions
	Education techniques
	• Basic facts about asthma
	  • Describe the contrast between asthmatic and normal airways
	  • Describe what happens to the airways during an asthma attack
	• Describe the roles of the medications
	  • How the medications work
	  • Long-term control: medications that prevent symptoms, often by reducing inflammation
	  • Quick relief: short-acting bronchodilators relax muscles around the airways
	Stress the importance of long-term control medications, and emphasize that the patient should not expect quick relief
	• Skills
	  • Inhaler use (patient demonstration)
	  • Spacer and holding chamber use
	  • Symptom monitoring, peak flow monitoring, and recognizing early signs of deterioration
	• Environmental control measures
	  • Identifying and avoiding environmental precipitants or exposures
	  • When and how to take rescue actions
	• Responding to changes in asthma severity (i.e., daily self-management plan and action plan)

TABLE 54-5

The "5 As" Model for Treating Tobacco Use and Dependence as a Chronic Disease

Ask about tobacco use	Identify and document the tobacco use status of every patient at every visit • Expand the vital signs to include tobacco use
Advise to quit	Strongly urge all tobacco users to quit Advice should be clear, strong, and personalized
Assess every tobacco user's willingness to make a quit attempt	Ask every tobacco user if he or she is willing to make a quit attempt: "Are you willing to give quitting a try?" • If the patient is willing, provide assistance • If the patient is unwilling, provide a motivational intervention • If the patient is a member of a special population (e.g., pregnant, adolescent, minority), consider providing him or her with additional information
Assist by providing counseling and medication	• Set a quit date that is ideally within 2 weeks • Tell family and friends about quitting • Anticipate challenges, including nicotine withdrawal symptoms • Remove tobacco products from the environment Recommend the use of approved medications, except when they are contraindicated or if the patient is a member of a specific population (e.g., pregnant women, smokeless tobacco users, adolescents) • Explain how the medications work to increase success with quitting and to reduce withdrawal symptoms The medications approved for this purposed by the U.S. Food and Drug Administration include the following: • Bupropion SR • Nicotine gum • Nicotine inhaler • Nicotine lozenge • Nicotine nasal spray • Nicotine patch • Varenicline Provide practical counseling (i.e., problem solving, skills training): • Abstinence: striving for total abstinence is essential (i.e., "not one puff after the quit date") • Anticipate triggers and challenges: determine how the patient will successfully overcome these (i.e., avoid the triggers) • Alcohol should be avoided because it is associated with relapse (however, reducing alcohol intake could precipitate withdrawal in alcohol-dependent persons) • Other smokers in the home: quitting is more difficult when there is another smoker in the home; patients should encourage all to quit with them or to not smoke in their presence Provide intratreatment social support • Provide a supportive clinical environment while encouraging the patient in his or her quit attempt (i.e., "My office staff and I are here to assist you") Help the patient to obtain extra social support during treatment • Help the patient to develop social support in his or her environment outside of the treatment by asking the patient's spouse or partner, friends, and coworkers to support the quit attempt Provide supplementary materials, including information about quit lines • Sources: Federal agencies, nonprofit agencies, national quit line network (1-800-QUIT-NOW), and local/state/tribal health departments and quit lines • Type: culturally, racially, educationally, and age appropriate for the patient • Location: readily available Recommend counseling (there are three types): Practical counseling (i.e., problem solving, skills training) • Recognize danger situations • Develop coping skills • Provide basic information Supportive treatment counseling • Encourage the patient to quit • Communicate caring and concern • Encourage the patient to talk about quitting
Arrange for follow-up contacts, either in person or via the telephone	Timing: Follow-up contact should begin soon after the quit date, preferably during the first week; a second follow up is recommended within the first month, and follow up should be scheduled as indicated • Actions to take during the follow-up contacts: for all patients, identify problems that have been encountered, and anticipate challenges Assess the medication use and any associated problems: • Remind the patient of the support offered by quit lines • Address tobacco use at the next clinical visit • When patients have been abstinent, congratulate them on their success

TABLE 54-6

Components of a Tobacco Education Program for Those Who Are Unwilling to Quit Enhancing Motivation to Quit Tobacco: The "5 Rs"

Relevance	Encourage the patient to indicate why quitting is personally relevant and to be as specific as possible. Motivational information has the greatest impact if it is relevant to a patient's disease status or risk, to a family or social situation (e.g., having children in the home), or to health concerns, age, gender, and other important patient characteristics (e.g., prior quitting experience, personal barriers to cessation).
Risk	Ask the patient to identify potential negative consequences of tobacco use and suggest those that seem to be the most relevant to the patient. Emphasize that smoking low-tar or low-nicotine cigarettes or using other forms of tobacco (e.g., smokeless tobacco, cigars, pipes) will not eliminate these risks. Examples of risks include the following: • Acute risks: shortness of breath, exacerbation of asthma, harm to a pregnancy, impotence, infertility • Long-term risks: heart attack, stroke, lung and other cancers, chronic obstructive pulmonary disease, disability, need for extended care • Environmental risks: increased risk of lung cancer and heart disease in spouse, increased rates of smoking among children of tobacco users, sudden infant death syndrome, respiratory infections in the children of smokers
Rewards	Ask the patient to identify the potential benefits of stopping tobacco use: • Improved health • Food will taste better • Save money • Feel better • Home, car, clothing, and breath will smell better • Can stop worrying about quitting • Set an example for children • Have healthier babies and children • Reduce wrinkling and aging of skin
Roadblocks	Ask the patient to identify barriers to quitting: • Withdrawal symptoms • Fear of failure • Weight gain • Lack of support • Depression • Enjoyment of tobacco
Repetition	Repeat the motivational intervention information every time that an unmotivated patient is seen.

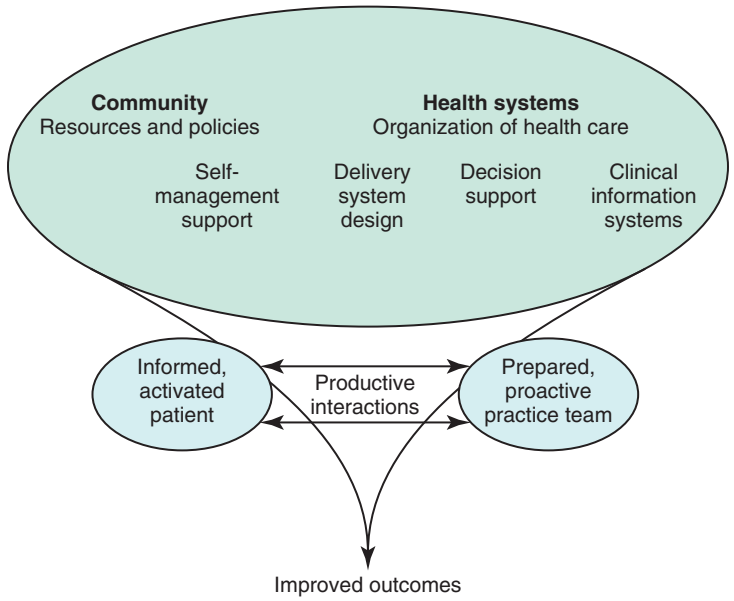

FIGURE 54-1 Illustration of a chronic care model that is focused on productive interactions and improved patient outcomes. (Modified from Wagner E: System changes and interventions: delivery system design. Improving chronic illness care, Orlando, Fl, 2001, Institute for Healthcare Improvement National Forum.)

interdisciplinary or multidisciplinary teams—physician, RT, nurse, PT, OT, pharmacist, and other health team members)
- A population-identification process (for a specific disease or condition)
- The use of evidence-based guidelines, protocols, and pathways
- Collaborative and coordinated components of care
- Active patient self-management and education (e.g., empowerment, behavior modification)
- Quality improvement methods to include outcomes measurement and evaluation
- The use of information technology to create a routine reporting and feedback loop

If you were interested in creating a disease management program, you would want to make sure to include these components. There are many disease management programs offered to patients with chronic diseases such as COPD, asthma, amyotrophic lateral sclerosis, and cystic fibrosis. RTs are ideal to create, coordinate, and participate as members of a disease management program. The patients whom RTs care for have chronic diseases, and these individuals need to be taught about the health risks associated with the disease, the prophylactic measures used to maintain quality health, and disease-specific respiratory therapy. For example, in a disease management program for a patient with COPD, RTs would provide one-on-one counseling for tobacco cessation education (if the patient continued to use these products); discuss pulmonary rehabilitation that included exercise as well as strength and endurance training; and recognize and manage an acute situation and appropriate medication management. The RT would work with the patient to establish personal goals, including changing the person's behaviors and reducing the risks associated with the chronic disease. Outcomes would be measured to include health care utilization or hospital admissions, dyspnea scores, medication use, missed work or school days, quality of life surveys, and number of ER visits.

Implications for the Respiratory Therapist

Because the RT can practice as both an individual counselor and a public health advocate, depending on the setting or circumstances, it is useful to examine the most likely settings in which the RT's health promotion and disease prevention knowledge can be put to good use.

Health Care Institutions

Health care institutions in which RTs provide both health education and promotion include inpatient facilities (e.g., hospitals, skilled nursing facilities) and ambulatory care centers (e.g., physicians' offices, clinics, health insurance organizations). RTs may practice in outpatient or long-term acute care settings as well as in corporate wellness programs for staff and patients that are aimed at improving cardiopulmonary health through disease management education that includes nutrition, medication management, and exercise (e.g., pulmonary rehabilitation, asthma management education programs).

Work Site

Healthier workers are absent from work less often; they are also more satisfied with their jobs and more productive. This all translates into a more cost-effective workplace. RTs may find themselves involved in work-site wellness by participating in the following: (1) performing pulmonary function or blood pressure screenings; (2) developing and implementing stress management or nicotine intervention programs; and (3) consulting on policies related to smoking and occupational or environmental exposure to foreign dusts (e.g., silica, asbestos) or noxious fumes (e.g., smog).

Home

Home health care continues to be a rapidly growing segment of the health care industry. It has been proved repeatedly to be more cost-effective than hospital care. RTs can perform a wide variety of services in the patient's home, including oxygen therapy and mechanical ventilation on either a temporary or long-term basis. Generally the focus is on prevention (i.e., preventing further decline). Patient education is of primary importance in the home so that the patient may become as self-reliant as possible (see Chapters 55 and 56).

Community

Most of the health promotion activities described earlier pertain to the individual. At the community level, the focus is on the group. Community health promotion activities provided by the RT may include the following: pulmonary function screening at health fairs, smoking cessation programs, family asthma management education programs, and COPD (i.e., better breathing) support groups. RTs, who are certified in basic cardiac life-support instruction, may also volunteer to perform certification in this practice for various groups.

Educational Institutions

Because many unhealthy behaviors begin during early childhood or adolescence, elementary, middle, and secondary schools are excellent places to begin health education activities. Education about smoking is one example.

Cigarette smoking is a primary risk factor that is associated with many of today's leading causes of death. Because most smoking begins during late childhood or early adolescence, schools provide the best setting in which to educate children about the dangers of tobacco. RTs are trained to provide these educational experiences. It is never too early to begin sending the antismoking message.

SUMMARY CHECKLIST

- Patient education and general approaches to health promotion are key issues in health care today.
- Incorporating health literacy and cultural beliefs into patient education programs affects patient compliance.
- Educators should use learning objectives to direct teaching strategies toward individuals or large groups of patients.

- Learning objectives call for the use of an action verb to define the performance that is expected of the patient at the end of instruction.
- Learning occurs in three domains: cognitive (knowledge), psychomotor (skills), and affective (attitudes).
- Patients tend to learn by doing. Passive participation usually does not cause a change in behavior.
- Evaluate the cognitive domain objectives with written tests. Evaluate psychomotor and affective domain objectives with a skills checklist.
- The clinician should evaluate his or her teaching in an effort to improve.
- The RT can have an impact on several areas of health education and health promotion, including tobacco cessation programs, asthma education programs, pulmonary rehabilitation and community health screenings.
- RTs can be key players in disease management programs because of their understanding of the manifestations of the chronic cardiopulmonary diseases and their abilities to teach patients self-management with the use of the patient education tools discussed in this chapter.

CHAPTER 55

Cardiopulmonary Rehabilitation

KENNETH A. WYKA

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- State the definition and general goals of pulmonary rehabilitation programs.
- Explain the rationale for exercise conditioning and psychosocial support of patients with chronic pulmonary disease.
- Describe how to evaluate and select patients for pulmonary rehabilitation.
- Describe pulmonary rehabilitation program design including format and content.
- List the educational content to be addressed in a pulmonary rehabilitation program.
- Describe the implementation of a pulmonary rehabilitation program, including staffing, facilities, scheduling, class size, equipment, costs, and reimbursement.
- Discuss the outcome measures that can be used to evaluate pulmonary rehabilitation programs.
- Identify the potential hazards associated with pulmonary rehabilitation.
- Compare the focus of pulmonary rehabilitation to that of cardiac rehabilitation.

CHAPTER OUTLINE

KEY TERMS

6- or 12-minute walk
aerobic exercises
cardiopulmonary exercise evaluation (CPX)
comprehensive outpatient rehabilitative facilities (CORFs)
Karvonen's formula
onset of blood lactate accumulation (OBLA)
Patient Protection and Affordable Care Act (PPACA)
progressive resistance
psychosocial support needs
pulmonary rehabilitation
reconditioning
target heart rate
ventilatory threshold

Steady improvements in acute care have resulted in improved patient survival and increasing numbers of individuals with chronic disorders. These chronic disorders are associated with a wide spectrum of physiologic, psychologic, and social disabilities. Foremost among these disorders is chronic obstructive pulmonary disease (COPD), which is now the third leading cause of death in the United States.[1]

Although differences in diagnoses can have an impact on treatment outcomes and survival, patients with chronic pulmonary disorders have much in common. All of these patients have difficulty coping with the physiologic limitations of their diseases and these physiologic limitations result in many psychosocial problems. The end result often is an unsatisfactory quality of life. The high incidence of repeated hospitalizations and the progressive disability of these patients require well-organized programs of rehabilitative care. With the passage in 2010 of the **Patient Protection and Affordable Care Act (PPACA)**, the reduction of early hospital readmissions for various chronic diseases, including COPD, is a major concern and focus of health care today. This chapter provides foundational knowledge regarding the goals, methods, and issues involved in providing planned programs of rehabilitation for individuals with chronic pulmonary disorders.

DEFINITIONS AND GOALS

The Council on Rehabilitation defines rehabilitation as "the restoration of the individual to the fullest medical, mental, emotional, social, and vocational potential of which he or she is capable."[2] The overall goal is to maximize functional ability and to minimize the impact the disability has on the individual, the family, and the community. **Pulmonary rehabilitation** is the "art of medical practice wherein an individually tailored, multidisciplinary program is formulated, which through accurate diagnosis, therapy, emotional support and education stabilizes or reverses both the physio- and psychopathology of pulmonary diseases and attempts to return the patient to the highest possible functional capacity allowed by his or her pulmonary handicap and overall life situation."[3]

The general goals of pulmonary rehabilitation are to control and alleviate symptoms, restore functional capabilities as much as possible, and improve quality of life.[4] Pulmonary rehabilitation does not reverse or stop progression of the disease, but it can improve a patient's overall quality of life.

HISTORICAL PERSPECTIVE

Pulmonary rehabilitation is not a new concept. In 1952, Barach and colleagues recommended reconditioning programs for patients with chronic lung disease to help improve their ability to walk without dyspnea.[5] Decades passed before clinicians paid any attention to this concept. Instead of having their patients participate in reconditioning programs, most physicians simply prescribed oxygen (O_2) therapy and bed rest. The result was a vicious cycle of skeletal muscle deterioration, progressive weakness and fatigue, and increasing levels of dyspnea including at rest. Patients became homebound, then room-bound and eventually bed-bound. Improved avenues of therapy and rehabilitation were needed.

In 1962, Pierce and associates published results confirming Barach's insight into the value of reconditioning. They observed that patients with COPD who participated in physical reconditioning exhibited lower pulse rates, respiratory rates, minute volumes, and carbon dioxide (CO_2) production during exercise. However, they also found that these benefits occurred without significant changes in pulmonary function.[6] Soon thereafter, Paez and associates showed that reconditioning could improve both the efficiency of motion and O_2 consumption in patients with COPD.[7] Subsequently, Christie showed that the benefits of reconditioning could be achieved on an outpatient basis with minimal supervision.[8] Since Christie's work in 1968, other investigators have continued to research the benefits of pulmonary rehabilitation.

The available evidence at the present time consistently indicates that pulmonary rehabilitation benefits patients with chronic obstructive and restrictive pulmonary diseases.[9-12] When combined with smoking cessation, optimization of blood gas results (arterial pO_2, pCO_2, and pH), and proper medication use, pulmonary rehabilitation offers the best treatment option for patients with symptomatic pulmonary disease. Programs for pulmonary rehabilitation must be founded on the sound application of current knowledge in the clinical and social sciences. In fall 2006, the American College of Chest Physicians (ACCP) and the American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR) released their evidence-based guidelines relating to pulmonary rehabilitation aimed at improving the way pulmonary rehabilitation programs are designed, implemented, and evaluated through patient outcomes.[13]

SCIENTIFIC BASIS

Rehabilitation must focus on the patient as a whole and not solely on the underlying disease. For this reason, effective pulmonary rehabilitation programs combine knowledge from both the clinical and the social sciences. Knowledge from the clinical sciences can help quantify the degree of physiologic impairment and establish outcome expectations for reconditioning. Application of the social sciences is helpful in determining the psychological, social, and vocational impact of the disability on the patient and family and in establishing ways to improve the patient's quality of life.

Physical Reconditioning

At rest, an individual maintains homeostasis by balancing external, internal, and cellular respiration. Physical activity, such as **aerobic exercises**, increases energy demands. To maintain homeostasis during exercise, the cardiorespiratory system must keep pace. Figure 55-1 shows how the body responds to exercise. Ventilation and circulation increase to supply tissues and cells with additional O_2 and to eliminate the higher levels of CO_2 produced by metabolism.

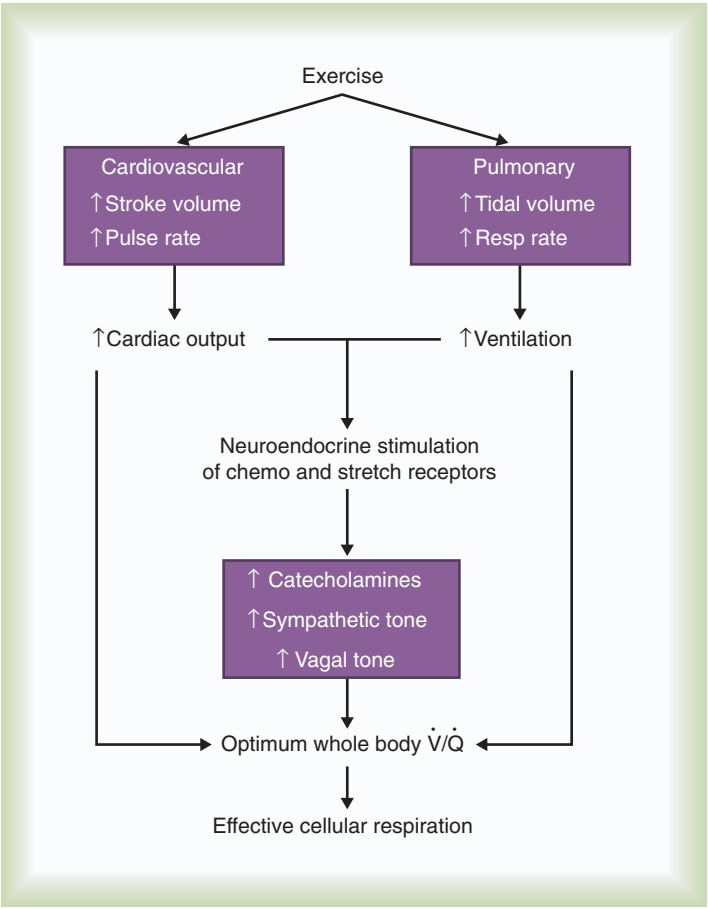

FIGURE 55-1 The body's response to increased levels of activity such as exercise.

As depicted in Figure 55-2, O_2 consumption and CO_2 production also increase in linear fashion as exercise intensity increases. If the body cannot deliver sufficient O_2 to meet the demands of energy metabolism, blood lactate levels increase above normal. In exercise physiology, this point is called the **onset of blood lactate accumulation (OBLA)**. As this excess lactic acid is buffered, CO_2 levels increase and the stimulus to breathe increases. The result is an abrupt upswing in both CO_2 and $\dot{V}_E$ (referred to as the **ventilatory threshold**). Beyond this point, metabolism becomes anaerobic, the efficiency of energy production decreases, lactic acid accumulates and fatigue sets in.

RULE OF THUMB

A good estimate of a patient's maximum voluntary ventilation (MVV) is derived by multiplying the FEV_1 (forced expiratory volume in 1 second) by a factor of 35. To estimate the MVV of a patient with FEV_1 of 1.5 L, multiply 1.5 L by 35:

$$MVV = FEV_1 \times 35$$
$$MVV = 1.5\ L \times 35 = 52.5\ L/min$$

Box 55-1 Benefits from Exercise Reconditioning

ACCEPTED BENEFITS
Increased physical endurance
Increased maximum O_2 consumption
Increased activity levels with:
- Decreased ventilation
- Decreased $\dot{V}O_2$
- Decreased heart rate
- Increased ventilatory threshold
- Improved blood lipids

POTENTIAL BENEFITS
Increased sense of well-being
Improved secretion clearance
Increased hypoxic drive
Improved cardiac function

UNPROVEN BENEFITS
Prolonged survival
Improved pulmonary function test results
Decreased pulmonary artery pressure
Improved blood gases
Change in muscle O_2 extraction
Change in step desaturation

Data from references 15 and 16.

Patients with COPD who lack adequate pulmonary function have severe limitations to their exercise capabilities. Their high rate of CO_2 production during exercise results in respiratory acidosis and a shortness of breath out of proportion to the level of activity. In addition, as ventilation increases, the rate of O_2 consumption in a patient with COPD increases significantly as depicted in Figure 55-3. Together, these factors limit patient tolerance for any significant increase in physical activity.

Pulmonary rehabilitation must include efforts to recondition patients physically and increase their exercise tolerance. **Reconditioning** involves strengthening essential muscle groups, improving overall O_2 utilization and enhancing the body's cardiovascular response to physical activity as noted in Box 55-1.

Psychosocial Support

If the overall goal of pulmonary rehabilitation is to improve the quality of patients' lives, physical reconditioning alone is insufficient. Psychosocial indicators generally are good predictors of morbidity in patients with COPD. Studies show that the relative success of reconditioning plays less of a role in determining whether patients complete a program than meeting their **psychosocial support needs**.[14]

There is a well-established relationship between physical, mental, and social well-being in humans. However, emotional states such as anxiety and stress can aggravate an existing physical problem. Likewise, physical manifestations of disease, such as recurrent dyspnea, can increase an individual's stress level.

The progressive nature of COPD can negatively affect the patient's overall outlook on his or her disease and reduce motivation to adapt to its consequences. The best medical care

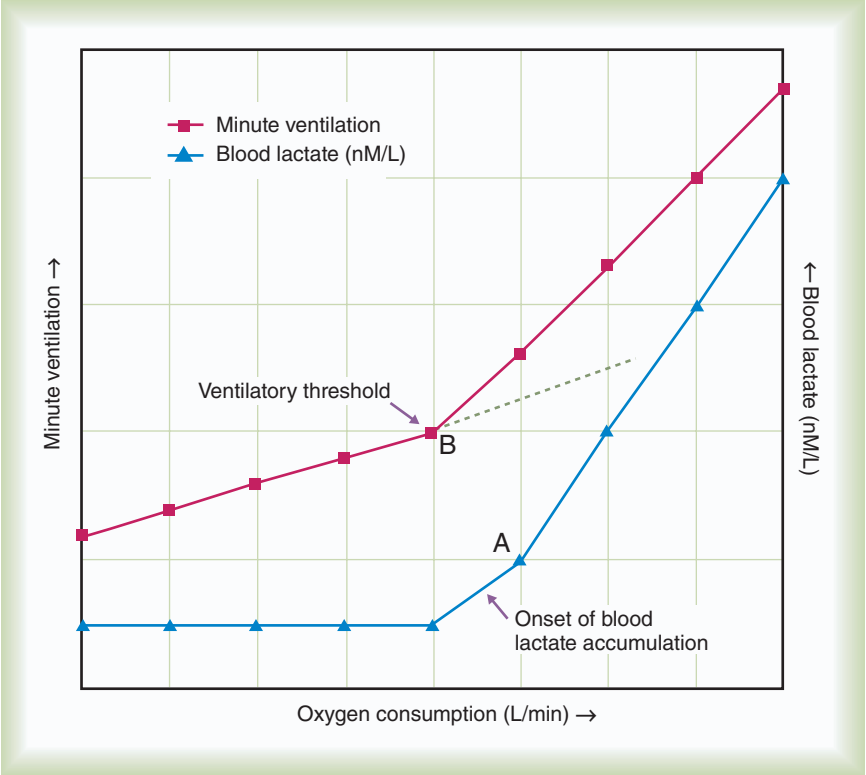

FIGURE 55-2 Minute ventilation, blood lactate, CO_2 production, and O_2 consumption during graded exercise to maximum. The dashed line represents the linear extrapolation between $\dot{V}E$ and $\dot{V}O_2$ during submaximal exercise. Point A represents OBLA. At the same time, $\dot{V}E$ and $\dot{V}CO_2$ "break" from their extrapolated rate of increase and abruptly rise (point B). This is referred to as the ventilatory threshold. (Modified from McArdle WD, Katch FI, Katch VL: Exercise physiology: energy, nutrition and human performance, ed 6, Baltimore, 2007, Williams & Wilkins.)

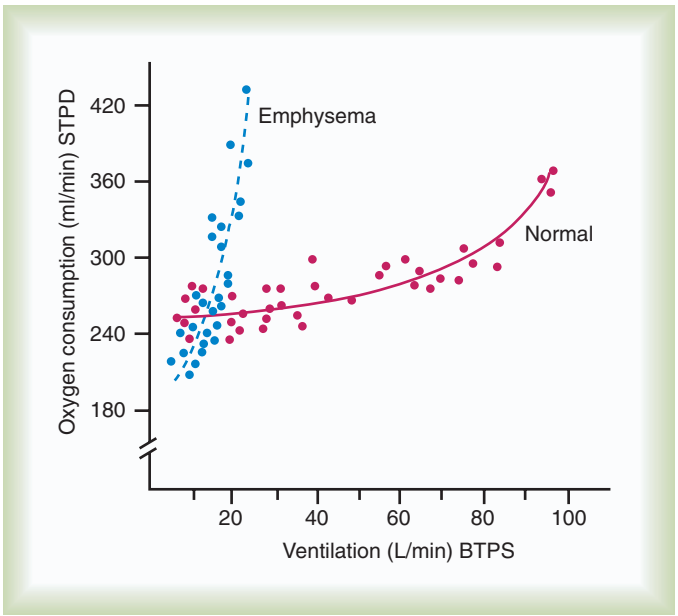

FIGURE 55-3 Changes in O_2 consumption with increasing ventilation in a normal subject and in a patient with emphysema. BTPS, Body temperature, body pressure saturated; STPD, volume of dry gas at 0° C and 760 mm Hg atmospheric pressure. (Modified from Cherniack RM, Cherniack L, Naimark A: Respiration in health and disease, ed 3, Philadelphia, 1984, Saunders.)

available can be negated and a patient can experience a progressively downhill course because of an unfavorable mental state. Patients with COPD often have a tendency to develop severe anxiety, hostility, and stress as a direct consequence of their disability.[15] Because patients are fearful of economic loss and death, they can develop hostility toward the disease and often toward the people around them. In terms of social function, the physiologic impairment of chronic lung disease combined with other variables can severely restrict a patient's ability to perform routine tasks requiring physical exertion. Moreover, patients' potential loss of confidence in their ability to care for themselves reduces feelings of dignity and self-worth.

Figure 55-4 presents elements of how chronic lung disease and other variables can have an impact on a patient's quality of life. It is here that the link between the physical reconditioning and psychosocial support components of rehabilitation becomes most evident. By reducing exercise intolerance and enhancing the body's cardiovascular response to physical activity, patients can develop a more independent and active lifestyle. For some patients, simply being able to walk to the market or play with their grandchildren can contribute to a greater feeling of social importance. For others, physical conditioning may allow a return to near-normal levels of activity, including vocational pursuits.

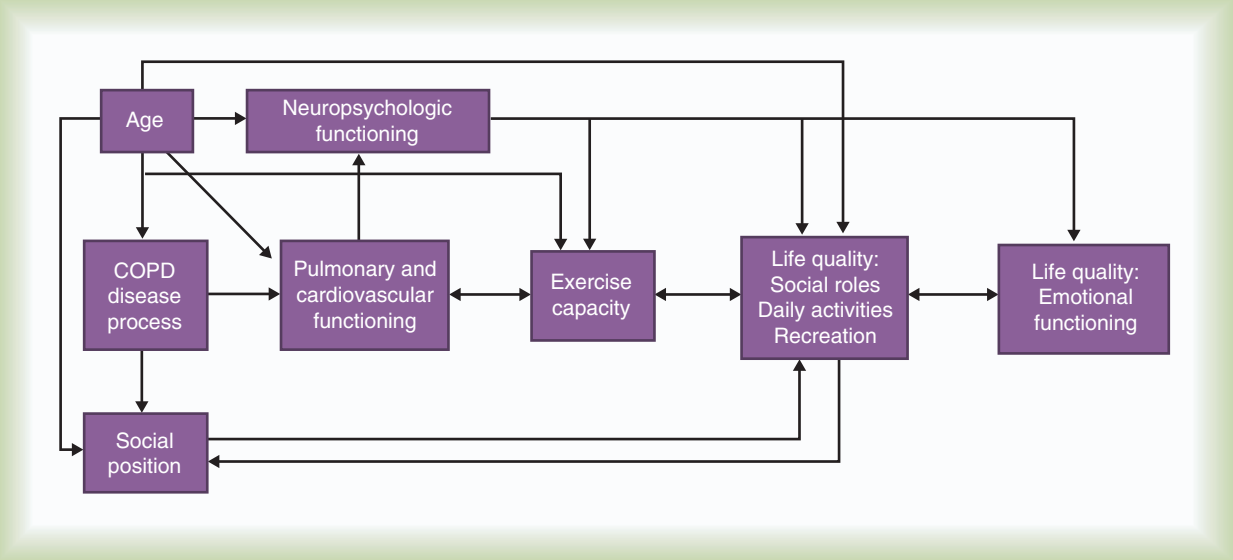

FIGURE 55-4 Model describing the relationship between physical and psychological dysfunction in patients with chronic lung disease. (Modified from McSweeney AJ, Grant I, Heaton RK, et al: Life quality of patients with chronic obstructive pulmonary disease. Arch Intern Med 142:473, 1982.)

Many patients disabled with pulmonary disease are in their economically productive years and are anxious to return to economic self-sufficiency. For these patients, occupational retraining and job placement are key ingredients in a good rehabilitation program. An occupational therapist can play a vital role here and should be included, if possible, as a member of the interdisciplinary rehabilitation team and in the pulmonary rehabilitation program. The pulmonary rehabilitation program should be based on the individual needs and expectations of each patient. Evaluation and placement of the rehabilitation patient may require the skills of vocational counselors and occupational therapists along with the cooperation of business and industry.

STRUCTURE OF A PULMONARY REHABILITATION PROGRAM

Program Goals and Objectives

Pulmonary rehabilitation programs vary in their design and implementation but generally share common goals. Examples of these common goals are listed in Box 55-2. These general goals assist planners in formulating more specific program objectives. When determining objectives, both patients and members of the rehabilitation team should have input. These objectives should always be stated in measurable terms because this helps facilitate the determination of both patient outcomes and the therapeutic success and value of pulmonary rehabilitation. Depending on the specific needs of the participants, program objectives can include the following:

- Development of diaphragmatic breathing skills
- Development of stress management and relaxation techniques
- Involvement in a daily physical exercise regimen to condition both skeletal and respiratory-related muscles
- Adherence to proper hygiene, diet, and nutrition
- Smoking cessation (if applicable)
- Proper use of medications, O_2, and breathing equipment (if applicable)
- Application of airway clearance techniques (when indicated)
- Focus on group support
- Provisions for individual and family counseling

When program objectives are specifically defined and structured in a measurable way, strategies can be tailored to ensure the maximum results and benefit. Demonstration of program effectiveness also becomes easier and more acceptable by the medical community. However, benefits realized by participating patients are not always easy to identify and may be controversial.

Box 55-2 Common Goals for Pulmonary Rehabilitation Programs

- Control of respiratory infections
- Basic airway management
- Improvement in ventilation and cardiac status
- Improvement in ambulation and other types of physical activity
- Reduction in overall medical costs
- Reduction in hospitalizations
- Psychosocial support
- Occupational retraining and placement (when and where possible)
- Family education, counseling, and support
- Patient education, counseling, and support
- Control of respiratory infections

Patient Evaluation and Selection

Before beginning a pulmonary rehabilitation program, clinicians need to define and establish criteria for entry or selection. They need to be aware of any comorbidity a patient may have along with the effects exercise may have on blood chemistry and a patient's overall physical status. Patient selection requires comprehensive evaluation and testing.[16]

Patient Evaluation

Pulmonary rehabilitation programs must have a qualified medical director, usually a pulmonologist, to provide overall medical direction of the program and to screen prospective patients.[17] Patient evaluation begins with a complete patient history—medical, psychological, vocational, and social. A well-designed patient questionnaire and interview form assist with this step. The patient history should be followed by a complete physical examination (see Chapter 16). A recent chest film, resting electrocardiogram (ECG), complete blood count, serum electrolytes, and urinalysis provide additional information on the patient's current medical status (see Chapter 17).

To determine the patient's cardiopulmonary status and exercise capacity, both pulmonary function testing and a cardiopulmonary exercise evaluation may be performed. Pulmonary function testing includes assessment of pulmonary ventilation, lung volume determinations, diffusing capacity (DLCO), and spirometry before and after bronchodilator use (see Chapter 20).

The **cardiopulmonary exercise evaluation (CPX)** serves two key purposes in pulmonary rehabilitation. First, it quantifies the patient's initial exercise capacity. This quantification provides the basis for the exercise prescription (including setting a **target heart rate**) and yields the baseline data for assessing a patient's progress over time. In addition, the evaluation helps determine the degree of hypoxemia or desaturation that can occur with exercise; this provides the objective basis for titrating O_2 therapy during the exercise program. To guide practitioners in implementing exercise evaluation, the American Association for Respiratory Care (AARC) has published clinical practice guidelines on exercise testing for evaluation of hypoxemia or desaturation or both[18] and pulmonary rehabilitation. Excerpts from these guidelines appear in Clinical Practice Guidelines 55-1 and 55-2.[19]

The exercise evaluation procedure involves serial or continuous measurements of several physiologic parameters during various graded levels of exercise on either an ergometer or a treadmill as described in Box 55-3. To allow for steady-state equilibration, these graded levels are usually spaced at 3-minute intervals. Work levels are increased progressively until either (1) the patient cannot tolerate a higher level or (2) an abnormal or hazardous response occurs.

Blood gas and arterial saturation measures are obtained at rest and at peak exercise. Samples from single arterial punctures are as good as samples drawn from indwelling catheters. If the peak exercise puncture is unsuccessful, a sample drawn within 10 to 15 seconds of test termination usually suffices. Owing to inherent problems, pulse oximetry has a limited but nonetheless important role in exercise evaluation. The best use of pulse oximetry is as a monitor to warn clinicians of gross desaturation events during testing. In addition, the pulse oximeter can be used to assess the patient's response to supplemental O_2 during exercise.

Relative contraindications to exercise testing include the following:

- Inability or unwillingness of patient to perform the test
- Severe pulmonary hypertension or cor pulmonale
- Known electrolyte disturbances (hypokalemia, hypomagnesemia)
- Resting diastolic blood pressure greater than 110 mm Hg or resting systolic blood pressure greater than 200 mm Hg
- Neuromuscular, musculoskeletal, or rheumatoid disorders exacerbated by exercise
- Uncontrolled metabolic disease (e.g., diabetes)
- SaO_2 or SpO_2 less than 85% with the subject breathing room air
- Untreated or unstable asthma
- Angina with exercise

Exercise evaluation also can help differentiate among patients with primary respiratory or cardiac limitations to increased

Modified Borg Dyspnea Scale (With Dyspnea Descriptors)

10	Maximal (worst possible you can imagine)
9	Very, very severe
8	Very, very severe
7	Very severe
6	Very severe
5	Severe
4	Somewhat severe
3	Moderate
2	Slight
1	Very slight
0.5	Very, very slight (just noticeable)
0	None at all

Box 55-3 Common Physiologic Parameters Measured During Exercise Evaluation

- Blood pressure
- Heart rate
- ECG
- Respiratory rate
- Arterial blood gases/O_2 saturation
- Maximum ventilation ($\dot{V}E_{max}$)
- O_2 consumption (either absolute $\dot{V}O_2$ or METS)
- CO_2 production ($\dot{V}E/\dot{V}CO_2$)
- Respiratory quotient (RQ)
- O_2 pulse ($\dot{V}O_2$:heart rate)

METS, Metabolic equivalents of O_2 consumption.

55-1 Exercise Testing for Evaluation of Hypoxemia, Desaturation, or Both

AARC Clinical Practice Guidelines (Excerpts)*

INDICATIONS

- The need to assess and quantify arterial oxyhemoglobin (HbO_2) levels during exercise in patients with suspected desaturation
- The need to quantify the response to therapeutic intervention
- The need to titrate the optimum level of O_2 therapy during activity
- The need for preoperative assessment for lung resection or transplant
- The need to assess the degree of impairment for disability evaluation

CONTRAINDICATIONS

Absolute contraindications include the following:

- Acute ECG changes indicating myocardial ischemia or serious cardiac dysrhythmias
- Unstable angina
- Acute pericarditis
- Aneurysm of the heart or aorta
- Uncontrolled systemic hypertension
- Recent (within prior 4 weeks) myocardial infarction or myocarditis
- Second-degree or third-degree heart block
- Recent systemic or pulmonary embolus
- Acute thrombophlebitis or deep venous thrombosis

Relative contraindications to exercise testing include the following:

- Inability or unwillingness of patient to perform the test
- Severe pulmonary hypertension or cor pulmonale
- Known electrolyte disturbances (hypokalemia, hypomagnesemia)
- Resting diastolic blood pressure >110 mm Hg or resting systolic blood pressure >200 mm Hg
- Neuromuscular, musculoskeletal, or rheumatoid disorders exacerbated by exercise
- Uncontrolled metabolic disease (e.g., diabetes)
- SaO_2 or SpO_2 <85% with the subject breathing room air
- Untreated or unstable asthma

PRECAUTIONS AND POSSIBLE COMPLICATIONS

Indications for ending testing include the following:

- ECG abnormalities (e.g., dangerous dysrhythmias, ventricular tachycardia, ST-T wave changes)
- Severe desaturation (SaO_2 <80% or SpO_2 <83% or 10% fall from baseline values)
- Angina
- Hypotensive responses
- Decrease of >20 mm Hg in systolic pressure, occurring after the normal exercise increase
- Decrease in systolic blood pressure below preexercise level
- Lightheadedness
- Request from patient to terminate test

Abnormal responses that may require discontinuation of exercise include (1) increase in systolic blood pressure to >250 mm Hg or diastolic pressure to >120 mm Hg, (2) increase in systolic pressure of >20 mm Hg from resting level, (3) mental confusion or headache, (4) cyanosis, (5) nausea or vomiting, (6) muscle cramping.

ASSESSMENT OF NEED

Indications for exercise testing to evaluate hypoxemia or desaturation or both include the following:

- History and physical examination indicators suggesting hypoxemia or desaturation or both
- The presence of abnormal diagnostic test results (e.g., DLCO, FEV_1, arterial blood gases)
- The need to titrate or adjust a therapy

MONITORING

The following should be monitored during testing:

- Physical assessment (chest pain, leg cramps, color, perceived exertion, dyspnea)
- Respiratory rate
- SpO_2
- Cooperation and effort level
- Borg or Modified Borg Dyspnea Scale
- Blood gas sampling site and technique
- Heart rate, rhythm, and ST-T wave changes
- Blood pressure

**For the complete guidelines, see American Association for Respiratory Care: AARC clinical practice guideline: exercise testing for evaluation of hypoxemia and/or desaturation. Respir Care 46:514, 2001.*
Refer to the Modified Borg Dyspnea Scale (immediately following).

work capacity. Table 55-1 summarizes these key similarities and differences. Besides helping to differentiate between the underlying cause of exercise intolerance, test results can assist in placing patients in the appropriate type of rehabilitation program.

To minimize patient risk during exercise evaluation, certain safety measures are implemented. First, the patient should undergo a physical examination just before the test, including a resting ECG. Second, a qualified physician should be present throughout the entire test. Third, emergency resuscitation equipment (cardiac crash cart with monitor, defibrillator, O_2, cardiac drugs, suction equipment, and airway equipment) must be readily available. Fourth, staff conducting and assisting with the procedure should be certified in basic and advanced life-support techniques. Last, the test should be terminated promptly whenever indicated.

55-2 Pulmonary Rehabilitation

AARC Clinical Practice Guideline (Excerpts)*

SETTINGS

Pulmonary rehabilitation (PR) may take place in any of the following sites:

- Inpatient setting, including medical center, skilled nursing facility, or rehabilitation hospital
- Outpatient setting, including outpatient hospital-based clinic, CORF, physician's office, alternative or extended care facility, or patient's home

INDICATIONS

Indications for PR include any of the following:

- Dyspnea during rest or exertion
- Hypoxemia or hypercapnia
- Reduced exercise tolerance
- Unexpected deterioration or worsening of symptoms against a background of chronic dyspnea and reduced but stable exercise tolerance
- Need for surgical intervention
- Chronic respiratory failure
- Ventilator dependence
- Increasing need for acute care intervention (i.e., emergency department visits, hospitalizations, or unscheduled physician office visits)

CONTRAINDICATIONS

Contraindications for PR include any of the following:

- Ischemic cardiac disease
- Acute cor pulmonale
- Severe pulmonary hypertension
- Significant hepatic dysfunction
- Metastatic cancer
- Renal failure
- Severe cognitive deficit
- Psychiatric disease affecting memory and compliance
- Substance abuse without the desire to cease use of substance
- Physical limitations, such as poor eyesight, impaired hearing, speech impediment, or orthopedic impairment, that may require modification of the PR setting but should not interfere with participation in the program

HAZARDS AND COMPLICATIONS

Hazards and complications are primarily related to the exercise portion of the program. During exercise, the cardiovascular and ventilatory systems must be able to respond to increased demands. Also, exercise can lead to muscle or ligament injuries.

ASSESSMENT OF NEED

Patients should be under the care of a physician for the pulmonary condition requiring PR. Appropriate members of the PR team participate in patient assessment. The initial evaluation should include medical history; diagnostic tests; assessment of current symptoms; physical assessment; determination of psychological, social, and vocational needs; assessment of nutritional status; assessment of exercise tolerance; determination of educational needs; and assessment of the patient's ability to carry out activities of daily living.

MONITORING

Patients should be monitored at baseline and at appropriate intervals to ensure validity of results and appropriateness of intervention. Monitoring should include the following:

- Patient's response to progressive and general reconditioning exercises in conjunction with breathing techniques
- Patient's O_2 requirements at rest and with exercise
- Knowledge and skills acquisition
- Patient's subjective comments
- Progress in achieving goals
- Patient appearance
- Vital signs
- Cardiac telemetry (if needed)
- Perceived exertion and dyspnea (use of Borg or Modified Borg Dyspnea Scale)

**For the complete guidelines, see American Association for Respiratory Care: AARC clinical practice guideline: pulmonary rehabilitation. Respir Care 47:617, 2002.*

With regard to test preparation, patients should fast 8 hours before the procedure. If the purpose of the test is to formulate an exercise prescription, the patient can take his or her regular medications. The patient should wear comfortable, loose-fitting clothing and footwear with adequate traction for treadmill or ergometer activity. The mouthpiece or face mask used during the test should be sized properly and fit comfortably with no leaks. Test conditions should be as standardized as possible to allow for comparison of results before and after rehabilitation periodically from year to year as the patient is treated and followed.

Patient Selection

Patients most likely to benefit from participation in pulmonary rehabilitation are patients with persistent symptoms caused by COPD who have low maximum O_2 uptakes at baseline. Pulmonary rehabilitation should be a part of the discharge planning process when a patient is released from the hospital after an exacerbation of the existing chronic respiratory condition. The feasibility of rehabilitation should be reviewed with the patient, physician, and respiratory therapist (RT). Other indications for pulmonary rehabilitation are listed in Box 55-4. Regardless of underlying conditions, patients also should be ex-smokers. Any

Box 55-4 Indications and Contraindications for Pulmonary Rehabilitation

INDICATIONS

Symptomatic patients with COPD—usually GOLD stage III (severe) and stage IV (very severe), but stage II (moderate) may also be considered
Patients with bronchial asthma and associated bronchitis (asthmatic bronchitis)
Patients with combined obstructive and restrictive ventilatory defects
Patients with chronic mucociliary clearance problems
Patients with exercise limitations because of severe dyspnea

CONTRAINDICATIONS

Cardiovascular instability requiring cardiac monitoring (consider cardiac rehabilitation)
Malignant neoplasms involving the respiratory system
Severe arthritis or neuromuscular abnormalities (a relative contraindication—refer to physical therapy for case-by-case review)

patients who smoke should enroll in a smoking cessation program before starting pulmonary rehabilitation. Patients are excluded from pulmonary rehabilitation activities if (1) concurrent problems limit or preclude participation in exercise or (2) their condition is complicated by malignant neoplasms, such as lung cancer (see Box 55-4).

Objectively, candidates considered for inclusion in a pulmonary rehabilitation program generally fall into one of the following groups[20]:

- Patients in whom there is a respiratory limitation to exercise resulting in termination at a level less than 75% of the predicted maximum O_2 consumption ($\dot{V}O_{2max}$)
- Patients in whom there is significant irreversible airway obstruction with a forced expiratory volume in 1 second (FEV_1) of less than 2 L or an $FEV_{1\%}$ (ratio of FEV_1 to forced vital capacity [FVC]) of less than 60% (refer to the Global Initiative on Obstructive Lung Disease [GOLD] standards for COPD severity)
- Patients in whom there is significant restrictive lung disease with a total lung capacity (TLC) of less than 80% of predicted and single breath carbon monoxide diffusing capacity (DL_{CO}) of less than 80% of predicted
- Patients with pulmonary vascular disease in whom single breath DL_{CO} is less than 80% of predicted or in whom exercise is limited to less than 75% of maximum predicted O_2 consumption (predicted $\dot{V}O_{2max}$)

Groups or classes for pulmonary rehabilitation should be kept homogeneous. Placing individuals in a program who are at different stages of cardiopulmonary disability can be very defeating. Individuals with mild to moderate impairment may become discouraged on how severe lung disease can become, and individuals with severe impairment may feel they cannot keep up with or maintain the level of activity exhibited by others with less severe impairment.

Program Design

A good design helps achieve specific programming objectives with the selected group of participating patients. Key design considerations involve both format and content, with emphasis on patient reconditioning and education.

Format

Programs can use either an open-ended or a closed design, with or without planned follow-up sessions. With an open-ended format, patients enter the program and progress through it until they achieve certain predetermined objectives. There is no set time frame. Depending on his or her condition, needs, motivation, and performance, an individual patient can complete an open-ended program over weeks or months. This format is good for self-directed patients or patients with scheduling difficulties. It also may be the best format for patients requiring individual attention. The major drawback of the open-ended format is the lack of group support and involvement. In addition, insurance reimbursement may be a factor when the program is open-ended.

The more traditional closed design uses a set time period to cover program content. These programs usually run 6 to 16 weeks, with classes meeting one to three times a week. However, insurance coverage may dictate how many sessions make up the program. Medicare covers 36 initial sessions with possible coverage of another 36 sessions if the patient qualifies and would benefit from the additional rehabilitation sessions. Class sessions usually last up to 2 hours. Presentations are more formal and group support involvement is encouraged. A major drawback to this format is that the schedule determines program completion, rather than the objectives. However, most programs allow patients to reenroll if the anticipated improvements are not achieved.

Regardless of the format used, long-term improvements cannot be expected without planned follow-up.[21] Follow-up must be ongoing and available to all patients who complete the

TABLE 55-2

Sample Pulmonary Rehabilitation Session

Component	Focus	Time Frame
Educational	Welcome (group interaction)	5 min
	Review of program diaries (activities of past week)	20 min
	Presentation of educational topic	20 min
	Questions, answers, and group discussion	15 min
Physical reconditioning	Physical activity and reconditioning	45 min
	Individual goal setting and session summary	15 min
Total session		120 min (2 hr)

program. Frequently, this essential element of the process is difficult, especially when it is not covered by most insurance plans, but program coordinators must ensure that it is routinely scheduled. Follow-up or reinforcement could be open-ended (available during regular rehabilitation sessions and offering open attendance) or could be scheduled weekly, monthly, bimonthly, or quarterly. The important thing is to have some type of follow-up available.[22,23]

Content

The content of the rehabilitation program usually combines physical reconditioning with education activities. Table 55-2 outlines a sample session incorporating these two complementary components. Programs providing reconditioning or education alone are unlikely to be effective.

As shown in Table 55-2, the ideal rehabilitation session should last about 2 hours. Group size, available equipment, and group interaction dictate session length. Patients should arrive 10 to 15 minutes before a scheduled session to allow for informal group interaction and support. Classes should begin on time and conclude promptly as scheduled. Educational presentations should be brief and to the point. The use of audiovisuals or demonstrations should enhance understanding. To facilitate patient comprehension, the language should be simple and unnecessary technical terms or concepts should be avoided. Handouts that enhance certain points made during a presentation are both useful and desirable. A folder or notebook in which program activities may be recorded and handout materials kept should be maintained by each patient.

Physical Reconditioning

The physical reconditioning component of the pulmonary rehabilitation program consists primarily of an exercise prescription with target heart rate based on the results of the patient's initial exercise evaluation. For most patients, an initial target heart rate is set using **Karvonen's formula**, or estimated as 20 beats/min greater than resting rate. Because of the severity of ventilatory impairment, some patients begin exercise reconditioning without a prescribed target heart rate.

MINI CLINI

Patient Selection for Pulmonary Rehabilitation

PROBLEM: A patient is being evaluated for possible inclusion in a pulmonary rehabilitation program. The patient undergoes a complete history and physical examination and pulmonary function testing, arterial blood gas analysis, and exercise evaluation. During the exercise test, the patient develops severe hypertension and premature ventricular contractions. The physician recommends that the patient be admitted to pulmonary rehabilitation and prescribes a modified exercise routine. The RT performing the test disagrees. How should the RT proceed?

Solution: The RT should contact the department medical director for intervention. Although this patient could possibly be admitted to pulmonary rehabilitation, there is a high risk that some type of adverse response might occur during the exercise component of the program. The best direction would be to treat the cardiac manifestations first. After identifying the causes of the exercise-induced hypertension and arrhythmia, these problems can be properly treated. When the patient's cardiac manifestations are under control, the patient may be admitted to pulmonary rehabilitation and safely participate in and complete the program. Any underlying condition should be treated and managed first before pulmonary rehabilitation begins.

RULE OF THUMB

To set a target heart rate for patient exercise, use Karvonen's formula:

$$\text{Target heart rate} = [(\text{MHR} - \text{RHR}) \times (50\% - 70\%)] + \text{RHR}$$

where MHR is maximum heart rate at limit of exercise tolerance and RHR is resting heart rate.

A good target exercise heart rate for a patient with COPD with MHR of 150 beats/min and RHR of 90 beats/min would be [(150 – 90) × 0.60] + 90 = 126 beats/min.

Typically, the exercise prescription includes the following four related components:[24,25]

1. Lower extremity (leg) aerobic exercises
2. Timed walking (**6- or 12-minute walk**)
3. Upper extremity (arm) aerobic exercises
4. Ventilatory muscle training

To ensure success with physical reconditioning, patients must actively participate both at the rehabilitation facility and at home. While exercising at the facility, patients should be monitored by pulse oximetry. Blood pressure measurements may also be made, but these are usually done at the start and end of each session unless a patient's condition dictates otherwise. In addition, exercise sessions should be upbeat. Lively

music helps to maintain a positive atmosphere. Clinicians must remember that these patients are ill and require a nurturing attitude from team members, family, and the group itself.

To ensure compliance with the program, a daily log or diary sheet is completed. Figure 55-5 depicts a sample log sheet that makes up a section of the patient manual. These log or diary forms are reviewed each time the patient attends a session. Based on this information, further individualized reconditioning goals are set.

Lower extremity exercises may include either walking or bicycling. Patients can walk on a stationary treadmill (with set goals for distance or time and grade) or on a flat, smooth surface. Patients can bicycle on an exercise cycle. With the treadmill or stationary bicycle, patients are required to cover a certain distance or duration every day that they are in the program. Commonly, the duration is set to 30 minutes daily, with patients encouraged to increase both their distance and equipment tension or resistance as tolerated. Patients with significant orthopedic disabilities can participate in aerobic aquatic exercises.

Walking also improves overall conditioning; this usually takes the form of a 6- or 12-minute walk performed once a day, depending on the patient's condition and tolerance. These walk exercises are a convenient way for patients to carry out a well-defined amount of activity with increasing vigor and results over a number of weeks. During the 6 or 12 minutes, patients should walk on flat ground for as far as possible. If dyspnea occurs, they should stop and rest, with the rest time included as part of the time interval. After resting briefly, they should try to continue walking at a comfortable pace. The objective is to walk as far as possible during the allotted time. Landmarks such as telephone poles, city blocks, or actual distance measures can be used to quantify progress. Under adverse weather conditions, walking can be done indoors in shopping malls, stores, or long hallways. Patients should record their progress in their manuals or diaries.

Aerobic upper extremity exercises improve rehabilitation outcomes for patients whose regular activities involve lifting or raising the arms.[24,26] Arm ergometers or rowing machines are available for this purpose; however, simple calisthenics using either a broomstick or free weights (by prescription and with training) are a satisfactory alternative. Upper body endurance generally is more limited, with many patients capable of only 2 to 3 minutes of daily activity to start. This limitation usually is related to the fact that patients may revert to using accessory muscles for breathing while doing the upper body exercise. Patients need to breathe diaphragmatically and perform the exercises at the same time. Arm exercises should get progressively longer, up to 20 minutes if possible. Upper body conditioning helps patients perform numerous useful activities at home and can increase overall physical endurance. As with other activity, patients should record daily results in their logs or manuals.

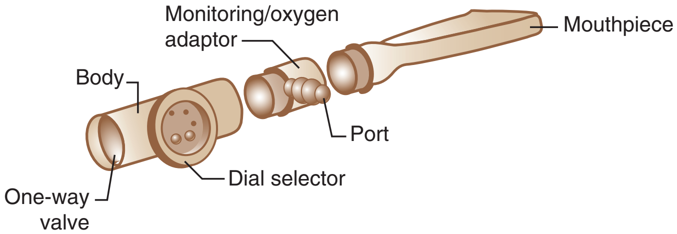

FIGURE 55-6 Flow-resistive breathing device.

Although controversy exists, ventilatory muscle training probably can enhance the benefits of these more traditional exercises.[27] Ventilatory muscle training is based on the concept of **progressive resistance**. By imposing progressively greater loads on the inspiratory muscles (mainly the diaphragm) over time, the patient's strength and endurance should increase. These improvements should increase the patient's exercise tolerance.

Figure 55-6 shows a typical inspiratory resistance breathing device. The device is an adjustable flow resistor with a one-way breathing valve. The inspiratory load is created by forcing the patient to inhale through a restricted orifice. Varying the size of this orifice varies the inspiratory load, as do changes in the

Typical Educational Topic Schedule for a 12-Week Pulmonary Rehabilitation Program

Session (Week)	Topic(s)	Recommended Facilitator(s)
1	Introduction and welcome; program orientation	Program administrator or rehabilitation team
2	Respiratory structure, function, and pathology	Physician or RT
3	Breathing control methods	PT or RT
4	Relaxation and stress management	Clinical psychologist
5	Proper exercise techniques and personal routines	PT or RT
6	Methods to aid secretion clearance (bronchial hygiene)	PT or RT
7	Home oxygen and aerosol therapy	RT
8	Medications—their use and abuse	Pharmacist, physician, or nurse practitioner
9	Medications—use of MDIs and spacers	RT
10	Dietary guidelines and good nutrition	Dietitian or nutritionist
11	Recreation and vocational counseling Activities of daily living	Occupational therapist
12	Follow-up planning and program evaluation Graduation	Rehabilitation team

MDIs, Metered dose inhalers; *PT*, physical therapist; *RT*, respiratory therapist.

patient's inspiratory flow. During expiration, gas flows unimpeded out the one-way exhalation valve. Other types of devices are also available. One model replaces the variable size orifice with an adjustable spring-loaded valve. This valve ensures a constant load regardless of how quickly or slowly the patient breathes.

Because variations in breathing strategy during ventilatory muscle training can affect outcomes, proper patient evaluation, training and follow-up are required. The RT initially measures the patient's maximum inspiratory pressure (PI_{max}) using a calibrated pressure manometer. The RT next compares the patient's maximum with established norms as noted in Table 55-3. This preliminary measure of inspiratory pressure helps to establish initial loads and provides the basis for the subsequent monitoring of patient progress.

Before beginning ventilatory muscle training, the patient should assume a position that relaxes the abdominal muscles, such as the position used for cough training. If using a flow resistive device, the RT begins at the maximum orifice setting, while measuring the inspiratory pressure generated through monitoring using the O_2 adapter (a second adapter may be needed if the patient is receiving supplemental O_2). The RT encourages the patient to breathe slowly through the device, at a rate no greater than 10 to 12 breaths/min. If the patient's inspiratory pressure is less than 30% of the measured PI_{max}, the next smaller orifice is selected, with this procedure repeated until the 30% effort is consistently achieved.

At this point, the RT instructs the patient to exercise with the device in one or two regular daily sessions lasting 10 to 15 minutes. As the level of resistance becomes more tolerable over time, the patient should progressively increase session duration up to 30 minutes. A self-maintained log of treatment times can help motivate the patient and assist the RT in subsequent progress monitoring.

Educational Component

The educational portion of the program covers topics that are both useful and necessary to the patient. Table 55-4 lists examples of topics covered during a 12-week rehabilitation program. Recommendations regarding the best facilitators for each session are included. Naturally, other topics can be included depending on the program schedule, but in terms of relative importance, the ones listed in Table 55-4 generally have the highest priority.

These topics should be presented in an orderly, coherent fashion using supplementary audiovisual tools and demonstrations, where appropriate. Team members should allocate sufficient time both for the class sessions themselves and for setup and breakdown of equipment.

The program facilitator or leader must ensure that sessions begin on time and encourage maximum participation by each patient. If available, health care professionals such as dietitians, occupational therapists, physical therapists, and psychologists should be invited to present their respective topics and discuss the subject matter with the group. However, this may add to the overall operating costs of the pulmonary rehabilitation program. In addition to technical knowledge, session leaders must possess group facilitation skills and be able to motivate patients to participate both in class and at home and to adhere to program guidelines. This task is not an easy one, but it can be accomplished with patience and persistence. The desired end result is to help patients lead more productive lives with decreased hospitalizations.

Respiratory Structure, Function, and Pathology, Including a Discussion of Dyspnea. This presentation lays the groundwork for the program and gives each patient some basic

information about the cardiorespiratory system and related disorders. The causes of shortness of breath are presented.

Breathing Control Methods. This presentation serves as the cornerstone for the physical reconditioning effort. Patients must learn how to control their breathing efforts to ensure maximum result (ventilation) at a minimum of effort (energy expenditure). Diaphragmatic breathing with pursed lips helps to accomplish this, but this technique requires daily practice on the part of the patient and continued reinforcement throughout the entire program by the group facilitator.

Methods of Relaxation and Stress Management. Patients must learn to avoid aggravation and upsetting circumstances and to adopt a more relaxed attitude about their particular life circumstances. This attitude can help to reduce unnecessary O_2 use, conserve energy, and avoid undesirable cardiovascular and nervous responses to stress.

Exercise Techniques and Personal Routines. The rationale for and value of exercise should be discussed with suggestions for the adoption of personal exercise routines after the rehabilitation program is over.

Secretion Clearance and Bronchial Hygiene Techniques. This topic is especially helpful to patients who have secretion clearance problems associated with chronic bronchitis and bronchiectasis. Family members and friends may be invited to attend this session to acquire basic skills with these procedures.

Home Oxygen and Aerosol Therapy. An RT with home care experience should provide this session. The focus should be on the care and use of home care equipment and self-administration of therapy. Patients who have not yet been prescribed this type of therapeutic regimen may have questions or fears and be unreceptive to the concept. Presenting the modalities available and having patients discuss their positive experiences with respiratory home care personnel can help alleviate the fears and anxieties of others.

Medications. This is another topic about which patients have numerous questions and concerns. Content should emphasize proper use of medications, along with possible abuses and adverse effects. Participants' current prescriptions should dictate which specific drugs to cover. Common categories include beta-adrenergic agents, anticholinergic agents, steroids, diuretics, and methylxanthines. The session leader should demonstrate proper use of metered dose inhalers including spacers or holding chambers, dry powder inhalers and hand-held nebulizers. Sufficient time should be provided for questions and answers. Two sessions should be allotted for this topic.

Dietary Guidelines. This subject focuses on weight management and good nutrition as it relates to cardiopulmonary health. Emphasis should be on the importance of a sound high-protein, low-carbohydrate diet. The facilitator also should cover proper eating habits, methods of gaining and losing weight, foods to avoid, ways to increase appetite, adequate hydration, and daily menu planning. This session can stimulate patients to eat better and supply their bodies with the necessary fuel for increased energy production.

Recreational and Vocational Counseling. This session should motivate participants to participate in recreational activities and, according to ability, return to work. This topic is often presented at the end of the program when patients have increased their physical endurance and are preparing for a more active and productive lifestyle. The class may brainstorm ideas for recreational or physical activities, from which members can generate action plans.

Psychosocial and Behavioral Components

Psychological and emotional stress is a common problem for patients with moderate to severe chronic lung disease. Pulmonary rehabilitation programs can bring in experts to implement psychosocial and behavioral therapies that provide patients with the opportunity to learn coping strategies. This component is most useful for patients with anxiety or depression or both.

Program Implementation

In 1987, the AARC and the AACVPR jointly conducted the first national survey of pulmonary rehabilitation programs. This National Pulmonary Rehabilitation Survey was published in 1988 and showed the variation existing in rehabilitation program structure, content, staffing, and cost throughout the United States.[28] In 2006, the ACCP, in conjunction with the AACVPR, released new evidence-based guidelines pertaining to the design and implementation of pulmonary rehabilitation programs.[13]

Staffing

Pulmonary rehabilitation is a multidisciplinary endeavor. Team care is enhanced by involving various health care professionals in the planning, implementation, and evaluation components of the program as illustrated in Figure 55-7. It is recommended that any staff conducting pulmonary rehabilitation program sessions be certified in basic life support or advanced cardiac life support through the American Heart Association. In addition to professional involvement, family members are needed to provide feedback and ensure that instructions and the exercise prescription are carried out at home.

Facilities

Location and quality of facilities can directly affect patient attendance. Patients are less likely to attend programs that are inaccessible to public transportation, have poor parking arrangements, or are physically difficult to reach. The facility must be wheelchair accessible. For elderly patients who do not drive, arrangements can be made with community organizations to provide transportation to and from the program. Ideally, the facility should provide two separate rooms for the program—one room for educational activities and one room for physical reconditioning. Rooms should be spacious and comfortable with adequate lighting, ventilation, and temperature control. Chairs should be comfortable with good back support. Restroom facilities need to be readily accessible. A room for individual counseling is helpful, but any private office would suffice. It is also preferable to have pulmonary function testing and blood gas analysis capabilities on site. If this space

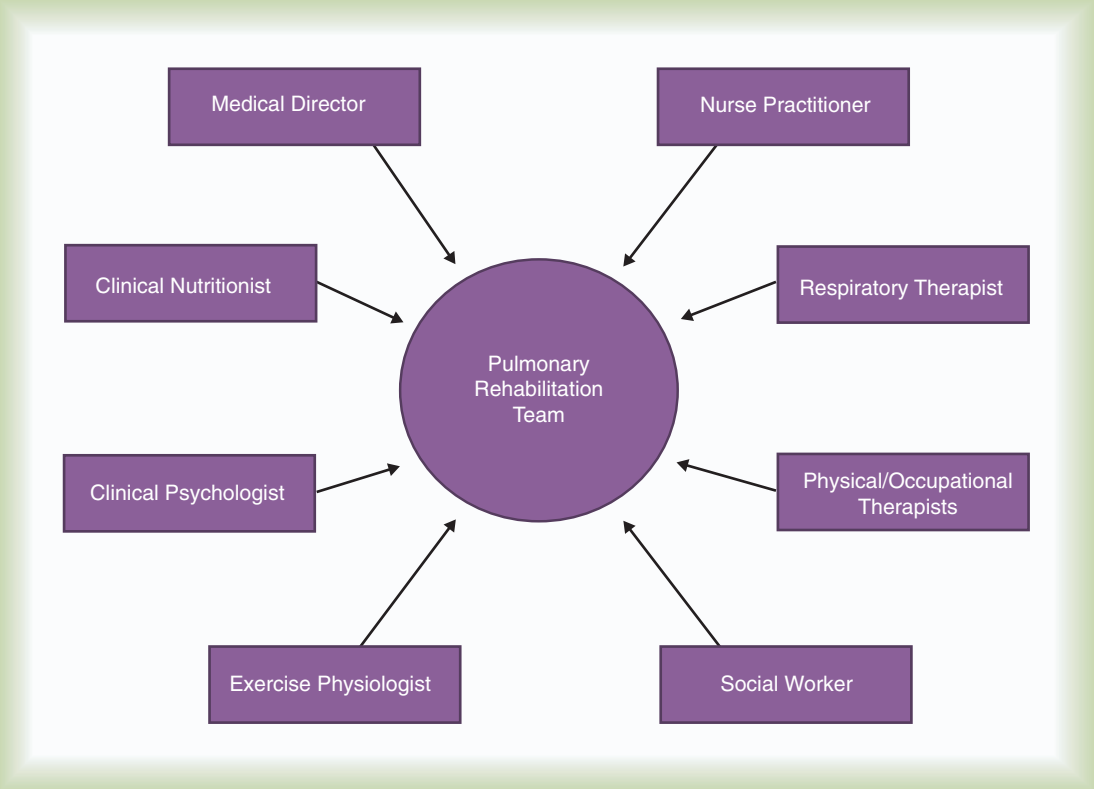

FIGURE 55-7 Multidisciplinary nature of pulmonary rehabilitation.

is used by other departments for other functions, proper scheduling of rehabilitation sessions needs to be considered.

Scheduling

Another aspect of program implementation involves timely scheduling of the rehabilitation sessions. Most sessions are scheduled one to three times per week for 1 to 2 hours, with programs running 8 to 16 weeks. The length of the program often depends on insurance coverage and expected reimbursement for sessions attended. Class times need to be scheduled when the largest number of patients can attend. Traffic patterns, bus schedules, and availability of rides are concerns that need to be addressed. Sessions can be conducted in the morning, afternoon, or evening and on weekends if necessary. Proper scheduling helps to encourage participation and removes potential stumbling blocks, which could undermine the rehabilitation process.

Class Size

Class size is another issue that must be addressed. Theoretically, class size for a rehabilitation program could range from 1 to 15 participants, depending on available space, equipment, staff, and patient condition/needs. However, to foster group identity, interaction, and support, small group discussions are encouraged. The ideal class size should range from 3 to 10 participants. Keeping the class size manageable facilitates vital group interaction processes and allows for more individualized attention. These factors help sustain motivation, reducing the likelihood of participant attrition.

Naturally, economic concerns surface when class size is considered. Although program quality must be the first priority, program viability realistically depends on the number of participants. Programs generally should be conducted with a class size that is comfortable with regard to space and staffing and that is economically feasible. Such an approach helps ensure that programs produce meaningful patient outcomes.

Equipment

Both the instruction and the reconditioning component of the program require equipment. To meet the educational needs of the program, a whiteboard or flipchart, computer with a PowerPoint projector screen, overhead projector, and/or CD player are needed. A DVD player with monitor may also be helpful, especially if individualized instruction or commercially available programs are used. Also, videos and formal learning packages dealing with the educational topics covered during the rehabilitation program should be available for group and individualized presentation. These can be purchased from outside sources or designed and developed in-house.

For physical reconditioning, stationary bicycles, treadmills, rowing machines, upper extremity ergometers, weights, pulse oximeters, and inspiratory resistance breathing devices constitute the minimum equipment requirements. The quantity of equipment needed depends on class size, scheduling, and

MINI CLINI

Facilities Planning for Pulmonary Rehabilitation

PROBLEM: The RT has been asked to assist in the planning process for starting a pulmonary rehabilitation program to support a 350-bed, full-service hospital. According to the strategic plan, the physical location of the rehabilitation center is about 3 blocks away from the hospital. The RT has not seen the proposed site but was asked to approve a recommendation that the facility be used. What factors should the RT take into account before making a decision on site selection?

Solution: Because the hospital is currently in the planning process for starting a pulmonary rehabilitation program and has not made a final facility selection, the RT is in a key position to assess, among other areas, issues related to the proposed site. Patient attendance and participation would be adversely affected if the facility is unreachable, such as at the top of a hill. If the location is in a high crime or unsafe area with little or no security, this too would discourage patients from attending. As is true with any program, public transportation that does not permit accessibility to the proposed facility would be a limiting factor, as would little or no available parking. Numerous other facility considerations outside the actual physical location of the rehabilitation center would also need to be addressed. The current square footage of available space and room for future expansion would need to be evaluated relative to anticipated needs, as would whether the facility itself is wheelchair accessible with no barriers present.

available space. Sufficient equipment should be on hand to keep all patients exercising and to monitor their activity. Emergency O_2 and bronchodilator medications should also be maintained in the rehabilitation area. Equipment guidelines for a class of 6 to 10 participants include the following: five stationary bicycles, two treadmills, two rowing machines, two upper extremity ergometers, five pulse oximeters for monitoring heart rate and O_2 saturation, one emergency O_2 cylinder (E), and bronchodilator medications. In addition, each patient should be supplied with an inspiratory resistance breathing device.

Because equipment can be expensive, care must be taken in its selection and purchase. Devices and appliances should be durable, easy and safe to use, simple to maintain, and not overly expensive. Initially, basic items are purchased. As a program develops and expands, equipment resources can be enhanced. Other program needs include the following:

- Maintaining individual patient manuals, including daily log forms or activity diaries
- Providing light refreshments for program participants
- Developing a communication network to announce schedule changes because of emergencies or cancellation of class sessions because of illness or weather
- Identifying available durable medical equipment providers for participants in need of specialized home care equipment

Box 55-5 Factors Affecting Pulmonary Rehabilitation Program Costs

- Marketing and program promotion
- Number of personnel involved in program facilitation and administration
- Space and utility expenses
- Audiovisual, exercise, and monitoring equipment (purchase and maintenance)
- Production and duplication of course materials
- Patient supplies
- Office supplies
- Refreshments
- Miscellaneous expenses

- Developing a system of charges and mechanism for patient payment

By considering all of the factors needed for effective implementation of pulmonary rehabilitation, programs have lower patient attrition and a greater chance for overall success. As programs are conducted, regular evaluations must be made by both patients and staff. Needed changes should be implemented on an ongoing basis. Only in this manner can one expect continued refinement of the process and improvement in patient outcomes.

Cost, Fees, and Reimbursement

Rehabilitation programs usually project their fees based on the average cost per participant. According to regional labor and material prices, costs vary throughout the United States. Several factors must be considered when projecting program costs as noted in Box 55-5. The larger the class size and the more participants involved in the overall program, the lower the cost would be per patient. The aim should be to offer and conduct the highest quality program possible at a reasonable cost that meets any existing budgetary constraints.

When determining patient charges, consideration must also be given to the type and amount of funding that has been received to offset program expenses and available insurance reimbursement. Preprogram and postprogram testing and evaluations naturally generate revenues but should not be included in the formulation of program charges. However, payments for pulmonary function testing, exercise testing, arterial blood gas analysis, and other evaluations may help to keep a pulmonary rehabilitation program financially viable.

Charges for an entire program or for each session must be structured in a way that does not deter patient attendance. Many patients with a chronic pulmonary disease are on a fixed income and have other living and medical expenses. A happy medium between a patient's ability to pay and program expenses must be identified. Funding from local charitable organizations, foundations, or agencies such as the American Lung Association and the COPD Foundation can help ease the financial burden. The most comprehensive and effective program available can have no impact if patients are unwilling or unable to attend and participate because of financial limitations.

Along with health care costs in general, the cost of providing pulmonary rehabilitation has increased over the years. Nationwide charges for pulmonary rehabilitation vary, depending on program length and, most importantly, insurance coverage. With most insurance plans reimbursing programs at 80% after a deductible, each patient would be responsible for the remaining 20% or copayment. Additional or supplemental medical coverage may cover this balance.

Charges for participation in these programs and inpatient rehabilitation reimbursement policies vary throughout the United States. In 1982, the Centers for Medicare and Medicaid Services (CMS), formerly the Health Care Financing Administration or HCFA, published the final rules for Medicare reimbursement guidelines for **comprehensive outpatient rehabilitative facilities (CORFs)**. Under Part B of Medicare, the scope of services of a CORF includes reimbursement for outpatient activities and one home visit. Reimbursement requires that the CORF meet the conditions of participation established in section 933 of Public Law 96-499; this also includes provisions for certification of the program. To establish reimbursement mechanisms, each CORF must present its program description and anticipated results to local third-party payers.[29] The AACVPR has also developed guidelines for program design, implementation, and recognition.

By following recognized guidelines, Medicare has established an allowable charge for pulmonary rehabilitation and reimburses 80% of this rate after the patient meets the annual prescribed deductible. In the past, inpatient and outpatient pulmonary rehabilitation programs obtained reimbursement from third-party payers by charging for rehabilitation sessions as physical therapy exercises for COPD, reconditioning exercise sessions, office visits with therapeutic exercises, serial pulse oximetry determinations, or physician office visits. The goal was to obtain as much insurance reimbursement as possible, decreasing the financial burden on the patient. Box 55-6 lists all possible sources of reimbursement.[30,31]

Box 55-6 Sources of Reimbursement for Pulmonary Rehabilitation Programs

- Nongovernment health insurance programs—private, single, or group health insurance plans
  - Health maintenance organizations (HMOs)
  - Preferred provider organizations (PPOs)
  - Medicare supplement
- Federal and state health insurance programs
  - Medicare
  - Medicaid
  - Uncompensated services (Hill-Burton)
  - CORF
  - Veterans Administration benefits
  - Civilian Health and Medical Programs of the Uniformed Services (CHAMPUS)
  - Federal workers insurance
- Ancillary liability and casualty insurance programs
  - Automobile insurance—related to automobile accidents
  - Workers' compensation—related to accidents on the job
  - Business insurance coverage—related to injuries sustained on business premises
  - Homeowner's insurance—related to injuries sustained on the owner's premises
  - Malpractice insurance on providers of health care
  - Product and service liability insurance—related to injuries caused by a product or service
- Other options of reimbursement
  - Senior care
  - Rehabilitation hospitals
  - Grants

RULE OF THUMB

To help ensure adequate reimbursement for pulmonary rehabilitation, identify patient goals and objectives; formulate and implement an effective exercise prescription for each patient; use diagnostic codes from the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM); use current and proper CPT (Current Procedural Terminology) coding; and document, document, document. Please note that ICD-9-CM will be replaced by ICD-10-CM beginning with FY 2015, which changes disease-related coding.

There is now a national coverage policy for pulmonary rehabilitation under Medicare, which took effect on January 1, 2010, as a result of the passage of HR 6331. Programs have to obtain reimbursement from their Medicare beneficiaries following accepted protocol, policies, and provisions specified by Medicare. Coverage is for patients with stage II, III, and IV COPD (moderate to very severe according to the GOLD standards). Pulmonary rehabilitation programs must include five components which must be documented in the patient's medical record. The five components include the following:

1. Physician-prescribed exercise, including aerobic exercise performed during each session
2. Education and training that relate to an individual patient's needs
3. Psychosocial assessment
4. Outcomes assessment
5. Treatment plan that details how these components are used for each individual patient[31]

According to CMS, claims for Medicare patients should be submitted to Medicare Part A for any component of pulmonary rehabilitation performed during a hospital stay and claims for rehabilitation components provided on an outpatient basis must be submitted to Medicare Part B. As with other forms of therapy covered by CMS, other insurance providers have already or will follow Medicare policy for reimbursement of pulmonary rehabilitation. This payment mechanism has already undergone changes and it is anticipated that Medicare will continue to change its reimbursement policy for pulmonary rehabilitation in the future. It is incumbent on clinicians who provide pulmonary rehabilitation to stay abreast of any changes

in reimbursement policy and procedure and to make necessary adjustments to receive payment.

At the present time, there is provision to reimburse pulmonary rehabilitation programs for two 1-hour rehabilitation sessions per patient per day up to 36 sessions. An additional 36 sessions over an extended period can be approved by the individual Medicare contractor based on patient need for continued rehabilitation and physician referral. Documentation of programs is essential for payment of services rendered. Current coding for pulmonary rehabilitation under Medicare Part B uses the HCPCS G0424 code. Provision has been made for face-to-face patient sessions and for group (two or more patients) sessions. Individual sessions must be at least 31 minutes in length. If two sessions are performed on the same day, services may be reported only if the duration of the combined treatments is at least 91 minutes. It is essential that the practitioner who conducts pulmonary rehabilitation is familiar with all current practices so that therapy provided and billed for complies with current Medicare policy, is properly documented for each patient, and is submitted in a timely manner.[31-33]

MINI CLINI

Obtaining Insurance Payment for Pulmonary Rehabilitation

PROBLEM: The RT is asked to design and implement a pulmonary rehabilitation program on an outpatient basis at her hospital. After completing the first class that ran for 12 weeks, the hospital scheduled another one. However, although the institution had been submitting bills on a timely basis to numerous insurance providers, including Medicare, no payment has been received. What is the problem and how can it be corrected?

Solution: The insurance companies apparently either have denied claims or have not responded to the claims being submitted. This problem is often associated with improper or inaccurate claim filing. The RT should work closely with the billing department at the hospital to ensure that all information is complete for each patient (i.e., correct patient identification numbers), that the hospital has the correct addresses to submit claims, and that diagnoses and procedures have been properly coded. Some insurance companies have their own coding schemes and these must be followed accordingly. Managed care companies also require preauthorization, which must be obtained before entering any patient with a managed care plan into pulmonary rehabilitation. Finally, follow-up telephone calls are always helpful and should be conducted if payment is not received in a timely fashion.

Program Results

Patient and program outcomes must be evaluated at the conclusion of the program and periodically thereafter as described in Box 55-7. This evaluation must compare patient status before the program with current patient status and may include physiologic, psychological, and sociologic data. Common outcome measures include exercise tolerance, levels of dyspnea at rest and with exertion, and quality-of-life surveys.

Box 55-7 Evaluation of Rehabilitation Program Outcomes

- Changes in exercise tolerance
- Before and after 6- or 12-minute walking distance
- Before and after pulmonary exercise stress test
- Review of patient home exercise logs
- Strength measurement
- Flexibility and posture
- Performance on specific exercises (e.g., ventilatory muscle, upper extremity)
- Changes in symptoms
- Dyspnea measurement comparison
- Frequency of cough, sputum production, or wheezing
- Weight loss or gain
- Psychological test instruments
- Other changes
- Activities of daily living changes
- Postprogram follow-up questionnaires
- Preprogram and postprogram knowledge tests
- Compliance improvement with pulmonary rehabilitation medical regimen
- Frequency and duration of respiratory exacerbations
- Frequency and duration of hospitalizations
- Frequency of emergency department visits
- Return to productive employment

Results of pulmonary rehabilitation must be communicated to the patient, family, referring physician, and home care company, if appropriate. Further goals and objectives for continued improvement may be established to provide the basis for follow-up and reinforcement activities. Quality of life for patients with chronic lung diseases is an outcome measure that many pulmonary rehabilitation programs are documenting.[34] A major predictor for improvement in health-related quality of life of a patient with COPD is frequent attendance in a maintenance program.[3,35]

If no improvements in physical or psychosocial measures occur within a class or group, program deficiencies are the most likely cause. Specifically, insufficient professional training in rehabilitation methods, a lack of uniformity in approach, inadequate program length, and lack of follow-up are the major reasons for unsatisfactory outcomes.

Finally, pulmonary rehabilitation has become recognized as a prerequisite for certain patients with emphysema who are able to undergo lung volume reduction (LVR) surgery. Physical reconditioning and patient education before the procedure help to increase the chances for a successful outcome. Pulmonary rehabilitation appears to have favorable results with this specific patient population because of added patient and practitioner commitment and focus. Patients who do not complete the presurgical rehabilitation protocol are at higher risk for postsurgical complications.[36-39]

Potential Hazards

Although most patients with COPD can expect to realize benefits through physical reconditioning and pulmonary rehabilitation, certain potential hazards do exist, as follows:

I. Cardiovascular abnormalities
   A. Cardiac arrhythmias (can be reduced with supplemental O_2 during exercise)
   B. Systemic hypotension and hypertension
II. Blood gas abnormalities
   A. Arterial desaturation
   B. Hypercapnia
   C. Acidosis
III. Muscular abnormalities
   A. Functional or structural injuries
   B. Diaphragmatic fatigue and failure
   C. Exercise-induced muscle contracture
IV. Miscellaneous
   A. Exercise-induced asthma (more common in young patients with asthma than in patients with COPD)
   B. Hypoglycemia
   C. Dehydration

Proper patient selection, education, supervision, and monitoring are key factors in reducing possible hazards.

MINI CLINI

What to Expect from Pulmonary Rehabilitation

PROBLEM: The RT is asked to consult on a 63-year-old man hospitalized with severe COPD for possible participation in an outpatient pulmonary rehabilitation program. During the patient interview, the patient tells the RT that if the program will not cure him, he sees no reason to participate. How should the RT respond to the patient, keeping in mind his expectations of what pulmonary rehabilitation should accomplish?

Solution: It is crucial for all RTs and other caregivers involved in pulmonary rehabilitation to recognize that the focus of any program should attempt to treat the patient as a whole and not solely the underlying disease. A well-constructed pulmonary rehabilitation program should be able both to quantify the extent of physiologic impairment and to assist in establishing outcome expectations for physical reconditioning. Regardless of setting or design, such programs must address the psychological, social, and vocational impact of the disability on the patient and family and seek ways to improve the patient's quality of life. In this case, the RT should describe the benefits of pulmonary rehabilitation outside the traditional measures of pulmonary function. Although pulmonary rehabilitation cannot affect the progressive deterioration in lung function that occurs with COPD, both education and exercise may improve the patient's ability to perform activities of daily living and exercise tolerance. In addition, effective breathing techniques may lessen the frequency and severity of "panic breathing" episodes.

CARDIAC REHABILITATION

Patients with primary cardiac disease are often referred to cardiac rehabilitation programs where the focus is on improving cardiovascular fitness. Cardiac rehabilitation is defined as a comprehensive exercise and educational program designed for patients with cardiovascular diseases. Similar to pulmonary rehabilitation, good cardiac rehabilitation programs are multidisciplinary in approach and focus. Goals include patient education promoting heart-healthy living, physical reconditioning to improve work capacity, weight loss, and a return to work.

Enrollment in a cardiac rehabilitation program is based on a thorough cardiovascular evaluation and related parameters. The goal of a structured cardiac rehabilitation program is to assist patients in developing a regular pattern of safe exercise to achieve greater cardiovascular performance during activity. Most cardiac rehabilitation programs are conducted within a hospital facility. Programs are generally divided into monitored and maintenance segments, with home options available. Exercise prescriptions are individualized for participating patients to maximize outcomes and reduce the likelihood of adverse effects.

Pulmonary and cardiac rehabilitation share many similarities and differences. Similarities include the need for patient evaluation before program enrollment, patient education, the focus on exercises to increase fitness and stamina, and the need to monitor patients during exercise and for compliance. Differences include disease focus, patient age (most cardiac patients range in age from late 30s to 60s and 70s, whereas pulmonary patients for the most part are ≥50 years), and exercises used within the program. Many cardiac patients can walk for up to 1 hour, whereas this may be virtually impossible for most pulmonary patients. Breathing exercises to improve ventilation are essential to the pulmonary patient but are not that important to cardiac patients.

Reimbursement varies between the two types of programs with cardiac rehabilitation being more recognized by insurance payers, including Medicare. Because cardiac rehabilitation has existed longer than pulmonary rehabilitation and because outcomes tend to have greater validity and acceptance, insurance reimbursement has been more readily available. There are four phases to cardiac rehabilitation from program introduction to the ongoing fitness aspect. Patient reimbursement depends on the phase of cardiac rehabilitation the patient is in. This division into phases does not currently exist for patients in pulmonary rehabilitation.

Finally, respiratory involvement in cardiac rehabilitation is significantly less. For the most part, the RT is involved with instruction on O_2 use and may assist with patient exercise sessions during cardiac rehabilitation. Most often, the cardiologist and cardiac nurse specialist are involved with program facilitation and administration. Other health care providers who may be involved include a dietitian, physical therapist or occupational therapist or both, and a psychologist.

MINI CLINI

Reacting to Adverse Outcomes

PROBLEM: A 73-year-old man with stage III COPD was accepted into a pulmonary rehabilitation program. Because of the severity of his disease, his preprogram cardiopulmonary exercise evaluation was stopped after 5 minutes because of excessive dyspnea and oxygen desaturation. He was placed on O_2 but was unable to complete the study. However, because of the desire of the patient's physician to get him into a program of pulmonary rehabilitation and the patient's desire to participate, the patient was put on home O_2 and admitted to the program. While exercising on a treadmill with supplemental O_2, the patient complained of headache and nausea. The RT stopped the exercise session and documented a significant increase in the patient's blood pressure (220/130 mm Hg). How should the RT proceed in this case?

Solution: The RT should document the elevated blood pressure and notify the physician overseeing the pulmonary rehabilitation program and the patient's prescribing physician (if different) immediately. It is likely that the preprogram cardiopulmonary exercise test was stopped before the excessive increase in blood pressure was noted. While in pulmonary rehabilitation, the patient (on supplemental O_2) was able to exercise to a level greater than that during the exercise test. This elevated blood pressure will result in the patient going on some type of antihypertensive therapy and being reevaluated during another exercise test to determine the extent of his hypertensive condition. Depending on the instability of the patient's hypertension, it is also possible that this patient will be admitted to cardiac rehabilitation first before returning to the pulmonary rehabilitation program. This case shows the importance of a thorough and complete assessment of a patient's status before any admission to pulmonary rehabilitation.

CONCLUSION

A properly planned and implemented pulmonary rehabilitation program can produce positive and measurable patient outcomes. Goals and objectives of pulmonary rehabilitation should be written in these measurable terms and explained to the patient in a clear, concise fashion to achieve optimum therapeutic outcomes. The success of pulmonary rehabilitation depends on this along with careful application of current clinical knowledge and the use of a multidisciplinary approach throughout all phases of program organization, implementation, and evaluation. Within this context, pulmonary rehabilitation will continue to gain greater acceptance and the role of the RT in pulmonary rehabilitation will be increasingly more important.

SUMMARY CHECKLIST

- Pulmonary rehabilitation has two major aims: (1) to control and alleviate disease symptoms and (2) to help patients achieve optimal levels of activity.
- Patients best able to benefit from pulmonary rehabilitation are patients with symptomatic COPD; patients with unstable cardiovascular disorders should be referred for cardiac rehabilitation.
- Effective rehabilitation programming requires a multidisciplinary approach and combines physical reconditioning with education and psychosocial support.
- Rehabilitation does not alter the progressive deterioration in pulmonary function that occurs with chronic lung disease.
- Increased exercise tolerance, decreased intensity of symptoms, and improved activity levels are the best-documented benefits of pulmonary rehabilitation.
- The exercise evaluation provides the basis for the exercise prescription, yields the baseline data needed to assess a patient's progress, and helps determine the degree of hypoxemia or need for supplemental O_2 during exercise.
- Reconditioning should combine lower extremity and upper extremity aerobic exercises with ventilatory muscle training.
- The educational portion of a rehabilitation program should provide patients with knowledge they can use to help cope with their disease and manage symptoms better.
- Decisions regarding facilities, scheduling, class size, and equipment all can affect rehabilitation program outcomes.
- Patient charges should be based on projected costs, as offset by external funding or available insurance reimbursement.
- Cardiac rehabilitation should be considered first if a patient with pulmonary disease also has an underlying cardiac condition that needs to be addressed and appropriately managed.

CHAPTER 56

Respiratory Care in Alternative Settings

ALBERT J. HEUER

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe alternative care settings in which respiratory care is often performed.
- Discuss more recent developments and trends in respiratory care at alternative sites.
- Identify who regulates alternative care settings.
- List the standards that apply to the delivery of respiratory care in alternative settings.
- Describe how to help formulate an effective discharge plan.
- List factors to evaluate when assessing alternative care sites and support services.
- Discuss how to justify, provide, evaluate, and modify oxygen (O_2) therapy in alternative care settings.
- Explain how to select, assemble, monitor, and maintain O_2 therapy equipment in alternative settings.
- Identify the special challenges that exist in providing ventilatory support outside an acute care hospital.
- Describe how to instruct patients or caregivers and confirm their ability to provide care in alternative settings.
- Identify which patients benefit the most from ventilatory support outside acute care hospitals.
- Explain how to select, assemble, monitor, and maintain portable ventilatory support and continuous positive airway pressure equipment, including applicable interfaces or appliances.
- Describe proper documentation regarding patient evaluation and progress in alternative settings.
- State how to ensure safety and infection control in alternative patient care settings.

CHAPTER OUTLINE

KEY TERMS

alternative (nonacute) care
Centers for Medicare and Medicaid Services (CMS)
conditions of participation
durable medical equipment (DME) supplier
inexsufflator
long-term acute care hospitals (LTACHs)
molecular sieve
noninvasive ventilation (NIV)
O_2-conserving device
skilled nursing facility (SNF)
transtracheal oxygen therapy (TTOT)

Although home care remains the most common alternative site for providing health care, numerous other **alternative (nonacute) care** settings, including subacute facilities, **long-term acute care hospitals (LTACHs)**, rehabilitation facilities, and **skilled nursing facilities (SNFs)**, provide respiratory care to patients.[1] Alternative health care settings offer advantages over acute care facilities which include lower costs and enhanced patient comfort. In general, caring for respiratory patients in alternative sites can reduce patient care cost by as much as four- to five-fold.[1] However, improper or premature discharging of patients to alternative care settings and poor care plan implementation can erase these benefits and result in short-term readmission.

This chapter summarizes recent policy developments, discusses aspects of optimal discharge and patient care planning, and reviews various therapeutic respiratory modalities in alternative care sites. A major alternative site is the sleep laboratory where respiratory therapists (RTs) may conduct polysomnography, or sleep studies. However, the pathophysiology, diagnosis, and treatment of disorders of sleep is covered in Chapter 33.

MORE RECENT DEVELOPMENTS AND TRENDS

There have been several developments in the area of respiratory care in alternative sites. Such changes range from governmental initiatives affecting reimbursement, to enhancements involving respiratory equipment used in such settings.

Over the past two decades, an assortment of legislation and regulations was enacted that has reduced reimbursement for respiratory care in alternative settings. Furthermore, with the exceptions described below, reimbursement for RT time spent setting up the equipment and assessing and administering prescribed treatment to patients is not generally recognized. This has presented challenges to organizations and agencies attempting to provide quality care in alternative settings.[2-5]

The Patient Protection and Affordable Care Act (ACA) of 2010 has expanded health care coverage to many uninsured Americans, prohibits the exclusion of preexisting conditions, and increases the scope of coverage for certain types of preventive care. This law also encourages the formation of Accountable Care Organizations (ACOs), which are groups of doctors, hospitals, and health care providers who voluntarily come together to deliver coordinated patient care. However, many provisions of this law are still being modified and others are just beginning to be implemented. Consequently, the exact impact of this bill on respiratory care in general, and in alternative settings, is still somewhat unclear.[6]

Even more recently, some states have and continue to review and pilot programs to reimburse for certain therapies and education done by RTs in alternative settings. Specifically, some states' Medicaid programs are planning to begin reimbursement for certain types of education done by RTs for purposes such as asthma management. Furthermore, the American Association for Respiratory Care (AARC), through its Government Affairs initiatives, continues to promote legislation and sponsor efforts to expand the recognition of RTs.[7]

A further development stemming mainly from the aging U.S. population is a significant increase in the popularity of another form of alternative care site known as *assisted living facilities*. These facilities permit residents, who are generally elderly or disabled, to live in their own units either alone or with a companion. These arrangements permit residents to live relatively independently with the convenience and safety of routine health services nearby. A growing number of home care and other alternative sites have RTs providing care to their patients at such locations.

Other changes affecting RTs in alternative sites have resulted from research study outcomes. Starting in the late 1990s, there has been a small but growing body of research indicating that patients in alternative settings have better outcomes when treated by RTs.[8,9] It is hoped that this trend continues and

encourages public agencies and private health care payers to recognize the value of RTs in alternative care settings and shape policies accordingly.

RELEVANT TERMS AND GOALS

As the elderly population increases and managed care becomes the dominant delivery model, more health care services are being provided outside the acute care hospital in such settings as SNFs, LTACHs, and at home. Rather than representing distinct entities, these alternative settings are part of an evolving continuum of care, are often elements of ACOs, and share the common goal of providing appropriate medical services cost-effectively and at settings suitable to a patient's condition.

Similar to the acute care setting, alternative care settings accomplish this goal through a coordinated team effort among many disciplines. The patient care team in alternative settings uses various specialized respiratory care services and equipment, including continuous O_2 therapy, long-term mechanical ventilation, aerosol drug administration, airway care, sleep apnea monitoring and treatment, and pulmonary rehabilitation. Each of the major alternative settings, the respiratory equipment used within them, and other relevant considerations including patient and family education are discussed in subsequent sections of this chapter.

Long-Term Subacute Care Hospitals

Advances in technology, research, and clinical specialization have permitted more acutely ill patients to be treated outside of large-scale, acute care hospitals. Over the past decade, LTACHs have become more prevalent. These facilities provide highly focused care to patients with complex medical conditions, including patients who have been ventilator-dependent and difficult to wean. Generally, LTACHs employ a highly experienced clinical staff, including RTs, to provide integrated interdisciplinary care using the latest equipment and protocols. During the 20- to 30-day typical length of stay at an LTACH, patients commonly experience significant improvement, including successful ventilator weaning and increased functionality.[10]

Subacute Care

According to the National Association of Subacute/Post Acute Care, *subacute care* is a comprehensive level of inpatient care for stable patients who (1) have experienced an acute event resulting from injury, illness, or exacerbation of a disease process; (2) have a determined course of treatment; and (3) require diagnostic or invasive procedures but not those requiring acute care.[10] Typically, the severity of the patient's condition requires active physician direction with frequent on-site visits, professional nursing care, significant ancillary services, and an outcomes-focused interdisciplinary approach employing a professional team.

The goal of acute care is to apply intensive resources to stabilize patients after severe episodic illness, whereas subacute care aims to restore the whole patient back to the highest practical level of function—ideally self-care. This holistic approach requires goal-oriented interdisciplinary team care, with frequent assessment of progress and a time-limited plan of care.[11]

Although most patients receiving subacute care are elderly, all age groups can be found at these sites. Pediatric, adolescent, and adult patients requiring ventilatory support or extensive care, depending on their diagnosis, are also cared for at these sites.

Home Care

Currently, most respiratory care in the alternative setting is provided in the home. The primary goal of home care is to provide quality health care services to patients in their home setting, minimizing their dependence on institutional care. In regard to respiratory home care, several specific objectives are evident.[12] Respiratory home care can contribute to the following:

- Supporting and maintaining life
- Improving patients' physical, emotional, and social well-being
- Promoting patient and family self-sufficiency
- Ensuring cost-effective delivery of care
- Maximizing patient comfort near the end of life

Most patients for whom respiratory home care is considered have chronic respiratory diseases. Applicable categories of disorders include the following:

- COPD
- Cystic fibrosis
- Chronic neuromuscular disorders
- Chronic restrictive conditions
- Carcinomas of the lung

Although not all aspects of respiratory home care have proven effective, various studies have shown that carefully selected treatment regimens can be of significant benefit to patients. These benefits include increased longevity, improved quality of life, increased functional performance, and a reduction in the individual and societal costs associated with hospitalization.[13,14]

STANDARDS

Standards for the delivery of respiratory care in the subacute and home settings are derived from several different sources. First, the Clinical Practice Guidelines created and published by the AARC offer RTs an evidence-based clinical framework for performing numerous respiratory procedures, including many procedures used in alternative care settings. Several of these guidelines are described throughout this chapter. Other standards are established by federal and state laws and private-sector accreditation.

Regulations

Most reimbursement for care in alternative settings is through either the federal Medicare program or federal or state Medicaid programs. As the largest purchaser of health services, the federal government (in connection with state and local governments)

plays a major role in setting standards and regulating this industry. The federal agency responsible for the overall administration of Medicare and Medicaid is the **Centers for Medicare and Medicaid Services (CMS)**. Created in 1997, CMS oversees the framework for providing health coverage to elderly adults, disabled adults, and many disadvantaged young children in the United States.[5,6]

As part of this structure, CMS created the Medicare Provider Certification Program. This program ensures that institutional providers that serve Medicare beneficiaries, including hospitals, SNFs, LTACHs, home health agencies, and assisted living facilities, meet minimum health and safety requirements. These requirements are called **conditions of participation**. Current conditions of participation emphasize quality indicators, outcome measures, and cost efficiency designed to improve the quality and effectiveness of care provided to beneficiaries.[5,6] Institutions undergo certification surveys by either state survey agencies or private accrediting organizations, such as The Joint Commission (TJC), which is discussed in more detail in the following section.[15,16]

State survey agencies are partners with the federal government and principal agents in performing institutional certification. Typically, a state survey agency is either the state department of health or state licensing authority for health care facilities. The main function of the state survey agency is to ensure that facilities providing Medicare or Medicaid services comply with state and federal health, safety, and quality standards, as determined by periodic on-site inspections.

In addition to federal Medicare and Medicaid conditions of participation, most states set additional regulations that govern licensing of providers of care in alternative settings. Because these regulations are different in each state, readers should contact their state health department for details.

Private Sector Accreditation

The primary organization responsible for standard setting and voluntary accreditation of care providers in alternative settings is TJC. To assist hospitals and health care organizations with the accreditation process and overall performance improvement, TJC develops and publishes standards and National Patient Safety Goals for long-term and subacute care, home care, and assisted living facilities. The standards and goals relate to the delivery of quality patient care and the process and structure needed to do so. These categories include patient rights, ethics, and assessment and organizational leadership and management of information. The patient safety goals target for improvement common problem areas for health care organizations, such as proper patient identification, medication safety, and infection control.[15,16]

Approximately 90% of all hospitals and other health care organizations voluntarily subscribe to TJC accreditation and as a result are surveyed at least every 3 years. Insufficient or unsatisfactory compliance is flagged and requires formal follow-up to ensure correction. In certain circumstances, such unfavorable results may translate into a facility or an organization failing to maintain TJC accreditation.[15,16]

TRADITIONAL ACUTE CARE VERSUS ALTERNATIVE SETTING CARE

For the RT, working in the alternative care setting is distinctly different from working in an acute care hospital. Key differences involve resource availability, supervision and work schedules, documentation and assessment, and provider-patient interaction (Table 56-1).[17] Although some practitioners do not like the alternative work settings, many find the greater independence,

TABLE 56-1

Major Differences between Traditional Acute Care Setting and Alternative Settings for Delivery of Respiratory Care Services

Area	Traditional Setting (Acute Care Hospital)	Alternative Settings (Long-Term Acute Care, Subacute Care, Home Care)
Diagnostic resources	In-house laboratory, x-ray, ABG analysis, PFT	Must rely on outside vendors to provide diagnostic tests
Equipment support	Extensive; supported by piped-in O_2 and suctioning	Limited availability; must use portable O_2 and suctioning systems
Travel requirements	None; remain in one facility	Must travel between facilities or residences
Level of supervision	Direct supervision	Respiratory care provider works independently with minimal supervision
Patient assessment	Moderate—primarily provided by attending physician or residents	Heavy—core responsibility related to care planning
Documentation requirements	Moderate—limited to medical record keeping	Heavy—includes initial justification, ongoing follow-up, and often detailed financial record keeping
Work schedule	Specific hours	Varied work schedule, often including "on-call" off hours coverage
Time constraints	More than one shift to deliver therapy	Must complete all therapy during shift or visit
Patient-family interaction	Limited treatment time available; little family interaction	One-on-one therapy; intensive family interaction
Provider interaction	Primarily attending physicians and patient's nurses	Continuous interaction with all members of professional team

ABG, Arterial blood gas; *PFT,* pulmonary function testing.

professional team orientation, creativity, and higher level of patient and family interaction quite rewarding.

DISCHARGE PLANNING

Effective discharge planning provides the foundation for quality care in the alternative care setting. A properly designed and implemented discharge plan guides the multidisciplinary team in successfully transferring a respiratory care patient from the health care facility to an alternative site of care.[18] Effective implementation of the discharge plan also ensures the safety and efficacy of the patient's continuing care. In addition, Medicare's Readmission Reduction Program, which is part of the ACA, penalizes hospitals that have high short-term readmission rates for selected conditions, including COPD and CHF. Hence, it has become essential for hospitals and other health care providers to adopt and evaluate the effectiveness of evidence-based discharge protocols. In general, the key elements of such protocols include the following:

- Proper patient screening and evaluation
- Early identification of patients at high risk for short-term readmission
- Intensive patient and family education
- Multidisciplinary discharge planning that addresses all major potential barriers
- Patient follow-up.[4]

To guide practitioners in providing quality care, the AARC has published Clinical Practice Guideline: Discharge Planning for the Respiratory Care Patient.[4,19] Excerpts from this guideline appear in Clinical Practice Guideline 56-1.

Multidisciplinary Team

Although a physician normally initiates an order to discharge a patient to an alternative site, many other health care professionals are involved in the discharge process. Table 56-2 identifies these key professionals and their major responsibilities.[18] As with pulmonary rehabilitation (see Chapter 55), a team approach produces the best patient results. Communication and mutual respect for the talents and abilities of each team member are two key elements in making patient care in the alternative care setting work. Any breakdown in the system may delay or adversely affect patient discharge and the patient's physical health and mental well-being.

Site and Support Service Evaluation

The primary factors determining the appropriate site for discharge are the goals and needs of the patient. These goals and needs should be met in an optimal and cost-effective manner using the resources available at the proposed site. In terms of institutional personnel, the staff of the selected facility must have all the competencies required to meet the patient's respiratory needs, be able to provide other needed health care services (e.g., physical therapy), and provide adequate 24-hour coverage.[17,19]

For a successful discharge to the home, it is essential that the ability of caregivers to learn and perform the required care be evaluated before transfer. Caregivers must clearly demonstrate and have documented the competencies required to care for the specific patient and, in combination, provide 24-hour coverage.[17,19]

TABLE 56-2
Members of Patient Care Team in Alternative Settings

Discipline	Responsibilities
Utilization review	Advises or recommends consideration of patient discharge. Documents patient's in-hospital care
Discharge planning (social service or community or public health)	Brings all the needed elements together and ensures that a patient can be discharged to alternative care sites. Makes contacts with outside agencies that may assist with patient care
Physician	Writes order for patient discharge. Evaluates patient's condition and prescribes needed care. Establishes therapeutic objectives
Respiratory care	Evaluates patient and recommends appropriate respiratory care. Provides care and follow-up
Nursing	Writes and implements nursing care plan for patient. Assesses patient's status and provides necessary follow-up
Dietary and nutrition	Assesses patient's nutritional needs and writes dietary plan for patient. Makes arrangements for meals as necessary
Physical and occupational therapy	Provides necessary physical therapy and recommends any additional modalities or procedures
Psychiatry or psychology	Assesses patient's emotional status and provides any needed counseling or support
DME supplier or home care company	Provides needed equipment and supplies and handles any emergency situations involving delivery or equipment operation

RULE OF THUMB

To help ensure a successful discharge and confirm that a nonprofessional caregiver can perform a particular skill, the RT must go beyond demonstration and verbal confirmation of the caregiver's understanding. The RT must observe a return demonstration, whereby the caregiver properly performs the same procedural steps the RT demonstrated. In addition, providing the caregiver with written information relating to the procedural sets and equipment setup, maintenance, and basic troubleshooting can help reinforce key areas and ensure caregiver mastery of the competency.

Beyond the performance of a particular skill, it is imperative for the discharge team to ensure that an adequate number of professional and nonprofessional caregivers are part of the care plan to provide appropriate patient care coverage; this is particularly true when more complicated modes, such as

56-1 Discharge Planning for the Respiratory Care Patient

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS
Discharge planning is indicated for all respiratory care patients being considered for discharge or transfer to alternative sites. The plan should be developed and implemented as early as possible before transfer.

CONTRAINDICATIONS
There are no contraindications to the development of a discharge plan.

PRECAUTIONS AND POSSIBLE COMPLICATIONS
Undesirable or unexpected outcomes may occur if the patient is discharged before the full implementation of the plan. Undesirable or unexpected patient outcomes may also occur because of (1) the natural course of the disease or (2) other factors beyond the control of the discharge planning process.

METHOD
Discharge planning and implementation should begin as early as possible. The complexity of the plan is determined by the patient's medical condition, needs, and goals. The steps in the planning process are:

- Patient evaluation
  - Patient's medical condition
  - Psychosocial condition of patient and family
  - Respiratory and ventilatory support required
  - Desires for medical and ventilator care of patient and family
  - Patient's physical and functional ability and activities of daily living
  - Goals of care (patient and family, physician, health care professionals, bedside caregivers)
- Site evaluation for continuing care
  - Personnel
  - Physical environment (safety and suitability)
  - Equipment and supplies
  - Financial resources
- Development of multidisciplinary plan of care based on the patient's needs and goals
  - Plan for integration into the community
  - Medication administration
  - Plan for patient self-care as appropriate
  - Method for ongoing assessment of outcomes
  - Roles and responsibilities of team members for daily care management
  - Method to assess growth and development of pediatric patients
  - Documented mechanism for securing and training additional caregivers
  - Mechanism for communication among all members of health care team
  - Alternative emergency and contingency plan
  - Follow-up (e.g., medical, respiratory care) plans
  - Plan for use, maintenance, and troubleshooting of equipment
  - Plan for monitoring and appropriately responding to changes in patient's medical condition
  - Time frame for implementation
- Education and training with clear demonstration and documentation of competencies must occur before discharge and address key elements of the plan of care

ASSESSMENT OF NEED
All patients with a respiratory diagnosis should be assessed for a discharge plan.

ASSESSMENT OF OUTCOME
The desired outcome of the discharge plan is determined by the following:

- No readmission occurs because of discharge plan failure
- The equipment meets the patient's needs
- All treatments and modalities are performed satisfactorily by caregivers as instructed
- Caregivers are able to assess the patient, troubleshoot, and solve problems as they arise
- The treatment meets the patient's needs and goals
- The patient and family are satisfied
- The site provides the necessary services

MONITORING
The discharge plan coordinator and the physician should monitor the progress of the discharge plan. Each team member should participate in regularly scheduled team conferences to assess the progress of the discharge plan. Modifications may be made according to the goals and needs of the individual patient.

**For the complete guideline, see American Association for Respiratory Care: Clinical practice guideline: discharge planning for the respiratory care patient. Respir Care Clin N Am 40:1308, 1995.*

mechanical ventilation, or multiple therapies are required by the patient. Generally, substantial caregiver strain is associated with the care of such patients in alternative settings. Proper assessment of the capabilities and number of potential caregivers in light of the therapy needed at home and appropriate training of such individuals can help address this concern.

Equipment support and selected clinical services for patients receiving respiratory home care are often provided by a **durable medical equipment (DME) supplier**. DME suppliers range in size from multimillion-dollar national corporations offering a broad range of services to small local companies. Both large and small companies usually provide the following services:

- Service 24 hours, 7 days a week
- Third-party insurance processing
- Home instruction and follow-up by an RT
- Most forms of respiratory care

MINI CLINI

Minimizing Short-term Readmissions

PROBLEM: A COPD patient who was admitted to the hospital for an exacerbation, is now improving and targeted for discharge in two days. Due to patient quality-of-life considerations and newer financial penalties for excessive short-term readmissions, the patient care team wishes to help minimize the likelihood of a short-term (30-day) readmission for this individual and similar patients. What are some of the major considerations that should be addressed in the discharge plan for this patient to help avoid a short-term readmission?

Solution: COPD patients, especially those with moderate to severe disease, may often be deemed more clinically "fragile" and therefore especially prone to short-term readmissions. Hence, it is imperative for the multidisciplinary patient care team to quickly recognize the predisposition and to carefully plan to address the major risks. Education and patient follow-up are at the core of most short-term readmission reduction protocols. In this case, the education should focus on the pathophysiology of COPD and, more important, the purpose and importance of each element of the care plan. Reinforcing proper medication use such as bronchodilators and steroids as well as safe use of home oxygen are priorities. Phone, computer-aided or in-person patient follow-up should focus on continued compliance with the treatment plan, adherence to scheduled physician visits, and participation in any prescribed pulmonary rehabilitation programs. Barriers such as those related to transportation issues and assistance with activities of daily living should also be promptly identified and addressed. In some instances, transportation to physician visits and pulmonary rehabilitation sessions, or certified home-health aids, can be arranged in advance by the discharge planning team or patient follow-up clinicians.

When selecting a DME supplier from the available choices, the patient and family members and other members of the discharge planning team should consider the company's accreditation status, cost and scope of services, dependability, location, personnel, past track record, and availability. Charges should be reasonable and competitive, and clinical respiratory services should generally be provided by credentialed RTs.[17]

Finally, the selected site must meet basic safety standards and be suitable for managing the patient's specific condition. It should be free of fire, health, and safety hazards; provide adequate heating, cooling, and ventilation; provide adequate electrical service; and provide for patient access and mobility with adequate patient space (room to house medical and adaptive equipment) and storage facilities. The selected site must be capable of operating, maintaining, and supporting all equipment needed by the patient; including both respiratory and ancillary equipment and supplies as needed, such as the ventilator, suction, O_2, intravenous therapy, nutritional therapy, and adaptive equipment.[17,19] Box 56-1 lists key factors one should assess in planning the discharge of a respiratory care patient to the home environment.

Box 56-1 Assessing the Home Environment

ACCESSIBILITY
- In and out of house or apartment
- Accessibility between rooms
- Doorway width and threshold heights
- Stairways
- Wheelchair mobility
- Bathroom
- Kitchen
- Carpeting

EQUIPMENT
- Available space
- Electrical power supply
- Amperage
- Grounded outlets
- Presence of hazardous appliances

ENVIRONMENT
- Heating and ventilation
- Humidity
- Lighting
- Living space

A variety of equipment is available when a patient with a pulmonary disorder is discharged to an alternative setting. The most common types of respiratory therapy equipment used in alternative settings are discussed in the following sections.

MINI CLINI

Assessing the Home Environment

PROBLEM: A wheelchair-bound patient with a tracheostomy who requires mechanical ventilation is being discharged to the home care setting. Inspection of the two-story home reveals front and rear elevated porch entrances with all bedrooms upstairs. All room floors (except the kitchen and bathrooms) are covered with high pile carpeting. The largest bedroom is 12 ft by 14 ft. The electrical service is rated at 75 amps, and the only grounded outlets are in the kitchen and garage. Heating is provided by a forced hot-air system; there is a single window air conditioner in the patient's bedroom.

What problems do you see, and what changes would you recommend to provide the proper home environment for this patient?

Solution: Although wheelchair-bound, this patient is still mobile. Both the elevated porch entrances and the high pile carpeting restrict mobility. A ramp entrance needs to be constructed, and the carpeting needs to be removed or covered with a flat, hard surface material. Given the size of the patient's upstairs room and the obstacle of the stairwell, it would be best to identify a large first-story room for conversion to a bedroom. Because the patient is likely to need at least an electrical bed, ventilator, and suction machine, the electrical service capacity is inadequate and needs upgrading to ensure at least 15 to 20 amps in the patient area, with 200 amps overall. Appliance, counter, sink, and toilet heights need to be assessed for easy patient access.

OXYGEN THERAPY IN ALTERNATIVE SETTINGS

O_2 therapy is the most common mode of respiratory care in alternative care settings. This high use is based on the fact that O_2 therapy improves both survival and quality of life in selected patient groups, especially patients with advanced COPD.[20,21] In particular, studies have shown improved nocturnal O_2 saturation, reduced pulmonary artery pressure, and lower pulmonary vascular resistance with appropriate outpatient O_2 therapy.[22,23]

To guide practitioners in providing quality care, the AARC has published a Practice Guideline on Oxygen Therapy in the Home or Extended Care Facility.[24] Excerpts from the AARC guideline, including the indications, contraindications, precautions and possible complications, method, assessment of need, assessment of outcome, and monitoring, appear in Clinical Practice Guideline 56-2.

Oxygen Therapy Prescription

As indicated in Clinical Practice Guideline 56-2, O_2 prescriptions must be based on documented hypoxemia, as determined by either arterial blood gas analysis or oximetry. Prescriptions for O_2 therapy no longer can be based simply on patient diagnosis or signs and symptoms. In addition, as-needed O_2 therapy is no longer acceptable in the alternative care setting.

When the need for O_2 therapy is established, the physician writes a prescription. A prescription for O_2 therapy in the alternative care setting must include the following elements:[25]

- Flow rate in L/min or concentration or both
- Frequency of use in hours per day and minutes per hour (if applicable)
- Duration of need
- Diagnosis (severe primary lung disease, secondary conditions related to lung disease and hypoxia, related conditions or symptoms that may improve with O_2)
- Laboratory evidence (arterial blood gas analysis or oximetry under the appropriate testing conditions); home care companies cannot provide this testing
- Additional medical documentation (no acceptable alternatives to home O_2 therapy)

For home use, the ordering physician must authorize O_2 therapy using the CMS Certification of Medical Necessity form for O_2. After the need for long-term therapy is documented, repeat arterial blood gas analysis or SpO_2 measurements are not needed. However, blood O_2 levels may still be measured when the need arises to assess changes in the patient's condition.[26]

Supply Methods

Most alternative care sites do not have bulk O_2 storage or delivery systems. In these settings, O_2 normally is supplied from one of the following three sources:[27] (1) compressed O_2 cylinders, (2) liquid O_2 systems, or (3) O_2 concentrators. Table 56-3 summarizes the major advantages and disadvantages of each system.

Compressed Oxygen Cylinders

For practical reasons, the primary use of compressed O_2 cylinders in alternative settings is either for ambulation (small cylinders) or as a backup to liquid or concentrator supply systems (H/K cylinders). Safety measures for cylinder O_2 are the same as those discussed in Chapters 40 and 41. For home use, the RT should thoroughly review these safety measures with both the patient and family members. After instruction, the RT should always confirm and document abilities of caregivers to use the delivery system safely.

TABLE 56-3

Advantages and Disadvantages of Major Alternative Oxygen Supply Systems

System	Advantages	Disadvantages
Compressed O_2	Good for small volume user	Large cylinders are heavy and bulky
	No waste or loss	High-pressure safety hazard
	Stores O_2 indefinitely	Provides limited volume
	Widespread availability	Requires frequent deliveries
	Portability (small cylinders)	Tight valves can be a problem
Liquid O_2 system	Provides large volumes	Must be delivered as needed
	Low-pressure system (20-25 psi)	Loss of O_2 because of venting of system when not in use
	Portable units can be refilled from reservoir (up to 8-hr supply at 2 L/min)	Low temperature safety hazard
		Cannot operate ventilators or other high-pressure devices
	Valuable for rehabilitation	Some difficulty in filling portable unit
O_2 concentrator	No waste or loss	Disruption in electrical service renders system inoperable
	Low-pressure system (15 psi)	Backup O_2 is needed
	Cost-effective when continual supply of O_2 is needed	Cannot operate ventilators or other high-pressure devices
		FiO_2 decreases with increasing flow
	Eliminates need for deliveries	High electrical costs possible

56-2 Oxygen Therapy in the Home or Alternative Site Health Care Facility

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

- Documented hypoxemia
- Adults, children, and infants >28 days old: PaO_2 ≤55 mm Hg or SaO_2 ≤88% (room air)
- PaO_2 56 to 59 mm Hg or SaO_2 ≤89% in association with specific clinical conditions (e.g., cor pulmonale, congestive heart failure, or erythrocythemia with hematocrit >56%)
- Patients who do not qualify for O_2 therapy at rest may qualify during ambulation, sleep, or exercise if SaO_2 decreases to <89% during these specific activities

CONTRAINDICATIONS

No absolute contraindications to O_2 therapy exist when indications are present.

PRECAUTIONS AND POSSIBLE COMPLICATIONS

- In spontaneously breathing hypoxemic patients with COPD, O_2 therapy may increase $PaCO_2$
- Problems may occur if the patient fails to comply with the physician's orders or receives inadequate instruction
- Complications may result from use of nasal cannulas or transtracheal catheters
- Fire hazard is increased in the presence of increased O_2 concentrations
- Bacterial contamination associated with certain nebulizers and humidifiers may occur
- Physical hazards include unsecured cylinders, ungrounded equipment, and liquid O_2 burns
- Power or equipment failure can lead to an inadequate O_2 supply

ASSESSMENT OF NEED

- Initial need is determined by documented hypoxemia at rest or during activity (see Indications)
- Additional measurements of blood gas tension or saturation by invasive or noninvasive methods may be indicated whenever there is a major change in clinical status that may be cardiopulmonary related
- Blood gases should be repeated after 1 to 3 months to determine the need for long-term O_2 therapy
- Once the need for long-term O_2 therapy has been documented, repeated measures are unnecessary other than to follow the course of the disease, to assess changes in clinical status, or to facilitate changes in the O_2 prescription

ASSESSMENT OF OUTCOME

Outcome is determined by clinical and physiologic assessment to establish adequacy of patient response to therapy.

MONITORING

- Patient
  - Initial and ongoing clinical assessment of patient's need for O_2 therapy should be performed by licensed or credentialed RTs (RRT or CRT) or other professional persons with equivalent training and documented ability to perform the tasks as part of a patient-specific plan of care/plan of service
  - Care plans should be developed at the initiation of O_2 therapy based on the needs of the individual patient and updated as necessary
  - Measurement of baseline O_2 tension or saturation is essential before O_2 therapy is begun. Measurements should be repeated when clinically indicated or to follow the course of the disease, as determined by the attending physician
  - Measurements of O_2 saturation also should be made to determine appropriate O_2 flow for ambulation, exercise, or sleep
- Equipment
  - All O_2 delivery equipment should be checked at least once daily by the patient or caregiver. Facets to be assessed include proper function of the equipment, prescribed flow rates, remaining liquid or compressed gas content, and backup supply
  - O_2 equipment should be serviced and maintained in accordance with the manufacturer's specification and consistent with all federal, state, and local laws and regulations
  - In the event there are no manufacturer specifications or guidance, O_2 equipment should be checked for proper function and performance by an appropriately trained or credentialed person no less than once per year

**For the complete guideline, see American Association for Respiratory Care: Clinical practice guideline: oxygen therapy in the home or alternate site health care facility. Respir Care 52:1063, 2007.*

In addition to the cylinder gas, a pressure-reducing valve with flowmeter is needed to deliver O_2 at the prescribed flow. Standard clinical flowmeters deliver flows up to 15 L/min; however, flows used in alternative settings are typically in the 0.25 to 5 L/min range. For this reason, the RT should select a calibrated low-flow flowmeter whenever possible (see Chapter 40).

As in the hospital, there is usually no need to humidify nasal O_2 at flows of 4 L/min or less.[24] If humidification is needed, a simple unheated bubble humidifier can be used. Because the mineral content of tap water may be high (hard water), water used in these humidifiers should be distilled. Otherwise, the porous diffusing element may become occluded. Although

complete blockage is unlikely, occlusion of the diffusing element can impair humidification and alter flow.

Liquid Oxygen Systems

Though the higher cost of liquid O_2 delivery systems versus other systems has greatly reduced its use, such systems offer some advantages over others and are therefore still used under certain conditions in alternative settings. One of the main advantages of liquid O_2 systems relates to the fact that 1 cubic ft of liquid O_2 equals 860 cubic ft of gas and therefore it is possible to store large quantities in small spaces. As shown in Figure 56-1, a typical personal liquid O_2 system is a miniature version of a hospital liquid oxygen system. Similar to its larger counterpart, this system consists of a reservoir unit similar in design to a thermos bottle. The inner container of liquid O_2 is suspended in an outer container, with a vacuum in between. The liquid O_2 is kept at approximately −300° F. Because of constant vaporization, gaseous O_2 always exists above the liquid. When the cylinder is not in use, this vaporization maintains pressures between 20 psi and 25 psi. When pressures increase above this level, gas vents out the pressure relief valve.

When flow is turned on, gaseous O_2 passes through a vaporizing coil, where it is warmed by exposure to room temperature. It leaves the system through an outlet, where it is metered by a flow control valve. These metering devices are usually calibrated in 0.5-L/min units and limited to a maximum flow of 5 to 8 L/min.

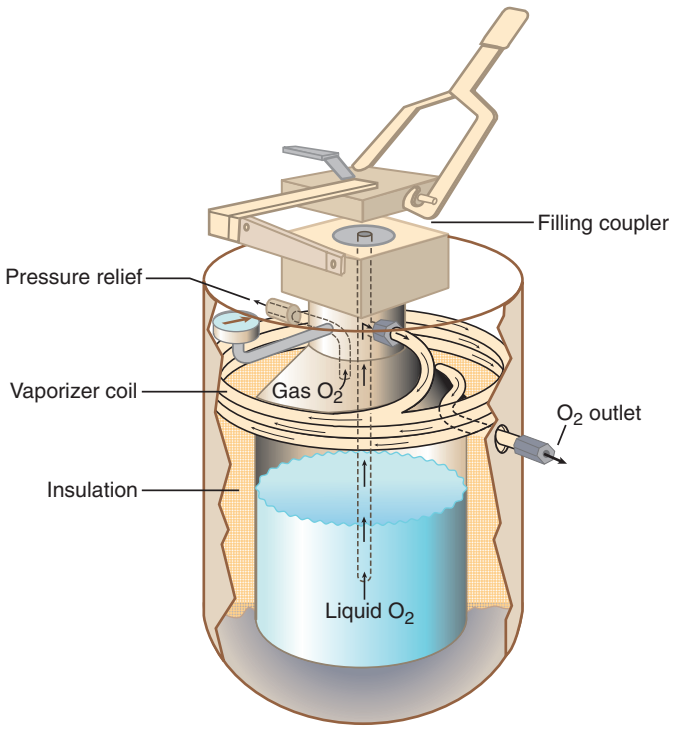

FIGURE 56-1 Diagram of a personal liquid oxygen supply system. (Modified from Lampton LM: Home and outpatient oxygen therapy. In Brashear RE, Rhodes ML, editors: Chronic obstructive lung disease, St Louis, 1978, Mosby.)

Depending on manufacturer and model, small liquid O_2 cylinders hold 45 to 100 lb of liquid O_2. To calculate duration of flow of a liquid O_2 system, one first converts the weight of liquid O_2 in pounds to the equivalent volume of gaseous O_2 in liters. At normal liquid cylinder operating pressures, 1 lb of liquid O_2 equals approximately 344 L of gaseous O_2. The accompanying Mini Clini provides an example of how the clinician can compute the duration of flow in a liquid O_2 system.

MINI CLINI

Computing Duration of Flow of a Liquid Oxygen System

PROBLEM: A home care patient receives nasal O_2 at 2 L/min from a 100-lb liquid O_2 system. The system gauge indicates that the cylinder is half full. Approximately how long will this system last until empty?

Solution:

Step 1: Compute the available liquid O_2 (in lb)

$$100 \times 0.5 = 50 \text{ lb}$$

Step 2: Compute the available gaseous O_2

$$\text{Weight (lb) remaining} \times \text{factor}$$
$$50 \text{ lb} \times 344 \text{ L/lb} = 17{,}200 \text{ L}$$

Step 3: Divide the available volume of gaseous O_2 by the prescribed liter flow

$$\text{Duration of flow (min)} = \frac{\text{Volume of gaseous } O_2 \text{ (L)}}{\text{Liter flow (L/min)}}$$

$$\text{Duration of flow (min)} = \frac{17{,}200 \text{ L}}{2 \text{ L/min}} = 8600 \text{ min} = 143.3 \text{ hr}$$
$$= 6 \text{ days}$$

To help avoid these computations, many manufacturers provide simple conversion charts. Table 56-4 is an example of a conversion chart for a typical 100-lb personal liquid O_2 system.

Many personal liquid O_2 systems also come with smaller portable units (Figure 56-2). This system is suitable for an

TABLE 56-4

Conversion Chart for Computing Duration of Flow for 100-lb (40-L) Liquid Oxygen Reservoir

Gauge reading	1	2	3	4	4
Weight (lb)	12.5	25	50	75	100
Liquid liters	5	10	20	30	40
Gaseous liters	4303	8606	17,212	25,818	34,424
Duration of Flow (Hours)					
Flow (L/min)					
1	72	143	287	430	574
2	36	72	143	215	287
3	24	48	96	143	191

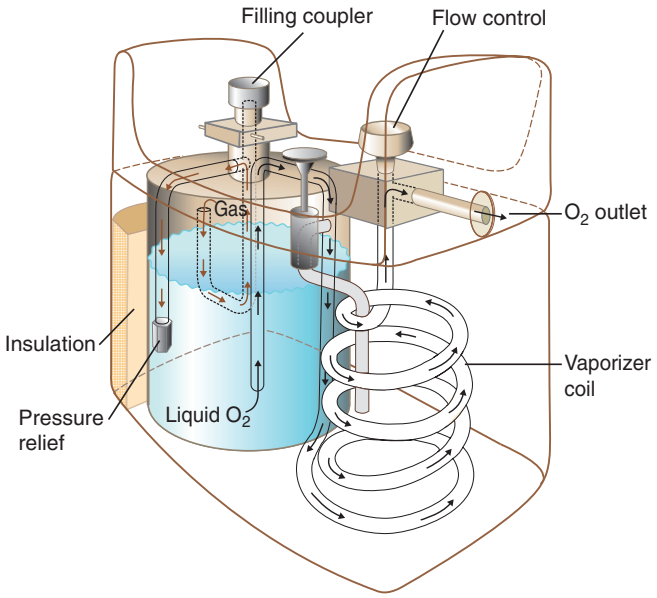

FIGURE 56-2 Diagram of a portable liquid oxygen unit. (Modified from Lampton LM: Home and outpatient oxygen therapy. In Brashear RE, Rhodes ML, editors: Chronic obstructive lung disease, St Louis, 1978, Mosby.)

Box 56-2 Steps for Filling a Portable Liquid Oxygen Unit from the Reservoir

1. Check the gauge on the reservoir unit to ensure there is enough liquid O_2 in the reservoir to fill the portable unit.
2. Check the connectors on both units to ensure that they are clean and dry. Moisture on these connectors could cause the connectors to freeze together.
3. Connect the portable unit to the reservoir according to the manufacturer's instructions, generally by engaging the fittings on the portable unit and reservoir, then carefully twisting the portable unit until it "seats." The flow-rate controller should be turned off.
4. Open the portable unit vent. Allow the portable unit to fill. The portable unit is filled when excess O_2 begins venting and the sound emitted from the unit changes. Close the vent valve.
5. Disengage the portable unit according to the manufacturer's instructions, generally by carefully twisting the portable tank until it is released from the liquid reservoir.

ambulatory patient who is capable of physical activity. Typical portable units weigh 5 to 14 lb and can be refilled directly from the stationary reservoir. Most portable units come with a carrying case or small cart and can provide 5 to 8 hours of O_2 at a flow of 2 L/min. Either an adjustable flow restrictor or a Bourdon-type gauge is used to meter flow, with a weight gauge used to indicate O_2 contents. The functional use time of portable liquid O_2 units can be extended with O_2-conserving devices, including the demand-flow systems discussed later in this chapter.

Because of the extremely low temperature of liquid O_2, patients and caregivers must be extremely careful when refilling these portable systems. Box 56-2 lists the steps needed to fill a portable liquid O_2 unit from a reservoir.[27]

Oxygen Concentrators

An O_2 concentrator is an electrically powered device that physically separates the O_2 in room air from nitrogen. These systems are much more common than either gaseous tanks or liquid systems. The most common type of concentrator uses a **molecular sieve** to extract O_2.[27]

The molecular sieve concentrator uses a pump to compress and deliver filtered room air to one of two sets of sieves (Figure 56-3). These sieves contain sodium-aluminum silicate pellets that absorb nitrogen, carbon dioxide (CO_2), and water vapor. To remove these unwanted gases from the pellets, an automatic pressure swing cycle switches back and forth between the sieve sets. One set is pressurized to produce O_2, and the other is depressurized to purge nitrogen, CO_2, and water vapor.

Gas leaving the sieves is stored in a small accumulator. At flows of 1 to 2 L/min, the typical molecular sieve concentrator provides between 92% and 95% O_2. At 5 L/min or greater, O_2 concentrations are between 85% and 93%.[27] The output of many concentrator models has been limited to 5 L/min. However, more recently, models capable of delivering 10 L/min, have been introduced. In addition, technologic advances have accounted for other enhancements to O_2 production and delivery devices in alternative care settings. One example is portable battery-powered concentrators with demand-flow conserving capabilities. These units afford patients receiving low-flow O_2 increased mobility and have been approved for use in most commercial aircraft.

O_2 concentrators are the most cost-efficient supply method for patients in alternative care settings who need continuous low-flow O_2. For home use, a concentrator running 24 hours/day increases the average monthly electrical bill by only 5% to 10%. Depending on the season, heat given off by the concentrator's compressor can also affect energy usage by increasing room temperature. Nonetheless, when used with patients receiving low-flow O_2, concentrators are just as effective in increasing blood O_2 levels as most other systems.

Problem Solving and Troubleshooting

Technical problems with O_2 supply systems in alternative settings are similar to problems encountered in the acute care hospital (see Chapter 40). In addition to these technical problems, situations can arise when patients or caregivers fail to follow instructions properly. To avoid communication problems, verbal instructions should always be reinforced by providing simple written instructions for subsequent reference. In addition, the clinician should always confirm and document the ability of caregivers to use the delivery system safely, including how to troubleshoot simple problems. The ability of caregivers and patients to give an adequate return demonstration on proper equipment usage should also be recorded.[24]

To avoid problems before they occur, the patient or caregiver should be instructed to check all O_2 delivery equipment at least once a day.[18] The proper function of all equipment, including

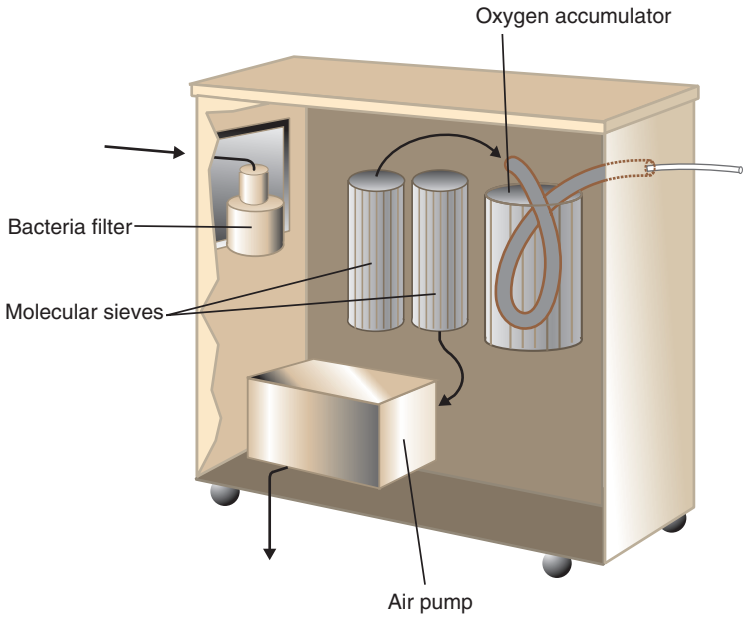

FIGURE 56-3 A molecular sieve oxygen concentrator.

liter flow, connections, and fractional inspired oxygen (FiO_2) levels, should also be confirmed. If the FiO_2 is less than the manufacturer's specification at the given flow, the pellet canisters are probably exhausted and should be replaced.[28, 29] Last, concentrator air inlet filters must be cleaned weekly. In the home setting, providing the patient or caregiver with a simple checklist form can help ensure that these important tasks are performed regularly.

In contrast to the hospital setting, O_2 supply problems in the alternative care setting cannot always be addressed immediately. For this reason, the clinician must ensure that all such systems have an emergency backup supply. This backup supply is normally provided by a large H/K gaseous cylinder, or at a minimum, an E cylinder. If the primary O_2 supply of a home care patient is by concentrator, the home care RT should notify the electric power company in writing that life-support equipment is in use; in the event of a power outage, many utility companies will try to give priority to that location. For patients in more remote geographic areas, an emergency gasoline electrical generator is often recommended.

Possible physical hazards to patients and caregivers include unsecured cylinders, ungrounded equipment, mishandling of liquid (resulting in burns), and fire.[24] Careful preliminary instruction, followed by ongoing assessment of the environment, can help minimize these problems. Bacterial contamination of nebulizer or humidification systems is another potential problem.[24] Infection control procedures designed to minimize bacterial contamination are discussed later in this chapter.

RULE OF THUMB

If an O_2 concentrator cannot supply at least 85% O_2 at 5 L/min, the pellet canisters are probably exhausted and should be replaced.

Delivery Methods

The most common O_2 delivery system for long-term care is the nasal cannula. Simple O_2 masks and air entrainment masks may also be used but are much less common. To decrease O_2 use and costs, numerous O_2-conserving devices have been developed, including transtracheal O_2 catheter, reservoir cannula, and demand or pulsed-dose O_2 delivery systems.

RULE OF THUMB

O_2-conserving devices exhibit performance comparable to a nasal cannula at approximately one-third to one-half the flow. Based on this knowledge, when switching a patient from a nasal cannula at 2 L/min to an O_2-conserving device, the RT would start out at half the original flow, in this case, 1 L/min. The RT would then assess the response using a pulse oximeter and adjust the flow accordingly.

The performance characteristics, advantages, and disadvantages of transtracheal O_2 catheters and reservoir cannulas are described in detail in Chapter 41. We focus here on the application of the transtracheal O_2 catheter and the technical aspects of demand-flow systems.

Transtracheal Oxygen Therapy

Transtracheal oxygen therapy (TTOT) is O_2 delivered via a catheter with a small orifice that is inserted through the skin and neck tissue into the trachea. Although uncommon, as described in Chapter 41, this delivery method offers advantages of improved cosmetic appearance and lower flows to achieve the same therapeutic effect. However, not all long-term O_2 patients are good candidates for TTOT, and only those who

Box 56-3 Self-Care Guidelines for Patients With Transtracheal Oxygen Catheters

- Never remove the catheter for more than a few minutes to avoid tract closure.
- Always keep the catheter clean.
- If you believe the catheter is not working properly even after cleaning it or if you cannot reinsert it, put on a nasal cannula and call your physician.
- If your humidifier pop-off is sounding, clear any hose blockage and clean the catheter.
- Never remove or insert the catheter while O_2 is flowing.
- Do not use antibiotics or other ointments at the site of catheter insertion.
- Try to keep the O_2 hose under your shirt, blouse, T-shirt, or pajama top and clipped to the top of your pants, skirt, or pajama bottom.
- Treat the O_2 hose as your lifeline by avoiding abuse or damage.
- If the equipment becomes split or broken or develops a permanent kink or foul odor, immediately discard and replace it. Catheters and hoses should be routinely replaced every 3 months.
- Always take catheter cleaning supplies, a nasal cannula, and a spare catheter when traveling.

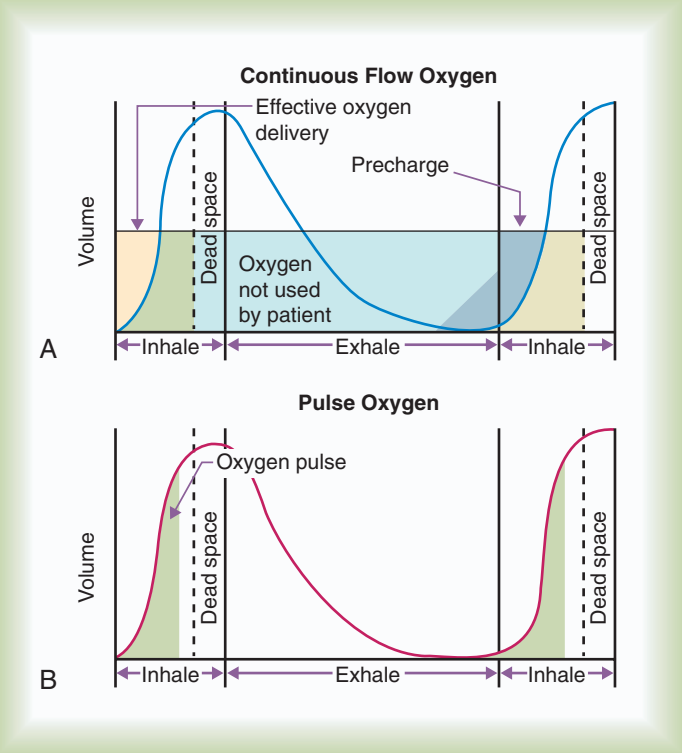

FIGURE 56-4 Demand-flow oxygen delivery. With continuous flow **(A),** most oxygen is delivered during the first half of inhalation, with the remainder wasted. With a coordinated pulse **(B),** most oxygen is delivered during the first 25% of inspiration, and no waste occurs. (Modified from O'Donohue WJ: The future of home oxygen therapy. Respir Care 33:1125, 1988.)

meet one or more of the following criteria should be considered: (1) cannot be adequately oxygenated with standard approaches, (2) do not comply well when using other devices, (3) exhibit complications from nasal cannula use, (4) prefer TTOT for cosmetic reasons, and (5) have need for increased mobility.[30]

As with most modalities in alternative care settings, the success of TTOT depends mainly on effective patient education and ongoing self-care with professional follow-up. Key patient responsibilities include routine catheter cleaning and recognizing and troubleshooting common problems. Box 56-3 describes key self-care guidelines for patients with transtracheal O_2 catheters.

Demand-Flow Oxygen Systems

A demand-flow O_2 delivery device, also known as a pulsed-dose **O2-conserving device**, uses a flow sensor and valve to synchronize gas delivery with the beginning of inspiration.[31] As indicated in Figure 56-4, *A*, with continuous O_2 flow, most of the effective O_2 delivery occurs during the first half of inspiration. All the O_2 delivered during the latter half of inspiration and throughout most of expiration is wasted. Figure 56-4, *B*, shows the effect of a synchronized pulse of O_2 delivered at the beginning of inspiration. Ideally, this O_2 pulse should occur during the first quarter of inspiration. Under these conditions, a pulsed O_2 system can produce SaO_2 levels equal to levels seen with continuous flow, while using 60% less O_2.[32]

In theory, demand-flow O_2 systems provide the greatest savings in O_2 use for a given level of arterial saturation. Recent improvements to demand-flow systems have made them more reliable and user-friendly, addressing the major disadvantages of earlier versions. As a result of these improvements and the ability of these devices to increase the duration of flow by two or three times, they have now gained wide acceptance.[31,33]

Selecting a Long-Term Oxygen Delivery System

As when selecting hospital-based O_2 therapy systems, the "three P's" should always be considered when selecting a long-term O_2 system: purpose, patient, and performance. The goal is always to match the *performance* of the equipment to both the objectives of therapy *(purpose)* and the *patient's* special needs. Patients requiring low-flow home O_2 and enhanced mobility should be considered for a portable concentrator alone, or one with a conserving feature or a liquid O_2 setup with a pulsed-dose O_2-conserving device.

Problem Solving and Troubleshooting

Most problems with long-term O_2 delivery systems are related to people. Patients and caregivers often fail to follow instructions or comply with the prescribed therapeutic or maintenance regimen.[24] Generally, caregivers should be allowed to operate and maintain O_2 delivery devices only after they have been instructed by credentialed RTs and have demonstrated the appropriate level of skill. In no case should the patient or caregiver be allowed or instructed to alter flow settings. Instead,

MINI CLINI

Selecting a Long-Term Oxygen Delivery System

PROBLEM: The following three patients require long-term O_2: (1) a stable home care patient with restricted activity needing low FiO_2; (2) an active home care patient with low FiO_2 needs who desires increased mobility; and (3) a patient in a long-term care facility with a tracheostomy who needs moderate levels of O_2 and high humidity. Select the best O_2 delivery system for each patient.

Solution: *Patient 1:* Because most home care patients who need O_2 are relatively stable, and because FiO_2 needs are minimal, traditional low-flow therapy by nasal cannula (using a concentrator) is the most common and accepted approach. When combined with a portable gas cylinder (for backup and limited walking), this combination is ideal for patients with restricted activity.

Patient 2: For an active patient with low FiO_2 needs who desires increased mobility, a conserving device used in conjunction with a portable concentrator (coupled with a home-based concentrator) is the ideal choice. Given that selected models of reservoir cannulas are poorly accepted by some patients, the choice of conserving device usually narrows to a transtracheal catheter or a demand-flow/pulse-dosed system. Patients who meet the criteria for TTOT and can provide meticulous self-care should be considered for TTOT. Alternatively, demand-flow/pulsed-dose systems are also a viable choice.

Patient 3: Patients with artificial airways in alternative sites who need O_2 present a special problem. Because of high O_2 use and infection concerns, an O_2-powered air entrainment nebulizer is unsatisfactory. Instead, a compressor-driven humidifier with supplemental O_2, bled in at low flows from a concentrator or liquid system, should be used. In this case, the RT must confirm the FiO_2 by calibrated analyzer.

when in doubt, they should be taught to switch to the backup supply at the same liter flow.

Technical problems are most common with TTOT and demand-flow systems. Most problems with TTOT are related to initial catheter insertion or ongoing maintenance. Most problems with demand-flow systems are based on the current limits of this technology.

The most common complications of TTOT are listed in Box 56-4. Although these problems occur infrequently, the clinician must be on constant guard for their occurrence. In particular, the RT should immediately report any evidence of tract tenderness, fever, excessive cough, increased dyspnea, or subcutaneous emphysema to the patient's physician.

To avoid complications or product failure, catheters and their tubing should be replaced every 3 months, at which time a checkup by the physician is also recommended. The patient or caregiver should clean the catheter every day, per the self-care guidelines listed within this chapter. Patients should be instructed always to put on a nasal cannula and to call the physician if any major problem occurs.

Box 56-4 Complications of Transtracheal Oxygen Therapy

- Bleeding*
- Pneumothorax*
- Bronchospasm*
- Subcutaneous emphysema
- Catheter dislodgment or lost tract
- Increased sputum production
- Blockage by inspissated mucus
- Infection or abscess
- Extensive self-care and cleaning to avoid infection or blockage
- Tract tenderness

*Complications associated mainly with insertion.

Box 56-5 Potential Problems With Demand-Flow Oxygen Delivery Systems

- The devices can be cumbersome and cosmetically unattractive.
- The initial and maintenance costs of equipment can be high and not fully reimbursed.
- Earlier devices may possess poor response times and delays in valve opening or closing.
- The devices tend to be fragile and can be damaged easily if they fall.
- Most units require a battery, which needs to be charged or replaced.
- The catheters and sensors may malfunction because of sensor dislodgment or plugging or changes in breathing problems.

Similarly, there can be problems with the use of demand-flow or pulsed-dose O_2-conserving systems. Although improvements to these devices have significantly increased their use, these units tend to add to the weight of portable setups, and they can easily be damaged. These and other potential problems with demand-flow O_2 delivery systems are listed in Box 56-5.[33]

VENTILATORY SUPPORT IN ALTERNATIVE SETTINGS

Providing successful ventilatory support outside the acute care hospital requires careful patient selection and good discharge planning.[34] Key factors include an interdisciplinary team approach, effective caregiver and family education, thorough assessment and preparation of the environment, and careful selection of needed equipment and supplies. Properly planned ventilatory support delivered in alternative settings can provide major benefits for both the patient and family, with substantial savings in health care costs.[35]

Patient Selection

Most patients needing ventilatory support outside the acute care hospital fall into one of the following three broad categories:[36]

1. Patients unable to maintain adequate ventilation over prolonged periods (in particular, noninvasive nocturnal or intermittent use)
2. Patients requiring continuous mechanical ventilation for long-term survival
3. Patients who are terminally ill with short life expectancies

Table 56-5 provides more detailed profiles of these patient groups. In addition to adults, a growing number of ventilator-assisted children are being managed in alternative settings. The same basic principles of discharge planning and patient care for adult patients should be followed for ventilator-assisted children.[37]

Regardless of diagnosis, patients being considered for ventilatory support in alternative settings must be medically and psychologically stable. In regard to assessing patient stability, Box 56-6 outlines the criteria developed by the American College of Chest Physicians (ACCP).[38]

Settings and Approaches

The most common setting for ventilatory support outside the acute care hospital is the home. Additional sites include long-term care facilities, including specialized long-term units such as LTACHs, designed specifically for ventilator patients.[38,39]

TABLE 56-5

Profiles of Patient Groups Requiring Ventilatory Support in Alternative Settings

Group Description	Diseases Involved
Profile 1	
Mainly composed of neuromuscular and thoracic wall disorders; particular stage of disease process allows patient certain periods of spontaneous breathing time during day; generally requires only nocturnal mechanical support	Amyotrophic lateral sclerosis Multiple sclerosis Kyphoscoliosis and related chest wall deformities Diaphragmatic paralysis Myasthenia gravis
Profile 2	
Requires continuous mechanical ventilatory support associated with long-term survival rates	High spinal cord injuries Apneic encephalopathies Severe COPD Late-stage muscular dystrophy
Profile 3	
Usually returns home at request of patient and family; patient's condition is terminal, life expectancy is short, and patient and family wish to spend remaining time at home; patients usually pose management problems in the home because of their rapidly deteriorating conditions	Lung cancer End-stage COPD Cystic fibrosis

Based on individual evaluation of patient need, one of the following two major support approaches may be considered: (1) invasive or (2) noninvasive support. In alternative settings, invasive ventilatory support always involves application of positive pressure ventilation by tracheotomy. Noninvasive approaches include positive pressure and negative pressure ventilation via an intact upper airway or abdominal displacement methods.[40,41]

Standards and Guidelines

Standards and guidelines for ventilatory support outside the acute care hospital continue to evolve.[38,42] The AARC developed a clinical practice guideline on long-term invasive mechanical ventilation in the home.[43] Excerpts from these guidelines appear in Clinical Practice Guideline 56-3.

Special Challenges in Providing Home Ventilatory Support

Institutions that provide ventilatory support in alternative settings differ from acute care facilities mainly in their level of technology support. The home setting not only lacks this support but also must depend extensively on nontechnical, nonprofessional caregivers. For these reasons, providing ventilatory support in the home presents many special challenges.

Prerequisites

For home ventilatory support to be successful, several prerequisites must be met, including the following:[44]

- Willingness of family to accept responsibility
- Adequacy of family and professional support
- Overall viability of the home care plan
- Stability of patient
- Adequacy of home setting

In regard to the home setting, the same factors listed in Box 56-1 should be evaluated for patients being considered for home ventilatory support.

Box 56-6 Criteria to Determine Patient Stability for Ventilatory Support in Alternative Care Settings

- Ability to tolerate mechanical ventilation
- Acceptable arterial blood gas results and other blood chemistry (e.g., complete blood count)
- Relatively low FiO_2 needs (generally ≤40%)
- Psychological stability
- Absence of life-limiting comorbidities, including cardiac dysfunction and arrhythmias
- PEEP should not exceed 10 cm H_2O
- Ability to clear airway secretions by cough, suction, or cough-assist device
- Tracheostomy tube, as opposed to endotracheal tube, for invasive ventilation
- No readmissions expected for >1 month

56-3 Long-Term Invasive Mechanical Ventilation in the Home

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

Patients requiring invasive long-term ventilatory support have shown:

- Inability to be completely weaned from invasive ventilatory support *or*
- Progression of disease etiology that requires increasing ventilatory support

Conditions that meet these criteria may include but are not limited to:

- Ventilatory muscle disorders
- Alveolar hypoventilatory syndrome
- Primary respiratory disorders
- Obstructive diseases
- Restrictive diseases
- Cardiac disorders including congenital anomalies

CONTRAINDICATIONS

Contraindications to long-term home mechanical ventilation include:

- Unstable condition that requires a level of care or resources unavailable in the home
  - FiO2 requirement >0.40
  - PEEP >10 cm H_2O
  - Need for continuous invasive monitoring (adults)
  - Lack of mature tracheostomy
- Patient's choice not to receive home mechanical ventilation
- Lack of an appropriate discharge plan
- Unsafe physical environment as determined by the patient's discharge planning team
  - Presence of fire, health, or safety hazards, including unsanitary conditions
  - Inadequate basic utilities (e.g., heat, air conditioning, electricity)
- Inadequate resources for care in the home
  - Financial
  - Personnel (e.g., inadequate medical follow-up, inability of patient to care for self, inadequate respite care for caregivers, inadequate numbers of competent caregivers)

PRECAUTIONS AND POSSIBLE COMPLICATIONS

Deterioration or acute change in clinical status of patient. The following may cause death or require rehospitalization for acute treatment:

- *Medical:* Hypocapnia, respiratory alkalosis, hypercapnia, respiratory acidosis, hypoxemia, barotrauma, seizures, hemodynamic instability, airway complications, respiratory infection, bronchospasm, exacerbation of underlying disease, or natural course of the disease
- *Equipment-related:* Failure of the ventilator, malfunction of equipment, inadequate warming and humidification of the inspired gases, inadvertent changes in ventilator settings, accidental disconnection from ventilator, accidental decannulation
- *Psychosocial:* Depression, anxiety, loss of resources (caregiver or financial), detrimental change in family structure or coping capacity

ASSESSMENT OF NEED

- Determination that indications are present and contraindications are absent
- Determination that one or more of the following goals can be met
  - To sustain and extend life and enhance quality of life
  - To reduce mortality
  - To improve or sustain physical and psychological function and enhance growth and development of pediatric patients
  - To provide cost-effective care
- Determination that no continued need exists for higher level of services
  - Determination that frequent changes to the plan of care will not be needed

ASSESSMENT OF OUTCOME

At least the following aspects of patient management and condition should be evaluated periodically as long as the patient receives mechanical ventilation in the home:

- Implementation and adherence to plan of care
- Quality of life
- Patient satisfaction
- Resource satisfaction
- Growth and development in the pediatric patient
- Change in prognosis
- Unanticipated morbidity, including need for higher level site of care
- Unanticipated mortality

MONITORING

Frequency of monitoring should be determined by the ongoing individualized care plan and be based on the patient's current medical condition. The ventilator settings, proper function of equipment, and the patient's physical condition should be monitored and verified (1) with each initiation of invasive ventilation to the patient, including altering the source of ventilation, as from one ventilator or resuscitation bag to another ventilator; (2) with each ventilator setting change; (3) after moving the patient; (4) on a regular basis as specified by individualized plan of care.

All appropriately trained caregivers, both professional and appropriately trained lay caregivers, should follow the care plan and implement the monitoring that has been prescribed. After being trained and evaluated on their level of knowledge and ability to respond to each intervention, lay caregivers, with documented competency, may operate equipment, perform routine maintenance tasks, monitor equipment, and perform personal care required.

After completing training and demonstrating competency and if directed in the plan of care, lay caregivers should monitor the following:

- Patient's physical condition
  - Respiratory rate
  - Heart rate
  - Color changes
  - Chest excursion
  - Diaphoresis
  - Lethargy
  - Blood pressure
  - Body temperature

Continued

56-3 Long-Term Invasive Mechanical Ventilation in the Home—cont'd

AARC Clinical Practice Guideline (Excerpts)*

- Ventilator settings (frequency should be specified in the plan of care)
  - Peak pressures
  - PEEP level (if applicable)
  - Preset tidal volume
  - Appropriate humidification of inspired gases
  - Frequency of ventilator breaths
  - Temperature of inspired gases (if applicable)
  - Verification of FiO_2
  - Heat and moisture exchanger function
- Equipment function (frequency should be specified in the plan of care)
  - Appropriate configuration of circuit
  - Internal and external battery power levels
  - Alarm function
  - Overall condition of all equipment
  - Cleanliness of filters—according to manufacturer's recommendation
  - Self-inflating bag-valve-mask—cleanliness and function

Health care professionals should perform a thorough, comprehensive assessment of the patient and the patient-ventilator system on a regular basis as prescribed by the plan of care. In addition, the health care professional should implement, monitor, and assess results of other interventions as indicated by the clinical situation and anticipated in the care plan.

- Pulse oximetry—should be used to assess patients requiring a change in prescribed FiO_2 or in patients with a suspected change in condition; a physician's order for pulse oximetry must be obtained before testing is performed
- End-tidal CO_2—may be useful for establishing trends in CO_2 levels; a physician's order for end-tidal CO_2 monitoring must be obtained before it is performed
- Ventilator settings
- Exhaled tidal volume
- Analysis of fraction of inspired O_2

Health care professionals are also responsible for maintaining interdisciplinary communication concerning the plan of care. Health care professionals should integrate the respiratory plan of care into the patient's total care plan. The plan of care should include:

- All aspects of patient's respiratory care
- Ongoing assessment and education of the caregivers involved

**For the complete guideline, see American Association for Respiratory Care: Clinical practice guideline: long-term invasive mechanical ventilation in the home—2007 revision and update. Respir Care 52:1056, 2007.*

Planning

Successful home ventilatory support requires extensive planning, education, and follow-up by all members of the home care team. Basic steps in the discharge process for a ventilator-dependent patient include the following:

1. Family is consulted regarding feasibility.
2. Physician writes appropriate orders.
3. Discharge planner coordinates efforts of team members and discharge plan is formulated.
4. Physician and other team members discuss plan with family and caregivers.
5. Education and training are initiated and completed.
6. Patient and family are prepared for discharge.
7. Home layout is assessed with necessary changes made.
8. Equipment and supplies are readied.
9. Discharge planner meets with team and makes final preparations.
10. Patient is discharged (with trial period, if necessary).
11. Local power company is notified regarding the presence of life-support equipment; appropriate backup power (battery or compressed gas source) is made available.
12. Ongoing and follow-up care is provided by visiting nurse, RT, and other health care professionals (as necessary).

Caregiver Education

To prepare patients, family members, and other caregivers properly for home discharge, a comprehensive educational program must be undertaken and completed. Essential skills that must be taught include the following:[34]

- Simple patient assessment
- Airway management, including tracheostomy and stoma care, cuff care, suctioning, cough-assist, changing artificial airways or ties
- Chest physical therapy techniques, including percussion, vibration, and coughing
- Medication administration, including oral and aerosol
- Patient movement and ambulation
- Equipment operation and maintenance
- Equipment troubleshooting
- Cleaning and disinfection
- Emergency procedures

Emergency situations that caregivers must be trained to recognize and deal with properly include the following:

- Ventilator or power failure
- Ventilator circuit problems
- Airway emergencies
- Cardiac arrest

All caregivers should successfully complete this educational process. Training generally requires a minimum of 1 to 2 weeks, over which time several education sessions can take place and cover instruction, demonstration, caregiver practice, and evaluation. Caregivers should be strongly encouraged to complete a course in basic life support, such as is offered by the American Heart Association, before the patient is discharged. Ideally, the patient should have a trial period on the actual home ventilator before discharge. In the early stages after discharge, patient follow-up by an RT likely should occur every day. As patient and caregivers become more familiar with the equipment and procedures, follow-up visits generally decrease to about once per month.[45,46]

Invasive Versus Noninvasive Ventilatory Support

Until recently, invasive positive pressure ventilation by tracheostomy was the default standard for long-term mechanical ventilation, especially for patients requiring 24-hour support. However, long-term tracheostomy is associated with some potential problems, including secretion retention, infection, aspiration, and ventilator-associated pneumonia, as well as communication difficulties between caregivers and patients. Because many long-term care facilities treat a tracheostomy as an open wound, patient placement at certain sites is prohibited.[47] Last, invasive ventilation by tracheostomy poses significant limits on the patient's quality of life. For these reasons, noninvasive support is becoming increasingly popular. Noninvasive ventilatory support involves any method designed to augment alveolar ventilation without an endotracheal airway. **Noninvasive ventilation (NIV)** is usually the first choice. Any individual requiring mechanical ventilation can be supported with NIV if the following conditions are met:[47]

- The patient is mentally competent, cooperative, and not using heavy sedation or narcotics.
- Supplemental O_2 therapy is generally minimal (FiO_2 ≤40%).
- SaO_2 can be maintained at greater than 90% by aggressive airway clearance techniques.
- Bulbar muscle function is adequate for swallowing and airway protection.
- No history exists of substance abuse or uncontrollable seizures.
- Unassisted or manually assisted peak expiratory flows during coughing exceed about 3 L/sec.
- No conditions are present that interfere with NIV interfaces (e.g., facial trauma, inadequate bite for mouthpiece, presence of orogastric or nasogastric tube, or facial hair that can hamper an airtight seal).

Patients who can benefit from NIV generally fall into one of two categories.[48] Patients in the first category have conditions in which cessation of ventilation could lead to imminent death. This category includes both acutely ill patients (patients with asthma, acute exacerbation of COPD, or pulmonary edema) and patients requiring long-term, 24-hour support (some patients with quadriplegia or patients with certain neuromuscular disorders). Patients in the second category have conditions in which NIV may offer clinical benefit, but cessation is not life-threatening. These patients generally require only intermittent or nocturnal support. Patients in this category include patients with chronic neuromuscular and chest wall diseases, such as muscular dystrophy and kyphoscoliosis. The application of long-term NIV for patients with obstructive disorders such as end-stage COPD or cystic fibrosis is much less common.[48] Relative contraindications to NIV include severe upper airway dysfunction, copious secretions that cannot be cleared by spontaneous or assisted cough, and O_2 concentration requirements exceeding 40%.[48]

Equipment

Box 56-7 lists the essential equipment and supplies needed for ventilator-dependent patients in alternative settings.[34,37]

Selecting Appropriate Ventilator

The choice of ventilator for a patient in an alternative care setting should be based on the patient's clinical need and the

Box 56-7 Essential Equipment and Supplies for Ventilator-Dependent Patients in Alternative Care Settings

EQUIPMENT

- Ventilator(s)
- Manual resuscitator (bag-valve-mask unit)
- Heated ventilator humidifier with thermostat and heat and moisture exchanger
- Monitoring or alarm devices (including remote where necessary)
- 12-V battery and battery charger
- Air compressor
- O_2 source
- Power strip or surge protector
- Suction machine with backup (manual or battery)
- Stethoscope and sphygmomanometer
- O_2 analyzer
- Pulse oximeter
- Hospital bed with table
- Patient lift
- Bedside commode, urinal, or bedpan
- Wheelchair

SUPPLIES

- O_2
- O_2 delivery devices, including manual resuscitator
- Airway interface (masks, mouthpieces, tracheostomy tubes)
- Tracheostomy tube inner cannulas
- Extra tracheostomy tubes including a tube one size smaller
- Tracheostomy care kits
- Ventilator circuits
- Bacterial filters
- Connecting tubing (aerosol, O_2, suction)
- Suction catheters
- Disposable gloves
- Distilled or sterile water
- Small volume nebulizer or metered dose inhaler with ventilator adapters, if appropriate
- Cleaning and disinfection supplies (10-ml syringe, 15- to 22-mm tubing adapters)

Box 56-8 Absolute Contraindications Against Using Noninvasive Ventilation

- Need for immediate intubation
- Hemodynamic instability
- Uncooperative patient
- Facial burns or trauma
- Inadequate airway protection
- Patent tracheoesophageal fistula

available support resources. In some cases, patient needs may dictate that more than one ventilator be provided.[43] A second backup ventilator should be provided for patients who cannot maintain spontaneous ventilation for more than 4 consecutive hours, for patients living in an area where a replacement ventilator cannot be secured within about 2 hours, and for patients whose care plan requires mechanical ventilation during mobility.[48]

Generally, ventilators chosen for care in alternative settings must be dependable and easy for caregivers to operate. If mobility is an essential element of the patient's care plan, the ventilator system selected should be portable. If the patient is receiving continuous ventilatory support in any alternative setting, external battery backup is required, and emergency AC power by way of a generator is recommended.

If invasive ventilation by tracheostomy is the selected approach, the best choice is a positive pressure ventilator. The invasive route also requires a humidification system, preferably a servo-controlled heated humidifier with alarms. Patients with a tracheostomy without retained secretions may use a heat and moisture exchanger during transport or to enhance their mobility.[43] For patients with an intact upper airway, a device capable of NIV is the first choice, unless contraindicated (Box 56-8 lists the absolute contraindications against using NIV).[49] In patients with an intact upper airway for whom NIV is contraindicated or unsuccessful, a negative pressure ventilator may be considered.

Positive Pressure Ventilators

Table 56-6 lists the essential, recommended, and optional features of positive pressure ventilators used in alternative care settings. An *essential* feature is basic to safe and effective operation in most patient care settings. A *recommended* feature helps provide optimal patient management. An *optional* feature is possibly useful in limited situations but not needed for most patients.[42,50]

As in the acute care setting, the use of volume-cycled versus pressure-limited ventilators is debated in alternative settings. Although volume-cycled ventilation has been the predominant mode of support in these settings, pressure-limited ventilation is gaining popularity for use in selected patients.

As shown in Figure 56-5, there are many new positive pressure ventilators designed for use in alternative settings. These ventilators can be used on adults or pediatric patients weighing at least 5 kg. Some are approximately the size and weight of a laptop computer and have many of the capabilities of much larger mechanical ventilators used in alternative sites and in acute care. These new ventilators offer ventilator-dependent patients the advantages of greater mobility and space conservation. Many of these models also offer pressure support and can provide positive end expiratory pressure (PEEP) without having to add an adapter to the ventilator circuit.[51-53]

Many new positive pressure ventilators designed for alternative care settings (see Figures 56-5 and 56-6) have an internal battery, which can provide several hours of use in the event of a power failure. For longer periods of use away from AC line power, many of these devices can run for 10 to 12 hours using an external battery.

TABLE 56-6

Essential, Recommended, and Optional Features of a Positive Pressure Ventilator for Use in an Alternative Care Setting

Feature	Necessity
Positive pressure tidal breaths	Essential
Mandatory rate	Essential
Flow or inspiratory-to-expiratory or inspiratory time	Recommended*
Expiratory pressure (PEEP)	Recommended*
FiO_2 to 1	Optional
Patient spontaneous breath (e.g., CPAP, intermittent mandatory ventilation)	Optional
Breath-triggering mechanism (flow or pressure sensors to initiate ventilator breath)	Recommended*
Flow-timing interaction (e.g., pressure support)	Optional
Feedback control (e.g., mandatory minute ventilation)	Optional

*Essential if the patient has intact ventilatory drive and respiratory muscles or if the possibility of partial or complete ventilator independence is anticipated.

TABLE 56-7

Adverse Effects of Noninvasive Ventilation Interfaces and Possible Corrective Actions

Interface	Adverse Effect	Remedy
Nasal and oronasal masks	Discomfort	Proper fit, adjust strap tension, change mask type
	Nasal bridge redness, pressure sores, conjunctivitis	Reduce strap tension, use forehead spacer, try nasal pillow, use artificial skin
	Acneiform rash	Cortisone cream, alternative (gel) mask
Oronasal masks	Impede speech and eating	Permit periodic removal if tolerated by the patient
	Claustrophobia	Choose clear masks with minimal bulk
	Aspiration	Exclude patients unable to protect airway; nasogastric tubes for patient with nausea and abdominal distention
Mouthpieces/ lip seals	Interference with swallowing, salivary retention	Coaching, adaptation
	Pressure on lips, cheeks	Proper fit, strap adjustment
	Dental deformity	Orthodontic consultation
	Aerophagia	Simethicone, coaching
	Allergic reactions	Change prosthetic materials
	Nasal air leaking	Nose clips
	Accidental disconnection	Appropriate alarms in ventilator-dependent patients

Additionally, time-triggered or patient-triggered, pressure-limited, flow-cycled devices (pressure support with timed backup) have been successfully applied in alternative settings.[41,54,55] Many units are currently available (Figure 56-7) that are specifically designed to provide this type of support, usually noninvasively by nasal or oronasal (full-face) masks.[41,56,57]

Most positive pressure ventilators can be used to provide NIV.[48,58] NIV is normally provided by pressure-targeted ventilation regardless of the cause of ventilatory failure. The newest generation of these ventilators include alarm capabilities and internal battery backup.[56]

The biggest challenge with NIV is not selecting the right ventilator but getting a good, comfortable, minimal leak interface. Interfaces commonly found in alternative care settings include oronasal (full-face) masks; nasal masks; nasal "pillows"; and simple, flanged, or custom mouthpieces. For long-term use, some patients prefer alternating between devices. A patient may prefer a simple mouthpiece for easy accessibility during the day, with a nasal mask providing support at night.[48] Table 56-7 summarizes common problems associated with NIV interfaces and how to correct them.[41,59]

All positive pressure ventilators used in alternative settings must have an alarm to indicate loss of power (pneumatic or electrical). Portable volume-cycled ventilators should also incorporate a high-pressure alarm or cycle override. For patients with conditions in which cessation of ventilation would cause death, a patient-disconnect alarm (low-pressure or low-exhaled volume) must be provided.[43,48] In some settings, a remote alarm or secondary disconnect alarm, or both, may be needed. A secondary alarm may be based on chest wall impedance and cardiac activity, exhaled volume, end-tidal CO_2, or pulse oximetry with alarm capabilities.[43] For patients in alternative settings who require only intermittent NIV, a loss-of-power alarm is generally sufficient.[48]

Negative Pressure Ventilators

Compared with NIV, negative pressure ventilation is harder to apply, more cumbersome, and less well tolerated (because of poor breath synchronization). Negative pressure ventilation tends to limit patient mobility and can worsen upper airway obstruction in susceptible patients. Nonetheless, negative pressure ventilation may be appropriate in patients who are unable to use NIV or who have failed NIV trials.[41] Negative pressure ventilation may also be considered for patients who require frequent airway access for suctioning.[47,60]

The original negative pressure ventilator was the *iron lung*, used for patients needing ventilator assistance after poliomyelitis. For practical reasons, the cumbersome iron lung was essentially replaced by the chest cuirass and wrap or "pneumosuit."

The chest cuirass (a rigid shell) and wrap-type systems (nylon fabric surrounding a semicylindrical tentlike support) are simply enclosures that allow application of negative pressure to the thorax. These devices require a separate electrically powered negative pressure generator. An example of a negative pressure generator used to power cuirass or wrap-type systems is the Philips-Respironics NEV-100 (Phillips-Respironics, Murrysville, PA).[60]

Evaluation and Follow-Up

Patient parameters to be monitored during positive pressure ventilation are essentially the same parameters that are assessed in the acute care setting, with an emphasis on simplicity.[61] The caregiver should assess the patient's vital signs, lung sounds, and sputum production on a daily basis; arterial blood gas analysis (by the RT) may be conducted monthly or only when changes in the care plan appear to be needed. Likewise, compliance and resistance measures are performed only when other evidence indicates the need.

Routine follow-up visits by the RT help ensure the success of patient management within the home and proper equipment maintenance and functioning. The patient's status should be carefully assessed, and appropriate care plan modifications should be recommended to the prescribing physician. Follow-up visits should occur about monthly, and a report documenting the status of the patient and equipment and progress toward care plan goals should be completed after each visit and maintained as part of the patient record.

OTHER MODES OF RESPIRATORY CARE IN ALTERNATIVE SITES

In addition to O_2 therapy and ventilatory support, other modes of respiratory care are now common in the alternative care setting. These may represent the primary therapy or may be used to supplement other modes of care. Included for discussion here are bland aerosol therapy, aerosol drug administration, airway care and clearance methods, nasal CPAP, and apnea monitoring.

Bland Aerosol Therapy

The delivery of bland aerosols has been common in alternative sites for many years. According to the AARC's Clinical Practice Guideline, bland aerosol therapy includes the delivery of sterile water or various concentrations of saline solution in aerosol form.[62] The aerosol can be produced by either an ultrasonic or jet (large volume) nebulizer. If using a jet nebulizer, a 50-psi air compressor is also required. Supplemental O_2 is provided by either a concentrator or liquid supply system.

Depending on the patient's condition and therapeutic objectives, bland aerosol therapy may be either continuous or intermittent. Though bland aerosol alone may have little effect on the properties of mucus or its clearance, it may be useful as an adjunct to other airway clearance procedures.[62,63]

The potential problem is infection from contaminated equipment. To reduce the incidence of infection, equipment and patient delivery systems must be cleaned and changed regularly, as noted elsewhere in this chapter.

Aerosol Drug Administration

As in the acute care setting, the aerosol route is popular for drug administration to respiratory patients in alternative care settings. As described in Chapter 39, drug categories commonly administered by the aerosol route include beta-adrenergic bronchodilators, anticholinergic agents, and antiinflammatory drugs.

Most pulmonary drugs are available in either metered dose inhaler or dry powder inhaler form. Alternatively, the caregiver can use a small volume nebulizer powered by a low output diaphragm compressor.[64]

Airway Care and Clearance Methods

Patients in alternative care settings with tracheostomies require both daily stoma care and tracheobronchial secretion clearance. Tracheostomy care can be provided by any trained caregiver, but tube changes should generally be performed only by an RT or a physician.

In most alternative care settings, tracheobronchial clearance is often accomplished by suctioning using a portable electrically powered suction pump with collection bottle and connection tubing. In accordance with the AARC Clinical Practice Guideline for suctioning of the patient at home, some patients may be taught to suction themselves. Proper suctioning procedures should also be taught to caregivers. Education and training on proper suctioning methods may begin before patient discharge from the acute care setting, with reinforcement and follow-up as needed.[65] Because many of these systems measure pressure in inches of mercury (in Hg), care must be taken to teach proper adjustment according to patient age. Daily maintenance and cleaning are required. In an alternative care setting, a single suction catheter commonly may be used for up to 24 hours but to prevent bacterial growth, catheters are often placed in a disinfecting solution between suctioning attempts.

RULE OF THUMB

For portable suction units calibrated in inches of mercury (in Hg), the following vacuum ranges are recommended (adjustment may be needed based on volume and viscosity of secretions):

Patient Category	Vacuum Setting (in Hg)
Infants	5-7
Children	7-12
Adults	12-15

Numerous methods are available for patients in an alternative care setting with an intact upper airway who need help with secretion clearance. These methods include both

patient-independent and caregiver-dependent techniques.[66] Patients can be taught to apply independently coughing, forced exhalation, active cycle of breathing, and autogenic drainage methods. Caregiver assistance is required with traditional postural drainage, percussion and vibration, and directed or assisted cough. Additional assistance can be provided by mechanical devices such as positive expiratory pressure mask, flutter valve, intrapulmonary percussive ventilator, and high-frequency chest compression vest.

Another airway clearance method involves the use of cough-assist devices such as the Emerson mechanical **inexsufflator**, or "coughlator." The inexsufflator uses alternating positive and negative pressure to simulate a cough as a form of lung expansion and airway clearance therapy. These devices can be especially effective with patients receiving NIV. The application of secretion clearance devices or techniques by nonprofessional caregivers should involve good preliminary instruction and ongoing follow-up by the RT working in any alternative site.[66] See Chapter 36 for more in-depth discussion of the inexsufflator and other secretion clearance devices.

Nasal Continuous Positive Airway Pressure Therapy

Nasal CPAP therapy has become an accepted form of home care used to treat sleep apnea-hypopnea syndrome. For Medicare reimbursement of home nasal CPAP equipment, the diagnosis of sleep apnea must be confirmed by polysomnography, also known as a *sleep study*. With proper application and patient compliance, CPAP therapy can dramatically lessen or resolve the many problems associated with sleep apnea-hypopnea syndrome (morning headaches, daytime hypersomnolence, cognitive impairment). The patient's quality of life can be enhanced, and more severe complications, such as systemic and pulmonary hypertension and cor pulmonale, may be reduced.[67]

Equipment

A typical nasal CPAP apparatus consists of a flow generator capable of establishing varying levels of PEEP or CPAP, a circuit, and a patient interface (e.g., nasal mask, nasal pillows). One of the most common interfaces in alternative settings is the nasal mask (Figure 56-8). However, many patients requiring nocturnal CPAP do prefer to use a full-face mask instead of a nasal mask. Most systems provide manually adjustable pressures in the range of 2.5 to 30 cm H_2O. Most units have a ramp feature that gradually increases the pressure to the prescribed level over a time interval to increase comfort and therapy compliance.

Some patients with sleep apnea require NIV. The difference in PEEP and peak airway pressure aids the patient's inspiratory effort, improving ventilation. NIV in these patients may also reduce the adverse effects associated with nasal CPAP therapy and improve patient tolerance.[68]

Determining Proper Continuous Positive Airway Pressure Level

The proper CPAP level for a patient is determined by one of several methods. The most common method is to conduct the sleep study, titrating different levels of CPAP. Observed changes in the apnea-hypopnea index are correlated with the various CPAP levels. The prescribed level of CPAP is the lowest pressure at which apneic episodes are reduced to an acceptable frequency and duration.

FIGURE 56-8 An example of a nasal mask. (Mirage Kidsta Mask, Courtesy ResMed Inc, San Diego, CA.)

More recently, CPAP units that automatically adjust the pressures to maintain airway patency are commonly used. These self-titrating or auto-CPAP devices generally result in use of the lowest effective pressures and better patient compliance, while reducing the need for a subsequent sleep study and titration.[69]

Alternatively, CPAP may be titrated against pulse oximetry data (Figure 56-9). In this case, the goal is to use the lowest CPAP that maintains adequate arterial saturation (SpO_2 <90%).

Use and Maintenance

Once proper CPAP level is determined, the patient is fitted for a mask and trained in the proper use, cleaning, and maintenance of the equipment. Typical patient instructions for self-administration of nasal or full-face mask CPAP therapy are provided in Box 56-9.

Problem Solving and Troubleshooting

Patient problems associated with nasal or full-face mask CPAP therapy include skin irritation, conjunctivitis, epistaxis, and nasal discomfort (dryness, burning, and congestion). Skin irritation is usually because of tight mask straps or a dirty patient interface. Persistent redness on the face or around the nose is the primary sign. Adjusting the straps (while maintaining a good mask seal) can help prevent irritation. In addition, the patient interface should be cleaned daily to remove dirt and

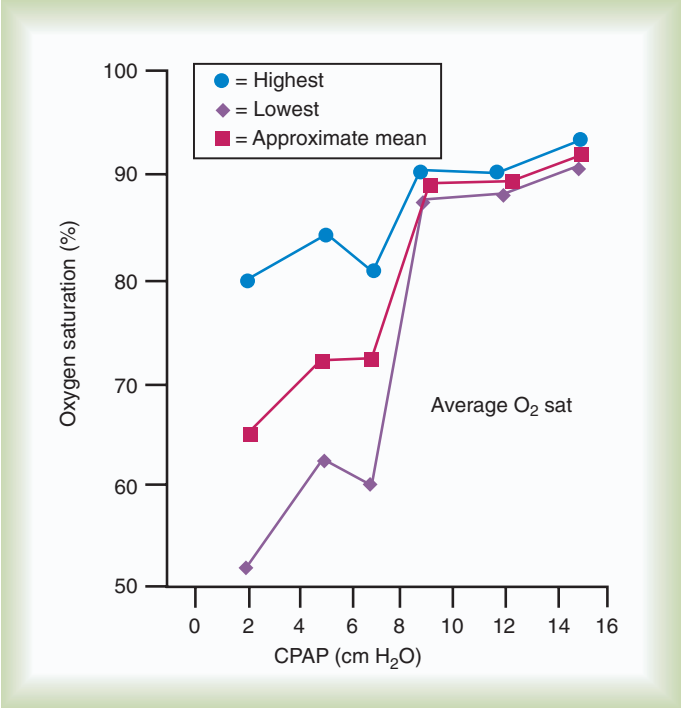

FIGURE 56-9 Illustration of CPAP levels and corresponding oxygen saturations while patient was asleep and using nasal CPAP. (Modified from Sleeper GP, Strohl KP, Armeni MA: Nasal CPAP for at-home treatment of obstructive sleep apnea: a case report. Respir Care Clin N Am 30:90, 1985.)

facial oils. Even with proper care, masks and nasal pillows should be replaced approximately every 3 to 6 months or sooner if leakage or discomfort occurs.

Conjunctivitis probably is the result of mask leakage around the bridge of the nose, which is easily corrected by ensuring a good seal in this area. Epistaxis and nasal discomfort are associated with drying of the nasal mucosa—a particular problem in cold, dry winter climates. Methods used to overcome excessive drying include in-line humidifiers, chin straps (to decrease loss of upper airway moisture), and saline nasal sprays.[70] Because none of these methods have proved satisfactory for all patients, selection should be based on individual patient acceptance and observed improvement in comfort. However, almost all patients receiving nocturnal CPAP therapy benefit from the addition of an in-line humidifier.

The most common problem with the CPAP apparatus is an inability to reach or maintain the set pressure. This problem is usually due to either inadequate flow or, more commonly, system leaks. Common causes of leaks include inappropriate patient interface (mask vs. nasal pillows) or pressure loss through an open mouth. As part of their initial training, patients and caregivers should be taught how to recognize and correct these common problems. Box 56-10 outlines the procedures patients or caregivers can use to troubleshoot inadequate flows and system leaks.[71]

Follow-up with patients soon after they begin CPAP therapy is important to resolve complications promptly. If left

Box 56-9 Typical Patient Instructions for Self-Administration of Nasal or Full-Face Mask Continuous Positive Airway Pressure Therapy

EQUIPMENT PREPARATION

1. Place blower unit on a level surface (table or nightstand) close to where you sleep.
2. Ensure that the air exhaust and inlet vents are not obstructed.
3. Plug machine into a standard grounded (three-prong) electrical outlet.
4. Check air inlet filter to ensure it is in place and free of dust.
5. Connect one end of the tubing to the interface (e.g., mask, nasal pillows).
6. Attach interface to the nose or face.
7. Adjust headgear strap tightness to seat interface firmly onto the nose or face.
8. Turn on the blower and verify a flow of air.
9. Ensure proper fit and adjustment of mask and headgear. Air should not be leaking out around the bridge of the nose into the eyes or from the mask to upper lip.
10. CPAP therapy is now fully functional, but minor adjustments may be needed as use continues.

IN THE MORNING

1. Remove mask by slipping strap off back of head (you may leave the head strap connected between cleaning).
2. Turn off blower.
3. Wash interface every morning with a mild detergent, then rinse it with water.
4. Once dry, store interface in a plastic bag to keep it clean.

WEEKLY

1. Wipe off the blower unit with a clean, damp cloth.
2. Wash the head strap and circuit tubing.
3. Service the filters according to the instructions in your patient manual.

Box 56-10 Patient and Caregiver Instructions for Troubleshooting Continuous Positive Airway Pressure Equipment

INADEQUATE FLOW

1. Ensure that unit is plugged into a working electrical outlet.
2. Confirm that unit is turned on.
3. Ensure all connections are tight.
4. Confirm that airflow is coming from blower.
5. Ensure that the intake/exhaust vents are not obstructed.
6. Check the blower inlet filter to confirm that air can easily enter unit. If the filter appears obstructed, wash or replace it.
7. If there is still no flow, contact your home care provider.

AIR LEAKS

1. Check interface fit, and readjust mask or headgear if necessary.
2. Request a chin strap to help keep mouth closed.
3. If problem is not resolved, contact the home care provider for adjustments or a different interface such as nasal pillows.

unresolved, these issues often discourage the patient and result in decreased compliance and a return of original symptoms.[71]

MINI CLINI

Troubleshooting Nasal Dryness With Continuous Positive Airway Pressure

PROBLEM: A 43-year-old obese man with documented obstructive sleep apnea has been advised by his attending physician that home CPAP therapy at night is needed. The home care RT makes an appointment with the patient to assess his tolerance to the CPAP unit. During the visit, the patient notes that he has been experiencing nasal discomfort. How can the RT assist in problem solving with this specific complaint, and what are some of the other potential patient problems associated with CPAP therapy that the clinician should be alerted to?

Solution: CPAP devices use some type of patient interface such as a nasal mask or pillows, or full-face mask with supporting headgear. Complaints of nasal discomfort are common and are most likely due to the effects of dry airflow through the CPAP unit blower. However, other factors may aggravate the sensation of nasal irritation. Poor systemic hydration could worsen nasal mucosal drying. In addition, environmental humidity may be a factor. Cold, dry, winter climates can aggravate symptoms, as can dry, forced-air heating systems. In these cases, the RT might recommend increasing oral intake of fluids (if no restrictions on fluid intake), the installation of a room or heating system humidifier or the as-needed use of a saline nasal spray. Also, almost all patients receiving nocturnal CPAP therapy benefit from the addition of an in-line humidifier.

In addition to the above-mentioned factors, large leaks in the system can significantly increase flows and worsen the drying effect of these devices. Often such leaks originate from a poorly fitting patient interface. Consequently, these problems can be remedied by ensuring a proper fit via repositioning the interface or switching to one of the many alternative masks or nasal pillows available today.

Apnea Monitoring

Apnea monitors alert clinicians and caregivers of certain life-threatening events, most notably recurrent apnea, bradycardia, and hypoxemia. At-risk infants are frequently set up on apnea monitors while they are in the hospital. After extensive family instruction in both equipment use and resuscitation, some of these infants may be discharged to the home with this equipment.[72]

Most apnea monitors detect both respirations and heart rate and activate audio and visual alarms when preset high or low limits are reached. Follow-up visits by the RT are usually frequent at first but occur less often as the family becomes skilled with the equipment and monitoring routine. Some models record each alarm event and can be useful in monitoring the patient's progress. The "memory" of such monitors can be monitored continuously via an Internet connection or via periodic downloading. Apnea monitors are usually discontinued after an infant has a negative pneumocardiogram (sleep study) or when recorded memory reveals no events during a prescribed time frame—often 2 to 4 months from the initial setup.[72]

PATIENT ASSESSMENT AND DOCUMENTATION

Alternative care sites demand extensive patient assessment and documentation. These requirements are based on both stringent reimbursement criteria and the rehabilitation orientation characterizing these settings.

Institutional Long-Term Care

In institutions providing long-term care, the assessment and documentation process involves four key components: screening, treatment planning, ongoing assessment, and discharge (Figure 56-10).

Screening

On admission to a long-term care facility, all patients with a respiratory-related admitting diagnosis should be screened by an RT.[17] This screening is often accomplished mainly by a medical record review. During screening, the RT reviews the pertinent respiratory diagnosis, onset and severity of symptoms, current radiograph results, pulmonary function tests, arterial blood gas values, and other nonrespiratory treatment orders (e.g., physical therapy).

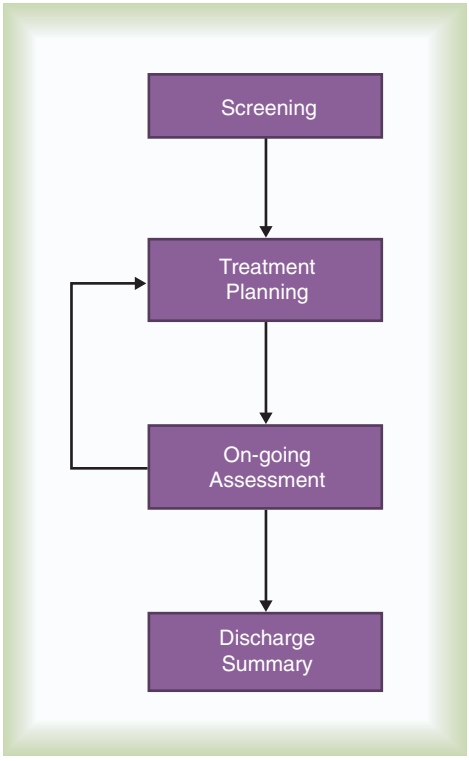

FIGURE 56-10 The assessment and documentation process in institutional subacute or long-term care.

If the review indicates the need for a more in-depth assessment, the RT can recommend a more complete evaluation. On receipt of the appropriate orders, the RT interviews the patient and conducts a physical assessment, including inspection, palpation, auscultation, and percussion. Key clinical findings include description of breath sounds; rate, depth, and pattern of respirations; heart rate; signs of dyspnea; cough; sputum production; level of consciousness; and ability of the resident to understand and follow commands. Also noteworthy are the resident's prior respiratory status, use of supplemental O_2, pulse oximetry, skin turgor, and medications.[17,18]

Treatment Planning and Ongoing Assessment

Based on the information obtained during the initial screening process, the RT designs a specific treatment plan. A typical treatment plan includes patient demographics, assessment information, short-term and long-term goals reflective of overall rehabilitation potential, and measures to be used to achieve such goals. A treatment plan for a resident of a long-term care facility with moderate to severe COPD would likely reflect the treatment goal of correcting hypoxemia through the use of low-flow O_2 and patient monitoring.[17,18]

After therapy has been initiated, the RT uses several other tools to monitor a patient's progress. In addition to regular treatment documentation, the RT should document a regular summary on each patient. This summary provides a synopsis of progress toward goal attainment, including changes in respiratory status, results of any additional tests, explanation of any patient education, and recommendations for additional therapy. Additionally, treatment plans and progress summaries become part of the resident's permanent record and are often required documentation for third-party reimbursement.[17,18]

Discharge Summary

When a patient reaches his or her maximum potential, has attained all set goals, or is discharged, the RT must complete a discharge summary. The discharge summary describes the complete course of respiratory therapy, including its success or failure.[17-19]

Home Care

A home care plan must specify not only the types of care provided but also a strategy for patient follow-up. The individual making the follow-up visits is often the visiting nurse, a physical therapist, or an RT. For patients receiving respiratory care at home, follow-up by a home care team member should occur regularly, particularly for patients on "hi-tech" equipment such as ventilators and apnea monitors.[12] Some patients may require more frequent follow-up, especially patients recently discharged or patients requiring ventilatory support. Factors relevant to the frequency of home visits include the following:

- Patient's condition and therapeutic needs (objectives)
- Level of family or caregiver support available
- Type and complexity of home care equipment
- Overall home environment
- Ability of the patient to provide self-care
- Third-party reimbursement for such visits

When a visit is made by the RT, numerous functions must be performed, including the following:

- Patient assessment (objective/subjective data and pretreatment/posttreatment data)
- Patient's compliance with prescribed respiratory home care
- Equipment assessment (operation, cleanliness, and need for related supplies)
- Identification of any problem areas or patient concerns
- Statement related to patient goals and therapeutic plan

A standard written report, consistent with the care plan, should be completed by the visiting RT. Copies are often sent to the patient's physician, the home care referral source, and any other member of the patient care team requiring this information. The report should become part of the patient's medical record and should be referred to when following the patient's course and overall progress.[12,16]

EQUIPMENT DISINFECTION AND MAINTENANCE

With many patients receiving respiratory care outside the hospital, the danger of infection caused by direct contact with caregivers and visitors or indirect contact with contaminated articles has grown. To help minimize home-related infection, guidelines for disinfecting home respiratory care equipment have been established. Accepted infection control techniques are based on clinical evidence, such as the evidence outlined in several of the AARC Clinical Practice Guidelines that pertain to respiratory care provided in alternative settings.[24,43,62,65,73]

Collectively, these guidelines focus on sources of infection, basic principles of infection control, patients at high risk, disinfection methods, equipment processing, and care of solutions and medications. Procedures focus significantly on surveillance, prevention, and control of infection.[15,16]

In regard to infection control, all guidelines and procedures mandate proper hand hygiene techniques by all caregivers—proper handwashing and use of antiseptic hand lotions. In addition, visits to the patient by friends or relatives with respiratory infections are discouraged. Relating to medical equipment suppliers, the guidelines suggest that all permanent equipment (e.g., ventilator circuits, O_2 delivery equipment, and aerosol systems) be sterilized or receive high-level disinfection before being supplied to another patient. Disposable or single-patient use equipment must be used by one patient only. It is recommended that all equipment be completely disassembled and washed first in water, followed by a soak in warm soapy water for several minutes, with equipment scrubbed as needed to remove any remaining organic material. Following this step, the equipment must be thoroughly rinsed to remove any residual soap and drained of excess water. Air drying on a clean surface or rack is recommended to minimize recontamination.

Additionally, the broad bactericidal activity exhibited by many premanufactured disinfectant solutions makes them the first choice. Other disinfection solutions to be considered

include a 1:50 dilution of 5.25% to 6.15% sodium hypochlorite (household bleach) with water for a minimum of 3 minutes.

In regard to using water for humidification or nebulization, it is recommended that distilled water be used as a first choice. However, boiled water, cooled in a refrigerator and discarded after 24 hours, is also generally acceptable. It is recommended that manufacturers' guidelines for the proper handling of specific medications be strictly followed. Detailed instructions for patients and caregivers on how to clean and disinfect selected respiratory care equipment are generally available from most manufacturers.[73-74]

PALLIATIVE CARE

This chapter would not be complete without some discussion of palliative respiratory care in alternative settings. Although the primary goal of home care involves minimizing a patient's dependence on institutional care, an additional goal is to maximize the comfort and well-being of a terminally ill patient near the end of life.

The definition of *palliative care* by the World Health Organization involves the control of pain and other symptoms such as dyspnea of terminally ill patients and maximizing the psychological, social, and spiritual well-being of family members and patients nearing the end of life.[75] Many terminally ill patients have respiratory dysfunction directly or indirectly resulting from their terminal illness. Some of these patients choose to experience the remainder of their life at home. Hospice is a philosophy of care that helps support the efforts of such patients by providing clinician coverage and equipment to these patients at home.[75]

Respiratory modalities, such as O_2 therapy and mechanical ventilation or aerosol drug administration, can be combined with other therapies, such as pain management, to increase patients' comfort and permit them to die at home with their family and friends nearby. The RT can help such patients and families by providing training on the proper use and maintenance of such equipment. The presence of the RT can also be a supportive influence for patients and their families. Although such cases can place a psychological strain on the RT, maximizing the comfort of terminally ill patients can be rewarding, and not easily forgotten.

SUMMARY CHECKLIST

- An increasing number of health services are being provided in alternative care settings.
- Subacute care aims achieve the highest level of patient functioning—ideally self-care.
- Standards for subacute and home health care derive from federal and state laws and private-sector accreditation, mainly TJC.
- Acute and alternative care settings differ in regard to resource availability, supervision and work schedules, documentation and assessment, and professional-patient interaction.
- Effective discharge planning (1) guides the multidisciplinary team in transferring patients to alternative sites of care and (2) ensures the safety and efficacy of the patient's continuing care.
- Alternative site caregivers must have all the competencies required to meet the patient's ventilatory and respiratory needs and provide adequate 24-hour coverage. The selected site also must be safe and suitable for the patient's specific condition.
- O_2 prescriptions for patients in alternative settings must be based on documented hypoxemia, as determined by either blood gas analysis or oximetry.
- In most alternative care sites, O_2 normally is most often supplied by concentrators with gaseous cylinders as backup and for portability.
- Most patients in alternative care settings needing O_2 use a nasal cannula; conserving devices such as transtracheal catheter, reservoir cannula, and demand-flow O_2 system can decrease O_2 use and costs and provide greater patient mobility.
- Because most problems with long-term O_2 therapy are "people" problems, caregivers should be allowed to operate and maintain O_2 delivery devices only after they have been properly instructed by credentialed RTs.
- Key factors needed for successful ventilatory support in alternative sites include (1) careful patient selection, (2) effective discharge planning, (3) interdisciplinary team approach, (4) effective caregiver and family education, (5) thorough assessment and preparation of the environment, and (6) careful selection of needed equipment and supplies.
- Patients being considered for ventilatory support in alternative settings must be medically and psychologically stable.
- Most patients requiring mechanical ventilation in alternative settings can be supported with NIV if they are alert and cooperative, can maintain acceptable oxygenation without high FiO_2, and have intact airway reflexes and adequate clearance mechanisms.
- Positive pressure ventilators used in alternative settings should be electrically powered, easy to operate, and portable (run on both AC and DC power). Loss-of-power alarms are essential, high-pressure alarms are needed on volume-cycled ventilators, and patient-disconnect (low-pressure) alarms should be provided.
- Negative pressure ventilators, such as the chest cuirass and "pneumosuit," are a second-line choice for ventilatory support in alternative care settings.
- Patients with tracheostomies in alternative care settings require both daily stoma care and secretion clearance; tube changes should be performed only by a qualified health professional.
- A typical nocturnal CPAP system consists of a flow generator or blower, PEEP or CPAP valve, and nasal or full-face mask; some units can increase pressure to the prescribed level over time (ramping); others can autoadjust the CPAP level in response to apnea, hypopnea, airflow limitation, or snoring.
- The proper CPAP level can be determined by polysomnography, continuous monitoring of hemoglobin saturation, or by an auto-CPAP system.

- A common problem with nocturnal CPAP systems is an inability to reach or maintain the set pressure, usually because of either inadequate flow or system leaks.
- Proper caregiver hand hygiene, limiting visits by persons with respiratory infections, providing sterile or disposable clean equipment, and proper equipment processing are the keys to infection control in such settings.
- Providing palliative care to keep terminally ill patients as comfortable as possible is an important aspect of respiratory care in alternative sites.

Glossary

A

AARC abbreviation for the *American Association for Respiratory Care,* the primary voluntary professional association for respiratory therapists. (Chapter 1)

abdominal compartment syndrome the abdomen has become a fixed compartment with increased pressure resulting in ischemia and organ dysfunction. (Chapter 16)

abdominal paradox abnormal breathing pattern seen as a sinking inward motion of the abdomen with each inspiratory effort; a sign of diaphragm fatigue. (Chapter 16)

abdominal thrust external pressure forcefully exerted on the abdomen, under the diaphragm, to expel obstructing objects from the upper airway. (Chapter 37)

absolute humidity actual mass or content of water in a measured volume of air, usually expressed in grams per cubic meter or pounds. (Chapter 6)

absorption atelectasis atelectasis resulting from the absorption of O_2 from obstructed or partially obstructed alveoli with high O_2 concentrations. (Chapter 11)

A/C alternative abbreviation for *assist/control ventilation;* see *assist/control.* (Chapter 42)

accessory muscles of breathing muscles of the neck, back, and abdomen that may assist the diaphragm and the internal and external intercostal muscles in respiration, especially in some breathing disorders or during exercise. (Chapter 9)

accountable care organizations (ACOs) are groups of doctors, hospitals, and health care providers who voluntarily come together to deliver coordinated patient care. (Chapter 56)

acid compound that yields hydrogen ions (H^+) when dissolved in an aqueous solution. (Chapter 13)

acidemia state in which arterial blood is more acidic than normal (pH < 7.35). (Chapter 14)

acid-fast of or pertaining to a bacterial stain that does not decolorize easily when washed with an acid solution; also refers to certain bacteria (especially mycobacteria) that retain red dyes after an acid wash. (Chapter 17)

acid-fast bacterium type of bacteria that resists decolorizing by acid after accepting a stain. (Chapter 17)

acinus any small, saclike structure, particularly one found in a gland. (Chapter 9)

acoustic respiratory monitoring (ARM) provides imaging of ventilation that allows localization of the injury and an assessment of the extent of injury. The technique produces a two-dimensional video or graphic representation of ventilation; quiet regions without ventilation are not "seen." With this technique there is an opportunity at the bedside to perform a real-time evaluation of the effects of positive end expiratory pressure, recruitment maneuvers, or other changes in ventilatory support. (Chapter 51)

activated clotting time the amount of time it takes blood to form a clot. (Chapter 28)

active cycle of breathing (ACB) airway clearance strategy consisting of repeated cycles of breathing control and thoracic expansion, followed by the forced expiratory technique. (Chapter 40)

active transport movement of molecules across membranes in a direction opposite that expected because of diffusion or osmotic pressure. (Chapter 13)

acute chest syndrome a syndrome developed in patients with sickle cell disease. The chief complaints are acute chest pain, cough, and shortness of breath caused by the sickling of red blood cells. (Chapter 12)

acute exacerbation of COPD state of worsening of chronic obstructive pulmonary disease (COPD), often defined by the need to increase medication or to escalate care. (Chapter 25)

acute hypoxemic respiratory failure (AHRF) respiratory compromise characterized by severely decreased oxygenation that develops over a relatively short period of time. (Chapter 29)

acute lung injury (ALI) condition characterized by alveolar flooding caused by an acute insult (e.g., sepsis). Normally a rapidly developing bilateral pulmonary process of noncardiac origin with a PaO_2 to FiO_2 ratio greater than 200 mm Hg but less than 300 mm Hg. (Chapter 29)

acute respiratory distress syndrome (ARDS) respiratory disorder characterized by respiratory insufficiency and hypoxemia; triggers include gram-negative sepsis, O_2 toxicity, trauma, pneumonia, and systemic inflammatory responses. (Chapter 29)

adaptive support ventilation (ASV) mode of ventilation guided by evaluation of the patient's lung mechanics; the ventilator tries to impose a ventilatory pattern that results in the least amount of patient work. (Chapter 52)

adenocarcinoma type of cancer characterized by glandular structures. (Chapter 31)

adhesion band of scar tissue that binds anatomic surfaces that normally are separate from each other. Adhesions most commonly form in the abdomen, after abdominal surgery, inflammation, or injury. (Chapter 6)

adrenergic of or pertaining to the sympathetic nerve fibers of the autonomic nervous system that use epinephrine or epinephrine-like substances as neurotransmitters; any chemical or drug that mimics the effect of these neurotransmitters. Also called a *sympathomimetic drug; catecholamine.* (Chapter 35)

Advanced Cardiac Life Support (ACLS) emergency medical procedures beyond basic life support; includes intravenous fluid line establishment, defibrillation, drug administration, control of cardiac arrhythmias, and use of ventilation equipment. ACLS usually requires direct or indirect supervision by a physician. (Chapter 37)

advanced directive document in which an individual specifies what medical care he or she desires to receive in the future, should he or she no longer be able to make decisions about medical treatment; may be in the form of a living will or durable power of attorney. (Chapters 5, 16)

adventitious lung sounds abnormal lung sounds. (Chapter 16)

aerobic exercise any physical activity that requires increased cardiac output and ventilation to meet the increased O_2 demands of the skeletal muscles. (Chapter 55)

aerophagia swallowing of air. (Chapter 46)

aerosol suspension of solid or liquid particles in a gas. (Chapter 39)

aerosol medications any medication that is delivered by aerosol via the respiratory tract. (Chapter 1)

aerosol output weight or mass of aerosol particles produced by a nebulizer per unit time or volume. (Chapter 39)

affective domain a learning domain addressing the area of emotion, mood, or feeling. (Chapter 54)

afterload load against which an activated muscle must try to shorten; greater afterloads result in lower velocities. (Chapters 10, 51)

ageing growing older. (Chapter 39)

agonist of or pertaining to a chemical substance or drug that has affinity for a receptor and exerts a desired or expected effect (as opposed to an antagonist). (Chapter 35)

air bronchograms lucent tubular shadows running through areas of consolidation. (Chapter 21)

airway hyperresponsiveness state of airways that causes them to constrict abnormally in response to stress or insults (e.g., exercise, inhaled materials such as dust or allergens). (Chapter 25)

airway inflammation localized protective response to pathogens occurring within the routes for passage of air into and out of the lungs and involving the release of mediators including mast cells, eosinophils, macrophages, epithelial cells, and T lymphocytes. (Chapter 25)

airway management the process of ensuring that the upper airway is free of foreign substances and patent to gas flow. (Chapter 1)

airway obstruction state of abnormally slowed expiration, characterized most commonly by a decrease in FEV_1. (Chapter 25)

airway occlusion pressure inspiratory pressure generated 100 msec after airway occlusion; P0.1 is effort-independent and is thought to be a good measure of central respiratory drive. (Chapter 52)

airway pressure release ventilation (APRV) form of pressure ventilation that uses two levels of continuous positive airway pressure in an intermittent mandatory ventilation breathing pattern. (Chapter 29)

airway resistance measure of the impedance to ventilation caused by the movement of gas through the airways; abbreviated as Raw, airway resistance is computed as the change in pressure along a tube divided by the flow. (Chapter 11)

airway stents devices designed for internal splinting of the airway lumen to help reduce airway obstruction from malignant or benign processes that compress the airway from the outside. (Chapter 22)

alae the lateral surface of the external nose; the alae may flare out during respiratory distress. (Chapter 9)

algorithm predetermined group of directions to solve a problem in a finite number of steps. (Chapter 2)

alkalemia a decreased hydrogen ion concentration in the blood; as applied to arterial blood, denotes pH greater than 7.45. (Chapter 14)

alveolar-arterial oxygen tension difference ($P(A-a)O_2$) difference between the alveolar and arterial PO_2, usually about 5 to 10 mm Hg when breathing room air. (Chapter 51)

alveolar-capillary membrane tissue that separates air from blood in the lung; consists of alveolar epithelium, basement membrane, and capillary endothelium, along with their associated structures. (Chapter 9)

alveolar dead space alveoli that are ventilated but are not perfused. The condition may exist when pulmonary circulation is obstructed, as by a thromboembolus. (Chapters 11, 12)

alveolar shunt alveolar units that are closed to ventilation but are still perfused. (Chapter 12)

alveoli small outpouching of walls of alveolar space through which gas exchange between alveolar air and pulmonary capillary blood occurs. (Chapter 9)

alveolopleural fistula an abnormal communication between the alveoli and the pleura, often associated with pneumothorax. (Chapter 27)

ambulation process of helping a bedridden patient begin to sit up, stand, and walk around independently. (Chapter 3)

American Association for Respiratory Care (AARC) profenssional association of respiratory therapists. (Chapter 1)

American Respiratory Care Foundation (ARCF) a nonprofit organization formed for the purpose of supporting research, education, and charitable activities in respiratory care. (Chapter 1)

American Society for Testing and Materials (ASTM) nongovernment agency that establishes performance standards for various equipment and materials. (Chapters 33, 38)

American standard safety system (ASSS) specifications adopted in the United States and Canada for threaded high-pressure connections between compressed gas cylinders and their attachments. (Chapter 40)

amniocentesis process of direct sampling and quantitative assessment of the amniotic fluid. (Chapter 53)

ampere basic unit of electrical energy current; equivalent to the amount of electrons flowing when 1 V of electromotive force is applied to a circuit with 1 ohm of resistance. (Chapter 3)

amyotrophic lateral sclerosis (ALS) degenerative disease of the motor neurons often characterized by atrophy of the muscles of the hands, forearms, and legs and eventually involving most of the body, including the muscles of respiration. (Chapter 32)

analyte a chemical substance that is being measured as in a broad test. (Chapter 19)

analyzer a person or device that evaluates some submitted material (e.g., a machine that measures blood chemistry components). (Chapter 19)

anemia abnormal condition characterized by a reduction in the number of circulating red blood cells or the amount of normal hemoglobin available to carry O_2. (Chapter 17)

anergy lack of activity; an immunodeficient condition characterized by a lack of or diminished reaction to an antigen or group of antigens. This state may be seen in advanced tuberculosis and other serious infections, AIDS, and some malignancies. (Chapter 23)

angina spasmodic, cramplike choking feeling. (Chapter 16)

angle of Louis slightly oblique angle where the manubrium articulates with the body of the sternum. (Chapter 9)

anion a negative ion that migrates to the anode (positive electrode) in an electrolyte solution; a negative ion. (Chapter 13)

ankylosing spondylitis chronic inflammatory disease of unknown origin, first affecting the spine and adjacent structures and commonly leading to eventual fusion (ankylosis) of the involved joints. (Chapter 32)

antagonist in pharmacology, a drug that has affinity but produces no effect; an antagonist can be competitive (forms reversible bond with receptor) or noncompetitive (forms irreversible bond). (Chapter 35)

anterior nares opening to the nose. (Chapter 9)

anthropometrics science of measuring the human body—height, weight, and size of component parts, including skin folds—to study and compare the relative proportions under normal and abnormal conditions. Also called *anthropometric measurement*. (Chapter 23)

antiadrenergic pertaining to blocking of the effects of impulses transmitted by the adrenergic postganglionic fibers of the sympathetic nervous system. (Chapter 35)

antibiotic therapy treatment of infections with antimicrobial agents, such as the penicillins. (Chapter 24)

anticholinergic of or pertaining to blockade of acetylcholine receptors that results in the inhibition of transmission of parasympathetic nerve impulses. (Chapter 35)

antiseptic tending to inhibit growth and reproduction of microorganisms. (Chapter 4)

APACHE scoring system *Acute Physiology and Chronic Health Evaluation* scoring system; severity of illness scoring system used with critically ill patients. (Chapter 51)

Apgar score evaluation of an infant's physical condition, usually performed 1 minute and 5 minutes after birth, based on a rating of five factors that reflect the infant's ability to adjust to extrauterine life. (Chapter 53)

apices uppermost portions of the lungs. (Chapter 9)

apnea absence of spontaneous breathing. (Chapter 15)

apnea of prematurity disorder of preterm infants, probably of central nervous system origin, characterized by frequent apneic pauses lasting longer than 20 seconds and often associated with cyanosis, pallor, hypotonia, or bradycardia. (Chapter 34)

apneustic breathing pattern of respirations characterized by a prolonged inspiratory phase followed by expiratory apnea. (Chapters 15, 32)

apneustic center localized collection of neurons in the pons located at the level of the vestibular area that moderates the rhythmic activity of the medullary respiratory centers. (Chapter 15)

appropriate for gestational age (AGA) refers to a newborn whose size, growth, and maturation are normal for gestational age, whether delivered prematurely, at term, or later than term. (Chapter 53)

ARCF abbreviation for *American Respiratory Care Foundation,* a philanthropic agency that promotes the field of respiratory care through grants and awards. (Chapter 1)

argon plasma coagulation a medical endoscopic procedure used to stop bleeding or to remove tumor tissue. (Chapter 22)

arterialized blood blood that resembles the blood in arteries (e.g., from the finger or earlobe capillaries). (Chapter 19)

arteriovenous anastomosis communication between an artery and a vein, either as a congenital anomaly or as a surgically produced link between vessels. (Chapter 10)

artifacts an aberration as a result of interference or technical failure. These changes do not represent a normal or so-called physiologic change. (Chapter 51)

asbestosis restrictive lung disease caused by prolonged exposure to asbestos fibers; associated with a high incidence of malignant lung tumors and pleural abnormalities. (Chapter 26)

assault any conduct that creates a reasonable apprehension of being touched in an injurious manner; no actual touching is required to prove assault. (Chapter 5)

assist/control (A/C or ACV) volume ventilation continuous mandatory ventilation (CMV) in which the minimum breathing rate is

predetermined, but the patient can initiate mechanical ventilation at an increased rate. (Chapter 48)

assisted breath a breath whose delivery is aided by a mechanical device. (Chapter 45)

asthma respiratory disorder characterized by recurring episodes of paroxysmal dyspnea, wheezing on expiration or inspiration caused by constriction of the bronchi, coughing, and viscous mucoid bronchial secretions. The episodes may be precipitated by inhalation of allergens or pollutants, infection, cold air, vigorous exercise, or emotional stress. Also called *bronchial asthma*. (Chapter 25)

ataxic breathing type of breathing associated with a lesion in the medullary respiratory center and characterized by a series of increasing and decreasing inspirations and expirations. (Chapter 32)

atelectasis collapse of distal lung parenchyma. (Chapters 21, 42)

atelectrauma lung injury as a result of alveolar collapse secondary to inappropriate PEEP settings. (Chapter 46)

atmospheric pressure absolute (ATA) measure of pressure used in hyperbaric medicine; 1 ATA equals 760 mm Hg or 101.32 kPa. (Chapter 41)

atomizer device that produces an aerosol suspension of liquid particles without using baffles to control particle size. (Chapter 39)

atrial kick the propulsion of blood that results from contraction of the atrium heart chamber. (Chapter 18)

atrophy the loss of muscle mass as a result of disuse. (Chapter 47)

ATPS abbreviation for *ambient temperature, ambient pressure, saturated* (with water vapor). (Chapter 6)

attending title applied to the responsible most senior physician caring for the patient in an academic medical center. (Chapter 3)

atypical pathogens select organisms in *Legionella* species, *Chlamydophila pneumoniae,* and *Mycoplasma pneumoniae* that cause pneumonia. (Chapter 24)

auditory pertaining to the sense of hearing. (Chapter 3)

autogenic drainage (AD) modification of directed coughing, beginning with low lung volume breathing, inspiratory breath holds, and controlled exhalation and progressing to increased inspired volumes and expiratory flows. (Chapter 40)

automatic external defibrillator (AED) portable automatic device to perform defibrillation on patients outside a hospital. (Chapter 37)

automatic tube compensation (ATC) mode of ventilation that attempts to maintain tracheal pressure equal to end expiratory pressure during both inspiration and expiration. (Chapter 52)

automaticity refers to the heart's ability to generate its own intrinsic electrical rhythm. (Chapters 10, 18)

autonomy quality of having the ability or tendency to function independently. (Chapter 5)

auto-PEEP pressure above atmospheric remaining in the alveoli at end-exhalation due to air trapping. Also called *intrinsic PEEP*. (Chapter 44)

autoregulation automatic control of a mechanical or physiologic system; necessitates both a sensing mechanism (to measure what is regulated) and a feedback loop (to respond to changes). (Chapter 46)

auto-triggering triggering of a ventilator by any phenomenon that is not a result of the patient making an inspiratory effort. Most commonly a result of a small circuit leak. (Chapter 47)

Avogadro's law law in physics stating that equal volumes of all gases at a given temperature and pressure contain the identical number of molecules. (Chapter 5)

axiology the study of values (e.g., the way patients give priority to a choice). (Chapter 5)

azotemia buildup of excess nitrogenous waste products in the blood, usually secondary to renal failure. (Chapter 23)

B

bactericidal substances with the ability to kill microorganisms. (Chapter 4)

bacteriostatic ability to restrain the growth of microorganisms. (Chapter 4)

baffle surface in a nebulizer designed specifically to cause impaction of large aerosol particles, causing either further fragmentation or removal from the suspension via condensation back into the reservoir. (Chapter 39)

baffling process of removing large water particles from suspension in a jet nebulizer so that the particles entering the patient's airways are of a uniform therapeutic size. (Chapter 38)

bands bundle of fibers, as seen in striated muscle that encircles a structure or binds one part of the body to another. (Chapter 17)

baroreceptor one of the pressure-sensitive nerve endings in the walls of the atria of the heart, the vena cava, the aortic arch, and the carotid sinus. (Chapter 10)

barotrauma physical injury sustained as a result of exposure to ambient pressures above normal, most commonly secondary to positive pressure ventilation (e.g., pneumothorax, pneumomediastinum). (Chapters 29, 44, 46)

barrel chest abnormal increase in the anteroposterior diameter of the chest caused by hyperinflation of the lungs. (Chapter 16)

basal metabolic rate (BMR) amount of energy used in a unit of time by a fasting, resting subject. BMR, determined by the amount of O_2 used, is expressed in calories consumed per hour per square meter of body surface area or per kilogram of body weight. Also called *basal energy expenditure (BEE)*. (Chapter 23)

base compound that yields hydroxyl ions [OH^-] when dissolved in an aqueous solution. (Chapter 13)

base excess (BE) difference between the normal buffer base (NBB) and the actual buffer base (BB) in a whole-blood sample, expressed in mEq/L; a normal BE is +2 mEq/L. (Chapter 14)

basic chemistry panel (BCP) or basic metabolic panel includes the predominant electrolytes sodium (Na^+), potassium (K^+), chloride (Cl^-), and total CO_2/bicarbonate (CO_2) and glucose. (Chapter 17)

basic life support (BLS) cardiopulmonary resuscitation designed to reinstitute either circulatory or respiratory function without equipment or drugs. (Chapter 37)

battery (legal) an unconsented touching of an individual that causes injury. (Chapter 5)

Becker muscular dystrophy chronic degenerative disease of the muscles, characterized by progressive weakness; occurs in children 8 to 20 years old. (Chapter 32)

benchmarking establishing the relationship between an organization's ability to perform at a given level to that of other comparable organizations. (Chapter 7)

beneficence principle that requires that health providers go beyond doing no harm and actively contribute to the health and well-being of their patients. (Chapter 5)

benevolent deception actions in which the truth is withheld from the patient for his or her own good. (Chapter 5)

bias the state of having your opinion markedly affected by past experience or knowledge; an oblique or a diagonal line. (Chapter 8)

bibliographic database a collection of reference sources often used in research. (Chapter 8)

bilevel positive airway pressure (bilevel PAP) spontaneous breath mode of ventilatory support that allows separate regulation of the inspiratory and expiratory pressures. (Chapter 33)

Biot respiration breathing characterized by irregular periods of apnea alternating with periods in which four or five breaths of identical depth are taken. (Chapter 15)

biotrauma inflammation of the lungs in response to inappropriate mechanical ventilation that promotes alveolar overdistention in inspiration and derecruitment on exhalation. (Chapter 46)

bladder pressure pressure that is established in the bladder. (Chapter 51)

blood-brain barrier anatomic-physiologic feature of the brain thought to consist of walls of capillaries in the central nervous system and surrounding astrocytic glial membranes. The barrier separates the parenchyma of the central nervous system from blood. The blood-brain barrier prevents or slows the passage of some drugs and other chemical compounds, radioactive ions, and disease-causing organisms such as viruses from the blood into the central nervous system. (Chapter 15)

blunt trauma nonpenetrating trauma that may result in pulmonary contusion. (Chapter 30)

Board of Medical Advisors (BOMA) the medical advisory group for the American Association for Respiratory Care. (Chapter 1)

body humidity absolute humidity in a volume of gas saturated at a body temperature of 37° C; equivalent to 43.8 mg/L of water in the air. (Chapter 38)

body mass index (BMI) formula for determining obesity, calculated by dividing a person's weight in kilograms by the square of the person's height in meters. (Chapter 23)

Bohr effect effect of variations in blood pH on the affinity of hemoglobin for O_2. (Chapter 12)

Borg dyspnea scale validated scale used by patients to quantify the severity of dyspnea. (Chapter 20)

Bourdon gauge fixed orifice, variable pressure flowmeter. (Chapter 40)

BPF abbreviation for *bronchopleural fistula*. (Chapter 27)

brachytherapy a method to deliver short distance radiation therapy to a tumor via a bronchoscope. (Chapter 22)

bradycardia abnormally decreased heart rate. (Chapter 16)

bradypnea abnormal decrease in breathing rate. (Chapter 16)

breach of contract failure, without legal excuse, to carry out the terms of a legal agreement. (Chapter 5)

breath-actuated nebulizer aerosol device that is responsive to the patient's inspiratory effort and reduces or eliminates aerosol generation during exhalation. (Chapter 39)

breath-enhanced nebulizer nebulizers that entrain room air in direct relationship to the inspiratory flow of the patient. (Chapter 39)

breathing pattern the ventilation pattern assumed by a patient during normal or mechanical ventilation. (Chapter 42)

breathlessness distressful sensation of uncomfortable breathing that may be caused by certain heart conditions, strenuous exercise, or anxiety. (Chapter 16)

bronchial washings and brushings material sampled during bronchoscopy, specifically from instilling and withdrawing saline into the lung (washings) or inserting a brush into the lung. (Chapter 22)

bronchiectasis abnormal condition of the bronchial tree characterized by irreversible dilation and destruction of the bronchial walls. (Chapters 25, 40)

bronchiolitis acute infection of the lower respiratory tract causing expiratory wheezing, respiratory distress, inflammation, and obstruction of the bronchioles; bronchiolitis is usually caused by respiratory syncytial virus (RSV) and is most common in infants younger than 2 years old. (Chapter 33)

bronchoalveolar lavage (BAL) technique used to obtain specimens from the alveolar level of the lung. BAL is performed by instilling a small volume (up to 50 mL) of normal saline solution deep into the airways and then suctioning it back. (Chapter 22)

bronchodilator substance, especially a drug, that relaxes contractions of the smooth muscle of the bronchioles to improve ventilation to the lungs. Pharmacologic bronchodilators are prescribed to improve aeration in asthma, bronchiectasis, bronchitis, and emphysema. (Chapter 25)

bronchophony abnormal voice sounds heard over lung consolidation. (Chapter 16)

bronchopleural fistula any air communication from the lung to the pleural space. (Chapter 27)

bronchopneumonia acute inflammation of the lungs and bronchioles, characterized by chills, fever, high pulse and respirator rates, bronchial breathing, cough with purulent bloody sputum, and chest pain. (Chapter 41)

bronchopulmonary dysplasia (BPD) chronic respiratory disorder characterized by scarring of lung tissue, thickened pulmonary arterial walls, and mismatch between lung ventilation and perfusion. It often occurs in infants who have been dependent on long-term mechanical ventilation. (Chapters 33, 41)

bronchoscopy process of passing a bronchoscope into the airways for diagnostic testing or therapeutic purposes. (Chapter 36)

bronchospasm abnormal contraction of the smooth muscle of the bronchi, resulting in acute narrowing and obstruction. (Chapter 25)

BTPS abbreviation for *body temperature, ambient pressure, saturated* (with water vapor). (Chapter 6)

buffer base total blood buffer capable of binding hydrogen ions; normal buffer base (NBB) ranges from 48 to 52 mEq/L. (Chapter 14)

buffering the process of removing H^+ or OH^- in solution to minimize change in pH. (Chapter 13)

business intelligence (BI) a set of tools that permit capture, storage, and transformation of data into useful and actionable information. (Chapter 7)

C

cachexia general ill health and malnutrition characterized by weakness and emaciation. (Chapter 16)

cachexic the state of being of general ill health and suffering from malnutrition. (Chapter 23)

calibration media types of equipment used to test and ensure that the output of an analyzer (blood gas) is both accurate and linear across the range of measured values. (Chapter 19)

cannulation the process of placing a catheter in an artery or vein. (Chapters 19 and 20)

capnography process of obtaining a tracing of the proportion of CO_2 in expired air using a capnograph. (Chapters 19, 51)

capnometry measurement of CO_2 in a volume of gas, usually by methods of infrared absorption or mass spectrometry. (Chapters 19, 51)

capped-rental items eligible for reimbursement under the Medicare prospective payment system for only a predetermined number of months, after which the equipment is deemed owned by the patient and rental payments cease. (Chapter 51)

carbon monoxide poisoning exposure to carbon monoxide that allows the attachment of carbon monoxide to hemoglobin, preventing the attachment of O_2 to hemoglobin. (Chapter 30)

carboxyhemoglobin compound produced by the chemical combination of hemoglobin with carbon monoxide. (Chapter 12)

cardiac output volume of blood pumped per minute by the heart. (Chapters 10, 51)

cardiac tamponade compression of the heart caused by the collection of blood, fluid, or gas under pressure in the pericardium. (Chapter 10)

cardiopulmonary exercise evaluation (CPX) exercise-based assessment of a patient before pulmonary rehabilitation designed to determine the patient's exercise capacity and risk for desaturation. (Chapter 55)

cardiopulmonary resuscitation (CPR) basic emergency procedure for life support, consisting of artificial respiration and manual external cardiac massage. (Chapter 37)

cardiopulmonary system the combination of the respiratory and cardiac systems. (Chapter 1)

cardioversion using electrical energy to correct an abnormal heart rhythm to normal. (Chapter 37)

carina bifurcation of the trachea into the right and left main stem bronchi. (Chapter 9)

catecholamine any one of a group of sympathomimetic compounds composed of a catechol molecule and the aliphatic portion of an amine. (Chapter 35)

cation positively charged ion. (Chapter 13)

Centers for Medicare and Medicaid Services (CMS) federal agency within the U.S. Department of Health and Human Services that administers the Medicare program and works in partnership with state governments to administer Medicaid. (Chapter 56)

central cyanosis abnormal discoloration of the skin distributed in central structures like the nose and lips. (Chapter 16)

central neurogenic hyperinflation hyperinflation caused by a neurologic progress generally resulting in a markedly increased minute ventilation. (Chapter 32)

central sleep apnea absence of breathing as the result of medullary depression that inhibits respiratory movement, which becomes more pronounced during sleep. (Chapter 33)

cephalization refers to increased visualization of pulmonary blood vessels on a chest radiograph in the nondependent regions of the lung; often a sign of left heart failure. (Chapter 21)

channel passageway or groove that conveys fluid, such as the central channels that connect the arterioles with the venules. (Chapter 3)

chemoreceptor sensory nerve cell activated by changes in the chemical environment surrounding it; the chemoreceptors in the carotid artery are sensitive to PCO_2 in the blood, signaling the respiratory center in the brain to increase or decrease ventilation. (Chapters 10, 15)

chemotherapy treatment of infections and other diseases with chemical agents. (Chapter 32)

chest cuirass device to deliver negative pressure ventilation that fits over the thorax. (Chapter 45)

chest physical therapy (CPT) collection of therapeutic techniques designed to aid clearance of secretions, improve ventilation, and enhance the conditioning of the respiratory muscles; includes positioning techniques, chest percussion and vibration, directed coughing, and various breathing and conditioning exercises. (Chapter 40)

chest radiograph x-ray image of the chest; a posteroanterior view and a lateral, or side, view are routinely obtained. (Chapter 21)

Cheyne-Stokes respiration abnormal breathing pattern with periods of progressively deeper

breaths alternating with periods of shallow breathing and apnea. (Chapters 15, 32)

CHF abbreviation for *congestive heart failure;* an abnormal condition that reflects impaired cardiac output, caused by myocardial infarction, ischemic heart disease, or cardiomyopathy. (Chapters 10, 29)

chlorofluorocarbons (CFCs) gaseous chemical compounds that were originally used to power metered dose inhalers but currently phased out of use. (Chapter 39)

cholinergic of or pertaining to nerve fibers that elaborate acetylcholine at the myoneural junctions. (Chapter 35)

chronic bronchitis common debilitating pulmonary disease, characterized by greatly increased production of mucus by the glands of the trachea and bronchi that results in a cough with expectoration for at least 3 months of the year for more than 2 consecutive years. (Chapter 25)

chronic cough cough that persists, sometimes defined as greater than 8 weeks (to distinguish from acute cough [<3 weeks] and subacute cough [3-8 weeks]). (Chapter 16)

chyle cloudy liquid products of digestion taken up by the small intestine. Consisting mainly of emulsified fats, chyle passes through finger-like projections in the small intestine, called *lacteals,* and into the lymphatic system for transport to the venous circulation at the thoracic duct in the neck. (Chapter 27)

chylothorax pleural fluid collection that is high in triglycerides, usually from disruption of the thoracic duct. (Chapter 27)

cilia tiny hairlike projections that line mucus-producing structures. Generally they operate in a wavelike motion moving mucous along the structure. (Chapter 9)

ciliary dyskinetic syndromes conditions in which respiratory tract cilia do not function properly. (Chapter 40)

circulatory failure the failure of the circulatory system to maintain normal cardiac output. (Chapter 37)

clinical decision support (CDS) health information technology functionality that builds on the foundation of an electronic health record to provide specific information, which is intelligently filtered and organized, at appropriate times, to enhance health and health care. (Chapter 7)

clinical queries search filter in PubMed effective in retrieving valid research studies. (Chapter 7)

clinical simulation the simulation of an actual clinical scenario using actors, manikins, and paper and pencil. (Chapter 7)

closed buffer system buffer system in which all components of acid-base reactions remain in the system. Products accumulate and reach equilibrium with reactants, and chemical activity ceases (no further buffering activity can take place). Closed buffer systems in the body include nonbicarbonate buffers, such as plasma proteins, hemoglobin, and phosphates. (Chapter 14)

closed-loop control control circuit that receives feedback from a measured variable that automatically adjusts a gas delivery variable based on the feedback. (Chapter 42)

clubbing bulbous swelling of the terminal phalanges of the fingers and toes, often associated with certain chronic lung diseases. (Chapter 16)

Coanda effect phenomenon in hydrodynamics whereby a fluid in motion may be attracted or held to a wall. (Chapter 6)

cognitive domain area of the mental processes of comprehension, judgment, memory, and reasoning. (Chapter 54)

cohesion attractive force between like molecules. (Chapter 6)

cohorting grouping individuals who share a common characteristic, such as the same age or the same sex or a common infection. (Chapter 4)

cold shock cardiorespiratory reflexes reflexes activated by water temperature less than 25° C. A breathing pattern characterized by gasping followed by hyperventilation and shallow breathing at total lung capacity. (Chapter 30)

collateral circulation redundant circulation in an area of tissue or an organ that supplies blood to the tissue through more than one path. (Chapter 19)

colloids substances that contains large molecules that attract and hold water; also a dispersion or a gel. (Chapter 13)

Committee on Accreditation for Respiratory Care (CoARC) committee that establishes standards and overseas approval of educational programs in respiratory care. (Chapters 1, 2)

competencies measurable or observable skills, knowledge, behaviors, or abilities to perform a job or task. (Chapters 2, 3)

community-acquired pneumonia acute inflammation of the lungs contracted from the environment (as distinguished from nosocomial, or hospital-acquired, pneumonia). (Chapter 24)

compensatory justice calls for the recovery of damages that were a result of the action of others. (Chapter 5)

complete blood count a determination of the number of red and white blood cells per cubic millimeter of blood. A complete blood count is one of the most routinely performed tests in a clinical laboratory and one of the most valuable screening and diagnostic techniques. (Chapter 17)

compliance volume change per unit in applied pressure. (Chapters 11, 20)

Comprehensive outpatient rehabilitation facilities (CORF) Medicare-approved facilities that provides a broad scope of ambulatory rehabilitation services as defined in section 933 of Public Law 96-499. (Chapter 55)

compressed volume volume of gas compressed in the ventilator circuit and not delivered to the patient during a positive pressure breath. (Chapter 45)

compression atelectasis collapse of a part of the lung as a result of an external force compressing the lung. (Chapter 41)

computed tomography (CT) radiographic technique that produces a film that represents a detailed cross section of tissue structure. (Chapters 21, 30)

computerized physician order entry (CPOE) a system by which medical orders can be electronically transmitted to the electronic health record saving time and reducing transcription errors resulting from illegible handwriting. (Chapter 7)

condensation change of state from gas to liquid, as with water vapor condensation. (Chapter 6)

conditions of participation a certificate awarded institutions that meet specific standards of quality and safety as determined by the Centers for Medicare and Medicaid Services. (Chapter 51)

conduction transfer of heat by the direct interaction of atoms or molecules in a hot area that contact atoms or molecules in a cooler area. (Chapter 6)

confidentiality nondisclosure of certain information except to another authorized person. (Chapter 5)

congestive heart failure (CHF) abnormal condition that reflects impaired cardiac pumping; caused by myocardial infarction, ischemic heart disease, or cardiomyopathy that results in either pulmonary or systemic edema. (Chapters 10, 29)

conjugate base the base associated with the weak acid in a buffer system. (Chapter 14)

conjunctivitis inflammation of the conjunctiva, caused by bacterial or viral infection, allergy, or environmental factors. (Chapter 45)

connective tissue disease group of acquired disorders that have in common diffuse immunologic and inflammatory changes in small blood vessels and connective tissue. The cause of most of these diseases is unknown. Also called *collagen vascular disease*. (Chapter 26)

consequentialism idea of judging an act to be right; an ethical viewpoint in which decisions are based on the assessment of consequences. (Chapter 5)

conservative fluid management a strategy of administering fluids that attempt to minimize fluid excess over output. (Chapter 29)

contact precautions safeguards designed to reduce the risk for transmission of epidemiologically important microorganisms by direct or indirect contact. (Chapter 4)

continuing respiratory care education education sought by respiratory therapists after graduation. (Chapter 7)

continuous mandatory ventilation (CMV) system of mechanical ventilation in which the patient is allowed to initiate breathing, but the ventilator delivers a set volume or pressure with each breath. The ventilator also can be programmed to initiate breathing if the patient's breathing slows beyond a certain point or stops altogether. (Chapter 45)

continuous positive airway pressure (CPAP) method of ventilatory support whereby the patient breathes spontaneously without mechanical assistance against threshold resistance, with pressure above atmospheric maintained at

the airway throughout breathing. (Chapters 33, 42, 45, 51, 53)

continuous quality improvement (CQI) aa process-based data driven approach that attempts to enhance the quality of care and patient safety. (Chapter 7)

continuous spontaneous ventilation (CSV) method of delivering ventilatory support in which the patient determines when a breath is initiated and when it is terminated. (Chapter 45)

contractility property of muscle tissue to shorten in response to a stimulus, usually electrical. (Chapters 10, 51)

control system the system used to determine how a mechanical ventilator delivers gas (e.g., targeting schemes). (Chapter 45)

control variable primary variable that the ventilator controls to provide inspiration: pressure, volume, time, or flow. (Chapter 42)

controlled ventilation use of an intermittent positive pressure breathing unit or other respirator that has an automatic cycling device that replaces spontaneous respiration. (Chapter 48)

convection heat transfer through the mixing of fluid molecules at different temperature states via thermal currents. (Chapter 6)

corticosteroid any one of the natural or synthetic hormones associated with the adrenal cortex, which influences or controls key processes of the body, such as carbohydrate and protein metabolism, electrolyte and water balance, and function of the cardiovascular system and kidneys. (Chapter 26)

costal cartilage fibrous tissues that connect the ribs to the sternum and to each other anteriorly. (Chapter 9)

costophrenic angle acute angle where the costal pleura meets the diaphragm. (Chapter 9)

cough forceful expiratory effort designed to expel mucus and other foreign material from the upper airway. (Chapter 16)

crackles discontinuous type of adventitious lung sound. (Chapter 16)

cricoid cartilage ring of cartilage that forms the lower border of the larynx. (Chapter 9)

critical illness myopathy a heterogeneous constellation of symptoms commonly occurring in the intensive care unit in which patients develop flaccid weakness of proximal muscles. Risk factors include corticosteroids, use of paralytic agents, hyperglycemia, hyperthyroidism, and possibly a systemic inflammatory response without sepsis. (Chapter 32)

critical illness polyneuropathy the development of muscle weakness and atrophy, loss of deep tendon reflexes, and loss of peripheral sensation to pinprick and touch in patients with severe sepsis. (Chapter 32)

critical pressure pressure exerted by a vapor in an evacuated container at its critical temperature. (Chapter 6)

critical temperature highest temperature at which a substance can exist as a liquid, regardless of pressure. (Chapter 6)

critical test value a test result that requires immediate communication of the result with a physician. (Chapter 17)

cross-training process of providing health care professionals with multiple skills in areas that span disciplines; for example, training a respiratory care practitioner to take chest radiographs. (Chapter 3)

croup infectious disorder of the upper airway occurring chiefly in infants and children that normally results in subglottic swelling and obstruction. (Chapters 33, 41)

CRT abbreviation for *certified respiratory therapist;* a respiratory therapist who has successfully completed the technician (entry-level) certification examination of the NBRC. (Chapter 1)

cryogenic related to very low temperature. (Chapter 40)

cryotherapy treatment using the application of cold temperatures, as for airway lesions during bronchoscopy. (Chapter 22)

current a flowing or streaming movement; a flow of electrons along a conductor in a closed circuit; an electric current. (Chapter 3)

cuvette small transparent tube or container with specific optical properties. The chemical composition of the container determines the vessel's use, such as Pyrex glass for examining materials in the visible spectrum or silica for examining materials in the ultraviolet range. (Chapter 19)

cyanide toxicity a result of the inhalation of gas produced by the burning of nitrogenous material. Cyanide combines with cytochrome oxide, the last receptor of the electron transport chain, which prevents the utilization of O_2. (Chapter 30)

cyanocobalamin chemical that reduces the half-life of the toxic compound that results from the reaction of cyanide with cytochrome oxide. (Chapter 30)

cyanosis abnormal bluish discoloration of the skin or mucous membranes. (Chapter 16)

cycle a complete breath of inspiration and expiration. (Chapter 45)

cytochrome oxidase the final electron acceptor on the electron transport chain in the mitochondrion. (Chapter 30)

cycle asynchrony a lack of coordination of the ending of a patient's inspiration with the ending of the ventilator inspiration. (Chapter 47)

cycle variable variable that terminates inspiration during mechanical ventilation. (Chapter 42)

cyclic guanosine 3,5-monophosphate (cGMP) substance that mediates the action of certain hormones in a manner similar to cyclic adenosine monophosphate. (Chapter 41)

cystic fibrosis autosomal recessive disease characterized by pancreatic insufficiency, abnormally thick secretions from the exocrine glands, and increased concentration of sodium and chloride in the sweat glands; known in Europe as *mucoviscidosis*. (Chapters 25, 34)

D

Dalton's law in physics, law stating that the total pressure exerted by a mixture of gases is equal to the sum of the pressures exerted by the individual gases if they were present alone in the container. (Chapter 6)

DataArc secure, password-protected, web-based database management system for documenting and reporting clinical educational activities for nursing and allied health professions, including respiratory care. (Chapter 7)

dead space respired gas volume that does not participate in gas exchange; may be anatomic, alveolar, or mechanical. (Chapter 12)

dead space/tidal volume ratio (V_D/V_T) percentage of tidal volume that does not participate in gas exchange, usually approximately 30% to 35%. (Chapter 51)

decannulation removal of a cannula or tube that may have been inserted during a therapeutic or surgical procedure. (Chapter 36)

decremental PEEP trial progressively decreasing the amount of PEEP to assess oxygenation and hemodynamic status immediately following a recruitment maneuver. (Chapter 30)

deep breathing/directed cough movements used to improve pulmonary gas exchange or to maintain respiratory function, especially after prolonged inactivity or general anesthesia. (Chapter 42)

deep venous thrombosis (DVT) blood clot forming in the deep veins, usually of the legs. (Chapter 28)

defendant person denying the party against whom relief or recovery is sought in an action or suit; also, the accused in a criminal case. (Chapter 5)

defibrillation termination of ventricular fibrillation by delivering a direct electrical countershock to the patient's precordium. (Chapter 37)

depolarization reduction of a membrane potential to a less negative value; in cardiac fibers, this results in the release of calcium ions into the myofibrils and activates the contractile process. (Chapter 18)

deposition testimony of a witness taken on interrogatories, either oral or in writing. (Chapter 39)

dermatomyositis condition characterized by inflammation of the muscles and/or skin. (Chapter 32)

dew point temperature at which water vapor condenses back to its liquid form. (Chapter 6)

diagnosis identifying the underlying cause for signs and symptoms, as in naming a disease the patient has. (Chapter 16)

diameter-indexed safety system (DISS) specifications established to prevent accidental interchange of low-pressure (<200 psig) medical gas connectors. DISS is used in respiratory care to connect equipment to a low-pressure gas source. (Chapter 40)

diaphoresis secretion of sweat, especially profuse secretion associated with an elevated body temperature, physical exertion, exposure to heat, and mental or emotional stress. (Chapter 16)

diaphragm large dome-shaped muscle that separates the thorax from the abdomen; the primary muscle of ventilation. (Chapter 9)

diaphragmatic dysfunction an inability of the diaphragm to contract normally. (Chapter 47)

diastolic pressure baseline blood pressure in the arteries during ventricular relaxation. (Chapter 16)

diffusing capacity of the lung (DL) number of milliliters of gas that transfer from the lungs to the pulmonary blood per minute for each 1 mm Hg partial pressure difference between the alveoli and pulmonary capillary blood. (Chapter 20)

diffusing capacity of the lung to alveolar volume ratio (DLCO/V_A) index of the diffusing capacity for each 1 L of lung volume and an index of the functional alveolar surface area available for diffusion. (Chapter 20)

diffusing capacity of the lung-to–effective total lung capacity ratio index of the diffusing capacity normalized to the total lung capacity, useful to distinguish between interstitial lung disease and extrathoracic causes of restriction. (Chapter 20)

diluent substance, generally a fluid, that makes a solution or mixture less concentrated, less viscous, or more liquid. (Chapter 13)

dilute solution a solution that contains a small amount of solute in relation to solvent. (Chapter 13)

dilution equation an equation used to determine the final concentration of a solution in which the original volume multiplied by the original concentration are equal to the final volume multiplied by the final concentration. (Chapter 13)

disease management an integrated process for the care of patients with a particular chronic disease. Generally, a multidisciplinary group of practitioners providing care, most of which are nonphysicians. (Chapters 3, 54)

disinfection process of destroying at least the vegetative phase of pathogenic microorganisms by physical or chemical means. (Chapter 4)

distributive justice refers to proper allotment of the benefits and burdens in a society, such as taxes and subsidies. (Chapter 5)

dorsal respiratory groups (DRGs) groupings of cells in the medulla oblongata that are active in controlling inspiration. (Chapter 15)

double effect the understanding that many good actions have both a good and bad effect. (Chapter 5)

double triggering the activation of a second ventilator-delivered breath without exhalation after the first breath. Normally occurs when tidal volume is too small and inspiratory time is too short. (Chapter 47)

downstream relative reference to a point more distal from the source in a stream of flowing fluid. (Chapter 40)

driving pressure the pressure that is driving a fluid from one point to another. During mechanical ventilation, this is the difference between plateau pressure and PEEP. (Chapter 51)

droplet nuclei residue of evaporated water droplets; owing to their small size (0.5 to 12 mm), droplet nuclei can remain suspended in the air for long periods. (Chapter 4)

droplet precautions safeguards designed to reduce the risk for droplet transmission of infectious agents. (Chapter 4)

drug signaling mechanism by which a drug exerts its effect on receptors. (Chapter 35)

dry drowning drowning without water entry into the lungs, occurs as a result of reflex laryngeal spasm. (Chapter 30)

dual-control mode of ventilation in which the control variable (pressure, volume, flow) switches during a breath. (Chapter 45)

Duchenne muscular dystrophy (DMD) abnormal congenital condition characterized by progressive symmetric wasting of the leg and pelvic muscles; predominantly affects males and accounts for 50% of all muscular dystrophy diseases. (Chapter 32)

ductus arteriosus vascular channel in the fetus that joins the pulmonary artery directly to the descending aorta; it normally closes after birth. (Chapters 9, 34)

ductus venosus vascular channel in the fetus passing through the liver and joining the umbilical vein with the inferior vena cava; before birth, it carries highly oxygenated blood from the placenta to the fetal circulation. (Chapter 9)

durable medical equipment (DME) supplier a company that provides medical equipment to patients in the home. (Chapter 51)

dynamic compression collapse of airways caused by a pressure gradient that occurs with breathing or forced breathing and normally occurs in diseased airways. (Chapter 11)

dynamic hyperinflation increase in functional residual capacity (FRC) above the elastic equilibrium volume of the respiratory system; causes include increased flow resistance, short inspiratory time, and increased postinspiratory muscle activity; see also *auto-PEEP*. (Chapters 11, 44)

dysoxia abnormal metabolic state in which the tissues are unable to use properly the O_2 made available to them. (Chapter 12)

dyspnea difficult or labored breathing as perceived by the patient. (Chapter 16)

E

ECLS extracorporeal lung support, the same process as ECMO. (Chapter 29)

ECMO extracorporeal membrane oxygenation is the process whereby blood is removed from the body, pumped through a membrane to exchange CO_2 for O_2, and then returned to the body. (Chapter 29)

ectopic beat impulse that originates in the heart at a site other than the sinus node. (Chapter 18)

ectopic focus origination of a heartbeat from some place in the heart other than the sinoatrial node. (Chapter 18)

edema excess fluid in the interstitial spaces between cells; in the lungs, edema fluid may also be present in the airways and alveolar spaces. (Chapter 29)

effective total lung capacity (V_A) single-breath technique distributes a gas mixture through unobstructed airways to an alveolar volume. (Chapter 20)

egophony physical examination finding of increased resonance of voice sounds when auscultating the chest (e.g., due to lung consolidation). (Chapter 16)

elastance tendency of matter to resist a stretching force and recoil or return to its original size or form after deformation or expansion; the reciprocal of compliance. Also called *elasticity*. (Chapters 11, 45)

elasticity ability of tissue to regain its original shape and size after being stretched, squeezed, or otherwise deformed. Muscle tissue is generally regarded as elastic because it is able to change size and shape and return to its original condition. (Chapter 11)

electrical impedance tomography (EIT) the process by which mapping of the lung is obtained by a series of electrodes placed around the chest that sequentially emit low level current. The variability among the impedance to the current between electrodes is used to map lung volume. (Chapter 51)

electrocardiogram (ECG) an important diagnostic tool used to measure the electrical activity of the heart. (Chapter 18)

electrochemical refers to processes where electrical changes drive chemical processes. (Chapter 19)

electromagnetic navigational bronchoscopy a bronchioscopic technique that facilitates accurate navigation to sample peripheral pulmonary target lesions. (Chapter 22)

electronic health record (EHR) the sum of all medical records produced for a patient during the different encounters with various health care entities throughout their lifetime, and which are available across the continuum of care in all geographic locations. These data are stored in an electronic system. (Chapter 7)

electronic medical record (EMR) a system for which the medical record is stored in a computer (rather than on paper records). (Chapter 7)

E-medicine is the term that relates to the use of computerized or digital technology to enhance efficiency and effectiveness of health care in general and more specifically patient care. (Chapter 7, 22)

emitted dose describes the mass of drug leaving the mouthpiece of a nebulizer or inhaler as aerosol. (Chapter 39)

emphysema destructive process of the lung parenchyma leading to permanent enlargement of the distal air spaces; classified as either centrilobular (CLE), which mainly involves the respiratory bronchioles, or panlobular (PLE), which can involve the entire terminal respiratory unit. (Chapter 25)

empyema pus within the pleural space. A pleural fluid Gram stain that shows bacteria. (Chapters 21, 27)

end-diastolic volume (EDV) volume of blood remaining in the ventricles just prior to contraction. (Chapter 10)

end-systolic volume (ESV) volume of blood in the ventricles at the end of contraction, or systole. (Chapter 10)

endobronchial biopsy a sampling of an abnormality seen within the bronchus on bronchoscopy. (Chapter 22)

endobronchial intubation the purposeful or accidental placement of an endotracheal tube into a

main stem bronchus, usually the right main stem bronchus. (Chapter 47)

endotracheal tubes artificial airways that pass through the oropharynx or nasopharynx into the trachea. (Chapter 36)

enterprise software packages computer software that is used by a whole health system. (Chapter 7)

epiglottis flat cartilage that extends from the base of the tongue backward and upward. (Chapter 9)

epiglottitis acute, often life-threatening infection of the upper airway, which causes severe obstruction secondary to supraglottic swelling; caused primarily by *Haemophilus influenzae* type B and affecting mainly children younger than 5 years old. (Chapter 34)

epistaxis to bleed from the nose. (Chapter 9)

equal pressure point (EPP) during forced exhalation, the point along an airway where the pressure inside its wall equals the intrapleural pressure; upstream beyond this point, the pleural pressure exceeds the pressure inside the airway, tending to promote bronchiolar collapse. (Chapter 11)

equilibrium constant a constant determined by the amount of a buffer that dissociates in solution. Identifies the pH at which the buffer is most effective. (Chapter 14)

equivalent weight weight of an element in any given unit (e.g., grams) that displaces a unit weight of hydrogen from a compound or combines with or replaces a unit weight of hydrogen. (Chapter 13)

erythrocyte red blood cell. (Chapter 17)

esophageal balloon a catheter with an elongated balloon placed in the esophagus used to measure pressure change that is reflective of pleural pressure change. (Chapter 51)

eustachian tubes bilateral tubes that connect the nasopharynx to the middle ear and mastoid sinus. (Chapter 9)

evaporation change in state of a substance from liquid to gaseous form occurring below its boiling point. (Chapter 6)

evidence-based medicine (EBM) is an approach to medical practice intended to optimize decision-making by emphasizing the use of evidence from well designed research projects. (Chapter 2)

expiratory cycling criteria the criteria employed by the ventilator to transition from inspiration to exhalation. In pressure support ventilation, this is usually flow. (Chapter 47)

expiratory positive airway pressure (EPAP) application of positive pressure to the airway during exhalation. Compare with *inspiratory positive airway pressure*. (Chapter 45)

expiratory reserve volume (ERV) total amount of gas that can be exhaled from the lung after a quiet exhalation. (Chapter 20)

external nares the external opening of the nasal passages. (Chapter 9)

external oblique abdominal muscle group that functions as an accessory muscle of ventilation. (Chapter 9)

external respiration part of the respiratory process that involves the exchange of gases in the alveoli of the lungs. (Chapter 9)

extracorporeal carbon dioxide removal ($ECCO_2R$) procedure whereby blood is passed from the patient through an external membrane, which filters CO_2 to support ventilation. (Chapter 29)

extracorporeal membrane oxygenation (ECMO) procedure whereby venous blood is pumped outside the body to a heart-lung machine for oxygenation and returned to the body. (Chapter 29)

extremely low birth weight (ELBW) a neonate weighting less than 1 kilogram at birth. (Chapter 53)

extubation process of withdrawing a tube from an orifice or cavity of the body. (Chapter 36)

exudate the fluid that oozes from cells and tissues. (Chapters 30, 41)

exudative relating to the oozing of fluid and other materials from cells and tissues, usually as a result of inflammation or injury. (Chapter 41)

exudative pleural effusion any pleural effusion high in protein or lactate dehydrogenase, which implies inflammation or vascular injury on the pleural surface. (Chapter 27)

ex vivo pertaining to outside of the body. (Chapter 18)

F

factitious events values that are real but "out-of-range" and often are temporary, such as the elevation in airway pressure during a cough. (Chapter 51)

false ribs of the 12 pairs of ribs forming a large part of the thoracic skeleton, the first 7 are called *true ribs,* and the next 5 are called *false ribs;* the first 3 attach to the ribs above, and the last 2 are free. (Chapter 9)

fatigue the inability of a muscle to carry its normal load. (Chapter 46)

fasciotomy a surgical procedure that cuts away the fascia to relieve tension or pressure. Used to treat burn patients with severe scar formation. (Chapter 30)

febrile to have a fever. (Chapter 16)

feedback in communication theory, information produced by a receiver and perceived by a sender that informs the sender of the receiver's reaction to the message. Feedback is a cyclic part of the process of communication that regulates and modifies the content of messages. (Chapter 3)

Fellow of the American Association for Respiratory Care (FAARC) a person who has been recognized for the AARC for sustained and substantial contributions to the field of respiratory care. (Chapter 1)

fenestrated an opening into a structure; from the Latin *fenestra,* meaning "window." (Chapter 36)

fetal hemoglobin (HbF) hemoglobin variant that has a greater affinity for O_2 than adult hemoglobin; HbF is gradually replaced over the first year of life by HbA. (Chapter 12)

fetid foul-smelling. (Chapter 16)

fever abnormal elevation of body temperature owing to disease. (Chapter 16)

fever of unknown origin (FUO) a fever for which the cause is not known nor attributable to common causes such as infection. (Chapter 16)

fiberoptic bundles individual coated fibers (or fibers formed into ribbons or bundles) that have a tough resin buffer layer which are used to transmit light from a light source to view the airways through a bronchoscope. (Chapter 22)

Fick equation equation for computing cardiac output based on knowledge of O_2 consumption and the arterial-venous O_2 content difference. (Chapters 12, 51)

Fick's first law of diffusion law for determining the rate of gaseous diffusion across biologic membranes. (Chapter 12)

filling density ratio between the weight of liquid gas put into a cylinder and the weight of water the cylinder could contain if full. (Chapter 40)

fine-particle fraction particles that are small enough to reach the lower respiratory tract. (Chapter 39)

fissures narrow clefts or slits; the lines that divide or separate the lobes of the lung glottis. (Chapter 9)

fixed acid titratable, nonvolatile acid representing the by-product of protein catabolism; examples include phosphoric acid and sulfuric acid. (Chapter 14)

flail chest traumatic chest injury in which a portion of the rib cage becomes unstable because of multiple rib fractures or costochondral separation; typically, the flail region exhibits paradoxical movement during inspiration, contributing to a maldistribution of ventilation. (Chapter 32)

flammable the ability of a substance to burn or ignite, causing fire or combustion. (Chapter 40)

flange rim used to strengthen an object, to help guide it, and to facilitate its attachment to another object. (Chapter 33)

flexible bronchoscopy a bronchoscopy that is flexible in structure, allowing it to be placed deep into the respiratory tract. (Chapter 32)

floating ribs last two rib pairs that are free at their ventral extremities. (Chapter 9)

flow asynchrony asynchrony as a result of the ventilator not providing sufficient flow to meet the patient's inspiratory demand. Most commonly occurs in volume ventilation. (Chapter 47)

flowmeter device operated by a needle valve that controls and measures gas flow according to the principles of viscosity and density. (Chapter 40)

flow resistance difference in pressure between the two points along a tube, divided by the actual flow. (Chapter 6)

fluid entrainment use of the Bernoulli effect to draw a second fluid into a stream of flow. (Chapter 6)

fluvial or brackish water sea water used in reference to drowning. (Chapter 30)

fomite nonliving material, such as bed linens or equipment, which may transmit pathogenic organisms to a person who comes into contact with the object. (Chapters 4, 24)

foramen ovale opening in the septum between the right and the left atria in the fetal heart. This

opening provides a bypass for blood that would otherwise flow to the fetal lungs. After birth, the foramen ovale functionally closes. (Chapter 9)

forced expiration technique (FET) modification of the normal cough sequence designed to facilitate clearance of bronchial secretions, while minimizing the likelihood of bronchiolar collapse. (Chapter 43)

forced expiratory flow between 200 ml and 1200 ml ($FEF_{200-1200}$) measure of average expiratory flow during the early phase of exhalation; specifically, it is a measure of the flow rate for the 1000 ml of expired gas immediately following the first 200 ml of expired gas. Formerly called *maximum expiratory flow rate (MEFR)*. (Chapter 20)

forced expiratory flow between 25% and 75% of forced vital capacity ($FEF_{25\%-75\%}$) measure of average expiratory flow during the middle half of forced vital capacity. (Chapter 20)

forced expiratory flow between 75% and 85% of forced vital capacity ($FEF_{75\%-85\%}$) measure of average expiratory flow during the end of forced vital capacity. (Chapter 20)

forced expiratory volume in half of a second ($FEV_{0.5}$) maximum volume of gas that the patient can exhale during the first half second of a forced vital capacity maneuver. (Chapter 20)

forced expiratory volume in 1 second (FEV_1) maximum volume of gas that the patient can exhale during the first second of the forced vital capacity maneuver. (Chapter 20)

forced expiratory volume in 1 second–to–vital capacity ratio (%FEV_1/FVC) percent of the measured forced vital capacity that can be exhaled in 1 second. (Chapter 20)

forced vital capacity (FVC) maximum volume of gas that the subject can exhale as forcefully and as quickly as possible. (Chapter 20)

formalism ethical viewpoint that relies on rules and principles. (Chapter 5)

fractional distillation process of separating the components of a liquid mixture according to their boiling points via the application of heat; the primary commercial process used to produce O_2. (Chapter 40)

Frank-Starling principle the more a muscle fiber is stretched, the greater is the tension the muscle fiber generates when contracted. (Chapter 10)

frequency/tidal volume ratio (f/V_T) ratio of the tidal volume in ml divided by the respiratory rate. (Chapter 51)

full ventilatory support ventilatory support modes in which the ventilator provides all the minute ventilation requirements of the patient. (Chapter 48)

functional residual capacity (FRC) total amount of gas left in the lungs after a resting expiration. (Chapter 20)

G

gallop rhythm abnormal heart sound that resembles the gallop of a horse, most often indicates heart failure. (Chapter 16)

gantry examination table used for computed tomography (CT) scans. (Chapter 21)

gas absorption atelectasis collapsing of airways due to hyperoxygenation and nitrogen washout. (Chapter 42)

gasping the process of breathing periodically with a labored forced inspiration. (Chapter 32)

gastric inflation introduction of air into the stomach and intestines. (Chapter 37)

gastroesophageal reflux disease (GERD) condition characterized by abnormal movement of stomach contents into the esophagus or mouth; acid from the stomach may be aspirated into the lung and cause asthma-like symptoms. (Chapter 34)

geometric standard deviation (GSD) describes the variability of particle size in an aerosol distribution set at 1 standard deviation above and below the median. (Chapter 39)

gladiolus the body of the sternum. (Chapter 9)

Glasgow Coma Scale (GCS) scale used to provide a score to classify the level of conscious awareness in patients suspected to have an acute brain injury. (Chapters 30, 51)

glomerular filtration rate the volume of water filtered out of the plasma through glomerular capillary walls into Bowman's capsule in the kidney per unit of time. (Chapter 30)

glottis variable opening between the vocal cords. (Chapter 9)

Graham law law stating that the rate of diffusion of a gas through a liquid (or the alveolar-capillary membrane) is directly proportional to its solubility coefficient and inversely proportional to the square root of its density. (Chapter 6)

ground connection between the electrical circuit and the ground, which becomes a part of the circuit. (Chapter 3)

grunting, flaring, and retracting (GFR) the respiratory pattern observed in infants in marked respiratory distress. The neonate makes a grunting sound during breathing with flaring of the nostrils. (Chapter 53)

Guillain-Barré syndrome idiopathic, peripheral polyneuritis characterized by lower extremity weakness that progresses to the upper extremities and face; may lead to flaccid paraplegia and marked respiratory muscle weakness. (Chapter 32)

H

Haldane effect influence of hemoglobin saturation with O_2 on CO_2 dissociation. (Chapter 12)

Hamburger phenomenon the shifting of Cl ions out of the red blood cell as HCO ion is formed in the cell by hydrolysis (combination of CO_2 with H_2O). (Chapter 12)

Harris-Benedict equation equation used to estimate the caloric expenditure in normal individuals under conditions of minimal activity. (Chapter 51)

health care–associated infection (HAI) is an infection which develops from a hospital or other health care environment. (Chapter 4)

health care–associated pneumonia (HCAP) pneumonia occurring in any patient hospitalized for 2 or more days in the past 90 days in an acute care setting or who, in the past 30 days, has resided in a long-term care or nursing facility; attended a hospital or hemodialysis clinic; or received intravenous antibiotics, chemotherapy, or wound care. (Chapter 24)

Health Care Infection Control Practices Advisory Committee (HICPAC) federal advisory committee composed of 14 external infection control experts who provide advice and guidance to the U.S. Centers for Disease Control and Prevention (CDC) and the Secretary of the Department of Health and Human Services regarding the practice of health care infection control and strategies for surveillance and prevention and control of health care–associated infections in U.S. health care facilities. (Chapter 4)

health education process of planned learning opportunities designed to enable individuals to make informed decisions about and act to promote their own health. (Chapter 54)

health informatics the systematic application of information and computer science and technology to clinical or public health practice. (Chapter 7)

***Health Information Technology for Economic and Clinical Health Act* (HITECH Act)** part of a national strategy for building a national health information infrastructure that, among other things, began providing incentives to hospitals, physicians, and other health service providers who demonstrate that they are meaningfully using their electronic health records by meeting predefined standards. (Chapter 7)

health literacy is the degree to which individuals can obtain, process and understand basic health information to make appropriate health decisions and recommendations. (Chapter 54)

health promotion combination of educational, organizational, economic, and environmental support necessary for behavior conducive to health; includes both disease prevention and wellness activities. (Chapter 54)

heart rate (HR) number of heart beats per unit of time, usually expressed as beats per minute (beats/min). (Chapter 10)

heat and moisture exchanger (HME) a device which recirculates moisture from exhaled gas to humidify the next inhaled breath. (Chapter 38)

heave a precordial impulse that may be felt (palpated) in patients with cardiac or respiratory disease. (Chapter 16)

heliox low-density therapeutic mixture of helium with at least 20% O_2; used in some centers to treat large airway obstruction. (Chapter 40)

heliox therapy used to reduce the work of breathing, especially in patients with severe acute asthma or upper airway obstructions, until the primary problem can be resolved. (Chapter 41)

hematemesis vomiting blood. (Chapter 16)

hematocrit packed red blood cell volume in relation to total blood volume, expressed as a percentage. (Chapter 17)

hematology branch of medicine involved in the study of blood morphology, physiology, and pathology. (Chapter 17)

hemolysis rupture of red blood cells. (Chapter 16)

hemoptysis the coughing up of blood from the lungs. (Chapter 16)

hemothorax accumulation of blood in the pleural cavity. (Chapter 27)

Henderson-Hasselbalch (H-H) equation the determination of pH as a measure of acidity (using pK_a, the negative log of the acid dissociation constant) in biological and chemical systems. (Chapter 14)

Henry law in physics, law stating that the solubility of a gas in a liquid is proportional to the pressure of the gas if the temperature is constant and if the gas does not chemically react with the liquid. (Chapter 6)

HEPA (high-efficiency particulate air/aerosol) filter filtration device, usually capable of 99.99% efficacy on particulate matter down to 0.3 mm in size. (Chapter 4)

hepatomegaly abnormal enlargement of the liver; usually a sign of disease. (Chapter 16)

Hering-Breuer inflation reflex parasympathetic inflation reflex mediated via the lung's stretch receptors that appears to influence the duration of the expiratory pause occurring between breaths. (Chapter 15)

heterodisperse referring to an aerosol consisting of particles of varying diameters and sizes. (Chapter 39)

high-flow nasal cannula (HFNC) a variation of the standard nasal cannula that can deliver both FiO_2 and relative humidity greater than 90% by using heated, humidified O_2 with flows up to 50 L/min. These systems have been shown to successfully treat moderate hypoxemia through a combination of a high FiO_2, distending positive airway pressure and meeting or exceeding the patient's minute ventilation. (Chapter 41)

high-flow system O_2 therapy equipment that supplies inspired gases at a consistent preset O_2 concentration. (Chapter 41)

high-frequency chest wall compression (HFCC) mechanical technique for augmenting secretion clearance; small gas volumes are alternately injected into and withdrawn from a vest by an air-pulse generator at a fast rate, creating an oscillatory motion against the patient's thorax. (Chapter 43)

high-frequency oscillatory ventilation (HFOV) is a type of mechanical ventilation which utilizes a respiratory rate greater than 4 times the normal value and very small tidal volumes. (Chapters 29, 48)

high-frequency ventilation (HFV) ventilatory support provided at rates significantly higher than normal breathing frequencies. (Chapters 44, 53)

hilum vertical opening on either side of the mediastinum through which all the airways and pulmonary vessels pass. (Chapter 9)

homeostasis relative constancy in the internal environment of the body, naturally maintained by adaptive responses that promote healthy survival. (Chapter 17)

Hoover sign inward movement of the lower lateral margins of the chest wall with each inspiratory effort owing to a low, flat diaphragm as seen in emphysema. (Chapter 16)

hospital-acquired or nosocomial infection infection acquired at least 72 hours after hospitalization, often caused by *Candida albicans, Escherichia coli,* hepatitis viruses, herpes zoster virus, *Pseudomonas,* or *Staphylococcus*. (Chapter 4)

hospital-acquired pneumonia (HAP) lower respiratory tract infection that develops in hospitalized patients more than 48 hours after admission and excludes community-acquired infections that are incubating at the time of admission. (Chapter 24)

huff cough type of forced expiration with an open glottis to replace coughing when pain limits normal coughing. (Chapter 43)

humidifier device that adds molecular water to gas. (Chapter 38)

hydrofluoroalkane (HFA) the current gaseous chemical compound used to power metered dose inhalers. (Chapter 39)

hydrophilic drugs drugs with strongly polar groups that readily interact with water. (Chapter 30)

hydrophobic pertaining to the property of repelling water molecules, a quality possessed by nonpolar radicals or molecules that are more soluble in organic solvents than in water. (Chapter 38)

hydropneumothorax a pneumothorax that is partially fluid filled. (Chapter 21)

hydrostatic relating to the pressure of fluids or to their properties when in equilibrium. (Chapter 27)

hydrostatic pressure pressure caused by the weight of fluid; related to the volume of fluid in a container and the effects of gravity. (Chapter 13)

hydrostatic pulmonary edema pulmonary edema that is caused by an increase in hydrostatic (water) pressure. (Chapter 29)

hydrothorax noninflammatory accumulation of serous fluid in one or both pleural cavities. (Chapter 20)

hygrometer instrument that directly measures relative humidity of the atmosphere or the proportion of water in a specific gas or gas mixture, without extracting the moisture. (Chapter 38)

hygroscopic attracting or absorbing moisture from the air. (Chapters 38, 39)

hyperbaric oxygen therapy therapeutic application of O_2 at pressures greater than 1 atm (or 760 mm Hg). Also called *hyperbaric oxygenation*. (Chapter 41)

hypercalcemia greater than normal amounts of calcium in the blood, most often resulting from excessive bone resorption and release of calcium, as occurs in hyperparathyroidism, metastatic tumors of bone, Paget disease, and osteoporosis. (Chapter 15)

hypercapnia abnormal presence of excess amounts of CO_2 in the blood (in arterial blood, $PCO_2 > 45$ mm Hg). (Chapter 14)

hypercapnic respiratory failure type II inability to maintain normal removal of CO_2 from the tissues; may be indicated by $PaCO_2$ greater than 50 mm Hg in an otherwise healthy individual. See *ventilatory failure*. (Chapter 44)

hyperglycemia is an abnormally elevated blood glucose level most often resulting from either diabetes or severe sepsis. (Chapter 17)

hyperkalemia greater than normal amounts of potassium in the blood. (Chapters 13, 17)

hypernatremia greater than normal concentration of sodium in the blood, caused by excessive loss of water and electrolytes secondary to polyuria, diarrhea, excessive sweating, or inadequate water intake. (Chapter 17)

hypersensitivity pneumonitis inflammatory form of interstitial pneumonia that results from an immunologic reaction in a hypersensitive person. The reaction may be provoked by various inhaled organic dusts, often containing fungal spores. The disease can be prevented by avoiding contact with the causative agents. Also called *extrinsic allergic alveolitis*. (Chapter 26)

hypertension persistently high blood pressure. (Chapter 16)

hypertonic saline hypertonic saline refers to a greater concentration of salt than what is found in normal saline solution and is often used to mobilize secretions. (Chapter 13)

hyperventilation ventilation greater than necessary to meet metabolic needs; signified by PCO_2 less than 35 mm Hg in the arterial blood. (Chapter 11)

hypocapnia presence of lower than normal amounts of CO_2 in the blood (in arterial blood, $PCO_2 < 35$ mm Hg). (Chapter 14)

hypoglycemia less than normal amount of glucose in the blood, usually caused by administration of too much insulin, excessive secretion of insulin by the islet cells of the pancreas, or dietary deficiency (normal blood glucose levels range from 70 to 105 mg/dl). (Chapter 17)

hypokalemia condition in which an inadequate amount of potassium, the major intracellular cation, is found in the circulating bloodstream. (Chapter 17)

hyponatremia less than normal concentration of sodium in the blood, caused by inadequate excretion of water or by excessive water in the circulating bloodstream. (Chapter 17)

hypopharynx lower portion of the upper airway between the oropharynx and the larynx. (Chapter 9)

hypotension abnormal condition in which the blood pressure is inadequate for normal perfusion and oxygenation of the tissues. (Chapter 16)

hypothermia abnormal and dangerous condition in which the temperature of the body is less than 32° C, usually caused by prolonged exposure to cold. (Chapters 16, 38)

hypothesis is a proposed explanation for a phenomenon to be proven or disproven through well founded research. (Chapter 8)

hypotonic having a tonicity less than normal saline (0.9% NaCl). (Chapter 13)

hypoventilation ventilation less than necessary to meet metabolic needs; signified by PCO_2 greater than 45 mm Hg in the arterial blood. (Chapter 11)

hypovolemia abnormally low circulating blood volume. (Chapter 16)

hypoxemia abnormal deficiency of O_2 in the arterial blood. (Chapter 12)

hypoxemic respiratory failure inability to maintain normal oxygenation in the arterial blood. (Chapters 44, 45)

hypoxia abnormal condition in which the O_2 available to the body cells is inadequate to meet metabolic needs. (Chapter 12)

hysteresis failure of two associated phenomena to coincide, as in the observed difference between the inflation and deflation volume-pressure curves of the lung. (Chapter 11)

I

idiopathic pulmonary fibrosis formation of scar tissue in the connective tissue of the lungs without known cause resulting in severe chronic restrictive lung disease. (Chapter 26)

immunocompromised hosts individuals who have a weakened immune system and are more predisposed to infection. (Chapter 4)

imprecision implying a level of inaccuracy in a particular measurement. (Chapter 18)

impulse-conducting system Purkinje fibers within the heart muscle that conduct impulses controlling the contractions of the atria and ventricles. (Chapter 18)

incentive spirometry process of encouraging a bedridden patient to take deep breaths to avoid atelectasis; most often done with the use of an incentive spirometer that provides feedback to the patient when a predetermined lung volume is reached during inspiration. (Chapter 42)

inclusion body myositis inflammatory myopathy of unknown cause. (Chapter 32)

indirect calorimetry measurement of the amount of energy a body consumes (in kcal) by determining the consumption of O_2 and production of CO_2. (Chapter 23)

inertial impaction deposition of particles by collision with a surface; primary mechanism for pulmonary deposition of particles greater than 5 mm in diameter. (Chapter 39)

infiltrate fluid that passes through body tissues into a space or virtual space as seen in the lung. (Chapter 21)

inhaled mass the mass of the particles inhaled from an aerosol. (Chapter 39)

inhaled nitric oxide (INO) gas that is administered to decrease pulmonary hypertension. (Chapter 53)

innominate artery rupture a rupture of the innominate artery usually a result of a tracheostomy tube eroding the tissue leading to the artery and eventually causing the artery to rupture. (Chapter 47)

inspiratory capacity (IC) maximum amount of air that can be inhaled from the resting end expiratory level or FRC; sum of the tidal volume and inspiratory reserve volume. (Chapter 20)

inspiratory-to-expiratory ratio (I/E) the relationship between the time devolved to inhalation versus that related to the exhalation portion of the breathing cycle, expressed as a proportion. (Chapter 29)

inspiratory positive airway pressure (IPAP) application of positive pressure to the airway during inspiration. (Chapter 45)

inspiratory reserve volume (IRV) maximum volume of air that can be inhaled after a normal quiet inspiration. (Chapter 20)

inspissated (of a fluid) thickened or hardened through the absorption or evaporation of the liquid portion, as can occur with respiratory secretions when the upper airway is bypassed. (Chapters 38, 40)

insufflator-exsufflator mechanical device that provides an artificial cough by alternately applying positive pressure and negative pressure to the airway. (Chapter 51)

Intellivent the ability of a mechanical ventilator to utilize programmed algorithms to either make or recommend setting changes, including those related to weaning and discontinuance. (Chapter 52)

intercostal of or pertaining to the space between two ribs.

intercostal muscles referring to the muscle groups between the ribs. (Chapter 9)

intercostal nerves the nerves serving the intercostal muscles. (Chapter 9)

intermittent mandatory ventilation (IMV) mode of mechanical ventilatory support in which the patient receives a preset number of machine breaths per minute set by time. The patient is allowed to breathe spontaneously as often as desired in between machine breaths. Depending on the base rate, IMV can provide partial or full ventilatory support. (Chapter 45)

intermittent positive pressure breathing (IPPB) application of positive pressure breaths to a patient for a relatively short period (10 to 20 minutes). (Chapter 42)

internal oblique abdominal muscle group that functions as an accessory muscle of ventilation. (Chapter 9)

internal respiration the exchange of O_2 and CO_2 at the tissue level. (Chapter 9)

International Council for Respiratory Care (ICRC) a diverse group of worldwide health professionals addressing issues affecting educational, medical, and professional trends in the global respiratory care community. (Chapter 1)

International Standards Organization (ISO) nongovernment agency that sets standards for various technical equipment and procedures. (Chapter 38)

interstitial fluid fluid between cells but outside of the vascular spaces. (Chapter 13)

interstitial lung disease (ILD) respiratory disorder characterized by a dry, unproductive cough and dyspnea on exertion. X-ray films usually show fibrotic infiltrates in the lung tissue, usually in the lower lobes. (Chapters 21, 26)

intrapulmonary percussive ventilation (IPV) airway clearance technique that uses a pneumatic device to deliver a series of pressurized small volume breaths at high rates (1.6 to 3.75 Hz) to the respiratory tract, usually via a mouthpiece; usually combined with aerosolized bronchodilator therapy. (Chapter 40)

intubation passage of a tube into a body aperture; commonly refers to the insertion of an endotracheal tube within the trachea. (Chapter 36)

intuitionism an ethical viewpoint that holds that there are certain self-evident truths, usually based on moral maxims such as "treat others fairly." (Chapter 5)

invasive characterized by a tendency to spread or infiltrate; also refers to the use of diagnostic or therapeutic methods requiring access to the inside of the body. (Chapter 19)

in vivo (of a biologic reaction) occurring in a living organism. (Chapter 18)

ionic electrovalent; relating to or containing matter in the form of charged atoms or groups of atoms. (Chapter 13)

iron lung full-body negative pressure ventilator. (Chapter 45)

isohydric buffering a buffering process where the H ion produced by one buffer system is immediately buffered by another, such as the buffering of H ion by hemoglobin when H ion is formed by the combination of CO_2 and H_2O in the red blood cell. (Chapter 14)

isothermic saturation boundary (ISB) point at which inspired gas becomes fully saturated to 100% relative humidity at body temperature. (Chapter 38)

isotonic (of a solution) having the same concentration of solute as another solution and exerting the same amount of osmotic pressure as that solution, such as an isotonic saline solution that contains an amount of salt equal to that found in the extracellular fluid. (Chapter 13)

J

J-receptors vagal sensory sites that are located in the alveolar units; so named because they are found primarily in juxtaposition to the pulmonary capillaries. (Chapter 15)

Joint Commission private nongovernment agency that establishes guidelines for the operation of hospitals and other health care facilities, conducts accreditation programs and surveys, and encourages the attainment of high standards of institutional medical care in the United States; formerly Joint Commission on Accreditation of Healthcare Organizations (JCAHO). (Chapter 2)

jugular venous distention abnormal distention of the jugular veins, most often caused by heart failure. (Chapter 16)

justice principle of fair and equal treatment for all, with due reward and honor. (Chapter 5)

K

Karvonen formula simple formula used to set a target heart rate for patients during exercise. (Chapter 55)

Kerley B lines thin lines seen near the pleural edge on a chest film as a result of increased pulmonary capillary pressures. (Chapter 21)

key performance indicators specific measures which are used to determine the level of quality outcomes within a health care setting. (Chapter 7)

kinetic energy energy a body possesses by virtue of its motion. (Chapter 6)

Kussmaul respiration hyperpnea associated with diabetic ketoacidosis. (Chapter 16)

Kussmaul sign paradoxical increase in venous pressure with distention of the jugular veins during inspiration, as seen in constrictive pericarditis or mediastinal tumor. (Chapter 16)

kwashiorkor protein-energy malnutrition resulting from the stress of disease and the resulting increase in catabolic rate. (Chapter 23)

kyphoscoliosis abnormal condition characterized by anteroposterior and lateral curvature of the spine. (Chapter 32)

L

lactate anion of lactic acid. (Chapter 17)

Lambert-Eaton syndrome disorder of neuromuscular conduction commonly associated with an underlying malignancy that leads to muscle weakness frequently with sensory deficits that can often be improved by repetitive muscle contraction against pressure. (Chapter 32)

laminar flow pattern of flow consisting of concentric layers of fluid flowing parallel to the tube wall at linear velocities that increase toward the center. (Chapter 6)

Laplace law principle of physics that the tension on the wall of a sphere is the product of the pressure times the radius of the chamber, and the tension is inversely related to the thickness of the wall. (Chapter 6)

large cell carcinoma type of lung cancer characterized by large cells. (Chapter 32)

large for gestational age (LGA) refers to an infant whose fetal growth was accelerated and whose size and weight at birth are above the 90th percentile of appropriate-for-gestational-age infants, whether delivered prematurely, at term, or later than term. (Chapter 53)

laryngectomy the surgical removal of the larynx. (Chapter 36)

laryngopharynx one of the three regions of the throat, extending from the hyoid bone to the esophagus. (Chapter 9)

larynx organ of the voice that is part of the upper air passage connecting the pharynx with the trachea. It accounts for a large bump in the neck called the *Adam's apple* and is larger in men than in women, although it remains the same size in boys and girls until puberty. (Chapter 9)

laser photocoagulation a means of using a laser with a bronchoscope to stop the bleeding in the airway. (Chapter 22)

latent heat of fusion the amount of heat at a substance's melting point required to change 1 gram of the substance from a solid to a liquid. (Chapter 6)

latent heat of vaporization the amount of heat at a substances boiling point required to change 1 gram of the substance from a liquid to a gas. (Chapter 6)

law of continuity velocity of a fluid moving through a tube varies inversely with the available cross-sectional area. (Chapter 6)

law of mass action states that acids and bases in solution freely dissociate and reassociate in a solution at a constant rate relative to the structure of the acid and the temperature of the solution. (Chapter 13)

laws of thermodynamics laws that describe the relation between temperature and the kinetics of matter changing its state. (Chapter 6)

learning management systems computerized, web-based platforms which are used to offer courses and other learning resources. (Chapter 7)

leukocyte white blood cell. (Chapter 17)

leukocytopenia abnormal decrease in white blood cells.

leukocytosis abnormal increase in the number of circulating white blood cells. (Chapter 17)

leukopenia a low white blood cell count. (Chapter 17)

leukotriene class of biologically active compounds that occur naturally in leukocytes and produce allergic and inflammatory reactions similar to histamine. They are thought to play a role in the development of allergic and autoallergic diseases such as asthma, rheumatoid arthritis, inflammatory bowel disease, and psoriasis. (Chapter 35)

libel false accusation written, printed, or typewritten or presented in a picture or a sign that is made with malicious intent to defame the reputation of a person who is living or the memory of a person who is dead, resulting in public embarrassment, contempt, ridicule, or hatred. (Chapter 5)

lipophilic drugs drugs that can readily dissolve in lipid substances. (Chapter 30)

living will advance declaration by a patient that indicates agreement between a patient and physician to withhold heroic measures if the patient's condition is found to be irreversible. (Chapter 5)

lobar atelectasis a collapsing of the airways and or alveoli which is limited to a lung segment. (Chapter 42)

lobes major divisions of the lungs; the right lung has three lobes, and the left lung has two lobes. (Chapter 9)

long-term subacute care hospitals (LTACHs) facilities that provide highly focused care to patients with complex medical conditions outside of traditional acute care hospitals, including patients who have been ventilator-dependent and difficult to wean. (Chapter 56)

loud P-2 abnormally loud closure of the pulmonic valve as part of S_2; usually caused by pulmonary hypertension. (Chapter 16)

Lou Gehrig disease popular name for amyotrophic lateral sclerosis (ALS), a disease characterized by progressive muscle weakness secondary to nerve deterioration. (Chapter 32)

lower respiratory tract infection any infectious disease of the left and right bronchi and the alveoli. (Chapter 24)

low-flow system variable performance O_2 therapy device that delivers O_2 at a flow that provides only a portion of the patient's inspired gas needs. Also called *variable performance system*. (Chapter 41)

L/T ratio refers to aerosol, it is the lung availability of an aerosol divided by the total system availability of the aerosol. (Chapter 35)

lung protective ventilation (LPV) the use of low tidal volumes to help prevent ventilator induced lung injury. (Chapter 29)

lung protective ventilatory strategy approach to mechanical ventilation that attempts to avoid overdistention of the lung and recruitment and derecruitment of unstable lung units with each breath. (Chapter 48)

lung strain is the deformation of a structure compared to its overall size. As applied to the respiratory system it is equal to the tidal volume. (Chapter 51)

lung stress the force applied per unit area. As applied to the respiratory system it is equal to transpulmonary pressure. (Chapter 51)

lung ultrasonography the use of ultrasound technology to view lung structures. (Chapter 51)

lymphadenopathy of or pertaining to a disease of the lymph nodes; refers also to the visualization of enlarged lymph nodes on radiographs. (Chapter 16)

lymphangioleiomyomatosis (LAM) lung abnormality most commonly observed in women and characterized by abnormal proliferation of smooth muscle cells in the interstitium, dyspnea, abnormal radiographic findings, and commonly pneumothorax. (Chapter 26)

lymphatic drainage system the main conduit for the removal of filtered fluid and protein from the lung. (Chapter 27)

M

macroshock shock from an electrical current of 1 mA or greater that is applied externally to the skin. (Chapter 3)

magnetic resonance imaging (MRI) imaging technique using magnetic disturbance of tissue to obtain images. (Chapter 30)

Mallampati classification is one of the most commonly used methods to identify the ability to visualize the vocal cords and glottis and therefore assess the degree of difficulty clinicians may encounter during intubation. (Chapter 22)

malpractice in law, professional negligence that is the proximate cause of injury or harm to a patient, resulting from a lack of professional knowledge, experience, or skill that can be expected in others in the profession or from a failure to exercise reasonable care or judgment in the application of professional knowledge, experience, or skill. (Chapter 5)

mandatory breath ventilatory support breath either initiated or ended by the machine. (Chapter 45)

mandatory minute volume ventilation (MMV) variation of the intermittent mandatory ventilation mode of ventilatory support in which the ventilator keeps the total minute volume constant. (Chapter 52)

manifold pipe with many connections; in medical gas storage, a collection of gas cylinders linked together for purposes of bulk storage and usually including at least one reserve bank and other safety systems, such as low-pressure alarms. (Chapter 40)

manubrium upper triangular portion of the sternum. (Chapter 8)

marasmus protein-energy malnutrition caused by starvation. (Chapter 23)

mass physical property of matter that gives it weight and inertia; aggregate of cells clumped together, such as a tumor. (Chapter 32)

mass median aerodynamic diameter (MMAD) measure of central tendency that describes the particle diameter in micrometers in medical aerosols and pertains to cascade impaction. (Chapter 39)

maximum expiratory pressure (MEP) measure of the output of the expiratory muscles against a maximum stimulus, measured in cm H_2O positive pressure. (Chapter 44)

maximum inspiratory pressure (MIP) measure of the output of the inspiratory muscles against a maximum stimulus, measured in cm H_2O negative pressure. Also known as *negative inspiratory force (NIF)* or *maximum inspiratory force (MIF)*. (Chapters 44, 51)

maximum voluntary ventilation (MVV) maximum volume of air in L/min that a patient can breathe during a 12- to 15-second period. It is a very patient-dependent test. Formerly called the *maximum breathing capacity (MBC)*. (Chapters 20, 44, 51)

mean airway pressure average pressure applied to the airway. (Chapters 46, 51)

mechanical insufflation-exsufflation mechanical device that provides an artificial cough by alternately applying positive pressure and negative pressure to the airway, also referred to as an *in-exsufflator*. (Chapter 40)

mechanical ventilator an artificial device to assist a patient to breathe. (Chapter 1)

meconium material that collects in the intestines of a fetus and forms the first stools of a newborn. (Chapter 53)

meconium aspiration syndrome inhalation of meconium by a fetus or newborn; can block the air passages and cause failure of the lungs to expand. (Chapter 34)

mediastinum portion of the thoracic cavity lying in the middle of the thorax (between the two pleural cavities); extends from the vertebral column to the sternum and contains the trachea, esophagus, heart, and great vessels of the circulatory system. (Chapter 9)

melting point characteristic temperature at which the solid and liquid forms of a substance are in equilibrium. (Chapter 6)

membrane pressures the pressure across an oxygenator used in an ECMO circuit. (Chapter 50)

metabolic acidosis nonrespiratory processes resulting in acidemia. (Chapter 14)

metabolic alkalosis nonrespiratory processes resulting in alkalemia. (Chapter 14)

methemoglobin abnormal form of hemoglobin in which the iron component has been oxidized from the ferrous to the ferric state. (Chapter 12)

methemoglobinemia abnormal condition characterized by high levels of methemoglobin in the blood and reduction in O_2-carrying capacity; may be caused by nitrite poisoning or ingestion of a certain oxidizing agent or a genetic defect in the enzyme NADH methemoglobin reductase (an autosomal dominant trait). (Chapters 12, 22)

micrognathia underdevelopment of the jaw, especially the mandible. (Chapter 31)

microshock shock from a usually imperceptible electrical current (<1 mA) that is allowed to bypass the skin and follow a direct, low-resistance pathway into the body. (Chapter 3)

minute ventilation total lung ventilation per minute, the product of tidal volume and respiration rate. It is measured by expired gas collection for a period of 1 to 3 minutes; normal rate is 5 to 10 L/min. (Chapters 20, 52)

misallocation process of prescribing diagnostic or treatment services when not indicated, consisting both of overordering and underordering services. (Chapter 2)

missed triggering the inability of a patient to trigger the ventilator during a particular inspiratory effort. Usually a result of auto-PEEP or too large a tidal volume with a rapid respiratory rate. (Chapter 47)

mode (ventilatory) any one of many categories of mechanical ventilation that are determined by a number of characteristics, including how the breath is initiated and how the inhalation ceases and exhalation starts. (Chapter 45)

mode asynchrony the selection of a mode of ventilation that does not synchronously interact with the patient's inspiratory efforts. (Chapter 47)

moderate (conscious) sedation a form of sedation used for certain procedures such a bronchoscopy, whereby patients can respond to verbal stimuli and maintain protective airway reflexes. (Chapter 22)

modified Allen test most common technique to determine the adequacy of ulnar circulation. (Chapter 19)

molecular sieve crystalline chemical separation device with molecular size pores that adsorbs small but not large molecules. (Chapter 51)

monitor to observe and evaluate a function of the body closely and constantly; mechanical device that provides a visual or audible signal or a graphic record of a particular function, such as a cardiac monitor or a fetal monitor. (Chapter 19)

monodisperse referring to an aerosol in which particles are of uniform size. (Chapter 39)

morbid obesity a state of having a body mass index (BMI) of greater than 45 kg/m^2. (Chapter 30)

mucociliary escalator a term used to define the process in which the cilia of the airways continually move mucus from the lower respiratory tract to the oral cavity. (Chapter 9)

mucoid resembling mucus. (Chapter 16)

mucous plugging the partial or complete occlusion of the airway by thick mucus. (Chapter 40)

multiple organ dysfunction syndrome (MODS) condition in which dysfunction of many different organs occurs, usually accompanying acute lung injury. (Chapter 29)

murmur abnormal heart sound created by turbulent blood flow through a narrowed or incompetent heart valve. (Chapter 16)

Murray lung injury score a score used to define the severity of injury in patients with ARDS. (Chapter 51)

muscarinic stimulating the postganglionic parasympathetic receptor; pertaining to the poisonous activity of muscarine. (Chapter 35)

muscle fatigue condition involving loss of the capacity to develop force or velocity of a muscle resulting from muscle activity overload, which is reversible by rest. (Chapter 44)

myasthenia gravis disorder of neuromuscular conduction that leads to muscle weakness of the skeletal muscles, particularly the muscles of the face, throat, and respiratory system. Weakness and respiratory failure can occur rapidly as muscle strength decreases with repetitive contraction against a load. (Chapter 32)

mydriasis dilation of the pupil of the eye. (Chapter 32)

myopathy abnormal condition of skeletal muscle leading to muscle weakness, wasting, and histologic changes in the muscle tissue, as seen in muscular dystrophies. (Chapter 32)

myositis inflammation of the muscle. (Chapter 32)

myotonic dystrophy type of muscular dystrophy. (Chapter 32)

N

nanomole a quantity equal to 10^{-9} of a mole. (Chapter 13)

narrow band imaging an imaging technique for used in conjunction with bronchoscopy, where light of specific blue and green wavelengths is used to enhance the detail of certain aspects of the surface of the mucosa. (Chapter 22)

nasal flaring dilation of the alar nasi on inspiration; an early sign of an increase in ventilatory demands and the work of breathing, especially in infants. (Chapter 34)

nasopharynx upper portion of the airway behind the nasal and oral cavities. (Chapter 9)

National Board for Respiratory Care (NBRC) national credentialing agency for respiratory care practitioners and pulmonary function technologists. (Chapters 1, 2)

nebulizer device that produces an aerosol suspension of liquid particles in a gaseous medium using baffling to control particle size. (Chapters 38, 39)

needle capping device safety device used to prevent or minimize needlestick injuries when capping a syringe needle (as required after blood gas sampling). (Chapter 19)

negative feedback loop when the output of a system acts to oppose changes to the input of the system, with the result that the changes are attenuated and output is balanced. (Chapter 10)

negative inotropism decrease in contractility of the heart. (Chapter 10)

negative-pressure ventilation approach to ventilation in which negative pressure is intermittently applied to the chest surface in an effort to cause inflation of the lungs. (Chapter 45)

negligence omission to do something that a reasonable person, guided by ordinary considerations, would do. (Chapter 5)

neovascularization formation of new capillary beds. (Chapter 41)

neurally adjusted ventilatory assistance (NAVA) an approach to ventilation based on the electromyelographic (EMG) activity of the diaphragm. Airway pressure is increased proportional to the change in EMG activity. No control variable is set. (Chapters 47, 48)

neuropathy refers to abnormal conditions characterized by inflammation or degeneration of the nerves. (Chapter 32)

neutral thermal environment (NTE) ambient environment that prevents or minimizes the loss of body heat. (Chapter 41)

neutropenia abnormal decrease in the number of neutrophils in the blood. (Chapters 17, 35)

nitric oxide (NO) an inhaled gas used to reduce pulmonary artery pressure and improve arterial oxygenation. (Chapter 41)

nocturnal hypoventilation elevated $PaCO_2$ and accompanying decline in O_2 saturation that occurs in response to a progressive decrease in minute ventilation occurring during sleep, most often in the REM stage. (Chapter 45)

nodule small node; small nodelike structure. (Chapter 32)

nonflammable unable to support combustion. (Chapter 40)

nonhydrostatic pulmonary edema pulmonary edema that is caused by something other than an increase in blood pressure. (Chapter 29)

noninvasive pertaining to a diagnostic or therapeutic technique that does not require the skin to be broken or a cavity or organ of the body to be entered, such as obtaining a blood pressure reading by auscultation with a stethoscope and sphygmomanometer. (Chapter 19)

noninvasive positive pressure ventilation (NPPV) (also referred to as **noninvasive ventilation** or **NIV**) positive pressure ventilation without endotracheal intubation or tracheotomy, usually via a form-fitting mask. (Chapters 41, 45)

noninvasive ventilation mechanical ventilation performed without intubation or tracheostomy, usually with mask ventilation. (Chapters 25, 42, 44, 51)

nonmaleficence principle that obligates health care providers to avoid harming patients and actively to prevent harm where possible. (Chapter 5)

non–small cell carcinoma major category of histologic types of lung carcinomas, including adenocarcinoma of the lung, large cell carcinoma, and squamous cell carcinoma. Treatment depends on the stage of development of the cancer at the time of initial presentation. The treatment of choice for otherwise physically fit patients with early stages of disease is resection. (Chapter 32)

normal solution solution that contains the gram-equivalent weight of a reagent per liter; denoted by the symbols *N/I* or *N*. (Chapter 13)

normometabolic the normal level of metabolic function in a healthy individual. (Chapter 23)

nosocomial pneumonia infectious inflammatory process of the lung parenchyma that is contracted in the hospital. (Chapter 24)

O

O_2-conserving device an O_2 delivery system that minimizes the amount of O_2 actually delivered to a patient while also maintaining the FiO_2. (Chapter 51)

obesity hypoventilation general syndrome involving chronic hypercapnia and hypoxemia, sleep apnea, and decreased respiratory center responsiveness to CO_2. Complications, primarily owing to chronic hypoxemia, include polycythemia, pulmonary hypertension, and cor pulmonale. (Chapter 33)

obstructive pulmonary disease any respiratory disease characterized by decreased airway size and increased airway secretions. (Chapter 20)

obstructive sleep apnea (OSA) condition in which five or more apneic periods (lasting at least 10 seconds each) occur per hour of sleep and characterized by occlusion of the oropharyngeal airway with continued efforts to breathe. (Chapter 33)

obturator device used to block a passage or a canal or to fill in a space, such as the obturator used to insert a tracheostomy tube. (Chapter 36)

Occupational Safety and Health Administration (OSHA) a federal agency of the United States that regulates workplace safety and health. (Chapter 4)

occupational interstitial lung disease (ILD) interstitial lung disease resulting from an occupational exposure; asbestosis is a common example. (Chapter 26)

ohm unit of measurement to report the resistance to the flow of electricity. (Chapter 3)

Ondine curse apnea caused by loss of automatic control of respiration (derived from the name of a fabled water nymph). (Chapter 32)

onset of blood lactate accumulation (OBLA) point at which blood lactate levels increase above normal when the body cannot deliver sufficient O_2 to meet the demands of energy metabolism; term used in exercise physiology. (Chapter 55)

open buffer system the bicarbonate buffer system is an open buffer system because H_2CO_3 can be removed as CO_2, is broken down into H_2O and CO_2 as long as ventilation removes CO_2. (Chapter 14)

open loop control system in which there is no control over the delivered variable. (Chapter 42)

optical fluorescence the use of fluorescent dyes that are illuminated with light of a specific wavelength for the measurement of respiratory gases. (Chapter 19)

optode fluorescent chemosensor useful in measuring pH or gas tensions in arterial or mixed venous blood. (Chapter 19)

organizing pneumonia (OP) is the new term for bronchiolitis obliterans organizing pneumonia, that generally occurs in the setting of connective tissue disease. (Chapter 26)

oropharynx the portion of the pharynx which is located most closely to the mouth. (Chapter 9)

orthodeoxia decrease in PaO_2 owing to changes in position. (Chapter 16)

orthopnea labored breathing in the reclining position. (Chapter 16)

oscillation back-and-forth motion; vibration or the effects of mechanical or electrical vibration. (Chapter 40)

OSHA abbreviation for the Occupational Safety and Health Administration, a branch of the U.S. Department of Labor responsible for regulations pertaining to on-the-job safety. (Chapter 4)

osmolality is a measure of the concentration of a solute in a solution. (Chapter 13)

osmolarity osmotic pressure of a solution expressed in osmoles or mOsm/kg of the solution.

osmotic pressure force produced by solvent particles across semipermeable membranes. (Chapter 13)

oxidizing to combine or cause to combine with O_2, to remove hydrogen, or to increase the valence of an element through the loss of electrons. (Chapter 40)

oximetry a non-invasive method for monitoring how saturated a persons hemoglobin is with oxygen and other gases. (Chapter 19)

oxygen consumption (VO_2) the amount of O_2 consumed per minute; normal value 200 ml/min. (Chapter 51)

oxygen therapy any procedure in which O_2 is administered to a patient to relieve hypoxemia. (Chapter 1)

oxyhemoglobin chemical combination resulting from the covalent bonding of O_2 to the ferrous iron pigment in hemoglobin. (Chapter 12)

P

P_{50} quantifies variations in the affinity of Hb for O_2. It is the partial pressure of O_2 at which the Hb is 50% saturated, standardized to a pH level of 7.40. (Chapter 12)

pack-years a method of determining the quantity of cigarettes a patient smoked over time. The number of packs of cigarettes a person smoked divided by the number of years they smoked. (Chapter 16)

palate bony plate that separates the nasal cavity from the oral cavity. (Chapter 9)

Pancoast syndrome combination of signs associated with a tumor in the apex of the lung; signs include neuritic pain in the arm, atrophy of the muscles of the arm and the hand, and Horner syndrome and are caused by the damaging effects of the tumor on the brachial plexus and sympathetic ganglia. (Chapter 32)

PaO_2/FiO_2 ratio the PaO_2 divided by the FiO_2, indicative of the severity of lung injury. (Chapter 51)

paradoxical motion movement of the thoracic cavity where the cavity bows out with expiration and collapses inward during a spontaneous breath. The movement is associated with a decreased pressure gradient to drive inspiration

and expiration and can result in respiratory failure. (Chapter 32)

paraneoplastic syndrome effect of tumors remote from the tumor site and often mediated by reactions to tumor products or immune response to the tumor. (Chapter 32)

paresthesia any subjective sensation, experienced as numbness, tingling, or a "pins and needles" feeling. (Chapter 14)

parietal pleura thin membrane covering the surface of the chest wall, mediastinum, and diaphragm that is continuous with the visceral pleura around the lung hilum. (Chapters 9, 27)

partial ventilatory support modes of ventilatory support in which the patient must contribute to the total minute volume with spontaneous breathing. (Chapter 48)

Pascal principle law stating that a confined liquid transmits pressure equally in all directions. (Chapter 6)

passive (exhalation) the release of previously stored energy from the elastic recoil of the chest wall and lungs to facilitate exhalation. (Chapter 46)

patent ductus arteriosus (PDA) common cardiovascular anomaly of infants in which the ductus arteriosus either fails to close or reopens after birth. (Chapter 53)

***Patient Protection and Affordable Care Act* (ACA) of 2010** legislation that changed many aspects of the American health care system by expanding health care coverage to many uninsured people, prohibiting the exclusion of preexisting conditions, creating an exchange for purchasing health insurance coverage, increasing the scope of coverage for certain types of preventive care and many other provisions. (Chapter 56)

patient-ventilator asynchrony lack of coordinated gas delivery between the patient and the ventilator. (Chapters 46, 47)

peak expiratory flow rate (PEFR) maximum expiratory flow rate in L/sec. (Chapter 20)

pedal edema swelling of the ankles usually secondary to heart failure. (Chapter 16)

penetrating trauma chest trauma that is the result of bullet, knife, etc. that makes a singular entry into the chest. Normally pulmonary contusion does not occur with penetrating trauma. (Chapter 30)

percent total body surface area (%TBSA) that percent of the body surface that is affected. Normally used to identify the extent of body surface burns. (Chapter 30)

performance improvement measuring the results of a process and then changing it to enhance future results. (Chapters 2, 3)

pericardium fibrous, serous sac that surrounds the heart and roots of the great vessels. (Chapter 10)

peripheral cyanosis a bluish tinge of the extremities often caused by low arterial blood oxygen content or poor circulation. (Chapter 16)

periodic breathing abnormal pattern of respiration, characterized by alternating periods of apnea and deep, rapid breathing. (Chapter 32)

persistent pulmonary hypertension of the newborn (PPHN) clinical syndrome seen in infants soon after birth and characterized by abnormally increased pulmonary vascular resistance. (Chapter 33)

pharmacodynamic phase mechanisms of drug action that cause effects on the body. (Chapter 35)

pharmacokinetic phase time, course, and disposition of a drug in the body. (Chapter 35)

pharyngeal airways devices that maintain the patency of the pharyngeal structure. (Chapter 36)

pharynx the throat—tubular structure approximately 13 cm long that extends from the base of the skull to the esophagus and is situated immediately in front of the cervical vertebrae. The pharynx serves as a passageway for the respiratory and digestive tracts and changes shape to allow the formation of various vowel sounds. (Chapter 9)

phase variable signal that is measured and used by the ventilator to begin some part (phase) of the breathing cycle. (Chapter 42)

phlegm mucus from the tracheobronchial tree. (Chapter 16)

photoplethysmography light-emitting technology used to detect changes in blood flow. (Chapter 19)

phrenic nerves paired nerves that originate as branches of spinal nerves C3-5, pass down along the mediastinum, and innervate the diaphragm. (Chapter 9)

psychomotor domain the skills associated with the ability to physically manipulate an object. (Chapter 54)

physician assistant (PA) individual academically and clinically prepared to practice medicine under the supervision of a licensed doctor of medicine or osteopathy. Within the physician-PA relationship, PAs exercise autonomy in medical decisions and provide a wide range of diagnostic and therapeutic services. Training programs average 25 to 27 months. National certification is available to graduates of approved training programs. (Chapter 1)

physiologic dead space area in the respiratory system that includes the anatomic dead space together with the space in the alveoli occupied by air that does not contribute to the O_2-CO_2 exchange. (Chapter 11)

physiologic shunt (Q_s/Q_T) percentage of the cardiac output that does not participate in gas exchange in the lung. (Chapter 51)

picture archiving and communication systems a medical imaging technology which permits storage and convenient access to images. (Chapter 7)

piezoelectric crystal transducer capable of converting electrical energy into the physical energy of high-frequency vibrations. (Chapter 38)

pin-indexed safety system (PISS) part of the American standard safety system, these specifications apply only to the valve outlets of small cylinders, up to and including size E, that use a yoke-type connection. (Chapter 40)

plaintiff person who brings an action; a person who seeks remedial relief for an injury to his or her rights. (Chapter 5)

plasma watery, colorless fluid portion of the blood and lymph in which cellular elements are suspended. (Chapter 12)

plasma colloid osmotic pressure (oncotic pressure) osmotic pressure exerted by the colloid suspended in the blood. (Chapter 13)

plateau pressure (P_{plat}) pressure in the patient's airway during mechanical ventilation resulting from the application of an end inspiratory hold. This is equal to the average peak alveolar pressure. (Chapter 48)

plate (or platelike) atelectasis lung collapse that appears in distinct platelike structures. (Chapter 20)

platypnea opposite of orthopnea; an abnormal condition characterized by difficult breathing in the standing position that is relieved in the lying or recumbent position. (Chapter 16)

plethysmograph device for measuring pressure; in pulmonary physiology, a chamber in which the subject sits to measure lung pressures and volumes. (Chapter 11)

pleural effusion abnormal collection of fluid in the pleural space. (Chapters 21, 27)

pleurisy pain that comes from the pleural surface; usually a direct result of viral infections but has been generalized to any condition (e.g., pulmonary embolism) causing pleural pain. Synonymous with *pleurodynia*. (Chapter 27)

pleurodesis procedure of fusing the parietal and visceral pleura to prevent formation of pleural fluid or recurrence of pneumothorax. (Chapter 27)

pneumobelt ventilatory assist device that applies positive pressure to the abdominal contents during expiration. (Chapter 45)

pneumomediastinum presence of air or gas in the mediastinal tissues, which may lead to pneumothorax or pneumopericardium. (Chapter 21)

pneumonia inflammatory process of the lung parenchyma, usually infectious in origin. (Chapter 24)

pneumotachometer any device for measuring gas flow. (Chapter 11)

pneumotaxic center center in the upper part of the pons that rhythmically inhibits inspiration independently of the vagi. (Chapter 15)

pneumothorax presence of air or gas in the pleural space of the thorax; if this air or gas is trapped under pressure, tension pneumothorax exists. (Chapters 16, 21, 27)

point-of-care testing analysis of body fluids at the bedside, as opposed to conventional laboratory testing. (Chapters 7, 19)

Poiseuille's law the physical law which describes the difference in pressure required to produce a given flow under conditions of laminar flow, through a smooth tube of a fixed size. (Chapter 6)

polycythemia abnormal increase in the number of erythrocytes in the blood; termed *secondary* if attributable to defined causes other than direct stimulation of the bone marrow, such as occurs in chronic hypoxemia. (Chapter 17)

polymyositis condition characterized by inflammation of many muscles. (Chapter 32)

pores of Kohn small openings between adjacent alveoli. (Chapter 9)

portals a means by which authorized users can gain access to computerized medical records and health resources. (Chapter 8)

positive end expiratory pressure (PEEP) application and maintenance of pressure above atmospheric at the airway throughout the expiratory phase of positive pressure mechanical ventilation. (Chapters 29, 44)

positive expiratory pressure (PEP) airway clearance technique in which the patient exhales against a fixed-orifice flow resistor to help move secretions into the larger airways for expectoration via coughing or swallowing. (Chapters 42, 40)

positive inotropism increase in the contractility of muscle tissue. (Chapter 10)

positron emission tomography (PET) computerized radiographic technique that uses radioactive substances to examine the metabolic activity of various body structures. The patient either inhales or is injected with a metabolically important substance such as glucose, carrying a radioactive element that emits positively charged particles, or positrons. When the positrons combine with electrons normally found in the cells of the body, gamma rays are emitted. The electronic circuitry and computers of the PET device detect the gamma rays and construct color-coded images that indicate the intensity of metabolic activity throughout the organ involved. (Chapter 31)

postural hypotension sudden decrease in arterial blood pressure caused by a change in position; most often occurs when a hypovolemic patient moves from the reclining position to the upright position. (Chapter 16)

potential energy energy contained in a body as a result of its position in space, internal structure, and stresses imposed on it. (Chapter 6)

preanalytic error error that occurs outside of that actual testing procedure. (Chapter 19)

precision the accuracy of an instrument during the measurement of a particular substance. (Chapter 19)

preload pressure stretching the ventricular walls at the onset of ventricular contraction. (Chapters 10, 51)

premature ventricular contractions are abnormal and bizarre ECG rhythms that are much wider than normal. (Chapter 18)

preoperative of or pertaining to the period of time preceding a surgical procedure. (Chapter 39)

pressure controlled ventilation (PCV) mode of ventilatory support in which mandatory support breaths are delivered to the patient at a set inspiratory pressure. (Chapters 44, 45, 48)

pressure gradient the pressure difference between two points in a system. (Chapter 11)

pressure-regulated volume control (PRVC) pressure limited ventilation in which inspiratory time and a backup rate are set and a tidal volume is targeted. (Chapter 48)

pressure support ventilation (PSV) mode of ventilatory support designed to augment spontaneous breathing; patient-triggered, pressure-limited, flow-cycled ventilation. (Chapters 48, 52)

pressure-time product product of pressure over a time interval, usually pleural pressure times inspiratory time during breathing. (Chapter 51)

primary lobule the terminal bronchiole and the cluster of respiratory bronchioles that it supplies. (Chapter 9)

primary pulmonary hypertension of the newborn form of pulmonary hypertension that occurs in the absence of other heart or lung diseases and is characterized by diffuse narrowing of the pulmonary arterioles without obvious reason. (Chapter 53)

primary spontaneous pneumothorax pneumothorax that occurs without underlying lung disease. (Chapter 27)

problem-oriented medical record (POMR) method of recording data about the health status of a patient in a problem system. (Chapter 3)

process control a method of quality control which uses detailed information about a process to optimize outcomes. (Chapter 3)

prodrug inactive or partially active drug that is metabolically changed in the body to an active drug. (Chapter 35)

proficiency testing (PT) process of comparing measurements of a known value from different sources to establish a level of accuracy. (Chapter 19)

progressive resistance method of increasing the strength of a weak or injured muscle by gradually increasing the resistance against which the muscle works, such as by using graduated weights over a period. Also called *graduated resistance*. (Chapter 55)

prolonged mechanical ventilation a lengthy process of mechanical ventilatory support. No precise length has been determined but most would consider longer than 3 weeks prolonged ventilatory support. (Chapter 52)

prone positioning when a patient is placed in a face down position, often during mechanical ventilation to help improve ventilation and oxygenation. (Chapter 29)

propellant something that propels or provides thrust, as the propellant in a metered dose inhaler. (Chapter 39)

proportional assist ventilation (PAV) mode of ventilation without any control variable that delivers gas in proportion to the patient's actual inspiratory effort. (Chapters 47, 48)

protein-energy malnutrition (PEM) wasting condition resulting from a diet deficient in either protein or energy (calories) or both. (Chapter 23)

pseudostratified epithelia of or pertaining to an epithelial cell type that appears to be organized in layers but in which each cell actually contacts the basement membrane. (Chapter 9)

psig abbreviation for pounds per square inch-gauge—the pressure above atmospheric registered on a meter or gauge. (Chapter 40)

psychomotor domain area of observable performance of skills that require some degree of neuromuscular coordination. (Chapter 54)

psychosocial support needs of or pertaining to the mental, emotional, and social aspects of human existence or development. (Chapter 55)

PubMed a free, computerized search engine which facilitates access to peer-reviewed articles, abstracts and references related to life sciences. (Chapter 8)

pulmonary arterial hypertension an increase above normal levels in blood pressure in the pulmonary vasculature. (Chapter 28)

pulmonary contusion the internal pulmonary bleeding and edema that result from blunt trauma. Generally it is localized to the area adjacent to the trauma. (Chapter 30)

pulmonary edema condition in which excessive amounts of plasma enter the pulmonary interstitium and alveoli; usually accompanied by severe respiratory distress, tachypnea, and hypoxemia. (Chapter 29)

pulmonary embolism (PE) blockage of a pulmonary artery by foreign matter. The obstruction may be fat, air, tumor tissue, or a thrombus that usually arises from a peripheral vein (most frequently arising from the deep veins of the legs). Pulmonary embolism is detected by chest x-ray, pulmonary angiography, and radioscanning of the lung fields. (Chapter 28)

pulmonary function testing (PFT) procedure for determining the capacity of the lungs to exchange O_2 and CO_2 efficiently. There are two general kinds of pulmonary function tests: one measures ventilation, or the ability of the bellows action of the chest and lungs to move gas in and out of alveoli; the other kind measures the diffusion of gas across the alveolar capillary membrane and the perfusion of the lungs by blood. (Chapters 1)

pulmonary hypertension (PH) condition characterized by abnormally high pulmonary artery pressures (i.e., mean pulmonary artery pressures > 22 mm Hg). (Chapter 28)

pulmonary Langerhans cell histiocytosis (PLCH) condition characterized by abnormal proliferation of Langerhans cells, accompanied by interstitial markings on the chest film and dyspnea. (Chapter 26)

pulmonary rehabilitation an organized multidisciplinary approach to improve the functional status of patients with chronic obstructive pulmonary disease, usually including education, exercise, aerosolized medication, and O_2 therapy. (Chapter 55)

pulmonary surfactant a surface active lipoprotein formed by Type II cells which reduces surface tension and facilitates alveolar expansion during inhalation. (Chapter 9)

pulseless electrical activity (PEA) a serious condition characterized by a disassociation between the electrical and mechanical activity of the heart. In essence, the electrical ECG pattern on the monitor neither generates mechanical activity of the heart nor a pulse. (Chapter 18)

pulse co-oximetry a pulse oximetry that is capable of measuring carboxyhemoglobin and methemoglobin. (Chapter 19)

pulse deficit discrepancy between the ventricular rate auscultated at the apex of the heart and the arterial rate of the radial pulse. (Chapter 16)
pulse pressure difference between systolic blood pressure and diastolic blood pressure. (Chapter 16)
pulsus alternans alternating between strong and weak heartbeats. (Chapter 16)
pulsus paradoxus abnormal decrease in pulse pressure with each inspiratory effort. (Chapter 16)
pump flow the flow of blood pumped through on ECMO system in liters per minute. (Chapter 50)
purulent consisting of or containing pus. (Chapter 16)

Q

quality the extent to which a process, structure, product and/or organization adheres to current best-practices, is free of errors and achieves intended outcomes. (Chapter 2)
quality assurance any evaluation of services provided and the results achieved compared with accepted standards. (Chapters 2, 3)
quality control planned, systematic approach to designing, measuring, assessing, and improving performance. (Chapter 19)
quality improvement the enhancement of a process, structure, product and/or organization to more closely adhere to best-practices, reduce errors and achieve intended outcomes. (Chapter 3)

R

radiation treatment of neoplastic disease by using x-rays or gamma rays, usually from a cobalt source, to deter the proliferation of malignant cells by decreasing the rate of mitosis or impairing deoxyribonucleic acid synthesis. (Chapter 6)
radiograph x-ray image. (Chapter 21)
radiolucent of or pertaining to a substance or tissue that readily permits the passage of x-rays or other radiant energy. Compare with *radiopaque*. (Chapter 21)
radiopaque of or pertaining to a substance or tissue that does not readily permit the passage of x- rays or other radiant energy. Compare with *radiolucent*. (Chapters 21, 36)
radiotherapy treatment with radiation. (Chapter 31)
rales an abnormal breath sound also known as "crackles" and which is discontinuous and can be further characterized as "fine rales" associated with congestive heart failure or "coarse rales" most often associated with air moving through secretions in the airways. (Chapter 16)
random error variability of a measurement outside of accepted limits that occurs in a non-reproducible fashion. (Chapter 19)
rapid shallow breathing index (f/V_T) patient's spontaneous respiratory rate (f) in breaths per minute divided by the spontaneous tidal volume in liters. Values greater than 100 are associated with poor weaning outcomes. (Chapter 52)
recirculation the movement of blood from one cannula to another in an ECMO circuit. Specifically blood being infused in to a patient by a venous return catheter that is immediately removed from the patient by the venous drainage catheter during venovenous ECMO. (Chapter 50)
reconditioning physical activity to strengthen essential muscle groups, improve overall O_2 use, and enhance the cardiovascular response of the body to physical activity. (Chapter 55)
recruitment maneuvers a intermittent intervention used on mechanically ventilated patients involving the very brief, but repeated use of high ventilation pressures to expand previously collapsed alveoli. (Chapter 30)
rectus abdominis abdominal muscle group that functions as an accessory muscle of ventilation. (Chapter 9)
reducing valve valve that reduces gas pressure. (Chapter 40)
reexpansion pulmonary edema pulmonary edema that forms after rapid reexpansion of a lung that has been compressed with pleural fluid or pneumothorax. (Chapter 27)
reference range the acceptable range for a laboratory value measured during calibration or validation of operation. (Chapter 17)
regulator device that controls both pressure and flow. (Chapter 40)
regurgitation backward flow of blood through an incompetent valve of the heart. (Chapter 10)
relative humidity (RH) amount of moisture in the air compared with the maximum the air could contain at the same temperature. (Chapter 6)
repolarization process by which the cell is restored to its resting potential. (Chapter 18)
research protocol a documented procedure which described each step in conducting a research study. (Chapter 8)
reservoir system O_2 delivery system that provides a reservoir O_2 volume that the patient taps into when the patient's inspiratory flow exceeds the device flow. (Chapter 41)
residual drug volume medication that remains in a small-volume nebulizer after the device is no longer producing mist. (Chapter 39)
residual volume (RV) volume of gas remaining in the lungs after a complete exhalation. (Chapter 20)
res ipsa loquitur "the thing speaks for itself"; rule of evidence whereby negligence of an alleged wrongdoer may be inferred from the fact that the accident happened. (Chapter 5)
resistance impedance to flow in a tube or conduit; quantified as ratio of the difference in pressure between the two points. (Chapter 3)
respirable mass proportion of aerosolized drug of the proper particle size to reach the lower respiratory tract. (Chapters 39, 42)
respiratory acidosis hypoventilation resulting in acidemia. (Chapter 14)
respiratory alternans alternating between use of the diaphragm for short periods and use of the accessory muscles to breathe; indicative of end-stage respiratory muscle fatigue. (Chapters 16, 44)
x respiratory care health care discipline that specializes in the promotion of optimal cardiopulmonary function and health. Also called *respiratory therapy*. (Chapter 1)
respiratory care management information systems an information system specifically designed for managing data regarding the respiratory care provided to patients. (Chapter 7)
respiratory care practitioner health professional with special training and experience in the treatment and rehabilitation of patients with respiratory disorders. The respiratory care practitioner typically does not diagnose but must be competent with patient assessment in various clinical settings. (Chapter 1)
respiratory care protocol specification of actions that allows respiratory care practitioners to initiate and adjust therapy independently, within guidelines previously established by medical staff. Also called *therapist-driven protocol*. (Chapter 2)
respiratory distress syndrome (RDS) condition of respiratory distress in newborns, usually caused by inadequate surfactant production (owing to immaturity). (Chapter 33)
respiratory hygiene a state in which the respiratory tract is kept as free as possible from contaminents such as bacteria and other microbes. (Chapter 4)
respiratory inductive plethysmography device that, by measuring the change in the diameter of the chest and abdomen, can estimate inhaled and exhaled tidal volume. (Chapter 51)
respiratory therapist (RT) graduate of a CAAHEP/CoARC accredited school designed to qualify the graduate for the registry examination of the National Board for Respiratory Care (NBRC). (Chapter 1)
respiratory therapy any treatment that maintains or improves the ventilatory function of the respiratory tract. (Chapter 1)
respiratory therapy consult service program in which respiratory care services are determined by respiratory care practitioners based on prescribed guidelines or algorithms. Also called *evaluate-and-treat program*. (Chapter 2)
respondeat superior "let the master answer"; the master is liable in certain cases for the wrongful acts of his servant, meaning that a physician may be liable for the wrongful acts of someone working under the physician's supervision. The doctrine is inapplicable where injury occurs while the servant is acting outside the legitimate scope of authority. (Chapter 5)
resting energy expenditure (REE) caloric needs of the body estimated from O_2 consumption and CO_2 production, usually expressed in kcal/24 hr. (Chapter 23)
restrictive lung disease broad category of disorders with widely variable causes but all resulting in a reduction in lung volumes, particularly the inspiratory and vital capacities; categorized according to origin—skeletal/thoracic, neuromuscular, pleural, interstitial, and alveolar. (Chapter 20)
retinopathy of prematurity (ROP) abnormal ocular condition that occurs in some premature or low-birth-weight infants who receive O_2.

Previously called *retrolental fibroplasias*. (Chapters 41, 53)

retractions sinking inward of the skin around the chest cage with each inspiratory effort. (Chapter 16)

reverse triggering the stimulation of the respiratory center to inspire after the delivery of a controlled positive pressure breath in a sedated patient. (Chapter 47)

Reynold's number a dimensionless number used to determine if flow is laminar or turbulent. If the Reynold's number is above 2000 flow is turbulent. It is determined by multiplying the diameter of the system by the velocity of gas flow times the density of the gas divided by the viscosity of the gas. (Chapter 6)

rhonchi a discontinuous, abnormal breath sound, also known as coarse crackles or rales, caused by air moving through airways which have excessive mucous. (Chapter 16)

right-to-left shunt anatomic bypass in which blood flows from the venous to the arterial side of the circulation, bypassing the lungs; this lowers both the O_2 content and PO_2 of the arterial blood. (Chapter 12)

rise time the time it takes for the ventilator flow to reach its maximum flow. Rise time is a control variable available in all pressure-targeted modes. Functionally it changes the slope of the flow increase from baseline to maximum. (Chapter 47)

rocking bed bed that rocks back and forth moving the abdominal contents up and down facilitating inspiration and expiration. (Chapter 45)

roentgenogram an x-ray image. (Chapter 21)

root-cause analysis is a process by which the underlying primary, secondary, and other notable causes of a medical error or other safety issue are identified, and then an action plan is created and implemented. (Chapters 7, 20)

rule utilitarianism moral reasoning approach based not on which act has the greatest utility but on which rule would promote the greatest good if it were generally followed. (Chapter 5)

S

sarcoidosis chronic disorder of unknown origin characterized by the formation of tubercles of nonnecrotizing epithelioid tissue. (Chapter 26)

saturated solution solution in which the solvent contains the maximum amount of solute it can take up. (Chapter 13)

scalenes referring to the three muscles arising from the cervical vertebrae, inserting into the first and second ribs; accessory muscles of ventilation. (Chapter 9)

scintigraphy photograph showing the distribution and intensity of radioactivity in various tissues and organs after administration of a radiopharmaceutical. (Chapter 36)

screening preliminary procedure, such as a test or examination, to detect the most characteristic sign or signs of a disorder that may require further investigation. (Chapter 31)

secondary spontaneous pneumothorax pneumothorax that occurs because of underlying lung disease. (Chapter 27)

sedimentation primary mechanism for deposition of particles 1 to 5 mm in diameter in the central airways, when particles slow and settle out of suspension. (Chapter 39)

segments minor divisions of the lung; each segment is associated with a major branch of the airway. (Chapter 9)

segs refers to segmented neutrophils the mature form of circulating neutrophils. (Chapter 17)

sensorium general term referring to the relative state of a patient's consciousness or alertness. (Chapter 16)

servo-controlled heating system in a humidifier, heating unit that monitors the temperature of gas delivered to the patient, adjusting the power to the heater based on the difference between the temperature setting and the temperature monitored by a thermistor probe placed downstream from the humidifier, at or near the patient airway connection. (Chapter 38)

severe obesity the state of having a body mass index of greater than 40 kg/m^2. (Chapter 30)

shock condition in which perfusion to vital organs is inadequate to meet metabolic needs; includes hypovolemic, cardiogenic, septic, anaphylactic, and neurogenic forms. (Chapter 16)

sickle cell hemoglobin the presence of hemoglobin S causing the hemoglobin cell to form a sickle shape. (Chapter 12)

signs the objective manifestation of illness such as increased respiratory rate. (Chapter 16)

silicosis lung disorder caused by continued, long-term exposure to the dust of an inorganic compound, silicon dioxide, which is found in sands, quartzes, and many other stones; chronic silicosis is marked by widespread fibrotic nodular lesions in both lungs. (Chapter 26)

six or twelve-minute walk (6- or 12-minute) a test which involves walking and an established protocol to assess a patient's level of physical conditioning. (Chapter 55)

skilled nursing facility (SNF) institution or part of an institution that meets criteria for accreditation established by the sections of the *Social Security Act* that determine the basis for Medicaid and Medicare reimbursement for skilled nursing care. Skilled nursing care includes rehabilitation and various medical and nursing procedures. (Chapter 51)

slander any words spoken with malice that are untrue and prejudicial to the reputation, professional practice, commercial trade, office, or business of another person. (Chapter 5)

sleep-disordered breathing periods of an absence of attempts to breathe during sleep. (Chapter 33)

small cell cancer malignant, usually bronchogenic epithelial neoplasm consisting of small; tightly packed; round, oval, or spindle-shaped epithelial cells that stain darkly and contain neurosecretory granules and little or no cytoplasm. Many malignant tumors of the lung are of this type. Also called *oat cell carcinoma* or *small cell carcinoma*. (Chapter 31)

SOAP in a problem-oriented medical record, abbreviation for *subjective, objective, assessment,* and *plan,* the four parts of a written account of the health problem. (Chapter 3)

soft palate structure composed of mucous membrane, muscular fibers, and mucous glands, suspended from the posterior border of the hard palate forming the roof of the mouth. (Chapter 9)

solitary pulmonary nodule (SPN) a pulmonary parenchymal opacity smaller than 3 cm in diameter that is totally surrounded by aerated lung. (Chapter 21)

solubility coefficient (gas) volume of gas that can be dissolved in 1 ml of a given liquid at standard pressure and specified temperature. (Chapter 6)

solute substance dissolved in a solution. (Chapter 13)

solution mixture of one or more substances dissolved in another substance. The molecules of each of the substances disperse homogeneously and do not change chemically. A solution may be a gas, a liquid, or a solid. (Chapter 13)

solvent any liquid in which another substance can be dissolved. (Chapter 13)

specific gravity ratio of the density of a substance to the density of another substance accepted as a standard. The usual standard for liquids and solids is water. A liquid or solid with a specific gravity of 4 times as dense as water at the same temperature. Hydrogen is the usual standard for gases. (Chapter 6)

spectrophotometry measurement of color in a solution by determining the amount of light absorbed in the ultraviolet, infrared, or visible spectrum, widely used in clinical chemistry to calculate the concentration of substances in solution. (Chapter 19)

splinting process of immobilizing, restraining, or supporting a body part. (Chapter 40)

spontaneous awaking trial a trial of sedation removal or reduction preformed prior to a spontaneous breathing trial. (Chapter 47)

spontaneous breath ventilatory support breaths initiated and ended by the patient. (Chapter 45)

spontaneous breathing trial (SBT) trial of spontaneous breathing independent of the ventilator. (Chapter 47)

sporicidal destructive to the spore form of bacteria. (Chapter 4)

sputum mucus from the respiratory tract that has passed through the mouth. (Chapter 16)

squamous cell carcinoma type of lung cancer characterized by cells that appear platelike. (Chapter 31)

staging system See *TNM staging*. (Chapter 31)

standard bicarbonate plasma concentration of HCO_3^- in mEq/L that would exist if PCO_2 were normal (40 mm Hg). (Chapter 14)

standard precautions guidelines recommended by the U.S. Centers for Disease Control and Prevention to reduce the risk of transmission of blood-borne and other pathogens in hospitals. Standard precautions apply to (1) blood; (2) all body fluids, secretions, and excretions, excluding sweat, regardless of whether they contain blood; (3) nonintact skin; and (4) mucous membranes. (Chapter 4)

Starling equilibrium the filtration of fluid across a membrane is a result of equilibration of osmotic and hydrostatic forces across the membrane. (Chapter 13)

stenosis narrowing of a valve or vessel. (Chapters 10, 36)

sterilization complete destruction of all microorganisms, usually by heat or chemical means. (Chapter 4)

sternal angle the fused connection between the manubrium and the body of the sternum is known as the sternal angle or angle of Louis. (Chapter 9)

sternocleidomastoid muscles muscle of the neck that is attached to the mastoid process of the temporal bone and superior nuchal line and by separate heads to the sternum and clavicle; sternocleidomastoid muscles function together to flex the head. (Chapter 9)

sternum elongated flattened bone forming the middle portion of the anterior thorax. (Chapter 9)

stomata small holes within the parietal pleura that are the main route for pleural fluid to exit. (Chapter 27)

STPD conditions of a volume of gas at 0° C and 760 mm Hg and containing no water vapor (dry). It should contain a calculable number of moles of a particular gas. (Chapter 6)

strain-gauge pressure transducers a pressure measuring device that records pressures by the expansion and contraction of a flexible metal diaphragm connected to electrical wires. (Chapter 6)

stress index an index used to determine if during mechanical controlled inhalation there is over distention or recruitment of collapse lung; determined by the slope change in the airway pressure curve during volume controlled square wave ventilation. (Chapter 51)

strict liability theory in tort law that can be used to impose liability without fault, even in situations where injury occurs under conditions of reasonable care; the most common cases of strict liability involve the use of dangerous products or techniques. (Chapter 5)

stridor high-pitched, continuous type of adventitious lung sound heard from the upper airway. (Chapter 16)

stroke condition characterized by the sudden onset of a neurologic deficit. (Chapter 32)

stroke volume volume of blood ejected by the left ventricle during each contraction. (Chapter 10)

sub-atmospheric below atmospheric; used to describe pressures below ambient. (Chapter 11)

subcutaneous emphysema accumulation of air in the subcutaneous tissues owing to leakage from the lung. (Chapter 16)

suctioning process of mechanically aspirating airway secretions. (Chapter 36)

sudden infant death syndrome (SIDS) leading cause of death in infants less than 1 year old in the United States. Commonly called *crib death*. (Chapter 33)

super obesity the state of having a body mass index of greater than 50 kg/m^2. (Chapter 30)

supplemental oxygen O_2 delivered at concentrations exceeding 21% to increase the amount of O_2 circulating in the blood. (Chapter 25)

suprasternal above the sternum. (Chapter 9)

surface tension tendency of a liquid to minimize the area of its surface by contracting. This property causes liquids to rise in a capillary tube, effects the exchange of gases in the pulmonary alveoli, and alters the ability of various liquids to wet another surface. (Chapters 6, 11)

surfactant surface-acting agent that forms a monomolecular layer over pulmonary alveolar surfaces. These agents prevent alveolar collapse at lower lung volumes by reducing alveolar surface tension. (Chapter 53)

surgical resection the partial removal of an organ or tissues by surgical means. (Chapter 31)

surveillance (bacteriologic) ongoing process designed to ensure that infection control procedures are working; generally involves equipment, microbiologic identification, and epidemiologic investigation. (Chapter 4)

suspensions dispersion of large particles suspended in a fluid medium; without physical agitation, the particles eventually settle out. (Chapter 13)

Swan-Ganz catheter catheter that is positioned in the pulmonary artery to measure pressures in the heart and pulmonary circulation and can be used to determine the patient's circulatory status. (Chapter 51)

sweep flow the flow of gas in a direction opposite the flow of blood through an ECMO oxygenator to remove CO_2 and add O_2. Normally the gas is O_2 but on occasion small amounts of CO_2 are added. (Chapter 50)

symptoms the sensation or subjective experience of some aspect of an illness, such as breathlessness. (Chapter 16)

synchronized cardioversion countershock synchronized with the heart's electrical activity. (Chapter 37)

synchronous intermittent mandatory ventilation (SIMV) mode of ventilatory support using periodic assisted ventilation with spontaneous breathing in between. Assisted breaths are responsive to patient demand. (Chapters 48, 52)

syncope temporary unconsciousness; fainting. (Chapter 16)

synthesized database a set of computerized records or data which have been reviewed, interpreted and categorized in relation to an area of research. (Chapter 8)

systematic error nonrandom statistical error that affects the mean of a population of data and defines the bias between the means of two populations. (Chapters 19, 51)

systolic pressure peak blood pressure occurring in the arteries during ventricular contraction. (Chapter 16)

T

tachycardia abnormally elevated heart rate. (Chapter 16)

tachyphylaxis phenomenon in which the repeated administration of some drugs results in a marked decrease in effectiveness. (Chapter 35)

tachypnea abnormal elevation of breathing rate. (Chapter 16)

tamponade (cardiac) the accumulation of blood in the pericardial sac, increasing pericardial pressure and reducing cardiac output. (Chapter 30)

target heart rate heart rate achieved at 65% of a patient's maximum O_2 consumption during an exercise evaluation, used for aerobic conditioning. (Chapter 55)

target variable a variable that can be reached and maintained at a preset level before inspiration ends but does not terminate inspiration. (Chapter 42)

targeting scheme the approach used by a particular mode to achieve the various targets active during ventilation. (Chapter 42)

telemedicine refers to the use of electronic and telecommunication technologies to support health care at a geographically different location from the patient, thus increasing access to specialty patient care. (Chapter 7)

telemonitoring monitoring a patient's clinical condition through a computerized connection to a health care facility. (Chapter 7)

tension pneumothorax air in the pleural space that exceeds atmospheric pressure causing outward expansion of the ribs, downward depression of the diaphragm, mediastinal shift, and hypotension. (Chapters 27, 30, 47)

tension-time index product of contractile force (ratio of diaphragmatic pressure to maximum diaphragmatic pressure) and contractile duration (ratio of inspiratory time to total breathing cycle time) used to indicate a level of contraction associated with fatigue. (Chapter 44)

tetralogy of Fallot congenital cardiac anomaly that consists of four defects: pulmonic stenosis, ventricular septal defect, malposition of the aorta so that it arises from the septal defect or the right ventricle, and right ventricular hypertrophy. (Chapter 33)

therapeutic index difference between the minimum therapeutic and minimum toxic concentrations of a drug. (Chapter 39)

therapist-driven protocol specification of actions that allow respiratory care practitioners to initiate and adjust therapy independently, within guidelines previously established by medical staff. Also called *respiratory care protocol*. (Chapter 2)

thermal conductivity measure of gas concentrations in a sample calculated by detecting the rate at which different gases conduct heat. (Chapter 6)

thermodynamics science of the interconversion of heat and work. (Chapter 6)

thiosulfate a compound ($S_2O_3^{2-}$) that is an oxyanion of sulfur used in treating carbon monoxide poisoning. (Chapter 30)

thoracentesis surgical perforation of the chest wall and pleural space with a needle for diagnostic or therapeutic purposes or for the removal of a specimen for biopsy. (Chapter 27)

thoracic flap or flail chest two or more ribs broken in two or more places creating an unstable segment of the chest wall. (Chapter 30)

thoracic gas volume (TGV) technique that measures lung volume. (Chapter 20)

Thorpe tube variable orifice, constant pressure flowmeter. (Chapter 40)

thrill fine palpable vibration felt accompanying a cardiac or vascular murmur. (Chapter 16)

thrombocytes smallest cells in the blood; they are formed in the red bone marrow, and some are stored in the spleen. Platelets are disc-shaped, contain no hemoglobin, and are essential for the coagulation of blood and in maintenance of hemostasis. (Chapter 16)

thrombocytopenia abnormal condition in which the number of blood platelets is reduced, usually associated with neoplastic diseases or an immune response to a drug. (Chapter 17)

tidal volume (V_T) volume of air that is inhaled or exhaled from the lungs during effortless breath. (Chapters 11, 20)

time constant mathematical expression describing the relative efficacy of lung unit filling and emptying and computed as the product of compliance times resistance (measured in seconds). (Chapters 11, 45, 46)

tissue oxygen sensing the monitoring of the O_2 saturation or PO_2 at the tissue level. (Chapter 51)

tort legal wrong committed on a person or property independent of contract. (Chapter 5)

total lung capacity (TLC) total amount of gas in the lungs after a maximum inspiration. (Chapter 19)

trachea large main intrathoracic airway. (Chapter 9)

tracheal tugging effect of an aortic aneurysm in which the trachea is pulled downward with each heart contraction. (Chapter 16)

tracheoesophageal fistula a congenital malformation or an abnormality associated with disease in which there is an abnormal tubelike passage between the trachea and the esophagus. (Chapters 36, 47)

tracheoinnominate fistula a fistula (connection between the trachea and the innominate artery). (Chapter 36)

tracheal malacia softening of the tracheal cartilages. (Chapters 36, 47)

tracheal stenosis a narrowing of the tracheal diameter. (Chapter 47)

tracheostomy opening through the neck into the trachea, through which an indwelling tube may be inserted. (Chapter 36)

tracheostomy tubes artificial airways that are surgically placed directly into the trachea. (Chapter 36)

tracheotomy procedure by which an incision is made into the trachea through the neck below the larynx to gain access to the lower airways. (Chapter 36)

transairway pressure difference between airway pressure and alveolar pressure. (Chapters 11, 46)

transalveolar pressure difference between alveolar pressure and pleural pressure. (Chapters 11, 46)

transbronchial biopsy a lung tissue specimen which is obtained through a needle insertion, bronchoscopy or surgery. (Chapter 22, 31)

transbronchial needle aspiration technique of sampling lung tissue through a bronchoscope that involves passing a thin needle through a bronchus. (Chapters 22, 31)

trans–chest wall pressure difference between the pleural space and the body surface. Also called *transthoracic pressure*. (Chapters 11, 46)

transdiaphragmatic pressure (P_{di}) the pressure change across the diaphragm associated with breathing. (Chapter 46)

transtracheal oxygen therapy (TTOT) low-flow O_2 delivered via a catheter with a small orifice that is inserted through the skin and neck tissue into the trachea through the anterior tracheal wall. (Chapter 56)

transient tachypnea of the newborn (TTN) the periodic increase in respiratory rate that is commonly observed in low-birth-weight infants. (Chapter 34)

transposition of the great arteries congenital cardiac condition characterized by an anatomic abnormality in which the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle. (Chapter 34)

transpulmonary of or pertaining to the difference in a parameter (e.g., pressure) between the alveoli and pleural space. (Chapter 10)

transpulmonary pressure the difference between the alveolar pressure and intrapleural pressure of the lungs. (Chapters 46, 48, 51)

transpulmonary pressure difference difference between intraalveolar and intrapleural pressure, or the pressure acting across the ling from the pleural space to the alveoli. (Chapters 11)

transrespiratory across the respiratory system; of or pertaining to the difference in a parameter (e.g., pressure) between the alveoli and the body surface.

transrespiratory pressure the difference between the alveolar pressure and pressure on the body surface. (Chapter 46)

transrespiratory pressure gradient pressure differential between the mouth and the alveoli that causes gas to flow in and out of the lungs. (Chapters 43)

transthoracic across the thorax; of or pertaining to the difference in a parameter (e.g., pressure) between the pleural space and body surface.

transthoracic needle biopsy technique of obtaining a biopsy specimen of lung tissue by which a needle is passed into the chest, often guided by imaging. (Chapter 31)

transthoracic pressure of or pertaining to the difference in a parameter (such as pressure) between the pleural space and body surface. (Chapter 46)

transthoracic pressure difference (P_{TT}) difference between the pleural space and the body surface. Also called *trans–chest wall pressure*. (Chapter 11)

transtracheal oxygen therapy (T_{TOT}) administration of O_2 via a low-flow catheter inserted directly into the trachea. (Chapter 51)

transudate the fluid that moves out of a cell or tissue as a result of a concentration/pressure gradient. (Chapter 30)

transudative pleural effusion pleural effusion low in protein and lactate dehydrogenase, usually caused by congestive heart failure, nephrosis, or cirrhosis. (Chapter 27)

traumatic brain injury general term referring to any class of either focal or diffuse lesions that can result from head trauma; these lesions include injury to the nerve body (axon), hypoxic brain damage, swelling, hemorrhage, contusions, laceration, and infection. (Chapter 32)

Trendelenburg position position in which the head is low and the body and legs are on an inclined plane. (Chapter 45)

trepopnea shortness of breath which is experienced by a patient while lying on one side or the other. (Chapter 16)

trigger the inspiratory force a patient must generate to initiate a breath on a mechanical ventilator. (Chapter 45)

trigger asynchrony a lack of coordination between the patient's inspiratory effort and the response of the mechanical ventilator. (Chapter 47)

trigger delay a delay in ventilator response to a patient's inspiratory effort. (Chapter 47)

trigger variable variable that initiates inspiration during mechanical ventilation. (Chapter 45)

tripodding breathing technique most often used by patients with chronic obstructive pulmonary disease in which they lean forward and place their elbows on a table or arms of a chair to support breathing with the accessory muscles. (Chapter 16)

troponin protein in the striated cell ultrastructure that modulates the interaction between actin and myosin molecules. It is believed to be part of the calcium-binding complex of the thin myofilaments. The level of blood troponin is used to identify the presence of a myocardial infarction. (Chapter 17)

troponin I protein similar to CPK-2; troponin I levels peak 12 to 16 hours after myocardial infarction. It is associated with cardiac muscle damage. (Chapter 17)

true ribs the first seven ribs on each side of the thorax are called *true ribs*. (Chapter 9)

tuberculosis chronic granulomatous infection caused by an acid-fast bacillus, *Mycobacterium tuberculosis*. It is generally transmitted by the inhalation or ingestion of infected droplets and usually affects the lungs, although infection of multiple organ systems occurs. (Chapter 24)

tumor, node, metastasis (TNM) staging staging system based on a size of the tumor *(T)*, the presence and position of abnormal lymph nodes *(N)*, and the presence or absence of metastasis (or spread beyond the primary tumor site) *(M)*. (Chapter 28)

turbinates bony structures that extend from the lateral walls of the interior nasal passages. (Chapter 9)

turbulent flow flow of a fluid that does not occur in a straight line; flow in which molecules tumble over each other. (Chapter 6)

12-minute walk usually a part of a pulmonary rehabilitation program, performed once per day for the duration of the program. The objective is for the patient to walk on a flat, smooth surface as far as possible during the 12 minutes,

stopping as necessary and quantifying the total distance covered. (Chapter 55)

type I pneumocyte cuboidal, secretory epithelia that line the blind tubules of the acinus cells. (Chapter 9)

type II pneumocyte pneumocyte granular cells that are highly active and form part of the lining of the alveoli. These cells secrete surfactant and other substances. (Chapter 9)

U

ultrasonic nebulizer (USN) aerosol generator in which an electrical signal is used to produce high-frequency vibrations in a container of fluid. The vibrations break up the fluid into aerosol particles. (Chapter 38)

ultrathin bronchoscopy a bronchoscope which has a smaller than usual diameter and circumference to permit insertion into small airways. (Chapter 22)

upper airway stimulation a newer way of treating obstructive sleep apnea which involves implantation of a nerve stimulator to maintain upper airway patency. (Chapter 33)

upstream relative reference to a point closer to the source in a stream of flowing fluid. (Chapter 40)

uvula small cone-shaped process suspended in the mouth from the middle of the posterior border of the soft palate. (Chapter 9)

uvulopalatopharyngoplasty (UVPPP) surgical procedure used in treating severe obstructive sleep apnea, which involves shortening of the soft palate and removal of the uvula and tonsils. (Chapter 33)

V

VA ECMO venous arterial extracorporeal membrane oxygenation, the removal of blood from a vein that then moves to an O_2 and CO_2 exchanger before returning to the patient via an artery. VA ECMO is used to provide support for both the respiratory and cardiovascular system. (Chapter 50)

vagovagal reflexes reflexes caused by stimulation of parasympathetic receptors in the airways that can result in laryngospasm, bronchoconstriction, hyperpnea, and bradycardia; often associated with mechanical stimulation, as during procedures such as tracheobronchial aspiration, intubation, or bronchoscopy. (Chapter 15)

vallecula the anatomic depression immediately beyond the base of the tongue. (Chapter 9)

value-based purchasing (VBP) system is a system of reimbursement by the government CMS to hospitals and health care providers that is partially based on their ability to meet a predefined set of standards. (Chapter 7)

vaporization process whereby matter in its liquid form is changed into its vapor or gaseous form. (Chapter 6)

vasoconstriction narrowing of the blood vessels. (Chapter 10)

vasodilation widening or distention of blood vessels, particularly arterioles, usually caused by nerve impulses or certain drugs that relax smooth muscle in the walls of the blood vessels. (Chapter 10)

vasopressor a medication which causes constriction of the blood vessels, generally used to increase blood pressure. (Chapter 35)

VCV acronym for *volume-controlled ventilation,* a mode of ventilatory support in which volume (or flow × time) serves as the cycle variable. (Chapters 3, 27, 45, 48)

venous admixture mixing of venous blood with arterial blood, resulting in a decrease in the O_2 content of the latter; occurs in anatomic and physiologic shunting. (Chapters 12, 51)

venous reservoir the capacity of the venous system to pool large volumes of blood. (Chapter 10)

venous thromboembolism (VTE) clot that spreads from one venous bed to another, such as from the leg veins to the lung. (Chapter 28)

ventilation molecular exchange of O_2 and CO_2 within the body's tissues. (Chapter 11)

ventilation/perfusion ($\dot{V}/\dot{Q}$) ratio ratio of pulmonary alveolar ventilation to pulmonary capillary perfusion, both measured quantities being expressed in the same units. (Chapter 12)

ventilator-associated pneumonia lower respiratory tract infection that develops more than 48 to 72 hours after endotracheal intubation. (Chapter 24)

ventilator-induced lung injury (VILI) lung injury which occurs as a result of excessive pressure and/or volume during mechanical ventilation. (Chapter 29)

ventilatory threshold during exercise, the point at which increased levels of lactic acid result in increased CO_2 production and minute ventilation; the respiratory quotient equals or exceeds 1.0, indicating that CO_2 production equals or exceeds O_2 consumption; at this point, metabolism becomes anaerobic, decreasing energy production and increasing muscle fatigue. (Chapter 55)

ventral respiratory groups (VRGs) groupings of cells in the medulla oblongata that are active in controlling both inspiration and expiration. (Chapter 15)

ventricular fibrillation (VF) the most life-threatening electrocardiographic arrhythmia characterized by erratic quivering of the ventricular muscle mass. (Chapter 18)

ventricular tachycardia (VT) a run of three or more premature ventricular contractions that is usually easy to recognize as a series of wide, bizarre QRS complexes that have no preceding P wave. (Chapter 18)

veracity principle that binds the health provider and the patient to tell the truth, creating an environment of trust and mutual sharing of information. (Chapter 5)

very low birth weight (VLBW) a newborn who weights less than the 95% percentile of weight for newborns. (Chapter 53)

virtue ethics viewpoint that asks what a virtuous person would do in a similar circumstance; it is based on personal attributes of character or virtue, rather than on rules or consequences. (Chapter 5)

virucidal agent that destroys or inactivates viruses. (Chapter 4)

visceral pleura thin membrane covered by mesothelial cells that covers the entire surface of the lung, dipping into the lobar fissures. (Chapter 9, 27)

viscosity internal force that opposes flow of a fluid, either liquids or gases. (Chapter 6)

vital capacity (VC) total amount of air that can be exhaled after a maximum inspiration; the sum of the inspiratory reserve volume, tidal volume, and expiratory reserve volume. (Chapters 20, 51)

volatile acid acid that can be excreted in its gaseous form; physiologically, carbonic acid is a volatile acid; approximately 24,000 mmol/L CO_2 is eliminated from the body daily via normal ventilation. (Chapter 14)

voltage expression of electromotive force in terms of volts. (Chapter 3)

volume-controlled ventilation (CMV) a mode of ventilatory support in which a specific tidal volume is set and delivered for each breath under control ventilation conditions. (Chapters 3, 27, 45, 48)

volume-limited ventilation same as CMV, the primary control variable is tidal volume. (Chapter 27)

volume-median diameter (VMD) the median diameter of an aerosol particle measured in units of volume. (Chapter 39)

volume support pressure-limited ventilation in which tidal volume is targeted. (Chapter 48)

volumetric capnography a way of measuring the volume of exhaled carbon dioxide to assess the a patient's ventilatory status. (Chapter 19)

volutrauma alveolar overdistention and damage caused by ventilation with high peak inflation pressures. (Chapters 29, 46)

VV ECMO venovenous extracorporeal membrane oxygenation, the removal of blood from a vein which then moves to an O_2 and CO_2 exchanger before returning to the patient via a vein. VV ECMO is used to provide support for the respiratory system but not the circulatory system. (Chapter 50)

W

water vapor pressure the pressure exerted by water in its gaseous state. (Chapter 6)

wet drowning drowning that is a result of a large amount of water entering the lungs. (Chapter 30)

wheezes high-pitched, continuous type of adventitious lung sound. (Chapter 16)

work of breathing (WOB) amount of force needed to move a given volume into the lung with a relaxed chest wall; mathematically, work is the integral of pressure times volume. (Chapter 44)

X

xiphoid process pointed lower portion of the sternum. (Chapter 9)

Z

zone valve on/off piping valve that controls medical gas distribution to a prespecified zone of a building. (Chapter 40)

N-SiPAP	nasal positive airway pressure with periodic (sigh) bilevel positive airway pressure breaths or bilevel nasal continuous positive airway pressure
NTE	neutral thermal environment
O_2	oxygen
O_2Hb	oxygenated hemoglobin
OH^-	hydroxide ions
OHDC	oxyhemoglobin dissociation curve
OSA	obstructive sleep apnea
P	pressure
ΔP	change in pressure
P_{50}	PO_2 at which 50% saturation of hemoglobin occurs
P_{100}	pressure on inspiration measured at 100 msec
Pa	arterial pressure
PA	pulmonary artery
$P(A\text{-}a)O_2$	alveolar-to-arterial partial pressure of oxygen
P(A-awo)	pressure gradient from alveolus to airway opening
$PACO_2$	partial pressure of carbon dioxide in the alveoli
$PaCO_2$	partial pressure of carbon dioxide in the arteries
P_{al}	alveolar pressure
PAO_2	partial pressure of oxygen in the alveoli
PaO_2	partial pressure of oxygen in the arteries
PaO_2/FiO_2	ratio of arterial PO_2 to FiO_2
PaO_2/PAO_2	ratio of arterial PO_2 to alveolar PO_2
PAOP	pulmonary artery occlusion pressure (Also known as pulmonary capillary wedge pressure [PCWP])
PAP	pulmonary artery pressure
PAP	mean pulmonary artery pressure
$P(a\text{-}et)CO_2$	arterial-to-end-tidal partial pressure of carbon dioxide
PAGE	perfluorocarbon associated gas exchange
P_{aug}	pressure augmentation
PAV	proportional assist ventilation
P_{aw}	airway pressure
$\overline{P_{aw}}$	mean airway pressure
P_{awo}	airway opening pressure
PAWP	pulmonary artery wedge pressure
PB	barometric pressure
PBW	predicted body weight
P_{bs}	pressure at the body's surface
PC-CMV	pressure-controlled continuous mandatory ventilation
PCEF	peak cough expiratory flow
PCIRV	pressure control inverse ratio ventilation
PCO_2	partial pressure of carbon dioxide
PC-IMV	pressure-controlled intermittent mandatory ventilation
PC-SIMV	pressure-controlled synchronized intermittent mandatory ventilation
POCT	point of care testing
PCV	pressure-controlled ventilation
PCWP	pulmonary capillary wedge pressure
$PCWP_{tm}$	transmural pulmonary capillary wedge pressure
PDA	patent ductus arteriosus
PE	pulmonary embolism
PE_{max}	maximal expiratory pressure
PEA	pulseless electrical activity
P_ECO_2	partial pressure of mixed expired carbon dioxide
PEEP	positive end expiratory pressure
$PEEP_E$	extrinsic PEEP (set-PEEP)
$PEEP_I$	intrinsic PEEP (auto-PEEP)
$PEEP_{total}$	total PEEP (sum of intrinsic and extrinsic PEEP)
PEFR	peak expiratory flow rate
P_{es}	esophageal pressure
$PetCO_2$	partial pressure of end-tidal carbon dioxide
P_{flex}	pressure at the inflection point of a pressure/volume curve
PFT	pulmonary function test(ing)
P_{ga}	gastric pressure
pH	relative acidity or alkalinity of a solution
P_{high}	high pressure during APRV
PHY	permissive hypercapnia
PIE	pulmonary interstitial edema
PIF	pulmonary interstitial fibrosis
PI_{max}	maximum inspiratory pressure (also MIP, MIF, NIF)
P_{inside}	inside pressure
$P_{intrapleural}$	intrapleural pressure (also Ppl)
PiO_2	partial pressure of inspired oxygen
PIP	peak inspiratory pressure (also P_{peak})
PISS	pin-indexed safety system
P_L	transpulmonary pressure
P_{low}	low pressure during APRV
PLV	partial liquid ventilation
P_M	mouth pressure
pMDI	pressurized metered dose inhaler
P_{mus}	muscle pressure
PO_2	partial pressure of oxygen
$P_{outside}$	pressure outside
P_{peak}	peak inspiratory pressure (also PIP)
PPHN	primary pulmonary hypertension of the neonate
P_{pl}	intrapleural pressure
$P_{plateau}$	plateau pressure
ppm	parts per million
PPST	premature pressure support termination
PPV	positive pressure ventilation
PRA	plasma renin activity
PRVC	pressure regulated volume control
PS	pressure support
PSB	protected specimen brush
P_{set}	set pressure
psi	pounds per square inch
psig	pounds per square inch gauge
PS_{max}	maximum pressure support
P_{st}	static transpulmonary pressure at a specified lung volume
PSV	pressure support ventilation
P_{TA}	transairway pressure
$PtcCO_2$	transcutaneous PCO_2
$PtcO_2$	transcutaneous PO_2
P_{tm}	transmural pressure
P_{TR}	transrespiratory pressure
PTSD	posttraumatic stress disorder
P_{TT}	transthoracic pressure (also Pw)
P-V	pressure-volume
PV	pressure ventilation
PVC(s)	premature ventricular contraction(s)
$P\bar{v}O_2$	partial pressure of oxygen in mixed venous blood
PVR	pulmonary vascular resistance
PVS	partial ventilatory support
P_w	transthoracic pressure (also P_{TT})
Q	blood volume
$\dot{Q}$	blood flow
$\dot{Q}_{c'}$	pulmonary capillary blood flow
q2h	every 2 hours
$\dot{Q}_T$	cardiac output
$\frac{\dot{Q}_s}{\dot{Q}_t}$	shunt
$\dot{Q}sp$	physiologic shunt flow (total venous admixture)
R	resistance (i.e., pressure per unit flow)
$\bar{R}$	mean total resistance
RAM	random access memory
RAP	right atrial pressure
R_{aw}	airway resistance

rb	rebreathing
RCP	respiratory care practitioner
RDS	respiratory distress syndrome
Re	Reynolds number
R_E	total expiratory resistance
REE	resting energy expenditure
R_I	total inspiratory resistance
RICU	respiratory intensive care unit
R_L	total pulmonary resistance
RM	lung recruitment maneuver
ROM	read-only memory
ROP	retinopathy of prematurity
RQ	respiratory quotient
RSS	really simple syndication
RSV	respiratory syncytial virus
RT	respiratory therapist
Rti	tissue resistance
RV	residual volume
RV/TLC%	ratio of residual volume to total lung capacity
RVEDP	right ventricular end-diastolic pressure
RVEDV	right ventricular end-diastolic volume
RVP	right ventricular pressure
RVSW	right ventricular stroke work
S	saturation in the blood phase
SA	sinoatrial
SaO_2	arterial oxygen saturation
$SBCO_2$	single breath carbon dioxide curve
SCCM	Society for Critical Care Medicine
SFIM	sporadic fatal infectious mononucleosis
S.I.	Système International d'Unités
SI	stroke index
SIDS	sudden infant death syndrome
SIMV	synchronized intermittent mandatory ventilation
Sine	sinusoidal
SNF	skilled nursing facility
sp.	species
sPEEP	spontaneous positive end expiratory pressure
SpO_2	oxygen saturation measured by pulse oximeter
STPD	standard temperature, pressure saturated; 0° Celsius, 760 mm Hg, dry
SV	stroke volume
SVC	slow vital capacity
$S\bar{v}O_2$	mixed venous oxygen saturation
SVN	small volume nebulizer
SVR	systemic vascular resistance
t	time
T	temperature
TAAA	thoracoabdominal aortic aneurysm
Tc	time constant
$tcCO_2$	transcutaneous CO_2
TCPL	time-cycled, pressure-limited ventilation
TCPL/IMV	time-cycled, pressure-limited intermittent mandatory ventilation
TCT	total cycle time
T_E	expiratory time
TGI	tracheal gas insufflation
TGV	thoracic gas volume
T_I	inspiratory time
T_I%	inspiratory time percent
tid	three times per day
TI/TCT	duty cycle
T_{high}	time for high-pressure delivery in APRV
TJC	The Joint Commission (formerly The Joint Commission on Accreditation of Healthcare Organizations [JCAHO])
TLC	total lung capacity
T_{low}	time for low-pressure delivery in APRV
TLV	total liquid ventilation
TOF	tetralogy of Fallot
torr	measurement of pressure that is equivalent to mm Hg
TTN	transient tachypnea of the neonate
TTOT	transtracheal oxygen therapy
TV	tidal volume
U	unit
UN	urinary nitrogen
USN	ultrasonic nebulizer
V	gas volume
v	venous
$\bar{v}$	mixed venous
$\dot{V}$	flow
$\dot{V}_E$	expired minute ventilation
$\dot{V}_A$	alveolar ventilation per minute
V_A	alveolar gas volume
VAI	ventilator-assisted individual
VALI	ventilator-associated lung injury
VAP	ventilator-associated pneumonia
VAPS	volume-assured pressure support
VBP	value-based purchasing
VC	vital capacity
V_C	volume lost to tubing compressibility
VC-CMV	volume-controlled continuous mandatory ventilation
VC-IMV	volume-controlled intermittent mandatory ventilation
VCIRV	volume-controlled inverse ratio ventilation
$\dot{V}CO_2$	carbon dioxide production per minute
V_D	volume of dead space
$\dot{V}_D$	physiologic dead space ventilation per minute
$\dot{V}_{Dan}$	anatomic dead space ventilation per minute
V_{DAN}	volume of anatomic dead space
V_{Dalv}	alveolar dead space
V_{Dmech}	mechanical dead space
V_D/V_T	dead space-to-tidal volume ratio
V_{Dbr}	rebreathing volume
$\dot{V}_{Dbr}$	rebreathing ventilation per minute
$\dot{V}_E$	expired volume per minute
VEDV	ventricular end-diastolic volume
VF	ventricular fibrillation
$\dot{V}_I$	inspired volume per minute
VILI	ventilator-induced lung injury
$\dot{V}_L$	actual lung volume (including conducting airways)
VLBW	very low birth weight
VM	vestibular membrane
$\dot{V}O_2$	oxygen consumption per minute
VS	volume support
VT	ventricular tachycardia
V_T	tidal volume
V_TA	alveolar tidal volume
V_{Texp}	expired tidal volume
V_{Tinsp}	inspired tidal volume
vol%	volume per 100 ml of blood
$\frac{\dot{V}}{\dot{Q}}$	ventilation/perfusion ratio
VSV	volume support ventilation
VV	venovenous
W	work
WOB	work of breathing
WOBi	imposed work of breathing
wye	"wye" or Y connector
X	any variable
$\bar{X}$	mean value
Y	connects patient endotracheal tube to patient circuit
yr	year
ZEEP	zero end-expiratory pressure
