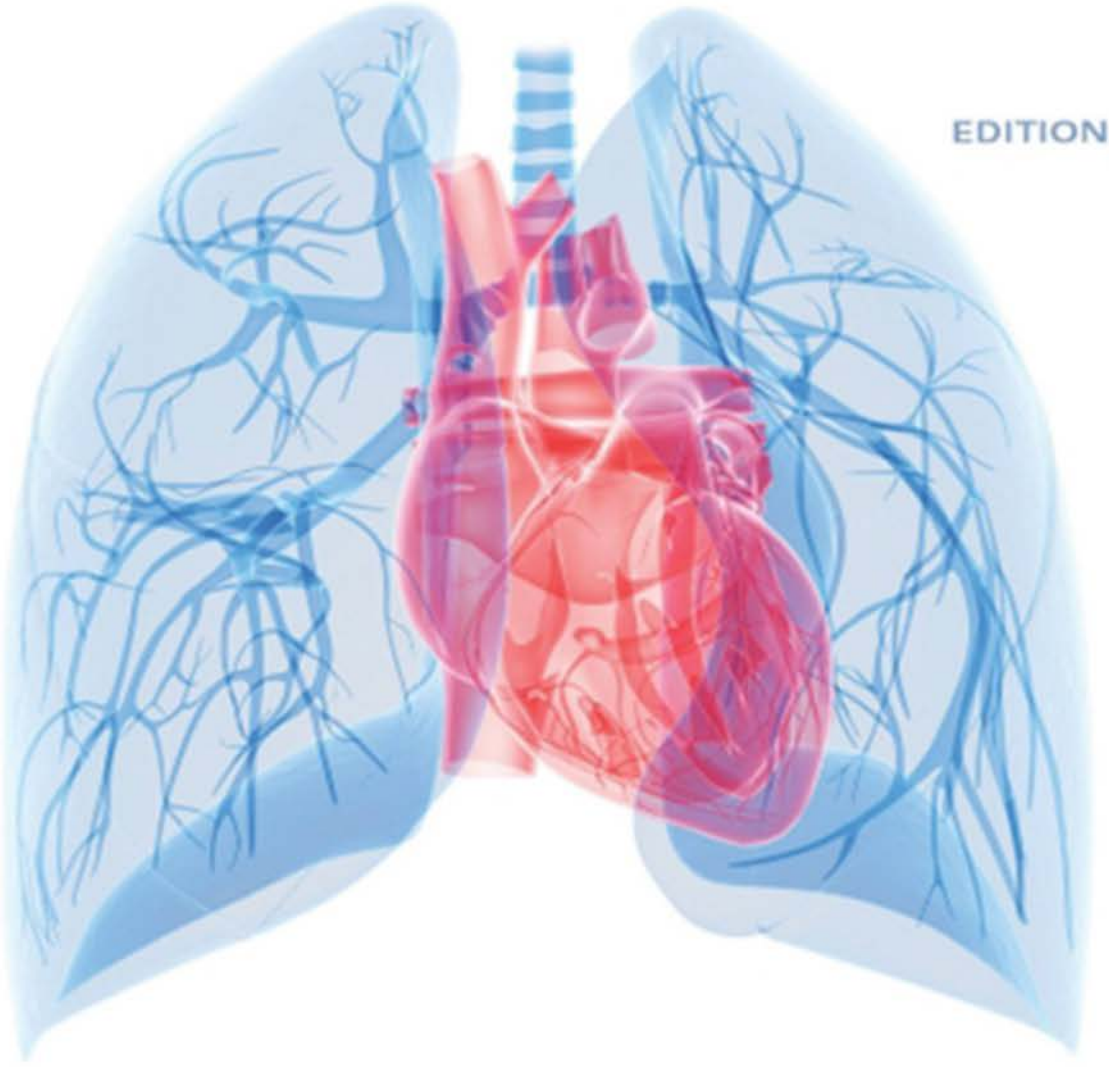
EGAN'S

Fundamentals OF Respiratory Care

EDITION 11



ROBERT M. KACMAREK | JAMES K. STOLLER | ALBERT J. HEUER

ELSEVIER

ABBREVIATIONS

Δ	change in
μ	micro-
μg	microgram
μm	micrometer
μV	microvolt
A	alveolar
a	arterial
AARC	American Association for Respiratory Care
ABG(s)	arterial blood gas(es)
A/C	assist/control
ACBT	active cycle of breathing technique
ADH	antidiuretic hormone
AIDS	acquired immunodeficiency syndrome
AII	airborne infection isolation
ALI	acute lung injury
ALV	adaptive lung ventilation
ANP	atrial natriuretic peptide
AOP	apnea of prematurity
APRV	airway pressure release ventilation
ARDS	acute respiratory distress syndrome
ARF	acute respiratory failure
ASV	adaptive support ventilation
ATC	automatic tube compensation
ATM	atmospheric pressure
ATPD	ambient temperature and pressure, dry
ATPS	ambient temperature and pressure, saturated with water vapor
auto-PEEP	unintended positive end expiratory pressure
AV	arteriovenous
AVP	arginine vasopressin
B	barometric
BAC	blood alcohol content
BE	base excess
bilevel PAP	bilevel positive airway pressure
BiPAP	registered trade name for bilevel PAP device
BP	blood pressure
BPD	bronchopulmonary dysplasia
BSA	body surface area
BTPS	body temperature and pressure, saturated with water vapor
BUN	blood urea nitrogen
C	compliance
c	capillary
C′	pulmonary-end capillary
° C	degrees of Celsius
C_aO_2	arterial content of oxygen
$C(a-\bar{v})O_2$	arterial-to-mixed venous oxygen content difference
CC	closing capacity
cc	cubic centimeter
$Cc'O_2$	content of oxygen of the ideal alveolar capillary
C_D	dynamic characteristic or dynamic compliance
CDC	U.S. Centers for Disease Control and Prevention
CDH	congenital diaphragmatic hernia
CHF	congestive heart failure
CI	cardiac index
CINAHL	Cumulative Index to Nursing and Allied Health Literature
C_L	lung compliance (also C_{Lung})
cm	centimeters
cm H_2O	centimeters of water pressure
CMS	Centers for Medicare and Medicaid Services
CMV	controlled (continuous) mandatory or mechanical ventilation
CNS	central nervous system
CO	carbon monoxide
CO_2	carbon dioxide
COHb	carboxyhemoglobin
COLD	chronic obstructive lung disease
COPD	chronic obstructive pulmonary disease
CPAP	continuous positive airway pressure
CPG	Clinical Practice Guideline
CPOE	computerized physician order entry
CPP	cerebral perfusion pressure
CPPB	continuous positive pressure breathing
CPPV	continuous positive pressure ventilation
CPR	cardiopulmonary resuscitation
CPT	chest physical therapy
CPU	central processing unit
CQI	continuous quality improvement
CRCE	continuing respiratory care education
C_s	static compliance
CSF	cerebrospinal fluid
CSV	continuous spontaneous ventilation
CT	computed tomography
C_T	tubing compliance (also C_{tubing})
CV	closing volume
CvO_2	venous oxygen content
$C\bar{v}O_2$	mixed venous oxygen content
CVP	central venous pressure
D	diffusing capacity
d	diameter
DC	discharges, discontinue
DC-CMV	dual controlled–continuous mandatory ventilation
DC-CSV	dual controlled–continuous spontaneous ventilation
DIC	disseminated intravascular coagulation
Dm	diffusing capacity of the alveolocapillary membrane
DO_2	oxygen delivery
DPAP	demand positive airway pressure
DPPC	dipalmitoyl phosphatidylcholine
DVT	deep venous thrombosis
E	elastance
EAdi	electrical activity of the diaphragm
$ECCO_2R$	extracorporeal carbon dioxide removal
ECG	electrocardiogram
ECLS	extracorporeal life support
ECMO	extracorporeal membrane oxygenation
EDV	end-diastolic volume
EE	energy expenditure
EEP	end expiratory pressure
EHR	electronic health record
EIB	exercise-induced bronchospasm
EMR	electronic medical record
EPAP	end positive airway pressure
ERV	expiratory reserve volume
ET	endotracheal tube
E_TCO_2 or $etCO_2$	end-tidal CO_2
F	fractional concentration of a gas
° F	degrees Fahrenheit
f	respiratory frequency, respiratory rate
FDA	U.S. Food and Drug Administration
FEF	forced expiratory flow
FEF_{max}	maximal forced expiratory flow achieved during FVC
FEF_X	forced expiratory flow, related to some portion of FVC curve
FET_X	forced expiratory time for a specified portion of FVC
FEV_1	forced expiratory volume at 1 second

$FiCO_2$	fractional inspired carbon dioxide
FIF	forced inspiratory flow
F_iO_2	fractional inspired oxygen
FIVC	forced inspiratory vital capacity
FRC	functional residual capacity
FVC	forced vital capacity
FVS	full ventilatory support
f/V_T	rapid shallow breathing index (frequency divided by tidal volume)
G_{aw}	airway conductance
g/dl	grams per deciliter
$[H^+]$	hydrogen ion concentration
HAP	hospital-acquired pneumonia
Hb	hemoglobin
HBO	hyperbaric oxygen (therapy)
HCAP	health care–associated pneumonia
HCH	hygroscopic condenser humidifier
HCO_3^-	bicarbonate
H_2CO_3	carbonic acid
He	helium
He/O_2	helium/oxygen mixture; heliox
HFFI	high-frequency flow interrupter
HFJV	high-frequency jet ventilation
HFNC	high-flow nasal cannula
HFO	high-frequency oscillation
HFOV	high-frequency oscillatory ventilation
HFPV	high-frequency percussive ventilation
HFPPV	high-frequency positive pressure ventilation
HFV	high-frequency ventilation
HHb	reduced or deoxygenated hemoglobin
HMD	hyaline membrane disease
HME	heat and moisture exchanger
HMEF	heat and moisture exchange filter
H_2O	water
HR	heart rate
ht	height
Hz	hertz
IBW	ideal body weight
I	inspired
IC	inspiratory capacity
ICP	intracranial pressure
ICU	intensive care unit
ID	inner diameter
I:E	inspiratory-to-expiratory ratio
ILD	interstitial lung disease
IMPRV	intermittent mandatory pressure release ventilation
IMV	intermittent mandatory ventilation
INO	inhaled nitric oxide
IPAP	inspiratory positive airway pressure
IPPB	intermittent positive pressure breathing
IPPV	intermittent positive pressure ventilation
IR	infrared
IRB	institutional review board
IRDS	infant respiratory distress syndrome
IRV	inverse ratio ventilation
IRV	inspiratory reserve volume
IV	intravenous
IVC	inspiratory vital capacity
IVH	intraventricular hemorrhage
IVOX	intravascular oxygenator
kcal	kilocalorie
kg	kilogram
kg-m	kilogram-meters
kPa	kilopascal
KPI	key performance indicator
L	liter
LAP	left atrial pressure
lb	pound
LBW	low birth weight
LED	light emitting diode
LFPPV-$ECCO_2R$	low-frequency positive pressure ventilation with extracorporeal carbon dioxide removal
LMS	learning management system
LTACH	long term acute care hospital
LV	left ventricle
LVEDP	left ventricular end-diastolic pressure
LVEDV	left ventricular end-diastolic volume
LVSW	left ventricular stroke work
m^2	meters squared
MABP	mean arterial blood pressure
MAlvP	mean alveolar pressure
MAP	mean arterial pressure or mean airway pressure
MAS	meconium aspiration syndrome
max	maximal
MDI	metered dose inhaler
MDR	multidrug resistant
mEq/L	milliequivalents per liter
MEP	maximum expiratory pressure
metHb	methemoglobin
mg	milligram
mg%	milligram percent
mg/dl	milligrams per deciliter
MI	myocardial infarction
MICP	mobile intensive care paramedic
MI-E	mechanical insufflation-exsufflation
MIF	maximum inspiratory force
MIGET	multiple inert gas elimination technique
min	minute
MIP	maximum inspiratory pressure
ml	milliliter
mm	millimeter
MMAD	median mass aerodynamic diameter
mm Hg	millimeters of mercury
mmol	millimole
MMV	mandatory minute ventilation
mo	month
MOV	minimal occluding volume
$mP_{aw} - \overline{P_{aw}}$	mean airway pressure
MRI	magnetic resonance imaging
msec	millisecond
MV	mechanical ventilation
MVV	maximum voluntary ventilation
NaBr	sodium bromide
NaCl	sodium chloride
NAVA	neurally adjusted ventilatory assist
NBRC	National Board of Respiratory Care
NEEP	negative end expiratory pressure
nHFOV	nasal high-frequency oscillatory ventilation
NICU	neonatal intensive care unit
NIF	negative inspiratory force (also see MIP and MIF)
NIH	National Institutes of Health
NIV	noninvasive ventilation
nM	nanomole
nm	nanometer
NMBA	neuromuscular blocking agent
nM/L	nanomole per liter
NO	nitric oxide
NO_2	nitrous oxide
NP	nasopharyngeal
NPO	nothing by mouth
NPV	negative pressure ventilation
NPPV	noninvasive positive pressure ventilation
NSAIDs	nonsteroidal antiinflammatory drugs
nSIMV	nasal synchronized intermittent mandatory ventilation

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

For Robert, Julia, Katie, and Callie, who all make it worthwhile, and for Cristina who has made me whole again.

RMK

I dedicate this work to the memory of my parents, Norma and Alfred Stoller, who instilled the values of rigor and commitment that inform this book; to my wife, Terry Stoller, whose love and support have been the foundation upon which my contribution to this book is possible; to our son, Jake Fox Stoller, whose shining promise gives purpose and illuminates the world; and to generations of Respiratory Therapists, whose daily activities and commitment better our health and give hope.

JKS

To my mother, who is long gone from this earth, but continues to be the most dominant, positive influence in my life. Mom taught me many lessons, including that failure is to be expected on the way to success, and excellence can only be achieved through hard work, sacrifice, and perseverance. These lessons have proven invaluable and, hence, my work on this text is dedicated to my mother, Edith; as well as my wife, Laurel; my faculty and students; fellow respiratory therapists; and the patients we tirelessly serve.

Preface

Donald F. Egan, MD, the original author of *Egan's Fundamentals of Respiratory Care,* sought to provide a foundation of knowledge for respiratory students learning the practice in 1969. However, the scope of the respiratory care profession is ever-expanding, and the skills and information needed to be an effective respiratory therapist have expanded with it. With improved technology and vast scientific and medical advances, the body of knowledge required for respiratory therapists has increased greatly since the first edition of the text was published.

Now in its eleventh edition, *Egan's Fundamentals of Respiratory Care* encompasses the most relevant information to date and has provided a comprehensive knowledge base for students and professionals for more than 45 years. While these updated editions of *Egan's Fundamentals of Respiratory Care* still accomplish Dr. Egan's original goal—"to present what is felt to be the minimum knowledge for the safe and effective administration of inhalation therapy"—this text also goes far beyond the minimum, delving into important concepts and providing detailed information and resources to enhance student comprehension.

Every editor, guest editor, and contributor to the book is a leading figure in respiratory care, and the vast experience of these individuals ensures that critical content is covered accurately. Using the combined knowledge of these individuals, *Egan's Fundamentals of Respiratory Care* covers the role of respiratory therapists, the scientific bases for treatment, and clinical application skills. With 56 detailed chapters all focused on a unique aspect of respiratory care, *Egan's Fundamentals of Respiratory Care* is without equal in providing the prerequisite information required of a respiratory therapist today.

ORGANIZATION

This edition of the text is organized in a logical sequence of sections and chapters that build on each other to facilitate comprehension of the material. The earlier sections provide a basis for the profession and cover the physical, anatomic, and physiologic principles necessary to understand succeeding chapters. The later chapters address specific cardiopulmonary diseases and the diagnostic and therapeutic techniques that accompany them. Details on preventive and long-term care are also provided in the later chapters. In order of presentation, the seven sections are:

I. Foundations of Respiratory Care
II. Applied Anatomy and Physiology
III. Assessment of Respiratory Disorders
IV. Review of Cardiopulmonary Disease
V. Basic Therapeutics
VI. Acute and Critical Care
VII. Patient Education and Long-Term Care

FEATURES

There are many characteristic features throughout the book designed with the student in mind, making *Egan's Fundamentals of Respiratory Care* unique and engaging as a primary textbook. Each chapter begins in a similar manner, outlining the content and drawing attention to what should be mastered through the use of:

- Chapter Objectives
- Chapter Outlines
- Key Terms

The most important features within each chapter are accented by the ample use of figures, boxes, and tables containing key information and by the use of:

- "Rules of Thumb"—"pearls" of information highlighting rules, formulas, and key points necessary to the study of respiratory therapy and to future clinical practice
- "Mini-Clinis"—critical thinking case studies illustrating potential problems that may be encountered during patient care
- Clinical Practice Guidelines—statements of care extracted from the AARC list of guidelines defining evidence-based practice
- Therapist-Driven Protocols—examples of decision trees developed by hospitals and used by respiratory therapists to assess patients, initiate care, and evaluate outcomes

Also, each chapter concludes with:

- A "Summary Checklist" of key points that the student should have mastered on completion of the chapter
- A complete list of references

NEW TO THIS EDITION

This edition has been updated to reflect the most current information in the National Board for Respiratory Care (NBRC) Therapist Exam Content Outline. Also featured is an expanded role for the NBRC Exam Matrix Correlation chart within all of the student and instructor offerings. Several chapters have been added, including Fundamentals of Respiratory Care Research; Flexible Bronchoscopy and the Respiratory Therapist;

Extracorporeal Life Support (ECLS); Patient Ventilator Interaction; and Trauma, Obesity, Burns, and Near Drowning; and many other chapters have been substantially revised or completely rewritten to reflect the dynamic and expanding field of respiratory care. Furthermore, the content of the entire text has been refined and simplified to be more easily understood and relevant to our key audiences: respiratory therapy students, faculty, and therapists throughout the world.

LEARNING AIDS

Workbook

The *Workbook for Egan's Fundamentals of Respiratory Care* is an exceptional resource for students. Offering a wide range of activities, it allows students to apply the knowledge they have gained using the core text. Presented in an engaging format, the workbook breaks down the more difficult concepts and guides students through the most important information. Beyond the many NBRC-style multiple-choice questions in the workbook, students are challenged with exercises such as fill-in-the-blanks, matching, case studies, short answers, and more. Answers to the Workbook are available on the Evolve site.

FOR THE INSTRUCTOR

Evolve Resources

Evolve is an interactive learning environment designed to work in coordination with this text. Instructors may use Evolve to provide an Internet-based course component that expands the concepts presented in class. Evolve can be used to publish the class syllabus, outlines, and lecture notes; set up "virtual office hours" and e-mail communication; and encourage student participation through chatrooms and discussion boards. Evolve also allows instructors to post exams and manage their grade books.

The intuitive and comprehensive Evolve Learning Resources associated with this text provide instructors with valuable resources to use as they teach, including:

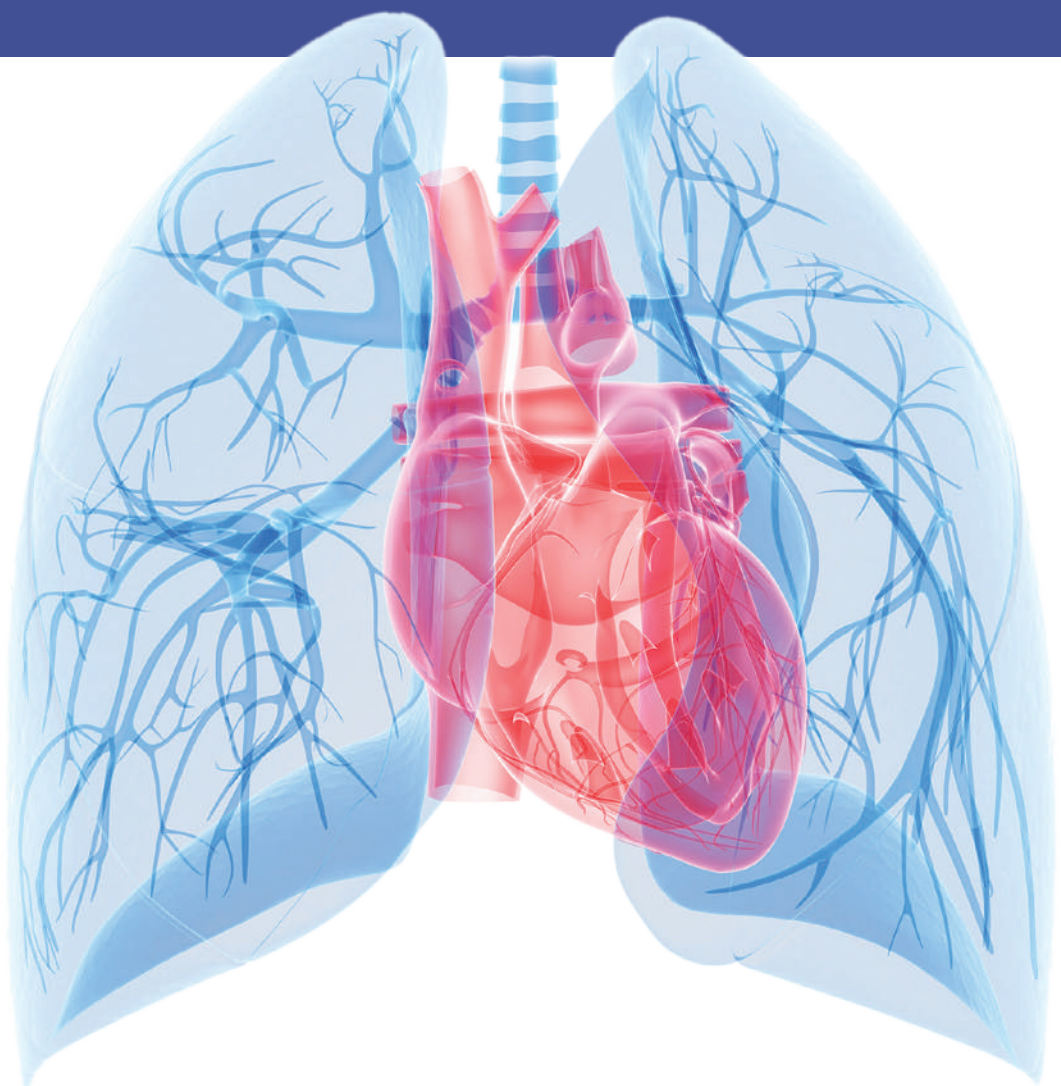
- More than 3000 test bank questions available in ExamView
- Comprehensive PowerPoint presentations for each chapter
- An image collection of the figures in the book
- Lesson plans
- Workbook answer key

For more information, visit http://evolve.elsevier.com/Egans or contact an Elsevier sales representative.

Contents

SECTION I

FOUNDATIONS OF RESPIRATORY CARE



CHAPTER 1

History of Respiratory Care

PATRICK J. DUNNE

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Define *respiratory care.*
- Summarize some of the major events in the history of science and medicine.
- Explain how the respiratory care profession began.
- Describe the historical development of the major clinical areas of respiratory care.
- Name some of the important historical figures in respiratory care.
- Describe the major respiratory care educational, credentialing, and professional associations.
- Explain how the important respiratory care organizations began.
- Describe the development of respiratory care education.
- Predict future trends for the respiratory care profession.

CHAPTER OUTLINE

KEY TERMS

aerosol medications
airway management
American Association for Respiratory Care (AARC)
American Respiratory Care Foundation (ARCF)
Board of Medical Advisors (BOMA)
cardiopulmonary system
Committee on Accreditation for Respiratory Care (CoARC)
Fellow of the American Association for Respiratory Care (FAARC)
International Council for Respiratory Care (ICRC)
mechanical ventilation
National Board for Respiratory Care (NBRC)
oxygen therapy
physician assistant
pulmonary function testing
respiratory care
respiratory care practitioner(s)
respiratory therapist(s) (RTs)
respiratory therapy

The history of science and medicine is a fascinating topic, which begins in ancient times and progresses to the twenty-first century. Although respiratory care is a newer discipline, its roots go back to the dawn of civilization. The first written account of positive pressure ventilation using mouth-to-mouth resuscitation is thought to have been recorded more than 28 centuries ago.[1] Air was thought to be one of the four basic elements by the ancients, and the practice of medicine dates back to ancient Babylonia and Egypt. The progression of science and medicine continued through the centuries, and development of the modern disciplines of anesthesiology, pulmonary medicine, and respiratory care during the twentieth

century depended on the work of many earlier scientists and physicians. This chapter describes the history and development of the field of respiratory care and possible future directions for the profession.

DEFINITIONS

Respiratory care, also known as **respiratory therapy**, has been defined as the health care discipline that specializes in the promotion of optimal cardiopulmonary function and health.[2] **Respiratory therapists (RTs)** apply scientific principles to prevent, identify, and treat acute or chronic dysfunction of the **cardiopulmonary system**.[2] Respiratory care includes the assessment, treatment, management, control, diagnostic evaluation, education, and care of patients with deficiencies and abnormalities of the cardiopulmonary system.[2] Respiratory care is increasingly involved in the prevention of respiratory disease, the management of patients with chronic respiratory disease, and the promotion of health and wellness.[2]

RTs, also known as **respiratory care practitioners**, are health care professionals who are educated and trained to provide respiratory care to patients. Approximately 75% of all RTs work in hospitals or other acute care settings.[3] However, many RTs are employed in clinics, physicians' offices, skilled nursing facilities, cardiopulmonary diagnostic laboratories, and public schools. Others work in research, disease management programs, home care, and industry. RTs also are employed by colleges and universities to teach students the skills they need to become RTs. Regardless of practice setting, all direct patient care services provided by RTs must be done under the direction of a qualified physician. Medical directors are usually physicians who are specialists in pulmonary medicine, anesthesiology, and/or critical care medicine.

A human resources survey conducted in 2014 by the American Association for Respiratory Care (AARC) revealed that there were approximately 172,000 RTs practicing in the United States[3]; this represented a 19% increase over a similar study conducted 4 years earlier in 2009. As the incidence of chronic respiratory diseases continues to increase, the demand for RTs is expected to be even greater in the years ahead. Although the RT as a distinct health care provider was originally a uniquely North American phenomenon, since the 1990s there has been a steady increase in interest of other countries in having specially trained professionals provide respiratory care. This trend is referred to as the *globalization of respiratory care.*

HISTORY OF RESPIRATORY MEDICINE AND SCIENCE

Several excellent reviews of the history of respiratory care have been written, and the reader is encouraged to review these publications.[1,4-6] Summaries of notable historical events in science, medicine, and respiratory care are provided in Tables 1-1 and 1-2. A brief description of the history of science and medicine follows.

Ancient Times

Humans have been concerned about the common problems of sickness, disease, old age, and death since primitive times. Early cultures developed herbal treatments for many diseases, and surgery may have been performed in Neolithic times. Physicians practiced medicine in ancient Mesopotamia, Egypt, India, and China.[1,4,7] However, the foundation of modern Western medicine was laid in ancient Greece with the development of the Hippocratic Corpus.[1,4,7,8] This ancient collection of medical treatises is attributed to the "father of medicine," Hippocrates,

TABLE 1-1

Major Historical Events in Science, Medicine, and Respiratory Care from Ancient Times to the Nineteenth Century

Dates	Historical Event
Ancient Period	
1550 BC	What may be the world's oldest medical document, known as *Ebers Papyrus,* describes an ancient Egyptian inhalational treatment for asthma.
800 BC	Biblical reference to what may be the first recorded episode of mouth-to-mouth resuscitation.
500-300 BC	Hippocrates (460-370 BC; Greece) describes diseases as "humoral disorders" and speculates that an essential substance in air enters the heart and is distributed throughout the body.
304 BC	Erasistratus of Alexandria describes the pneumatic theory of respiration, in which air travels through the lungs to the heart and then through the air-filled arteries to the tissues of the body.
100-200 AD	Galen (130-199 AD) in Asia Minor identifies "pneuma" as the vital substance in inspired air that enters the heart and then the blood.
Middle Ages (500-1500 AD) and Renaissance (1450-1600)	
500-1500 AD	The Middle Ages brings a period of little scientific progress in the West; however, this period coincides with the Golden Age of Arabian medicine (850-1050 AD).
1400s-1500s	da Vinci (1452-1519; Italy) performs human dissections and physiologic experiments on animals, learning that subatmospheric intrapleural pressures inflate the lungs and that there is a vital substance in air that supports combustion.
1542	Vesalius (1514-1564; Belgium), one of the great early pioneers in human anatomy, performs a thoracotomy on a pig, placing a reed tracheotomy tube for ventilation of the animal, and resuscitates an apparently dead person.

TABLE 1-1

Major Historical Events in Science, Medicine, and Respiratory Care from Ancient Times to the Nineteenth Century—cont'd

Dates	Historical Event
Seventeenth Century (1600s)	
1628	Harvey (1578-1657; England) describes the arterial and venous circulatory systems.
1643	Torricelli (1608-1647; Italy) builds the world's first barometer for measurement of atmospheric pressure.
1648	Pascal (1623-1662) describes the relationship between altitude and barometric pressure.
1662; 1666	Boyle (1627-1691; England) explains the inverse relationship between gas pressure and volume (Boyle's law: pressure [P] × volume [V] = *k* or $[P_1V_1] = [P_2V_2]$). Boyle also describes a mysterious substance in air that supports combustion.
1683	van Leewenhoek (1632-1723; Holland) improves the microscope and begins the science of microbiology.
Eighteenth Century (1700s)	
1738	Bernoulli (1700-1782; Switzerland) determines that as the velocity of a liquid or gas increases, the pressure decreases (Bernoulli principle). Bernoulli also proposed that gases are composed of tiny particles in rapid, random motion. This idea became the basis of the modern kinetic theory of gases, which was developed further by Maxwell (1831-1879; Scotland) in 1860.
1744	Fothergill (1712-1780; England) reports successful resuscitation methods.
1754	Black (1728-1799; Scotland) rediscovers carbon dioxide, which he calls "fixed air" (prior work had been done by van Helmot in the 1600s).
1771	Scheele (1742-1786; Sweden) makes "fire air" (oxygen) by heating magnesium oxide; Scheele's findings are published in June 1774.
1774	Priestley (1733-1804; England), usually credited with the discovery of oxygen, publishes his work on "dephlogisticated air" (oxygen) 3 months after Scheele's report.
1775	Lavosier (1743-1794; France) renames "dephlogisticated air" "oxygen," or "acid maker" and shows that oxygen is absorbed by the lungs and consumed by the body, producing carbon dioxide and water vapor, which are exhaled.
1776	Hunter (1728-1793; England) recommends use of a fireplace bellows for artificial ventilation.
1787	Charles (1746-1823; France) describes the relationship between gas temperature and volume; Charles' law: volume (V)/temperature (T) = constant; or $(V_1/T_1) = (V_2/T_2)$.
1794	Lavosier (1743-1794; France) describes oxygen absorption by the lungs and carbon dioxide production.
1798	Beddoes (1760-1808; England) establishes the Pneumatic Institute in Bristol and uses oxygen to treat various disorders.
Nineteenth Century (1800s)	
1800	Henry (1774-1836; England) determines that the amount of gas dissolved in a liquid is directly proportioned to its partial pressure (Henry's law).
1800s	Fick (1829-1911) describes a method to calculate cardiac output based on oxygen consumption and arterial and venous oxygen content: $Qt = (\dot{V}O_2)/(CaO_2 - CvO_2)$.
1801-1808	Dalton (1766-1844; England) describes his atomic theory and the relationship between the partial pressures and total pressure of a gas mixture; Dalton's law: $P_1 + P_2 + P_3 \ldots P_N = P_{Total}$, where P = pressure.
1806	de LaPlace (1749-1827; France) describes the relationship between pressure and surface tension in fluid droplets.
1808	Gay-Lussac (1778-1850; France) describes the relationship between gas pressure and temperature; Gay-Lussac's law: pressure (P)/temperature (T) = constant; or $(P_1/T_1) = (P_2/T_2)$.
1811	Avogadro (1776-1856; Italy) describes "Avogadro principle," in which equal volumes of all gases (at the same temperature and pressure) contain the same number of molecules.
1816	Laennec (1781-1826; France) invents the stethoscope for chest auscultation and lays the foundation for modern pulmonology with his book *Diseases of the Chest.*
1831	Graham (1805-1869; Scotland) describes diffusion of gases (Graham's law).
1837	Magnus (1802-1870; Germany) measures arterial and venous blood oxygen and carbon dioxide content.
1846	Hutchinson (1811-1861; England) develops the spirometer and measures the vital capacity of more than 2000 human subjects.
1864	Jones (United States) patents a negative pressure device to support ventilation.
1865	Pasteur (1822-1895; France) describes his "germ theory" of disease.
1876	Woillez develops the spirophore negative pressure ventilator.
1878	Bert (1833-1886; France) shows that low inspired oxygen levels cause hyperventilation.
1880	MacEwen reports success with oral endotracheal intubation.
1885	Miescher-Rusch demonstrates that carbon dioxide is the major stimulus for breathing.
1886; 1904	Bohr (1855-1911; Danish) describes the oxyhemoglobin dissociation curve.
1888	The Fell-O'Dwyer device combines a foot-operated bellows with a laryngeal tube for ventilatory support.
1895	Roentgen (1845-1923; Germany) discovers the "x-ray." A direct vision laryngoscope is introduced by Jackson in the United States and Kirstein in Germany.

Data from references 1, 3-9, 11-14, and 17.

TABLE 1-2

Major Historical Events in Science, Medicine, and Respiratory Care in the Twentieth and Twenty-First Centuries

Twentieth Century

Early 1900s	Bohr (1855-1911; Denmark), Hasselbach (1874-1962; Denmark), Krogh (1874-1940; Denmark), Haldane (1860-1936; Scotland), Barcroft (1872-1947; Ireland), Priestly (1880-1941; Britain), Y. Henderson (1873-1944; United States), L. J. Henderson (1878-1942; United States), Fenn (1893-1971; United States), Rahn (1912-1990; United States), and others make great strides in respiratory physiology and the understanding of oxygenation, ventilation, and acid-base balance.
1904	Bohr, Hasselbach, and Krogh (1874-1940) describe the relationships between oxygen and carbon dioxide transport. Sauerbruch (1875-1951; Germany) uses a negative pressure operating chamber for surgery in Europe.
1907	von Linde (1842-1934; Germany) begins large-scale commercial preparation of oxygen.
1909	Melltzer (1851-1920; United States) introduces oral endotracheal intubation.
1910	Oxygen tents are in use, and the clinical use of aerosolized epinephrine is introduced.
1911	Drager (1847-1917; Germany) develops the Pulmotor ventilator for use in resuscitation.
1913	Jackson develops a laryngoscope to insert endotracheal tubes.
1918	Oxygen mask is used to treat combat-induced pulmonary edema.
1919	Strohl (1887-1977; France) suggests the use of forced vital capacity as a measure of pulmonary function.
1920	Hill develops an oxygen tent to treat leg ulcers.
1926	Barach develops an oxygen tent with cooling and carbon dioxide removal.
1928	Drinker develops his “iron lung” negative pressure ventilator.
1938	Barach develops the meter mask for administering dilute oxygen. Boothby, Lovelace, and Bulbulian devise the BLB mask at the Mayo Clinic for delivering high concentrations of oxygen.
1940	Isoproterenol, a potent beta-1 and beta-2 bronchodilator administered via aerosol, is introduced. Most common side effects are cardiac (beta-1).
1945	Motley, Cournand, and Werko use intermittent positive pressure breathing to treat various respiratory disorders.
1947	The ITA is formed in Chicago, Illinois. The ITA later becomes the AARC.
1948	Bennett introduces the TV-2P positive pressure ventilator.
1948	FEV_1 is introduced as a pulmonary function measure of obstructive lung disease.
1951	Isoetherine (Bronkosol), a preferential beta-2 aerosol bronchodilator with fewer cardiac side effects, is introduced.
1952	Mørch introduces the piston ventilator.
1954	The ITA becomes the AAIT.
1958	Bird introduces the Bird Mark 7 positive pressure ventilator.
1960	The Campbell Ventimask for delivering dilute concentrations of oxygen is introduced.
1961	Jenn becomes the first registered respiratory therapist. Also, metaproterenol, a preferential beta-2 bronchodilator, is introduced
1963	Board of Schools is formed to accredit inhalation therapy educational programs.
1964	The Emerson Postoperative Ventilator (3-PV) positive pressure volume ventilator is introduced.
1967	The Bennett MA-1 volume ventilator is introduced, ushering in the modern age of mechanical ventilatory support for routine use in critical care units.
1967	Combined pH-Clark-Severinghaus electrode is developed for rapid blood gas analysis.
1968	Fiberoptic bronchoscope becomes available for clinical use. The Engström 300 and Ohio 560 positive pressure volume ventilators are introduced.
1969	ARDS and PEEP are described by Petty, Ashbaugh, and Bigelow.
1970	Swan-Ganz catheter developed for measurement of pulmonary artery pressures. The ARCF is incorporated. The JRCITE is incorporated to accredit respiratory therapy educational programs.
1971	Continuous positive airway pressure is introduced by Gregory. *Respiratory Care* journal is named.
1972	Siemens Servo 900 ventilator is introduced.
1973	IMV is described by Kirby and Downs. The AAIT becomes the AART.
1974	IMV Emerson ventilator is introduced.
1974	NBRT is formed.
1975	Bourns Bear I ventilator is introduced.
1977	The JRCITE becomes the JRCRTE.
1978	Puritan Bennett introduces the MA-2 volume ventilator. The *AAR Times* magazine is introduced.
1979	AIDS is recognized by the Centers for Disease Control (CDC [later, Centers for Disease Control and Prevention]).
1982	Siemens Servo 900C and Bourns Bear II ventilators are introduced.
1983	The NBRT becomes the NBRC.
1983	President Reagan signs proclamation declaring National Respiratory Care Week
1984	Bennett 7200 microprocessor controlled ventilator is introduced.
1984	The AART is renamed the AARC.
1991	Servo 300 ventilator is introduced.
1992, 1993	The AARC holds national respiratory care education consensus conferences.
1994	The CDC publishes the first guidelines for the prevention of ventilator-associated pneumonia.
1998	The CoARC is formed, replacing the JRCRTE.

TABLE 1-2

Major Historical Events in Science, Medicine, and Respiratory Care in the Twentieth and Twenty-First Centuries—cont'd

Twenty-First Century

2002	The NBRC adopts a continuing competency program for respiratory therapists to maintain their credentials.
2002	The Tripartite Statements of Support are adopted by the AARC, NBRC, and CoARC to advance respiratory care education and credentialing.
2003	The AARC publishes its white paper on the development of baccalaureate and graduate education in respiratory care. Asian bird flu appears in South Korea.
2004	The Fiftieth AARC International Congress is held in New Orleans.
2005	Number of working respiratory therapists in the United States reaches 132,651.
2006	The National Heart, Lung and Blood Institute (NHLBI) of the U.S. Department of Health and Human Services begins national awareness and education campaign for COPD. The AARC works with government officials to recruit and train respiratory therapists for disaster response
2007	The first AARC president to serve a 2-year term begins term of office.
2008	First of three conferences held for 2015 and Beyond strategic initiative of the AARC.
2010	The *Patient Protection and Affordable Care Act* is signed into law by President Barak Obama.

Data from references 1, 3-9, 11-14, and 17.

a Greek physician who lived during the fifth and fourth centuries BC.[1,7,8] Hippocratic medicine was based on four essential fluids, or "humors"—phlegm, blood, yellow bile, and black bile—and the four elements—earth (cold, dry), fire (hot, dry), water (cold, moist), and air (hot, moist). Diseases were thought to be humoral disorders caused by imbalances in these essential substances. Hippocrates believed there was an essential substance in air that was distributed to the body by the heart.[1] The Hippocratic Oath, which admonishes physicians to follow certain ethical principles, is given in a modern form to medical students at graduation.[1,8]

Aristotle (384-322 BC), a Greek philosopher and perhaps the first great biologist, believed that knowledge could be gained through careful observation.[1,8] Aristotle made many scientific observations, including observations obtained by performing experiments on animals. Erasistratus (~330-240 BC), regarded by some as the founder of the science of physiology, developed a pneumatic theory of respiration in Alexandria, Egypt, in which air *(pneuma)* entered the lungs and was transferred to the heart.[1,7] Galen (130-199 AD) was an anatomist in Asia Minor whose comprehensive work dominated medical thinking for centuries.[1,6,7] Galen also believed that inspired air contained a vital substance that somehow charged the blood through the heart.[1]

The Middle Ages, the Renaissance, and the Enlightenment Period

The Romans carried on the Greek traditions in philosophy, science, and medicine. With the fall of the Western Roman Empire in 476 AD, many Greek and Roman texts were lost and Europe entered a period during which few advances were made in science or medicine. In the seventh century AD, the Arabians conquered Persia, where they found and preserved many of the works of the ancient Greeks, including the works of Hippocrates, Aristotle, and Galen.[1,7] A Golden Age of Arabian medicine (850-1050 AD) followed.

An intellectual rebirth in Europe began in the twelfth century.[1,7] Medieval universities were formed, and contact with the Arabs in Spain and Sicily reintroduced ancient Greek and Roman texts. Magnus (1192-1280) studied the works of Aristotle and made many observations related to astronomy, botany, chemistry, zoology, and physiology. The Renaissance (1450-1600) ushered in a period of scientific, artistic, and medical advances. Leonardo da Vinci (1452-1519) studied human anatomy, determined that subatmospheric intrapleural pressures inflated the lungs, and observed that fire consumed a vital substance in air without which animals could not live.[1,4] Vesalius (1514-1564), considered to be the founder of the modern field of human anatomy, performed human dissections and experimented with resuscitation.[1] In 1543, the date commonly given as the start of the modern Scientific Revolution, Copernicus observed that the Earth orbited the sun.[8] Before this time, it had been accepted that the Earth was the center of the universe.

The seventeenth century was a time of great advances in science. Accomplished scientists from this period include Kepler, Bacon, Galileo, Pascal, Hooke, and Newton. In 1628, Harvey fully described the circulatory system.[4,8] In 1662, the chemist Boyle published what is now known as Boyle's law, governing the relationship between gas volume and pressure.[8] Torricelli invented the barometer in 1650, and Pascal showed that atmospheric pressure decreases with altitude.[1,4] van Leeuwenhoek (1632-1723), known as the "father of microbiology," improved the microscope and was the first to observe and describe single-celled organisms, which he called "animalcules."[7]

The eighteenth-century Enlightenment Period brought further advances in the sciences. In 1754, Black described the properties of carbon dioxide, although the discovery of carbon dioxide should be credited to van Helmont, whose work occurred approximately 100 years earlier.[1] In 1774, Priestley described his discovery of oxygen, which he called

"dephlogisticated air."[1,4] Before 1773, Scheele performed the laboratory synthesis of oxygen, which he called "fire air"; a general description of his discovery appeared in 1774, and a more thorough description appeared in 1777.[1,4] Shortly after the discovery of oxygen, Spallanzani worked out the relationship between the consumption of oxygen and tissue respiration.[1] In 1787, Charles described the relationship between gas temperature and volume now known as Charles' law.[8] In experiments performed between 1775 and 1794, Lavoisier showed that oxygen was absorbed by the lungs and that carbon dioxide and water were exhaled.[1,4] In 1798, Beddoes began using oxygen to treat various conditions at his Pneumatic Institute in Bristol.[1,4]

Nineteenth and Early Twentieth Centuries

During the nineteenth century, important advances were made in physics and chemistry related to respiratory physiology. Dalton described his law of partial pressures for a gas mixture in 1801 and his atomic theory in 1808.[8] Young in 1805 and de LaPlace in 1806 described the relationship between pressure and surface tension in fluid droplets.[8] Gay-Lussac described the relationship between gas pressure and temperature in 1808; in 1811, Avogadro determined that equal volumes of gases at the same temperature and pressure contain the same number of molecules.[1,8] In 1831, Graham described his law of diffusion for gases (Graham's law).[8]

In 1865, Pasteur advanced his "germ theory" of disease, which held that many diseases are caused by microorganisms.[8] Medical advances during this time included the invention of the spirometer and ether anesthesia in 1846, antiseptic techniques in 1865, and vaccines in the 1880s.[1,4,7] Koch, a pioneer in bacteriology, discovered the tubercle bacillus, which causes tuberculosis, in 1882, and the vibrio bacterium, which causes cholera, in 1883.[7] He also developed Koch's postulates, which are criteria designed to establish a causative relationship between a microbe and a disease. Respiratory physiology also progressed with the measurement in 1837 of blood oxygen and carbon dioxide content, description around 1880 of the respiratory quotient, demonstration in 1885 that carbon dioxide is the major stimulant for breathing, and demonstration in 1878 that oxygen partial pressure and blood oxygen content were related.[1,4,9] In 1895, Roentgen discovered the x-ray, and the modern field of radiologic imaging sciences was born.[8] Pioneering respiratory physiologists of the early twentieth century described oxygen diffusion, oxygen and carbon dioxide transport, the oxyhemoglobin dissociation curve, acid-base balance, and the mechanics of breathing and made other important advances in respiratory physiology (see Table 1-2).

DEVELOPMENT OF THE RESPIRATORY CARE PROFESSION

Clinical Advances in Respiratory Care

The evolution of the respiratory care profession depended in many ways on developments in the various treatment techniques that matured in the twentieth century. As the scientific basis for oxygen therapy, mechanical ventilatory support, and administration of medical aerosols became well established, the need for a health care practitioner to provide these services became apparent. Concurrent with this need was the continuing development of specialized cardiopulmonary diagnostic tests and monitoring procedures, which also required health care specialists to perform.

The first health care specialists in the field were oxygen technicians in the 1940s.[1,4,5] The first inhalation therapists were oxygen technicians or oxygen orderlies who could haul cylinders of oxygen and related equipment around the hospital and set up oxygen tents, masks, and nasal catheters. The development of positive pressure breathing during World War II for breathing support of high-altitude pilots led to its use as a method to treat pulmonary patients and deliver aerosol medications during the 1950s, expanding the role of the inhalation therapist. Inhalation therapists began to be trained in the 1950s, and formal education programs began in the 1960s.[1,4,5] The development of sophisticated mechanical ventilators in the 1960s naturally led to a further expansion in the role of RTs, who soon also found themselves responsible for arterial blood gas and pulmonary function laboratories. In 1974, the designation *respiratory therapist* became standard, and the RT became the allied health professional primarily concerned with the assessment, diagnostic testing, treatment, education, and care of patients with deficiencies and abnormalities of the cardiopulmonary system. The historical development of several clinical areas of respiratory care is described next, followed by an overview of the establishment of the major professional organizations in the field. The evolution of respiratory care education is also described.

RULE OF THUMB

When looking for information about the respiratory care profession, the best place to look is the AARC (see www.AARC.org). The AARC's newly constructed *Virtual Museum* can be accessed through the AARC Web site.

Oxygen Therapy

The therapeutic administration of oxygen first occurred in 1798, and in 1878 Bert showed that lack of oxygen caused hyperventilation. But the physiologic basis and indications for **oxygen therapy** were not well understood until the twentieth century.[1,4] Large-scale production of oxygen was developed by von Linde in 1907. The use of a nasal catheter for oxygen administration was introduced by Lane in the same year.[1,4] Oxygen tents were in use in 1910, and an oxygen mask was used to treat combat gas–induced pulmonary edema in 1918.[1] In 1920, Hill developed an oxygen tent to treat leg ulcers, and in 1926, Barach introduced a sophisticated oxygen tent for clinical use. Oxygen chambers and whole oxygen rooms were designed.[1,4] In 1938, a meter mask was developed by Barach to administer dilute oxygen.[1,4] The BLB mask (named for Boothby, Lovelace, and Bulbulian) to administer 80% to 100% oxygen to pilots was

introduced during World War II and later used on patients.[1,4] By the 1940s, oxygen was widely prescribed in hospitals, although there was still no good way to measure blood oxygen levels routinely until the mid-1960s, with the introduction of the Clark electrode, followed by the clinical use of the ear oximeter in 1974 and the pulse oximeter in the 1980s.[1,4,5] The Campbell Ventimask, which allowed the administration of 24%, 28%, 35%, or 40% oxygen, was introduced in 1960, and modern versions of the nasal cannula, simple oxygen mask, partial rebreathing mask, and nonrebreathing mask were available by the late 1960s. Portable liquid oxygen systems for long-term oxygen therapy in the home were introduced in the 1970s, and the oxygen concentrator soon followed. Oxygen-conserving devices, including reservoir cannulas, demand pulse oxygen systems, and transtracheal oxygen catheters, were introduced in the 1980s.

The 2000s saw further advances in home oxygen therapy equipment with the introduction of oxygen concentrators used in conjunction with a pressure booster to allow for the transfilling of small, portable oxygen cylinders in the home. Smaller, lightweight portable oxygen concentrators were also introduced. Both of these advances have greatly enhanced the ability of patients receiving long-term oxygen therapy to ambulate beyond the confines of their home. Furthermore, the National Institutes of Health launched the Long-Term Oxygen Treatment Trial (LOTT) as a randomized trial to explore the benefits of supplemental oxygen in patients with chronic obstructive pulmonary disease (COPD) and only mild resting hypoxemia (SpO_2 89% to 93%) or with exercise desaturation.[10]

Aerosol Medications

Aerosol therapy is defined as the administration of liquid or powdered aerosol particles via inhalation to achieve a desired therapeutic effect. Bland aerosols (sterile water, saline solutions) or solutions containing pharmacologically active drugs may be administered. In 1802, the use of inhaled *Datura* leaf fumes, which contain atropine, to treat asthma was described.[11] Early use of **aerosol medications** dates to 1910, when the first use of aerosolized epinephrine was reported. Later, other short-acting bronchodilators such as isoproterenol (1940), isoetharine (1951), metaproterenol (1961), albuterol sulfate (1980), and levalbuterol (2000) were introduced, primarily for the emergency treatment of acute asthma attacks.[11] In the late 1990s, long-acting bronchodilators—administered twice daily—were introduced for the maintenance treatment of COPD. Oral and injectable steroids were first used in the treatment of asthma in the early 1950s, and the use of aerosolized steroids for the maintenance of patients with moderate to severe asthma began in the 1970s.[11] Newer medications continued to be developed for aerosol administration, including even longer acting bronchodilators (once every 24 hours), mucolytics, antibiotics, antiinflammatory agents, and combination drugs such as long-acting bronchodilators and antiinflammatories in a single dose. Along with newer respiratory drugs, newer delivery devices such as dry powder inhalers and innovative designs for small-volume nebulizers have been introduced.

Mechanical Ventilation

Mechanical ventilation refers to the use of a mechanical device to provide ventilatory support for patients. In 1744, Fothergill advocated mouth-to-mouth resuscitation for drowning victims.[1,6] During the mid to late 1700s, there was a great deal of interest in resuscitation and additional procedures for cardiopulmonary resuscitation were developed.[1,4,6] Positive pressure ventilation using a bag-mask system or bellows was suggested. However, the observation that a fatal pneumothorax may result caused this technique to be rejected around 1827.[1,4] Interest in negative pressure ventilation developed, and the first negative pressure tank ventilator was described in 1832.[6] Other negative pressure ventilators began to appear in the mid-1800s; in 1928, the iron lung was developed by Drinker, an industrial hygienist and faculty member at Harvard University.[1] Emerson developed a commercial version of the iron lung that was used extensively during the polio epidemics of the 1930s and 1950s (Figure 1-1).[1,12] The chest cuirass negative pressure ventilator was introduced in the early 1900s, and a negative pressure "wrap" ventilator was introduced in the 1950s.[13] Other early noninvasive techniques to augment ventilation included the rocking bed (1950) and the pneumobelt (1959).[13]

Originally, positive pressure ventilators were developed for use during anesthesia and later were altered for use on hospital wards.[14] Early positive pressure ventilators included the Drager Pulmotor (1911), the Spiropulsator (1934), the Bennett TV-2P (1948), the Morch Piston Ventilator (1952), and the Bird Mark 7 (1958) (Figure 1-2).[1,14] More sophisticated positive pressure volume ventilators were developed in the 1960s and included the Emerson Postoperative Ventilator, MA-1 (Figure 1-3), Engstrom 300, and Ohio 560.[1,14] A new generation of volume ventilators appeared in the 1970s that included the Servo 900, Bourns Bear I and II, and MA-II. By the 1980s, microprocessor-controlled ventilators began to appear, led by the Bennett 7200 in 1984; in 1988, the Respironics bilevel positive airway pressure (BiPAP) device was introduced for providing noninvasive positive pressure ventilation in a wide variety of settings.[1] During

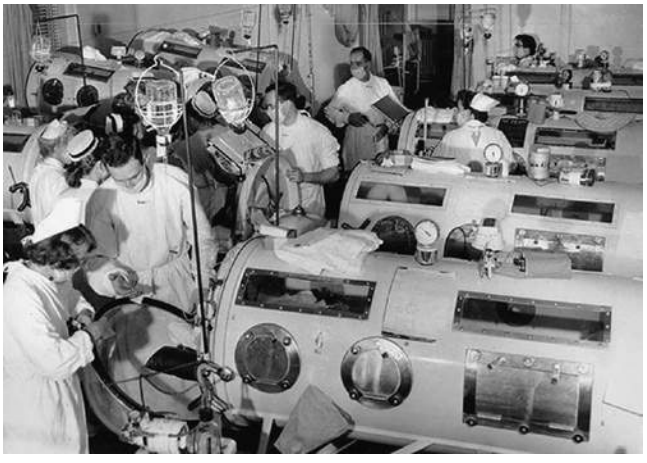

FIGURE 1-1 Iron lung patients in a 1950s polio ward. (From the Associated Press and Post-Gazette.com Health, Science and Environment. http://www.post-gazette.com/pg/05094/482468.stm.)

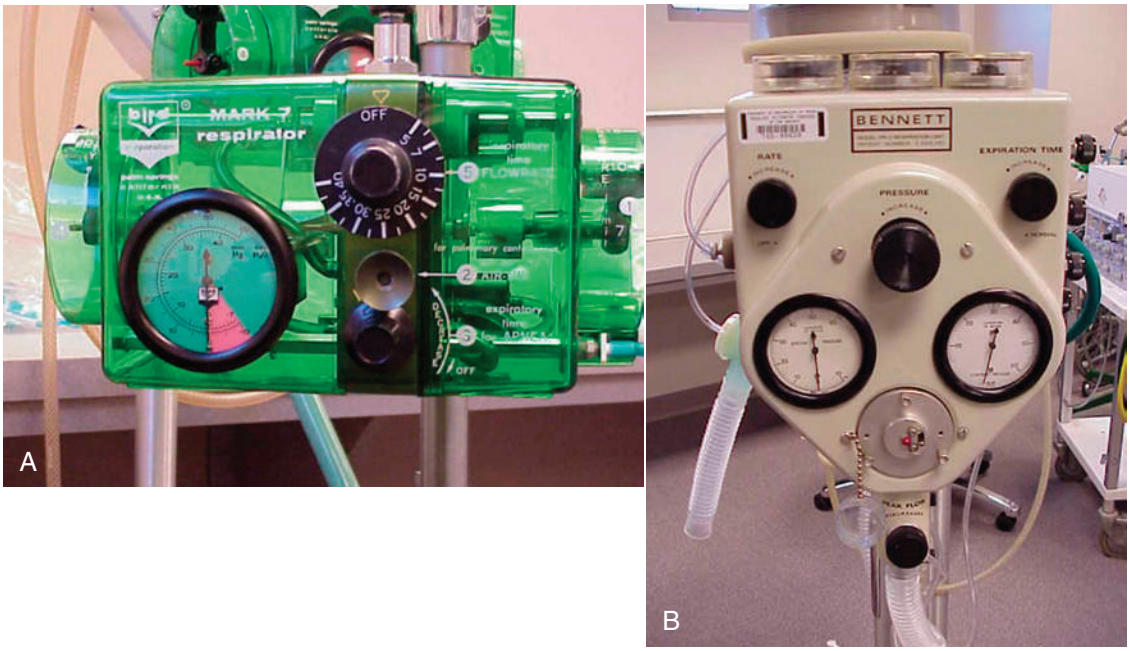

FIGURE 1-2 Bird Mark 7, introduced in 1958 by Bird **(A),** and Bennett PR-2, introduced in 1963 by Bennett **(B),** were pneumatically powered, pressure-limited positive pressure ventilators that could provide assist-control ventilation and were used to deliver intermittent positive pressure breathing treatments.

FIGURE 1-3 Bennett MA-1 ventilator, introduced in 1967, played a major role in making mechanical ventilatory support routinely available in intensive care units throughout the world.

the 1990s and early 2000s, new ventilators have continued to be developed, including the Hamilton G5, Servo-i, PB 980, and Drager V500 and VN500 series (see Chapter 45). Between 1970 and 2004, more than 50 new ventilators with various characteristics were introduced for clinical use.[15,16]

Early mechanical ventilators provided modes for which breaths were delivered according to a preset frequency and inspiratory time, regardless of any inspiratory effort on the part of the patient (what anesthesiologists of the time called "controlled" ventilation). The early Bird and Bennett ventilators invented in the 1950s allowed for initiating inspiration by detecting the patient' inspiratory effort, called "assist." This feature was incorporated in later modes that also had preset breath frequency (called *assist/control*, a term that is anachronistic but persistent to this day). The terminology related to modes of ventilation has evolved along with the complexity of ventilator technology (see Chapter 45). In 1967, the addition of positive end expiratory pressure (PEEP) as a mode feature was introduced for use in patients dying from the newly described acute respiratory distress syndrome (ARDS). The use of PEEP helped stabilize and keep alveoli from collapsing at the end of exhalation. Other forms of modern ventilation include intermittent mandatory ventilation (IMV), introduced in 1971, followed by synchronized IMV, in 1975, and mandatory minute volume ventilation in 1977.[1,4] Pressure support ventilation and pressure-controlled ventilation were introduced in the 1980s, followed by airway pressure release ventilation and inverse ratio ventilation. In the 1990s, volume support ventilation, pressure-regulated volume control, and adaptive support ventilation were introduced. Automatic tube compensation, proportional assist ventilation, neutrally adjusted ventilatory assist, and other modes of ventilation occurred in the twenty-first century. In fact, there are now hundreds of names of modes of ventilation, making a classification system essential for understanding ventilator technology (see Chapter 45).

Because traditional short-term mechanical ventilation, regardless of mode, necessitates using an endotracheal tube, there is always the potential for one or more serious complications

known as ventilator-associated events (VAEs). The most common (but preventable) VAE is an infection known as ventilator-associated pneumonia (VAP). VAP is a deadly and very costly complication of invasive mechanical ventilation that develops when external microorganisms accidentally enter the airway. There has been a concerted effort to try to support inadequate ventilation noninvasively, by using a nasal or full-face mask, to avoid the need for endotracheal intubation. When noninvasive ventilation does not work and endotracheal or tracheostomy tubes are necessary, RTs must be constantly vigilant in their efforts to prevent VAP and all other VAEs.

Airway Management

Airway management refers to the use of various techniques and devices to establish or maintain a functional air passageway. Tracheotomies may have been performed to relieve airway obstruction in 1500 BC.[6] Galen, the Greek anatomist, described a tracheotomy and laryngeal intubation in 160 AD. Vesalius, the anatomist, described a tracheotomy in an animal in 1555.[1,6] In 1667, Hooke described a tracheotomy and use of a bellows for ventilation.[6] In 1776, tracheal intubation was suggested for resuscitation.[6] In 1880, MacEwen reported success with oral endotracheal intubation in patients.[6] O'Dwyer further described the technique for endotracheal tube placement. By 1887, Fell had developed a bellows–endotracheal tube system for mechanical ventilation, and this system was used in 1900 to deliver anesthesia.[6]

In 1913, the laryngoscope was introduced by Jackson. Additional early laryngoscopes were designed by Kirstein, Janeway, and others.[1,6] Endotracheal intubation for anesthesia administration was firmly established by World War I. After the war, Magill introduced the use of soft rubber endotracheal tubes, and this made blind nasal intubation possible, as described by Magill in 1930.[6] In 1938, Haight advocated nasotracheal suctioning for secretion removal, and in 1941, Murphy described the ideal suction catheter, which included side holes known as "Murphy eyes."[6] The double-lumen Carlen tube for independent lung ventilation was introduced in 1940, followed by a double-lumen tube developed by Robertshaw in 1962. Damage to the trachea by the tube cuff was reduced with the introduction of low-pressure cuffs in the 1970s.[6]

Cardiopulmonary Diagnostics and Pulmonary Function Testing

Pulmonary function testing refers to a wide range of diagnostic procedures to measure and evaluate lung function. The volume of air that can be inhaled in a single deep breath was first measured in 1679, and the measurement of the lung's residual volume was first performed in 1800.[9] In 1846, Hutchinson developed a water seal spirometer, with which he measured the vital capacity of more than 2000 subjects.[9,17] Hutchinson observed the relationship between height and lung volume and that vital capacity decreases with age, obesity, and lung disease. Hering and Breuer described the effects of lung inflation and deflation on breathing—the Hering-Breuer reflex—in 1868.[4] In 1919, Strohl suggested the use of forced vital capacity (FVC), and in 1948, forced expiratory volume in 1 second (FEV_1) was suggested as a measure of obstructive lung disease by Tiffeneau.[9]

Arterial and venous oxygen and carbon dioxide contents were measured in 1837, and methods to measure blood oxygen and carbon dioxide levels were available in the 1920s. These early methods for measuring blood oxygen, carbon dioxide, and pH were slow and cumbersome. In 1967, the combined pH, Clark, and Severinghaus electrodes produced a rapid and practical blood gas analyzer for routine clinical use.[1,4] The ear oximeter was introduced in 1974, and the pulse oximeter was introduced in the 1980s. Sleep medicine became well established in the 1980s, and polysomnography became a routine clinical test, often performed by RTs.

PROFESSIONAL ORGANIZATIONS AND EVENTS

American Association for Respiratory Care (AARC)

Founded in 1947 in Chicago, the Inhalational Therapy Association (ITA) was the first professional association for the field of respiratory care.[1,4,5] The purpose of the ITA was to provide for professional advancement, foster cooperation with physicians, and advance the knowledge of inhalation therapy through educational activities.[5] The ITA provided a forum to discuss the clinical application of oxygen therapy, improve patient care, and advance the art and science of the field.[1] There were 59 charter members of the ITA.[1] The ITA became the American Association for Inhalation Therapists (AAIT) in 1954, the American Association for Respiratory Therapy (ARRT) in 1973, and the **American Association for Respiratory Care (AARC)** in 1982.[4,5] By 2014, membership in the AARC had reached 50,000 RTs, RT students, physicians, nurses, and others interested in respiratory care. The AARC also has a formal affiliation with all 50 state respiratory societies (known as *Chartered Affiliates*), as well as with similar organizations in several foreign countries.[17]

During the 1980s, the AARC began a major push to introduce state licensure for RTs based on the National Board for Respiratory Care (NBRC) credentials.[18] As of 2014, 49 states, the District of Columbia, and Puerto Rico have state licensure or some other form of legal credentialing required for the practice of respiratory care. State licensing laws set the minimum educational requirements and the method of determining competence to practice. Competency is typically determined by obtaining a passing grade on a credentialing examination (administered by the NBRC) after graduation from an approved training program. State licensing boards also set the number of continuing education credits required to keep a license active.

The stated mission of the AARC is to "encourage and promote professional excellence, advance the science and practice of respiratory care, and serve as an advocate for patients, their families, the public, the profession and the respiratory therapist."[19] The AARC serves as an advocate for the profession to legislative and regulatory bodies, the insurance industry, and

MINI CLINI

Preparing a Presentation for Respiratory Care Week

PROBLEM: You are a staff therapist in a 300-bed hospital. Your supervisor asks you to prepare a 20-minute presentation on the history and development of the respiratory care profession to be presented at the department's annual Respiratory Care Week luncheon. How would you gather the information needed and develop your presentation?

SOLUTIONS: First, review this chapter to get an overview of the history and development of the respiratory care profession. You may also want to read one or two of the supplemental references that are cited. Next, go to the AARC Web site (see www.AARC.org) and review the "Resources" and "Site Map" sections, which list many helpful resources. You should be able to find sections on "The History of the AARC," "Strategic Plan of the AARC," "Position Statements," and "White Papers." There will also be a portal to AARC's Virtual Museum. You should also find a section on Respiratory Care Week. Review the material that the AARC has provided and develop an outline for your presentation. Your outline may include a brief overview of the history of science and medicine, the development of the respiratory care profession, and the future of respiratory care in the twenty-first century. After you have your outline, decide on your delivery method. PowerPoint slides are easy to make and use. If you choose to do a PowerPoint presentation, a good rule of thumb is about one slide per minute, so you would need about 20 slides. Using your outline, begin to develop your presentation.

the general public. To fulfill its mission, the AARC sponsors many continuing educational activities, including international meetings, conferences and seminars, publications, and a sophisticated Web site (see www.AARC.org).[18] In addition to the monthly science journal *Respiratory Care,* the AARC publishes the monthly news magazine *AARC Times* and numerous electronic newsletters. In the fall of each year, the AARC also sponsors the International Respiratory Congress, the largest respiratory care scientific meeting in the world. Finally, in an effort to ensure that the unique practice interests of AARC members are addressed (e.g., neonatal/pediatrics, adult acute care, management, home care, diagnostics), members are invited to join one or more of 10 Specialty Sections (Box 1-1) within the AARC, designed to facilitate networking and the free exchange of ideas.

The leadership and direction of the AARC is provided by a Board of Directors, which comprises members who volunteer their time and services. The executive officers of the Board of Directors include the president, immediate past-president, president-elect, vice-president for internal affairs, vice-president for external affairs, and secretary-treasurer. The remainder of the Board of Directors consists of a minimum of six members-at-large plus the chairpersons of the Specialty Sections having at least 1000 members. At the present time, 6 of the 10 Specialty Sections meet this requirement. All members of the Board of Directors, including Specialty Section chairpersons, are elected directly by the AARC membership. The AARC Board of Directors meets three times per year to conduct the official business of the association.

Home Care
Long-Term Care
Management
Neonatal/Pediatrics
Sleep
Surface and Air Transport

Each year, the incoming AARC president assigns interested members to chair or serve on more than 50 standing or temporary AARC committees. Many of the initiatives of the AARC are undertaken and eventually brought to completion through committee work. The AARC Board of Directors also receives input from each of the 50 Chartered Affiliates that constitute the House of Delegates. Each Chartered Affiliate elects two of their members to represent the interests of their state affiliate in the meetings of the House of Delegates. The 100 delegates elect their own leaders so that they can conduct the business of the House of Delegates. The House of Delegates meets twice per year. The efforts of the Board of Directors, the House of Delegates, and the numerous committees of the AARC are supported by a staff of more than 35 employees of the AARC who work full time in the association's executive offices, which are located in Irving, Texas.

Many volunteers who have been elected to the AARC or House of Delegates leadership positions or have been asked to chair important committees started by volunteering at the affiliate level. Student members of the AARC are always welcomed as volunteers, especially at the affiliate level. Student members of the AARC have access to a wide array of resources that can greatly enhance the experience of becoming a professional RT.

Respiratory Care Week

In November 1982, President Reagan signed a proclamation declaring the third week of each October as National Respiratory Care Week. Since then, Respiratory Care Week has become a yearly event to promote lung awareness and the work of RTs in all care settings. RTs (and students) around the United States use Respiratory Care Week to celebrate their profession and dedication to high-quality patient care. Many respiratory care departments use the opportunity to conduct special events in their hospitals to help raise awareness of the vital role the RT plays as a member of the health care team. Other departments plan community activities to help the public understand the importance of good lung health and the role RTs play in diagnosing and treating breathing disorders. Respiratory Care Week is also an excellent opportunity for respiratory therapy students

to become ambassadors of the profession to the rest of the student body. Some respiratory therapy classes conduct free breathing tests on campus, in shopping malls, or in community centers.

Fellow of the American Association for Respiratory Care (FAARC)

In any given profession, there are always individuals who go above and beyond what is expected of the average practitioner. To recognize RTs and physician members who have achieved such distinction, in 1998, the AARC established the **Fellow of the American Association for Respiratory Care (FAARC)** award. To be considered for FAARC status, nominees must be either a registered RT or a licensed physician and have a minimum of 10 consecutive years of membership in the AARC. Of greater importance, nominees for FAARC demonstrate superior achievement, not only in patient care and research, but as a volunteer serving the profession. Individuals selected to receive this prestigious award are so noted by having "FAARC" appear after their name following educational degrees and credentials.

Board of Medical Advisors (BOMA)

Because RTs can practice only under medical direction, it is essential that the AARC leadership receive formal input from physicians on all matters and questions pertaining to patient care. The **Board of Medical Advisors (BOMA)** is the group of physicians who provide this valuable input. The BOMA comprises approximately 18 physicians who are appointed by their respective professional medical associations (e.g., American College of Chest Physicians, American Thoracic Society, Society for Critical Care Medicine) to serve this cause voluntarily. The BOMA meets annually, but the chairperson of the BOMA attends all meetings of the AARC Board of Directors. Individual members of the BOMA are assigned by the AARC president to serve as a medical liaison to each of the 10 Specialty Sections of the AARC and to standing committees. Effective medical direction at the hospital level is indispensable for the practice of safe, high-quality respiratory care.

American Respiratory Care Foundation (ARCF)

Established in 1970 by the AARC, the **American Respiratory Care Foundation (ARCF)** is a not-for-profit charitable foundation that helps promote and further the mission of the AARC. Commonly known as the Foundation, the ARCF collects and manages contributions from individuals, corporations, and other foundations to recognize individual achievements of excellence in clinical practice, chronic disease management, public respiratory health, scientific research, and literary excellence. A current focus of the ARCF is to promote the attainment of more advanced training among RTs to advance scientific inquiry in respiratory care. The ARCF also provides research grants to establish the scientific basis of respiratory care further. Finally, the ARCF oversees and distributes numerous scholarships for respiratory therapy students who are student members of the AARC. The ARCF awards and scholarships are presented at the awards ceremony held in conjunction with the annual International Respiratory Congress of the AARC. Respiratory therapy students who are interested in applying for an ARCF scholarship should visit the ARCF Web site (see www.arcfoundation.org) to learn more about this great opportunity.

International Council for Respiratory Care (ICRC)

The **International Council for Respiratory Care (ICRC)** is an AARC-sponsored organization dedicated to the globalization of high-quality respiratory care. As mentioned previously, having formally trained professionals working in a dedicated department to assume full responsibility for providing respiratory care under medical direction was a uniquely North American phenomenon (i.e., the United States and Canada). However, during the 1970s and 1980s, when many foreign physicians came to the United States to study, they became aware of what an RT was and the important role RTs played in hospitals nationwide. When these physicians returned to their native countries, they wished to have their own specialized team able to provide the same level of high-quality respiratory care. However, because the health care delivery system is structured differently in each country, the specially trained teams were most often nurses, physicians, or physical therapists, not RTs.

Formed in 1991, the ICRC (in close collaboration with the International Committee of the AARC) began to offer fellowships to interested foreign clinicians that provide the opportunity to visit the United States for 2 weeks before the annual International Respiratory Congress to observe how respiratory care is practiced in various settings. The idea is to allow these international fellows to observe how the various components of respiratory care are practiced in several cities. The international fellows can then take back to their home countries ideas and practices that can be integrated into their unique health care delivery systems. The program has been so successful that many countries (e.g., Mexico, Costa Rica, Taiwan) are starting to establish respiratory therapy training programs similar to the American model. As of 2014, participants in this program have included 142 international fellows from 54 countries.

National Board for Respiratory Care (NBRC)

The credentialing body for registered RTs began in 1960 as the American Registry of Inhalation Therapists (to test and credential registered therapists), and a certification board was established in 1968 to certify technicians.[1,4] These two groups merged in 1974 as the National Board for Respiratory Therapy, which became the **National Board for Respiratory Care (NBRC)** in 1983.[1,4] Also in 1983, the National Board for Cardiopulmonary Technologists joined the NBRC, and the credentialing examinations for pulmonary function technology were brought in under the respiratory care umbrella.[1,4] Currently, there are two levels of clinical practice credentialing examinations in the United States: the certified respiratory therapist (CRT) and the

registered respiratory therapist (RRT) (see www.NBRC.org). The NBRC also offers several specialty credentialing examinations for RRTs who satisfy additional requirements through experience in a specialized area of practice.

RULE OF THUMB

For requirements for testing, examination schedules, study guides, and requirements for maintaining your CRT or RRT credential, check with the NBRC (see www.NBRC.org).

In 1998, the NBRC renamed the lower level *certified respiratory therapist* (*CRT,* or *entry-level respiratory therapist*); the advanced level remained registered respiratory therapist (RRT, or advanced-level respiratory therapist).[20] The NBRC began offering specialty examinations for pulmonary function technology in 1984 and neonatal/pediatrics in 1991. Because of the proliferation of new technology and innovative medical practice, additional specialty credentialing examinations have been proposed in the areas of adult acute care and polysomnography.

Committee on Accreditation for Respiratory Care (CoARC)

In 1956, the first guidelines for respiratory care educational programs were published, followed by the formation of the Board of Schools to accredit programs in 1963.[1] The Board of Schools was replaced by the Joint Review Committee for Inhalation Therapy Education (JRCITE) in 1970, led by its first chairman, Helmholtz.[1,4] The JRCITE became the Joint Review Committee for Respiratory Therapy Education (JRCRTE) in 1977 and then the **Committee on Accreditation for Respiratory Care (CoARC)** in 1996 (see www.COARC.com).[4] Today, respiratory care educational programs in the United States are accredited by the CoARC in collaboration with the Association of Specialized and Professional Accreditors.[21,22]

RESPIRATORY CARE EDUCATION

The first formal educational course in inhalation therapy was offered in Chicago in 1950.[1] In the 1960s, numerous schools were developed to prepare students to become RTs. Early programs concentrated on teaching students the proper application of oxygen therapy, oxygen delivery systems, humidifiers, and nebulizers and the use of various intermittent positive pressure breathing (IPPB) devices. The advent of sophisticated critical care ventilators, blood gas analyzers, and monitoring devices in the 1960s and 1970s helped propel the RT into the role of cardiopulmonary technology expert.

Respiratory care educational programs in the United States are offered at technical and community colleges, 4-year colleges, and universities. These programs are designed to prepare competent RTs to care for patients. The minimum degree required to become an RT has traditionally been an associate degree.[21] However, many associate degree graduates see great opportunity in pursuing their bachelor's degree and some even higher degrees. There are approximately 300 associate, 50 baccalaureate, and 3 graduate-level degree programs in the United States; 19 programs in Canada; and a handful of respiratory care educational programs in Mexico, South America, Japan, India, Taiwan, and other countries.[23,24]

RULE OF THUMB

Jobs in management, education, research, or advanced clinical practice may require bachelor or graduate level educational preparation.

The AARC completed a Delphi study and held two important Education Consensus Conferences in the early 1990s to assess the status of respiratory care education and recommend future direction for the field.[25-28] The first conference suggested that major trends affecting the field were advances in technology; demographic trends and the aging of the population; a need to provide better assessment, outcome evaluation, problem solving, and analytic skills; use of protocol-based care; and the need to increase the focus on patient education, prevention, and wellness, to include tobacco education and smoking cessation.[27] The conference concluded that the curriculum should encompass a broad scope of clinical practice, a significant arts and science component, emphasis on communication skills, and a minimum of an associate degree to enter practice. The second Educational Consensus Conference, held in the fall of 1993, focused on strategies to implement the recommendations made at the first conference.[28] Both conferences identified the need for more baccalaureate and graduate education in respiratory care. The view that programs should prepare students better in the areas of patient assessment, care plan development, protocols, disease management, pulmonary rehabilitation, research, and geriatrics/gerontology became well accepted.[29,30]

In 1997, Mishoe and MacIntyre[31] described a profession as "a calling or vocation requiring specialized knowledge, methods, and skills as well as preparation, in an institution of higher learning, in the scholarly, scientific, and historical principles underlying such methods and skills." These authors noted that professional roles are different and more complex than technical roles, which are oriented to performing specific tasks as ordered by the physician. Examples of professional roles in respiratory care include patient assessment and care plan development, ventilator management, disease management, pulmonary rehabilitation, and respiratory care consulting services. Technical roles may include basic task performance (e.g., oxygen, aerosol therapy, bronchial hygiene), routine diagnostic testing (e.g., electrocardiography, phlebotomy), and other routine tasks in which little or no assessment is required and decisions are limited to device selection and fine-tuning therapy.[31] In professional practice, the therapist may function as a physician extender who applies protocols or guidelines.[31] Examples include making protocol-based ventilator adjustments, applying assessment-based care plans, and performance of advanced procedures such as arterial line insertion and management,

intubation and extubation of patients, application of ventilator weaning protocols, and application of advanced cardiopulmonary technologies (e.g., extracorporeal membrane oxygenation, nitric oxide therapy, aortic balloon pumps).

According to Mishoe and MacIntyre,[31] economic, educational, and institutional forces may limit respiratory care in certain settings to a task-oriented, technical role. There are many opportunities, however, for the RT to function as a physician extender, in a role similar to that of the **physician assistant**. Working under the supervision of a physician, the physician assistant may perform many medical procedures that might otherwise be performed by a physician. In a similar way, the respiratory physician extender could improve the quality of care while controlling costs and minimizing unnecessary care. Many authorities believe that the critical thinking, assessment, problem-solving, and decision-making skills needed for advanced practice in the twenty-first century require advanced levels of education.[31]

In 1998, Hess[32] observed that a task orientation has coincided with a pattern of overordering and misallocation of respiratory care services. Therapist-driven protocols and the increasing use of the RT as a consultant may allow physicians to order protocols as opposed to specific therapies. The therapist assesses the patient, develops a care plan, implements the plan, and evaluates and modifies care as appropriate.[32] Protocol-based care has been shown to be safe and effective, while reducing misallocation of care and helping to control costs.[33,34] Acceptance by physicians of RTs as consultants depends on the professionalism, education, and skill of the therapists at the bedside.[32]

In 2001, a report of the Conference Proceedings on Evidence-Based Medicine in Respiratory Care was published.[34] Evidence-based practice requires careful examination of the evidence for diagnosis, treatment, prognosis, and, in turn, practice using a formal set of rules.[35] The best evidence is used for clinical decision making, which should lead to optimal respiratory care.[35] Evidence-based practice has been advocated for all respiratory care delivered.

In 2002, the AARC, NBRC, and CoARC published their "Tripartite Statements of Support," which suggested that all RTs seek and obtain the RRT credential.[36] An AARC white paper followed in 2003, which encouraged the continuing development of baccalaureate and graduate education in respiratory care.[37]

FUTURE OF RESPIRATORY CARE

In 2001, David Pierson, MD, a prominent pulmonary physician and one of the many physician supporters of RTs, set out to describe the future of respiratory care.[38] Among other responsibilities, Pierson predicted a much greater use of patient assessment and protocols in chronic disease state management in all clinical settings. He also envisioned a more active role for RTs in palliative and end-of-life care, increasing emphasis on smoking COPD. Pierson also predicted an increase in the use of RTs acting as coordinators and caregivers in home care.

MINI CLINI

Educational Program Advisory Committee

PROBLEM: You are asked to serve on your respiratory care educational program advisory committee. The committee wants to know how respiratory care education has developed and where it should be headed. You are appointed as a member of a subcommittee to research these issues. What should you do?

SOLUTIONS: You may want to read the sections in this chapter that cover the history and development of respiratory care education to get an overview. You may wish to obtain copies of some of the reference materials that are cited. Items that may be helpful are the AARC Delphi Study,[26] reports of the AARC education consensus conferences,[27,28] and articles about the future of respiratory care. [30-33,37-41] You may wish to review the AARC strategic plan (see www.AARC.org) and AARC statements regarding respiratory care education and credentialing.[11,40,41] By reviewing these materials, you should be well-prepared to discuss the future direction of your educational program.

2015 and Beyond

In 2005, recognizing that many national politicians were beginning to call for an overhaul of the U.S. health care delivery system, the AARC Board of Directors began to think strategically, which led to the formation in 2007 of a special task force called "2015 and Beyond." The task force was charged with the envisioning potential new roles and responsibilities of RTs by 2015 and beyond. The leadership of the task force decided to convene three strategic conferences to answer the following five key questions about the profession[39]:

1. How will most patients receive health care services in the future?
2. How will respiratory care services be provided?
3. What new knowledge, skills, and attributes will RTs need to be able to provide care that is safe, efficacious, and cost-effective in 2015?
4. What education and credentialing systems will be needed to ensure RTs acquire the new knowledge, skills, and attributes?
5. How should the profession transition from traditional practice to the newer system without adversely affecting the existing workforce?

The initial 2015 and Beyond conference was held in the spring of 2008, and a consensus was reached that there were likely to be[40]:

- Eleven significant changes in how health care would be delivered (Box 1-2)
- Nine changes likely to occur in the U.S. health care workforce (Box 1-3)
- Five expected changes in how respiratory care services would be provided (Box 1-4)

Box 1-2 2015 and Beyond: *11 Predicted Changes in Health Care*

1. More patients will receive diagnoses of chronic and acute respiratory diseases.
2. Cost increases will continue to grow, creating challenges for all payers of health care services.
3. Personal electronic health records will become more widely used in all health care settings.
4. Health care consumers will pay a greater percentage of costs but will have new options for obtaining care.
5. Retail storefront health care and the Internet will stimulate consumer-driven cost competition.
6. Acute care hospitals will continue to provide episodic, cutting-edge respiratory life support technology; however, subacute and home care providers will continue to play important roles.
7. Subacute and long-term care will increase in volume and complexity.
8. The disconnect between prevention and acute care treatment will lessen but not disappear.
9. All health care delivery will undergo increasing scrutiny for quality that will be linked to reimbursement under a new system called *Pay for Performance.*
10. New models for the delivery of health care will emerge, such as *Accountable Care Organizations* and *Medical Home.*
11. Reimbursement and costs will influence the development and success of these new models.

From Bunch D: 2015 and beyond. AARC Times 33:50, 2009.

Box 1-3 2015 and Beyond: *Nine Likely Changes in the Health Care Workforce*

1. There will be national and regional shortages of certain providers in all sectors of health care.
2. There will be long-term competition for all health care professionals.
3. The clinical demand will increase at a faster pace than the workforce will be able to expand.
4. The imbalance in jobs and available workforce will be aggravated by the retirement of current providers.
5. Brutal work hours requiring 24/7 staffing will dissuade many individuals from pursuing health care careers.
6. Shortages of teaching faculty and a limited number of training programs will limit the number of entrants into allied health professional schools.
7. Traditional clinical sites will be limited in number and variety and will need to be expanded to alternative sites, such as physicians' offices and patients' homes.
8. Newer educational technologic resources will challenge traditional education.
9. Health care delivery organizations will find reinvestment in education an attractive way to secure competent and loyal workers.

From Bunch D: 2015 and beyond. AARC Times 33:50, 2009.

Box 1-4 2015 and Beyond: *Five Changes Expected in Respiratory Care*

1. The science of respiratory care will continue to evolve and increase in complexity, and clinical decisions will increasingly be data-driven.
2. Patient care teams will become the standard throughout health care.
3. New respiratory life-support technologies will be developed and deployed.
4. Reimbursement changes will be the most important impetus for more recognition of the importance of health promotion and disease state management.
5. Concerns over public health issues and military and disaster response will continue and require new skill sets for all respiratory care providers.

From Bunch D: 2015 and beyond. AARC Times 33:50, 2009.

Box 1-5 Seven Major Competencies Required by Respiratory Therapists by 2015

1. Diagnostics
2. Chronic disease state management
3. Evidence-based medicine and respiratory care protocols
4. Patient assessment
5. Leadership
6. Emergency and critical care
7. Therapeutics

From Barnes TA, Gale DD, Kacmarek RM, et al: Competencies needed by graduate respiratory therapists in 2015 and beyond. Respir Care 55:601, 2010.

In the words of one conference organizer, "the take home message was that indeed the scope and depth of respiratory care practice will increase by 2015."[39] The second conference was held in the spring of 2009 and built on the findings of the 2008 conference by identifying the competencies needed by graduate RTs and the educational content and curriculum that would be needed to practice in 2015 and beyond. Conference participants agreed that there would be seven major competencies (Box 1-5) that future RTs would need to practice effectively by 2015.[40,41] The third conference was held in the summer of 2010 to determine how the educational programs for entry-level RTs would have to be structured to accomplish the seven major competencies identified during the 2009 conference. The recommendations of the third conference were published in 2011.[42]

Although the respiratory care profession is undergoing substantial change, there will be a continuing demand for respiratory care services well into the future because of advances in treatment and technology, increases in the general population, and increases in the elderly population (the baby boomers). A growing population will result in increases in asthma, COPD, and other chronic respiratory diseases. There will also be a continuing demand for controlling costs and ensuring that care

provided is evidence-based, safe, and effective. Respiratory care will need to be provided using carefully designed protocols to ensure that patients get the appropriate care at the right time and that unnecessary care is reduced or eliminated. Aggressive steps to prevent disease and control the cost of chronic respiratory disease will be essential. Effective smoking cessation and tobacco education programs and aggressive disease management and pulmonary rehabilitation for patients with moderate to severe asthma, COPD, and other chronic respiratory disease will continue to be needed.

As exemplified by the 2015 and Beyond project, the knowledge, skills, and attributes needed by RTs will continue to expand, and it will become increasingly difficult to prepare RTs for expanded practice within the credit hour limitations of many existing programs. To alleviate this situation, associate degree programs may develop articulation agreements with 4-year colleges and universities to allow their graduates to complete the bachelor degree in respiratory care without leaving their home campus; distance education technology will play an important role and allow this to occur at minimal cost.

Bachelor degree programs often seek to provide students with a foundation for leadership in the profession in the areas of management, supervision, research, education, or clinical specialty areas. To meet the leadership needs of the profession, some baccalaureate programs have already implemented post-baccalaureate certificates or master degree programs. Clinical areas in which more graduate education programs could be beneficial include critical care, cardiopulmonary diagnostics, clinical research, sleep medicine, rehabilitation, and preparation as a pulmonary physician assistant. There also will be an increasing demand for RTs with master and doctoral degrees to serve as university faculty, educators, and researchers.

SUMMARY CHECKLIST

- RTs apply scientific principles to prevent, identify, and treat acute or chronic dysfunction of the cardiopulmonary system.
- Respiratory care includes the assessment, treatment, management, control, diagnostic evaluation, education, and care of patients with deficiencies and abnormalities of the cardiopulmonary system.
- The AARC is the professional association for the profession.
- RTs work under the direction of a physician who is specially trained in pulmonary medicine, anesthesiology, and critical care medicine.
- The NBRC, the credentialing board for RTs, was founded in 1974. The American Registry of Inhalation Therapists was founded in 1960.
- The CoARC accredits respiratory care educational programs. The first Board of Schools was established in 1963.
- As the physiologic basis for oxygen therapy became understood, use of oxygen to treat respiratory disease became established by the 1920s, and oxygen was used routinely in hospitals by the 1940s.
- Use of aerosolized medications for the treatment of asthma began in 1910, with numerous new drugs being developed in the twentieth century and continuing up to the present.
- Mechanical ventilation was explored in the 1800s. In 1928, Drinker developed his iron lung; this was followed by the Emerson iron lung in the 1930s, which was used extensively during the polio epidemics of the 1940s and 1950s, and the modern critical care ventilator, which became available in the 1960s.
- The ITA was founded in 1947, becoming the AAIT in 1954, the AART in 1973, and the AARC in 1982.
- The AARC now has 10 Specialty Sections to provide resources to members based on where they are employed and practice.
- The ARCF offers many scholarships and grants to respiratory therapy students and is promoting advanced training for RTs.
- Although originally found only in the United States and Canada, the practice of respiratory therapy is quickly expanding around the world.
- Respiratory Care Week is a yearly event to promote the profession and raise awareness of the importance of good lung health.
- In the future, there will be an increase in demand for respiratory care because of advances in treatment and technology; increases in and aging of the population; and increases in the number of patients with asthma, COPD, and other cardiopulmonary diseases.

The RT of the future will be focused on patient assessment, care plan development, protocol administration, disease management and rehabilitation, and patient and family education, to include tobacco education and smoking cessation.

CHAPTER 2

Delivering Evidence-Based Respiratory Care

JAMES K. STOLLER AND ARIEL M. MODRYKAMIEN

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Understand the elements for delivering high-quality respiratory care.
- Explain how respiratory care protocols improve the quality of respiratory care services.
- Understand evidence-based medicine.

CHAPTER OUTLINE

KEY TERMS

algorithms
Committee on Accreditation for Respiratory Care (CoARC)
evidence-based medicine
The Joint Commission (TJC)
misallocation
National Board for Respiratory Care (NBRC)
performance improvement
quality
respiratory care protocols
respiratory therapy consult service
therapist-driven protocols

Quality is defined as a characteristic reflecting a high degree of excellence, fineness, or grade. Ruskin, a nineteenth-century British author, stated, "Quality is never an accident. It is always the result of intelligent effort." Conclusions drawn from the assessment of quality are only temporary because the components of quality are constantly changing. Specifically, quality, as applied to the practice of respiratory care, has many dimensions. It encompasses the people who administer the respiratory care, the equipment used, and the manner in which the care is provided. Determining the quality of services provided by a respiratory care department requires intelligent efforts to establish guidelines for delivering high-quality care and a method for monitoring the care. The conclusions about how respiratory care has been delivered change as clinical practice and expectations change. In the current cost-attentive era of health care, quality can be challenged by pressures to minimize cost, making the measurement and monitoring of quality even more important. There is a new emphasis on the value of the care that is provided, where value is defined as quality/cost. The higher the quality and the lower the cost, the higher the value will be of the care delivered.

This chapter reviews systems for delivering respiratory care and the evidence that supports providing high-quality respiratory care. In particular, we review the elements of a hospital-based respiratory care program, focusing on medical direction, practitioners, and technical direction. With the goal of high quality being the competent delivery of care that is appropriate, we then discuss respiratory care protocols as an important way

to deliver high-quality respiratory care. Finally, we review the concept of evidence-based medicine as it applies to the practice of respiratory care. Other aspects of measuring and monitoring quality and patient safety are discussed in Chapter 3.

ELEMENTS OF A HOSPITAL-BASED RESPIRATORY CARE PROGRAM: ROLES SUPPORTING QUALITY CARE

Medical Direction

The medical director of respiratory care is professionally responsible for the clinical function of the department and provides oversight of the clinical care that is delivered (Box 2-1). Medical direction for respiratory care is usually provided by a pulmonary/critical care physician or an anesthesiologist. Whether the role of a respiratory care service medical director is designated as a full-time or part-time position, it is a full-time responsibility; the medical director must be available on a 24-hour basis for consultation with and to give advice to other physicians and the respiratory care staff. The current philosophy of cost containment and cost-effectiveness, dictated by medical care market forces, poses a challenge to the medical and technical leadership of respiratory care services to provide increasingly high-quality patient care at low cost. A medical director must possess administrative, leadership, and medical skills.[1]

Perhaps the most essential aspect of providing high-quality respiratory care is to ensure that the care being provided is appropriate (i.e., is clinically indicated) and that it is delivered competently. Traditionally, the physician has evaluated patients for respiratory care and has written the specific respiratory therapy orders for the respiratory therapist (RT) to follow. However, such traditional practices often have been associated with what has been called "misallocation of respiratory care."[2-4] Such **misallocation** may consist of ordering therapy that is not indicated, ordering therapy to be delivered by an inappropriate method, or failing to provide therapy that is clinically indicated.[5] Table 2-1 reviews studies evaluating the allocation of respiratory care services and the frequency of misallocated care.[3,6-12] These studies provide much evidence that misallocation of respiratory care occurs frequently. Such misallocation has led to the use of respiratory care protocols that are implemented by RTs (as described in the section on Methods for Enhancing the Quality of Respiratory Care).

Box 2-1 Responsibilities of a Medical Director of Respiratory Care

- Medical supervision of respiratory therapist in the following areas:
  - General medical, surgical, and respiratory nursing wards
  - Intensive care units
  - Ambulatory care (including rehabilitation)
  - Pulmonary function laboratory
- Development and approval of department clinical policies and procedures
- Supervision of ongoing quality assurance activities
- Medical direction for respiratory care in-service and training programs
- Education of medical and nursing staffs regarding respiratory therapy
- Participation in the selection and promotion of technical staff
- Participation in preparing the department budget

Respiratory Therapists

In addition to competent medical direction and using well-constructed respiratory care protocols (see Fig. 2-1), capable RTs are an indispensable element in delivering high-quality respiratory care. The quality of RTs depends primarily on their training, education, experience, and professionalism. Training teaches students to perform tasks at a competent level, whereas clinical education provides students with the knowledge they can use in evaluating a situation for making appropriate decisions.[13] Both adequate training and clinical education are required to produce qualified RTs for assessing patients and implementing respiratory care protocols.[14]

Designations and Credentials of Respiratory Therapists

The two levels of general practice credentialing in respiratory care are (1) certified respiratory therapists (CRTs) and (2) registered respiratory therapists (RRTs). Students eligible to become CRTs and RRTs are trained and educated in colleges and universities. After completion of an approved respiratory care educational program, a graduate may become credentialed by taking the entry-level examination to become a CRT. A CRT may be eligible to sit for the registry examinations to become a credentialed RRT. Students who complete a 2-year program graduate with an associate degree, and students who complete a 4-year program receive a baccalaureate degree. Some RTs go on to complete a graduate degree (e.g., master or doctorate) with additional study in the areas of respiratory care, education, management, or health sciences. The further development of graduate education in respiratory care has been encouraged by the American Association for Respiratory Care (AARC), and several masters-level RT programs are currently available.[15]

Respiratory care education programs are reviewed by the **Committee on Accreditation for Respiratory Care (CoARC).** This committee is sponsored by four organizations: the AARC, the American College of Chest Physicians (ACCP), the American Society of Anesthesiologists (ASA), and the American Thoracic Society (ATS). The CoARC is responsible for ensuring that respiratory therapy educational programs follow accrediting standards or essentials as endorsed by the American Medical Association (AMA). Members of the CoARC visit respiratory therapy educational programs to judge applications for accreditation and make periodic reviews. The mission of the CoARC, in collaboration with the Association of Specialized and Professional Accreditors, is to promote high-quality respiratory therapy education through accreditation services. An annual listing of accredited respiratory therapy programs is published.

TABLE 2-1

Frequency of Misallocation of Respiratory Care Services in Selected Series

Type of Service	Author	Date	Patient Type	No. Patients	Frequency of Overordering	Frequency of Underordering
Supplemental oxygen	Zibrak et al[6]	1986	Adults	NS	55% reduction in incentive spirometry after therapist supervision began	NA
	Brougher et al[7]	1986	Adult, non-ICU inpatients	77	38% ordered to receive O_2 despite adequate oxygenation	NA
	Small et al[8]	1992	Adult, non-ICU inpatients	47	72% of patients checked had PaO_2 > 60 mm Hg or SaO_2 > 90% but were prescribed O_2	NA
	Kester and Stoller[3]	1992	Adult, non-ICU inpatients	230	28% for supplemental O_2	8% for supplemental O_2
	Albin et al[9]	1992	Adult, non-ICU inpatients	274	61% ordered to receive supplemental O_2 despite $SaO_2 \geq 92\%$	21% underordered, including 19% prescribed to receive inadequate O_2 flow rates
	Shelledy et al[12]	2004	Adults	75	0	5.3% indicated but not ordered
Bronchial hygiene techniques	Zibrak et al[6]	1986	Adults	NS	55% reduction in incentive spirometry after therapist supervision began	NA
	Shapiro et al[10]	1988	Adult, non-ICU inpatients	3400 evaluations	61% reduction of bronchial hygiene after system implemented	NA
	Kester and Stoller[3]	1992	Adult, non-ICU inpatients	230	32%	8%
	Shelledy et al[12]	2004	Adults	75	37.5%	8%
Bronchodilator therapy	Zibrak et al[6]	1986	Adults	NS	50% reduction in incentive aerosolized medication after therapist supervision began	NA
	Kester and Stoller[3]	1992	Adult, non-ICU inpatients	230	12%	12%
	Shelledy et al[12]	2004	Adults	75	34.4%	5.3%
	Kester and Stoller[3]	1992	Adult, non-ICU inpatient	230	40%	6.7%
ABGs	Browning et al[11]	1989	Surgical ICU inpatients	724 ABGs	42.7% inappropriately ordered before guidelines implemented	NA

Modified from Stoller JK: The rationale for therapist-driven protocols. Respir Care Clin N Am 2:1, 1996.
ABGs, Arterial blood gases; *ICU,* intensive care unit; *NS,* Not stated; *NA,* not assessed.

As of May 2014, there were approximately 453 CoARC-approved respiratory care programs.

Credentialing is a general term that refers to recognizing individuals in particular occupations or professions. Generally, the two major forms of credentialing in the health fields are state licensure and voluntary certification. Licensure is the process in which a government agency gives an individual permission to practice an occupation. Typically, a license is granted only after verifying that the applicant has demonstrated the minimum competency necessary to protect the public health, safety, or welfare. Licensure laws are normally made by state legislatures and enforced by specific state agencies, such as medical, nursing, and respiratory care boards. In states where licensure laws govern an occupation, practicing in the field without a license is considered a crime punishable by fines or imprisonment or both. Licensure regulations are based on a practice act that defines (and limits) what activities the professional can perform. Two other forms of state credentialing are less restrictive. States that use title protection simply safeguard the use of a particular occupational or professional title. Alternatively, states may request or require practitioners to register with a government agency (registration). Neither title protection nor state registration constitutes a true practice act, and because both title protection and registration are voluntary, neither provides strong protection against unqualified or incompetent practice.

Certification is a voluntary, nongovernment process whereby a private agency grants recognition to an individual who has met certain qualifications. Examples of qualifications are graduating from an approved educational program, completing a specific amount of work experience, and performing acceptably on a qualifying examination. The term *registration* is often used interchangeably with the term *certification,* but it also may refer to a type of government credentialing. As a voluntary process, certification involves standards that are often higher than the minimum standards specified for entry-level competency. A major difference between certification and licensure is that certification generally does not prevent others from working

in that occupation, as do most forms of licensure. Both types of credentialing apply in respiratory care.

The primary method of ensuring quality in respiratory care is voluntary certification or registration conducted by the **National Board for Respiratory Care (NBRC).** The NBRC is an independent national credentialing agency for individuals who work in respiratory care and related services. The NBRC is cooperatively sponsored by the AARC, ACCP, ASA, ATS, and National Society for Pulmonary Technology. Representatives of these organizations make up the governing board of the NBRC, which assumes the responsibility for all examination standards and policies through a standing committee. The NBRC provides the credentialing process for both the entry-level CRT and the advanced-practitioner RRT. As established in January 2006, to be eligible for either the CRT or the RRT examination, all candidates must have an associate degree or higher. An additional advanced-practitioner credential, the neonatal/pediatric specialist (NPS), has been established for the field of pediatrics. The NBRC also encourages professionals in the field to maintain and upgrade their skills through voluntary recredentialing. Both CRTs and RRTs may demonstrate ongoing professional competence by retaking examinations. Individuals who pass these examinations are issued a certificate recognizing them as "recredentialed" practitioners. In addition to the certification and registration of RTs, the NBRC provides credentialing in the area of pulmonary function testing for certified pulmonary function technologists (CPFTs) and registered pulmonary function technologists (RPFTs). Since its inception, the NBRC has issued more than 350,000 professional credentials to more than 209,000 individuals. According to United States Bureau of Labor Statistics data from 2012, there were approximately 119,300 active RTs, many of whom hold more than one credential. Table 2-2 shows the distribution of these credentialed individuals.

At the time of publication, 48 states, the District of Columbia, and Puerto Rico have some form of state licensure. Many states use the NBRC entry-level respiratory care examination for state licensing, whereas others simply verify NBRC credentials. Most licensure acts require the RT to attain a specified number of continuing education credits to maintain his or her license. Continuing education helps practitioners keep up to date and aware of the changes and advances that occur in their health care field.

TABLE 2-2

Distribution of Credentialed Practitioners

Credential Type	No. Credentialed Practitioners
CRT	219,830
RRT	130,375
CPFT	12,711
RPFT	4279
NPS	11,491

NOTE: As of February 2013. Practitioners may hold more than one credential (i.e., RRTs are also CRTs and NPS are also CRTs or RRTs).

Licensure and certification help ensure that only qualified RTs participate in the practice of respiratory care. Many institutions conduct annual skills checks or competency evaluations in compliance with The Joint Commission (TJC, formerly the Joint Commission on Accreditation of Healthcare Organizations [JCAHO]) requirements. Beyond TJC-required skills checks, experience with respiratory care protocols suggests the need to develop and monitor additional skills among RTs (Box 2-2). Ensuring and maintaining these skills require ongoing training and quality review programs, which are discussed in Chapter 3 (see section on Monitoring Quality in Respiratory Care).

Professionalism

By definition, professionalism is a key attribute to which all RTs should aspire and that must guide respiratory care practice. *Webster's New Collegiate Dictionary* defines a *profession* as "a calling that requires specialized knowledge and often long and intensive academic preparation." A professional is characterized as an individual conforming to the technical and ethical standards of a profession. RTs demonstrate their professionalism by maintaining the highest practice standards, engaging in ongoing learning, conducting research to advance the quality of respiratory care, and participating in organized activities through professional societies such as the AARC and associated state societies. Box 2-3 lists the professional attributes of the RT. We emphasize the importance of these attributes because the continued value and progress of the field depend critically on the professionalism of each practitioner.[16]

Box 2-2 Additional Respiratory Therapist Skills Required for Implementing Protocols

- Assess and evaluate patients regarding indications for therapy and for the most appropriate delivery method
- Be cognizant of age-related issues and how they affect the patient's ability to understand and use various treatments
- Adapt hospital policies and procedures to alternative care sites
- Conduct and participate in research activities to ensure a scientific basis for advances in respiratory care technology
- Communicate effectively with all members of the health care team, and advance knowledge in the field of respiratory care

Box 2-3 Professional Characteristics of a Respiratory Therapist

- Completes an accredited respiratory therapy program
- Obtains professional credentials
- Participates in continuing education activities
- Adheres to the code of ethics put forth by the institution or state licensing board or both
- Joins professional organizations

Box 2-4 *Health Insurance Portability and Accountability Act* of 1996

The use and disclosure of protected health information (PHI) by a covered entity are prohibited by the *Health Insurance Portability and Accountability Act* unless it is a permitted use or disclosure for purposes of treatment, payment, or health care operations or is authorized by the patient. When disclosure or use of PHI is permitted, ensure that only the minimum necessary information is disclosed.

DEFINITION OF TERMS

Use: Release of PHI within the institution
Disclosure: Release of PHI outside the institution
PHI: Individually identifiable health information
Covered entity: Health care provider, health plan, health care clearinghouse
Permitted: As long as there are reasonable safeguards in place regarding the Privacy Rule and the information given is the "minimum necessary"
Treatment: Necessary information can be disclosed to all involved in treatment (physicians, nurses, allied health personnel)
Payment: To allow for billing, for insurance purposes and third-party payers
Authorized: Patient's written agreement for permitted use
Minimum necessary: Reasonably necessary to accomplish intended purpose

In the highly regulated careers of health care, professionalism also requires compliance with external standards, such as the standards set by TJC and the government. One such standard is defined by the *Health Insurance Portability and Accountability Act* (HIPAA) of 1996. HIPAA sets standards regarding the way personal health information is communicated and revealed in the transmission of medical records and in the written and verbal communication in the hospital. Some specific provisions of HIPAA are presented in Box 2-4. As with all hospital and health care personnel, standards of respiratory therapy professionalism require knowledge of HIPAA and compliance with its terms.

Technical Direction

Another important element for delivering quality respiratory care is technical direction. Technical direction is often the responsibility of the manager of a respiratory care department, who must ensure the equipment and the associated protocols and procedures have sufficient quality to ensure the safety, health, and welfare of the patient using the equipment. Medical devices are regulated under the *Medical Device Amendment Act* of 1976, which comes under the authority of the U.S. Food and Drug Administration (FDA). The FDA also regulates the drugs that are delivered by RTs. The purpose of the FDA is to establish safety and effectiveness standards and to ensure that these standards are met by equipment and pharmaceutical manufacturers.

Procedures and protocols related to the use of equipment and medications must be written to provide a guide for the respiratory care staff. In addition, equipment must be safety checked and specific maintenance procedures must be performed on a regular basis. Because of rapidly changing respiratory care technology, the job of the technical director poses significant challenges. Circuit boards and computers have replaced simpler mechanical devices. New medications and delivery devices for the treatment of asthma and newer strategies for treating other respiratory diseases (e.g., low-stretch ventilatory approaches for acute respiratory distress syndrome [ARDS]) continue to evolve. Individuals responsible for technical direction must ensure that these new devices, methods, and strategies not only are effective but also have value.

Respiratory Care Protocols

In an effort to improve the delivery and allocation of respiratory care services, **respiratory care protocols** (also known as **therapist-driven protocols**) have been developed and are in use in many hospitals in the United States, Canada, and other countries. Respiratory care protocols are guidelines for delivering appropriate respiratory care treatments and services (i.e., treatments and services that are clinically indicated, delivered by the correct method, and discontinued when no longer needed). Protocols may be written in outline form or may use **algorithms** (an example of which is a branching logic flow diagram [Figures 2-1 and 2-2]).

Gaylin and colleagues[17] conducted a telephone survey in 1999 of 371 RT members of the AARC, of whom 51% were practitioners, 26% were clinical supervisors, and 23% were administrators. When asked if their organizations used guidelines or protocols, 98% of the respondents indicated that they did. Of the 2% who did not, 53% were planning their use. A survey conducted by the AARC in 2005 indicated that of 681 responding hospitals, 73% were providing care by means of at least one protocol.[18] More recently, the 2009 AARC Human Resources Survey showed that of 2764 responders, approximately two-thirds (65.7%) indicated that they have delivered respiratory care by protocol.[19] Finally, in a survey of 348 RT program directors, more than 95% reported teaching RT students how to treat using RT protocols.[20] The use of respiratory care protocols by qualified RTs is a logical practice because well-trained RTs possess extensive knowledge of respiratory care modalities and have the assessment and communication skills required to implement the protocols effectively.[21]

The success of a respiratory care protocol program requires several key elements, including active and committed medical direction, capable RTs, collaboration with physicians and nurses, careful monitoring, and a responsive hospital environment (Box 2-5). As further evidence that RT protocols have been widely adopted, the ACCP has identified the elements of an acceptable respiratory care protocol (Box 2-6). This document may serve as a guide for developing protocols. Protocols may be constructed for individual therapies, such as aerosol therapy, bronchopulmonary hygiene, bronchodilators, O_2 therapy, hyperinflation techniques, suctioning, and pulse oximetry. Protocols also can be written for a specific purpose, such as arterial blood gas (ABG) sampling, weaning from mechanical ventilation, decannulating a tracheostomy, and titrating O_2 therapy.

MINI CLINI

A Specific Treatment Protocol: Aerosolized Bronchodilator Therapy

PROBLEM: A 54-year-old woman is admitted to the hospital with an exacerbation of chronic obstructive pulmonary disease (COPD). She has a history of smoking one and one-half pack of cigarettes per day for 32 years. She is alert and oriented, and her respiratory rate is 32 breaths/min. On auscultation, she has bilateral wheezes on inspiration and exhalation. Her vital capacity (1.3 L) is greater than the predicted minimal volume for effective incentive spirometry, but she is unable to take in a slow, deep breath and hold it for longer than 5 seconds, which is the criterion sometimes used for appropriate metered dose inhaler (MDI) use. What should the RT do now?

SOLUTION: Following the aerosol therapy protocol algorithm, this patient would receive an aerosolized bronchodilator treatment from a small-volume nebulizer with a mouthpiece. An algorithm for aerosolized bronchodilator therapy is shown in Figure 2-1.

MINI CLINI

A Specific Treatment Protocol: Aerosolized Bronchodilator Therapy

PROBLEM: A 70-year-old woman is admitted from the emergency department with an asthma exacerbation. She is a nonsmoker and has advanced dementia. She is alert and calm, and her respiratory rate is 24 breaths/min. She has bilateral wheezes on exhalation. The patient is able to take deep breaths, but she cannot follow simple directions. What would be the bronchodilator device of choice for this patient?

SOLUTION: This patient should receive a small-volume nebulizer, because she does not fulfill MDI criteria (because of her advanced dementia). The aerosolized bronchodilator therapy algorithm that guides this decision is shown in Figure 2-1.

MINI CLINI

A Specific Purpose Protocol: Oxygen Therapy Titration

PROBLEM: A 42-year-old man has returned to a medical-surgical nursing unit from the recovery room after a cholecystectomy. He has no history of lung disease and is wearing a nasal cannula at 2 L/min. He is alert and oriented; his respiratory rate is 18 breaths/min and heart rate is 82 beats/min. When the RT arrives to check his oxygen setup and pulse oximeter reading, his SpO_2 (pulse oximeter reading) is 97% on the 2 L/min nasal cannula. What should the RT do next?

SOLUTION: Following the O_2 therapy titration protocol algorithm, the RT removes the nasal cannula and returns in 15 minutes to recheck the patient's SpO_2 reading, which is now 93% on room air. The RT discontinues the O_2 therapy. An O_2 therapy titration algorithm is shown in Figure 2-2.

Box 2-5 Key Elements of a Respiratory Care Protocol Program

- Strong and committed medical direction
- Capable respiratory therapists (RTs)
- Active quality monitoring
- Collaborative environment among RTs, physicians, and nurses
- Responsiveness of all participants to address and correct problems

Box 2-6 Elements of an Acceptable Respiratory Care Protocol as Described by the American College of Chest Physicians

- Clearly stated objectives
- Outline that includes an algorithm
- Description of alternative choices at decision and action points
- Description of potential complications and corrections
- Description of end points and decision points at which the physician must be contacted
- Protocol program

Successful implementation of protocols requires acceptance by various stakeholders in the hospital, including the hospital administrators, physicians, nurses, and RTs. Hospital administrators are likely to accept RT protocols if they are convinced that protocols enhance patient care, improve allocation of respiratory care services, and reduce costs. Physicians are likely to accept RT protocols if they are convinced that protocols will enhance their patients' care, preserve the physician's ability to specify orders if desired, and maintain the physician's awareness of changes in a patient's condition and changes in the respiratory care plan. Physicians' acceptance also requires their having trust in the quality, professionalism, and competence of the respiratory therapy staff. Nurses are likely to accept protocols if they are persuaded that protocols will enhance the efficiency of care, help relieve sometimes excessive nursing workloads, and preserve communication with the bedside nurse regarding the patient's plan of treatment. Finally, successful implementation and acceptance of protocols by RTs requires a desire to be progressive, confidence in their own assessment and communication skills, "ownership" of the protocol process (e.g., by participating in drafting the protocol policies and strategies by which protocols are put in place), and willingness to change and to abandon outdated task-driven practices in respiratory care.

Features of RT departments that are ready for and embrace change have been studied[22] and are presented in Box 2-7. Steps and tactics to ensure successful implementation of respiratory care protocols are described in Box 2-8. Selecting a planning team with broad membership that includes physicians, nurses, and administrators is a key element in developing a protocol implementation process that avoids potential barriers and satisfies the institution's specific and unique requirements. Once

Box 2-7 "Highly Desired" Features of a Change-Avid Respiratory Therapy Department

1. Having a close and collegial working relationship between the medical director and the respiratory therapists (RTs)
2. Having a strong and supportive champion for change in the hospital administrative structure (e.g., hospital leaders, medical director)
3. Using data and other evidence to define problems and measure the effectiveness of proposed solutions
4. Using multiple and redundant types of communication to cascade information throughout the respiratory therapy department
5. Being attentive to the forces of resistance and obstacles to change and being able to navigate within institutional systems and people to achieve change
6. Being willing to confront, engage, and gain closure on tough issues
7. Having and maintaining a culture of internal, self-imposed, systematic, ongoing education and knowledge acquisition
8. Consistently rewarding and recognizing change-avid behavior among respiratory therapy department members
9. Fostering ownership for change rather than just complying with external policies and demands and, as part of this ownership, taking the time to identify and involve stakeholders (e.g., physicians, nurses, hospital thought leaders and decision makers) in change
10. Paying attention to leadership development and succession planning in the RTs
11. Having and communicating a vision in the department

From Stoller JK, Kester L, Roberts VT, et al: An analysis of features of respiratory therapy departments that are avid for change. Respir Care 53:871, 2008.

protocols have been designed, it is often advisable to do pilot studies, either of each protocol individually or of a group of protocols on a single hospital floor or unit. By using this staged rollout with an initial pilot trial, unexpected problems can be worked out and helpful feedback can be gathered from protocol users before the protocols are implemented on a hospital-wide basis.

A comprehensive approach for using protocols is to combine specific protocols to form a **respiratory therapy consult service** or an evaluate-and-treat program, which is used in institutions such as the Cleveland Clinic and the University of California at San Diego. With the use of a respiratory therapy consult service, the sequence of events for a respiratory therapy consult may occur as shown in Box 2-9.

A carefully structured assessment tool and care plan form (Figures 2-3 and 2-4) are essential elements for a comprehensive protocol program. These tools help ensure consistency among therapist evaluators. The following Mini Clini on Writing a

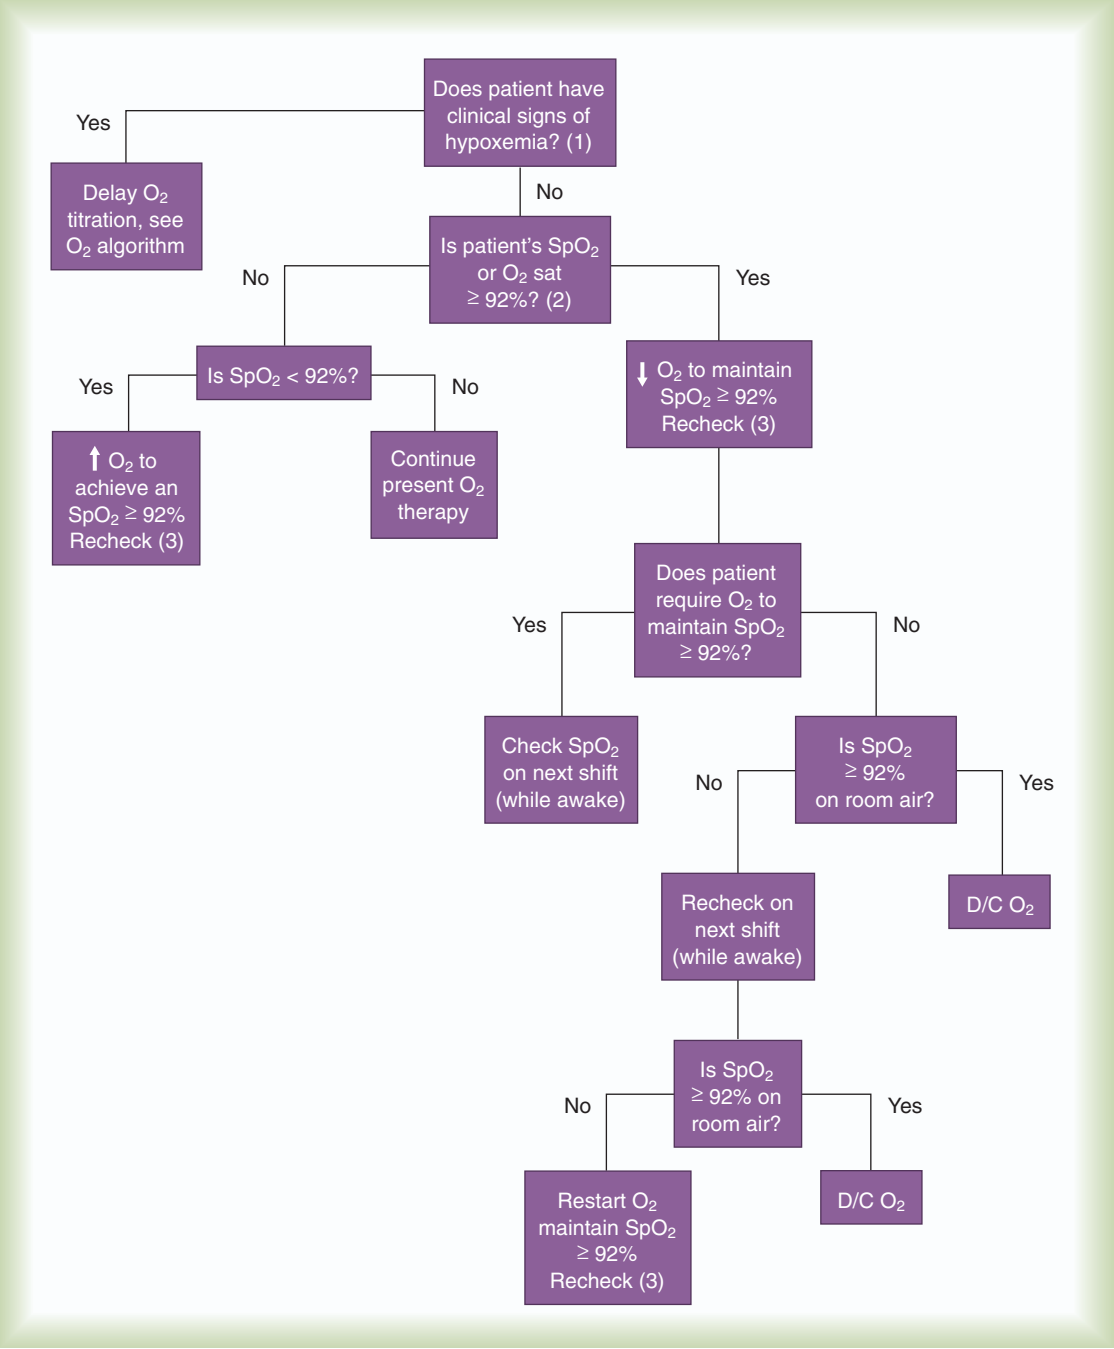

FIGURE 2-2 Respiratory care protocol to determine when oxygen concentration should be increased or decreased or when the therapy should be discontinued. *(1)* Shortness of breath, tachycardia, diaphoresis, confusion. *(2)* O_2 saturation measured by pulse oximeter (SpO_2) criteria may be modified with documented evidence of preexisting chronic hypoxemia. *(3)* Appropriate time lapse for recheck: 10 minutes for patients without pulmonary history; 20 minutes for patients with pulmonary history. *NOTE:* O_2 concentration should not be decreased more than once per shift. *D/C,* Discontinue.

Box 2-8 Tactics for Implementing Respiratory Care Protocols

1. Select a planning team with diverse membership.
2. Conduct an audit to assess the occurrence of misallocation of therapy to justify departure from usual care.
3. Identify sources of resistance (e.g., physicians, nurses, administrators, respiratory therapists [RTs]).
4. Design a protocol program that fits the individual hospital.
5. Develop a training program for RTs.
6. Develop an evaluation and quality monitoring system.

Box 2-9 Sequence of Events for a Respiratory Care Consult

1. A physician writes an order for a respiratory care protocol or consult.
2. A physician order entry system or the nursing unit secretary notifies a respiratory therapist (RT) evaluator.
3. The evaluator assesses the patient using specific guidelines.
4. The evaluator writes a care plan using designated indications and algorithms and documents the care plan in the patient's chart for review by the physician.
5. The RT covering the nursing unit delivers the care.
6. The patient is assessed on a shift-by-shift basis for changes in status and indicated modifications for the care plan, which are also documented.
7. The physician is notified of any deterioration in the patient's status.
8. When indications for respiratory care no longer exist, respiratory care treatment is discontinued, and notification is placed in the patient's chart.

Respiratory Care Plan shows how an assessment tool and care plan document, used along with corresponding algorithms, can guide therapists in developing an appropriate respiratory care plan. Other essential elements of a respiratory care protocol service include ensuring the respiratory therapist's competence to deliver the care as part of a quality control program (see Figure 2-5) and assessing the accuracy of audits (see Figure 2-6).

Demonstrated advantages of respiratory care protocols include better allocation of respiratory care services without an increased frequency of respiratory care treatments and cost savings (Tables 2-3 and 2-4). Other advantages include more responsive respiratory care with more adjustment of respiratory care services to keep pace with patients' changing clinical status and more versatile use of respiratory care services (Table 2-5).[12,23-26]

RULE OF THUMB

Respiratory care protocols have been shown to help ensure that the correct respiratory care treatments are delivered to the patients who are likely to benefit from the therapy (i.e., improved allocation of respiratory care).

MINI CLINI

Writing a Respiratory Care Plan

PROBLEM: A 40-year-old woman with a history of asthma was admitted to the hospital for gastrointestinal dysmotility with abdominal distention. Her chest radiograph showed an elevated diaphragm with accompanying atelectasis in the bases of the lung fields. Her laboratory test results were as follows: white blood cell count 10,200 cells/mcl, hemoglobin 11.6 g/dl, and platelet count 260,000/mm^3. Her pulse oximetry reading was 96% on room air; no ABGs were drawn. Her heart rate was 84 beats/min, blood pressure was 110/78 mm Hg, respiratory rate was 20 breaths/min, and temperature was 36.8° C. She was alert and oriented, and her vital capacity was 1.35 L. She is 5 feet 7 inches tall and has a predicted minimal vital capacity of 0.927 L (15 ml/kg of ideal body weight). On auscultation, her breath sounds were decreased bilaterally and she had slight inspiratory wheezes in the apices of her lung fields. She had a weak, nonproductive cough and was able to ambulate on her own. A respiratory care evaluation should be performed for this patient.

SOLUTIONS: The patient's assessment score sheet and her respiratory therapy care plan, using the respiratory therapy consult protocol and treatment algorithms currently in use at the Cleveland Clinic, are shown (see Figures 2-3 and 2-4).

TABLE 2-3

Cost Savings Associated With Respiratory Care Protocols

Author	Date	Duration of Study	Cost Savings
Hart et al[36]	1989	3 mo	$4316 (decrease in actual costs)
Walton et al[37]	1990	6 yr	9.7% (decrease in charges)
Orens[38]	1993	1 yr	$81,826 (decrease in costs for one nursing unit)
Ford[39]	1994	1 yr	$150,000 (decrease in costs)
Komara and Stoller[40]	1995	40 postsurgical patients; oxygen use up to 6 days	53.3% (decrease in costs)
Shrake et al[41]	1996	2 years, 4420 patients; cost comparisons: 3 months after protocol	$15,337 for 3 study months, annualized to $61,348/year
Stoller et al[25]	1998	1 year, 145 patients	$20 (decrease in true costs/patient)
Kollef et al[26]	2000	9 months, 694 patients	$186 (decrease in charges/patient)
Shelledy et al[12]	2004	3 months, 75 patients	$75,395 (estimated annual decrease)

Date _____ (mm/dd/yyyy) First name _____ Last name _____ Employee number _____ (Use your employee number only, Do NOT use any letters.)

Supervisor _____ Observed by _____ (Last name, first name)

Patient or simulation? ☐ Patient ☐ Simulation Last 4 digits of patient MRN _____ (If applicable) Unit _____ (Enter as unit-bed number ex. H81-15 or G111-09)

Age (If applicable) ☐ Neonate/infant (0-18 mos.) ☐ Child (19 mos.-8 yrs.) ☐ Adolescent (9-18 yrs.) ☐ Adult (19-69 yrs.) ☐ Geriatric (70+yrs.)

Did the RT interact appropriately with the patient with regard to the specific age category listed above? (If applicable) ☐ Yes ☐ No

According to section standards

Prepare equipment and assess patient ☐ Yes ☐ No
1. Verify order, verifies patient using at least 2 patient identifiers (Name, MRN, DOB)
2. Introduce self and explains procedure (If applicable)
3. Correctly assemble the equipment per procedure manual, suction kit, manual resuscitator, oxygen, saline for lavage, suction source (wall outlet: 80-120 mm Hg portable: 3-5 inches Hg), lubricating jelly for nasotracheal route

Observe OSHA standards for universal precautions ☐ Yes ☐ No

Pre-assesses patient ☐ Yes ☐ No
1. Heart rate
2. Respiratory rate
3. Breath sounds
4. Pulse oximetry

Perform suctioning procedure ☐ Yes ☐ No
1. Maintain sterile technique
2. Pre-oxygenate
3. Hyper-inflate at least 5-6 times with artificial airways
4. Suction
5. Lubricate catheter for nasotracheal route
6. Insert catheter smoothly as far as possible, careful to stop on encountering resistance
7. Apply suction intermittently as catheter is withdrawn
8. Suction period should not exceed 15 seconds
9. Oxygenate and hyper-inflate after each pass with the catheter
10. Lavage as needed
11. Repeat until airways are clear or as the patient tolerates
12. Note amount, color, and consistency of any secretions

Post treatment assessment ☐ Yes ☐ No
1. Heart rate
2. Respiratory rate
3. Breath sounds
4. Cough
5. Sputum
6. Mental status
7. Activity

Assures patient safety and clean environment ☐ Yes ☐ No
1. Removes all other trash from bed and area
2. Verifies medical support systems are intact (ex. oxygen)
3. Ensures patient safety (ex. bedrails are up)

Charts appropriately ☐ Yes ☐ No
1. Charts correctly in Mediserve in a timely manner
2. Includes any complications and/or adverse events and informs physician

EVIDENCE-BASED MEDICINE

Another important concept regarding high-quality care is evidence-based medicine. **Evidence-based medicine** refers to an approach to determining optimal clinical management based on several practices, as follows[28-32]: (1) a rigorous and systematic review of available evidence, (2) a critical analysis of available evidence to determine which conclusions are most sound and applicable, and (3) a disciplined approach to incorporating the literature with personal practice and experience. In a broader context, evidence-based medicine can be thought of as understanding and using the best quality evidence available (i.e., the best-designed, most rigorous clinical trials) to support the most appropriate and correct possible clinical decisions.

In rating the quality of scientific evidence, it is important to recognize the various designs and types of study designs from which scientific evidence comes.[32] This section reviews these designs. The simplest and least rigorous design is a single case

TABLE 2-4

Summary of Available Randomized Trials on the Effectiveness of Respiratory Care Protocols

Clinical Activity	Author	Date	No. Patients	Findings
Weaning from mechanical ventilation	Kollef et al[43]	1997	357	Use of protocols was associated with shorter duration of mechanical ventilation
	Ely et al[44]	1996	300	Routine daily trials of spontaneous breathing trials were associated with shorter duration of mechanical ventilation
	Marelich et al[45]	2000	253	Use of protocols shortened duration of mechanical ventilation
Respiratory care protocol service	Stoller et al[25]	1998	145	Use of respiratory therapy consult service was associated with improved allocation of respiratory care service with lower costs and no adverse events
	Kollef et al[26]	2000	694	Use of respiratory protocol service was associated with fewer orders discordant with guidelines and lower charges

report, in which a new clinical issue or problem is described in a single patient. A description of the favorable outcome of using a new mode of mechanical ventilation in one patient with refractory hypoxemia is an example of a single case report. Although single case reports have value in pointing out new insights and new possibilities for treatment, disease associations, or disease causation, they cannot prove the effectiveness of a treatment or the causality of a risk factor because, by nature, they lack a control or comparison group (i.e., a group that is similar to the patient or patients described, differing only in whether the risk factor of interest was present or the treatment of interest was applied). Collecting a group of patients with similar clinical features is called a case series and may have greater impact than a single case report because it suggests that the issue is more general than in a single patient alone. However, like a single case report, a case series cannot prove the efficacy of a treatment or the causality of a risk factor because no comparison or control group is included.

Cohort studies, which compare the clinical outcomes in two compared groups (or cohorts), generally have greater scientific rigor than case studies or case series and consist of two broad types of study designs: observational cohort studies and randomized controlled trials. In trying to establish whether a treatment works (i.e., has efficacy), an observational cohort study compares the outcomes between two groups of patients when the treatment is allocated to one group but not the other. More specifically, an observational cohort study of a new mode of mechanical ventilation would compare the outcomes between two groups of similar patients (i.e., especially similar with regard to their risk for developing the outcome measure that is being studied) when the mode of mechanical ventilation is determined either by physician choice (i.e., the physician decided to use this treatment in this patient) or by patient choice. In contrast to an observational cohort study, in a randomized controlled trial, sometimes regarded as the most methodologically rigorous study design (when well conducted), the outcomes of two similar groups of patients are compared when the use of the new mode of mechanical ventilation is determined not by patient or physician choice but rather by chance alone (randomization). When ideally designed and conducted, a randomized controlled treatment trial eliminates all sources of bias that would prevent attributing differences in outcomes between the compared groups to anything other than the treatment that is being studied. In this way, randomization can "isolate" the effect of the treatment. Said differently, at its best, a randomized controlled treatment trial provides rigorous evidence about the efficacy of the treatment because all other potential biases and confounding variables (e.g., features of the compared patient groups, other medications, or other treatments that the study participants are receiving) are eliminated from consideration. This allows the investigators and the readers of the clinical trial results to confidently attribute outcome

differences between the compared groups to the treatment that is being studied.

Different types of the randomized controlled trials exist and include the parallel-control study and the crossover study (Figure 2-7). Parallel-control treatment studies compare two groups: one receives the treatment being studied, and the other receives the control treatment. Sometime after the end of the treatment, outcomes in the two groups are assessed and compared, especially regarding the main outcome of interest in the study. For example, a parallel-control randomized trial of low-stretch ventilation for ARDS would compare one group of patients receiving low-stretch ventilation with another (otherwise similar) group receiving higher stretch ventilator settings, and the two groups would be compared after a prespecified period with regard to key outcomes, such as survival, discharge from the intensive care unit, and organ system failures. This very design was used in the ARDSNet parallel-control randomized controlled trial that showed the superiority of using a tidal volume of 6 ml/kg (ideal body weight) in managing patients with acute lung injury or ARDS.[33]

In the other type of randomized controlled trial—the crossover trial—the study treatment is first administered to one group of study subjects while the other group receives the control or comparison treatment, and then, after measuring outcomes and a subsequent "washout period" (in which the effects of the initial treatment decay and wear off fully), the group initially given the study treatment receives the control treatment and the group initially given the control treatment receives the study treatment. The crossover study design offers a statistical advantage of greater power to detect a difference between the compared groups, which means that fewer study participants are required to find a statistically significant difference, if one exists. However, crossover studies can be performed only when the effects of the initial treatment administered to the first study group can wear off completely (or so-called washout), allowing the study group to return to its baseline state before the alternative treatment is administered. When the effects of treatment are permanent (e.g., surgery, radiation therapy), a crossover trial involving that treatment cannot be done because washout of the treatment effect is not possible.

Evidence-based medicine requires knowledge of how to analyze carefully the results of clinical trials (e.g., randomized controlled trials and observational cohort studies) and how to apply the results of such research to high-quality clinical practice. Other tools of evidence-based medicine include systematically reviewing the available literature, or what is called *meta-analysis* of the literature.[29,30] A meta-analysis of a clinical question (e.g., does a low-stretch mechanical ventilation strategy improve survival in ARDS?)[33] identifies, analyzes, and summarizes the body of literature about this topic by assessing the quality of the available evidence and giving greater weight to better designed, more rigorous studies. Sometimes, meta-analyses pool the actual data from different trials together when pooling is scientifically and statistically permissible. In other instances (called *narrative analyses*), the meta-analysis simply evaluates the quality of the data from each available trial (based on explicit methodologic criteria) to offer a conclusion about the clinical issue.

A meta-analysis performed as part of an evidence-based approach to determining the optimal ventilatory approach for ARDS might weigh the results of large randomized clinical trials of low-stretch versus conventional tidal volume approach mechanical ventilation more heavily than the results of small observational studies. As an example of a narrative meta-analysis, a 2003 evidence-based review of the management of individuals with alpha-1 antitrypsin deficiency issued graded recommendations for testing for this genetic cause of COPD.[34]

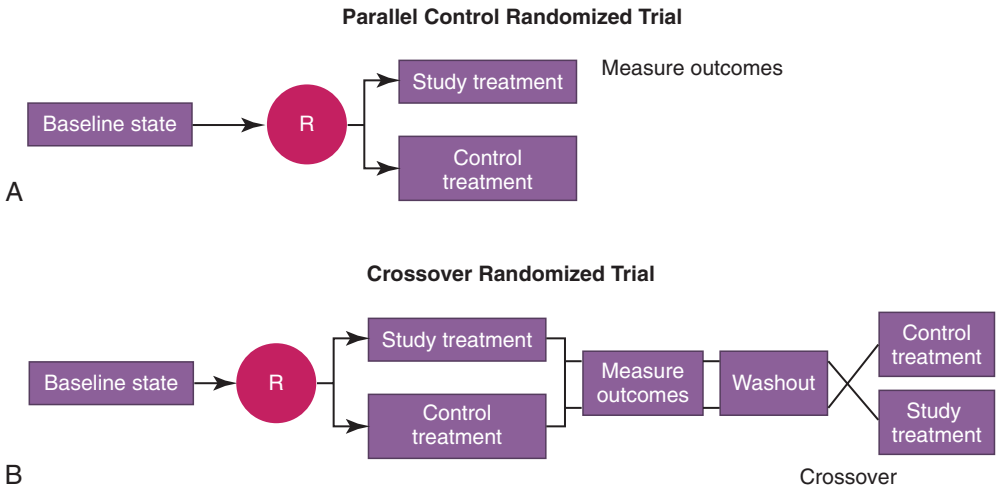

FIGURE 2-7 Study design of the two types of randomized controlled trial: parallel-control and crossover. In a parallel-control trial, after randomization *(R),* one group receives the study treatment, while the control group receives the comparison treatment (possibly a placebo). At the end of the subsequent observation period, study outcomes are measured, and the trial is over. In a crossover trial, one group initially receives the study treatment and the other group receives the comparison treatment; outcomes are measured; and after a washout period (see text), each group receives the alternative treatment for another period, after which outcomes are measured again.

A level A recommendation (i.e., that testing should be performed) was issued to test all symptomatic adults with airflow obstruction on pulmonary function tests (whether carrying the diagnosis of emphysema, COPD, or asthma in which airflow obstruction fails to reverse completely with bronchodilators), asymptomatic individuals with persistent airflow obstruction on pulmonary function tests with identifiable risk factors (e.g., cigarette smoking, occupational exposure), individuals with unexplained liver disease, and adults with the skin condition necrotizing panniculitis.[34] Although the hope is that issuing such evidence-based guidelines will improve the care that such individuals receive by allowing clinicians to access efficiently the best available information, experience suggests that clinicians may sometimes be slow to adopt the best available evidence in caring for their patients.[35]

RULE OF THUMB

The randomized controlled clinical trial is often considered to be the most rigorous type of study design to prove the efficacy of a treatment. The optimal randomized controlled clinical trial is designed to be free from bias that can confuse the study results and is well-conducted.

Although some authors point out that evidence-based medicine does not differ from prior practice in which clinicians were always called on to analyze carefully available data and make clinical judgments based on the best quality information available, evidence-based medicine does specify precise methods for analyzing available information and allowing the clinician to judge best the available evidence. As a measure of the importance of evidence-based medicine in respiratory care, several articles in *Respiratory Care* considered the effectiveness of RTs and of various respiratory care treatment modalities using an evidence-based approach.[28-30] The Clinical Practice Guidelines of the AARC are being systematically reviewed to reflect the rigorous techniques of evidence-based medicine and to ensure that guidelines for respiratory care management reflect the best available evidence.[30] The proof that low-stretch ventilation is associated with improved survival in patients with ARDS and the methods used to enhance awareness of this best practice are further examples of evidence-based medical practice.

SUMMARY CHECKLIST

- High-quality respiratory care can be defined as the competent delivery of indicated respiratory care services.
  - Essential elements for delivering quality respiratory care include:
    - Energetic and competent medical direction
    - Methods for providing indicated and appropriate respiratory care
    - Educated, competent respiratory care personnel
    - Adequate, well-maintained equipment
    - Intelligent system for monitoring **performance improvement**
- Delivery of high-quality respiratory care requires the combined activities of a qualified and committed medical director and capable RTs and can be enhanced by well-constructed respiratory care protocols.
- Respiratory care protocols are guidelines for delivering appropriate respiratory care services and are widely used in current respiratory care practice.
- Available evidence suggests that use of respiratory care protocols can improve allocation of respiratory care services. In doing so, the use of respiratory care protocols lessens misallocation of respiratory care.
  - Misallocation of respiratory care services, which hinders the delivery of high-quality respiratory care, can be defined as overordering or underordering of respiratory care services and is common in current practice.
- Practitioner credentialing is important in respiratory care; the RRT represents the highest credential and is based on successful completion of the NBRC examination.
- Maintaining and improving quality requires ongoing monitoring, as may be accomplished by quality audits and repeated competence testing of RTs.
- Evidence-based medicine is an approach to determining the best possible patient management based on critically assessing the available evidence. It is recommended that RTs use this approach as they assess the information that is available regarding respiratory care management strategies.

CHAPTER 3

Quality, Patient Safety, Communication, and Recordkeeping

SCOTT P. MARLOW AND UMUR HATIPOĞLU

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Define the meaning of *quality* in health care services.
- Understand the basic tools used in quality improvement projects.
- Describe established methods of quality improvement such as Six Sigma and Lean Management.
- Understand the importance of monitoring quality to promote better patient outcomes.
- Identify impediments to care and risk in the direct patient environment.
- State how communication can affect patient care.
- Describe the two-patient identifier system.
- List the factors associated with the communication process.
- Describe how to improve your communication effectiveness.
- Describe how to recognize and help resolve interpersonal or organizational sources of conflict.
- List the common components of a medical record.
- State the legal and practical obligations involved in recordkeeping.
- Describe how to maintain a problem-oriented medical record.
- Describe how to apply good body mechanics and posture to moving patients.
- Describe how to ambulate a patient and the potential benefits of ambulation.
- Write definitions of key terms associated with electricity, including voltage, current, and resistance.
- Identify the potential physiologic effects that electrical current can have on the body.
- State how to reduce the risk for electrical shock to patients and yourself.
- Identify key statistics related to the incidence and origin of hospital fires.
- List the conditions needed for fire and how to minimize fire hazards.

Provision of high-quality care in a safe environment is the focus of today's health care industry. Achieving this goal requires the integration of multiple disciplines, including respiratory therapy. Consequently, respiratory therapists (RTs) should be familiar with the concepts of **quality improvement** as it relates to health care.

This chapter will define quality and how it relates to health care. Through a narrative review, we will outline how quality is measured, monitored, and adapted to our health care environment. Discussions regarding quality in health care will demonstrate how RTs share the general responsibilities for providing a safe and effective health care environment with nurses and other members of the health care team. RTs are also required to have specific technical knowledge of the environment of direct patient care. In addition to technical skills, all health care professionals must be able to communicate effectively with each other and with patients and patients' families and to document pertinent information. Figure 3-1 shows this relationship for patient safety. This chapter aims to provide the foundational knowledge needed to understand the general aspects of patient safety considerations, communication in health care, conflict resolution, and recordkeeping that comprise essential components of high-quality patient care.

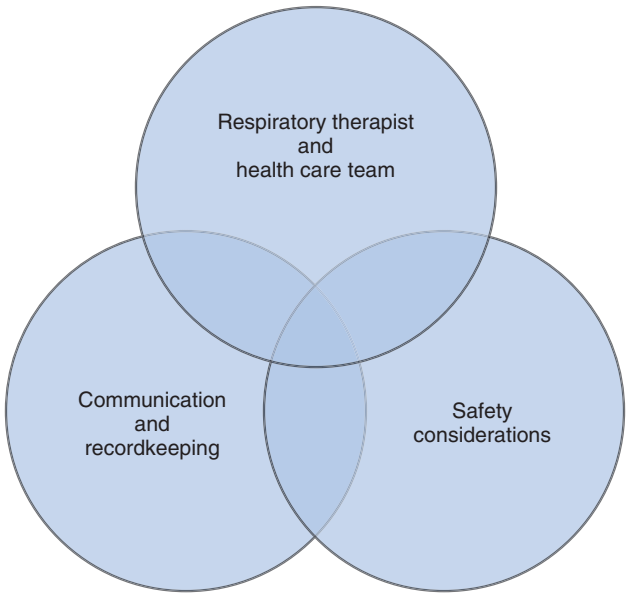

FIGURE 3-1 Patient safety continuum.

QUALITY CONSIDERATIONS

What Is Quality?

The quality of a service or product refers to the sum of its properties that serve to satisfy the needs of its consumer. High-quality services get high demand and also become a source of pride and financial success for the producer.

The Methods of Quality Improvement

Methods of attaining and ensuring quality were born in the automobile manufacturing industry in Japan, led by American engineers and scientists. These principles were only later adopted in the United States. William Edwards Deming (1900-1993), an electrical engineer and statistician, is credited for laying the foundations of quality control and management. Working first with the Japanese automobile industry and later with Ford Motor Company, Deming believed that high quality can be obtained only by a major culture change promoting a continuous improvement cycle in an organization. In essence, Deming suggested that the purpose of an organization is to constantly seek improvement of its product or service aligned with customer needs.[1] Rather than relying on constant inspection, quality should be built into the product from the beginning by design of the process or structure. Emphasis must be placed on the quality of the product and pride in the workmanship rather than on sheer quantitative productivity. Quality improvement must be everyone's job, starting from executive management to the front-line worker. Deming heavily relied on statistical quality control techniques, established by Walter A. Shewhart (1891-1967), another American engineer and scientist. Through statistical **process control** charts (SPCs), Shewhart pointed out that in every process associated with production, there was a variability, which he termed common cause variation. Common cause variation in a process can be quantitated by monitoring over time. Using sound statistical principles, an upper confidence limit (UCL) and a lower confidence limit (LCL) could be determined that define the range of common cause variation. A continuous monitoring of the process is possible by taking a small but representative sample and charting

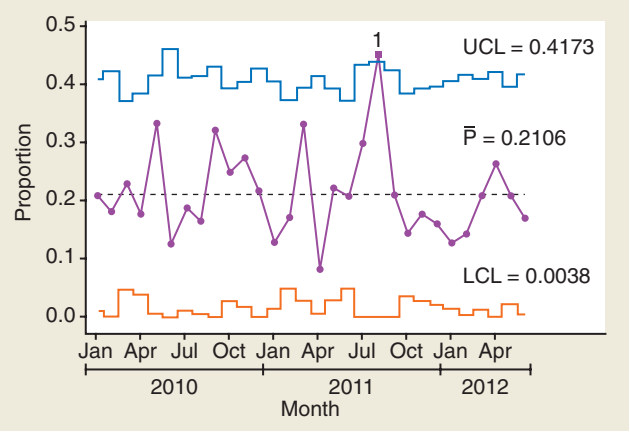

FIGURE 3-2 Statistical process control chart showing proportion of patients having to be readmitted to the hospital after discharge. Upper *(UCL)* and lower *(LCL)* control limits are marked with *gray lines*. At approximately September 2011, there appears to be a spike in readmissions to the hospital outside of the UCL that may require investigation.

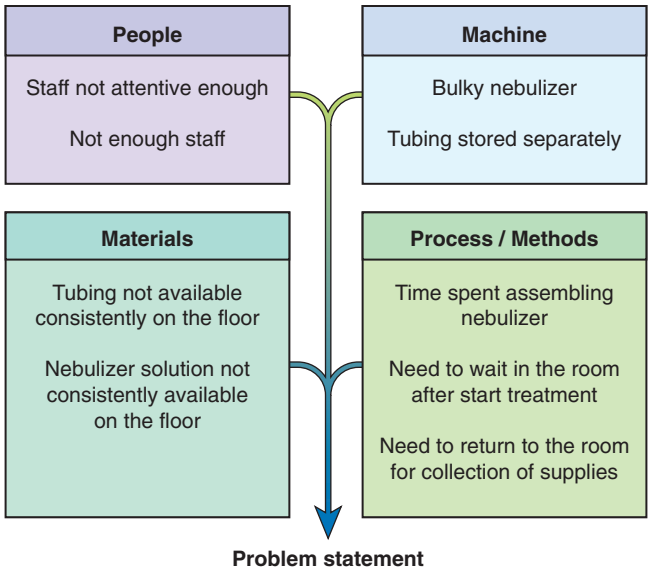

FIGURE 3-3 Fishbone diagram.

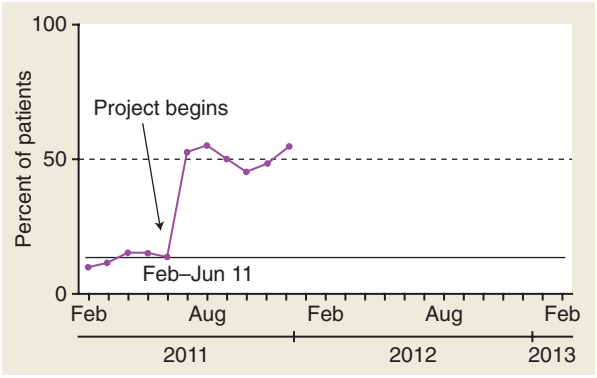

FIGURE 3-4 Run chart showing percentage of patients who received pneumonia vaccination over time.

numerical values on the SPC. Should the sample for any given time interval reveal values outside of the range—for example, higher or lower than UCL and LCL, respectively—then special cause variation is suspected (Figure 3-2). This unnatural pattern will then need to be investigated for a cause. Shewhart's SPCs continue to form the backbone of continuous quality improvement. Another important contribution to the practice of quality improvement by this brilliant engineer is the Plan-Do-Study-Act (or Plan-Do-Check-Act) cycle, also known as the Shewhart cycle.

Plan-Do-Study-Act Cycle

The Plan-Do-Study-Act Cycle (PDSA) can be seen visualized as the wheels of the car that is continuous quality improvement. As the wheels of PDSA turn, one gets closer to that difficult-to-achieve "perfect" product or service.

Plan Phase

In the *Plan* phase, clear goals are set for the quality improvement process. These goals are best stated in the form of hard numbers such as "a 20% increase in referrals to pulmonary rehabilitation on discharge for patients with chronic obstructive pulmonary disease (COPD." The planned intervention should be stated clearly. For instance, "respiratory therapist stationed on the nursing floor will distribute pulmonary rehabilitation program pamphlets to clinical team and remind clinicians to place the order for patients with COPD." A time limit should be specified, for example "a 20% increase in referrals to pulmonary rehabilitation on discharge over the next 3 months." During the planning phase, it is also helpful to create a diagram or a flow chart of the process that needs to be improved. The project team may choose to use tools such as the fishbone (or Ishikawa) diagram to systematically evaluate the different factors that affect the process and contribute to the problem, that is, people, technology, environment, materials, equipment, and methods (see Mini Clini and Figure 3-3).

Do Phase

In the *Do* phase, the intervention is begun and observations are recorded. On occasion, observations may need to be made on a limited sample that is representative of the entire process. The size of that sample should be determined by statistical methods that may require the help of a quality improvement professional or biostatistician. The observations are plotted on a statistical process chart or its simpler version, a so-called *run chart,* for analysis (Figure 3-4).

Run charts are graphic representations of data over a period of observation. In contrast to SPCs, there are no defined upper and lower limits. Rather, movement of the data points around the median value (the gray line) is visualized and interpreted. Rules of interpretation are based on statistical principles. A consistent change in the placement of data points on either side of the median indicates special cause variation. The run chart in Figure 3-4 displays the percentage of patients who have

received pneumonia vaccination before discharge from the hospital before and after the onset of a quality improvement project. In this instance, six data points are observed above the median value after the project starts. Five or more points on one side of the median indicates special cause variation (an interpretation rule), in this case, the consequence of an effective project.

Study (or Check) Phase

In the *Study* phase, the observations are analyzed, usually by examination of the process charts. The barriers to achieving the set goals are considered and discussed.

Act Phase

In the *Act* phase, based on the analysis performed in the Study phase, modifications to the intervention are made.

The Plan-Do-Study-Act Cycle Starts Over

The paradigm of the PDSA cycle has served as the foundation for modern quality management systems such as the lean management system and Six Sigma, which are discussed in the following section.

RULE OF THUMB

The crucial components of a quality improvement project are summarized in the PDSA cycle:

Plan: Determine the specific aim, duration, data collection strategy, and team that will run the quality improvement project.

Do: Collect data and record the observations.

Study: Analyze results and derive conclusions.

Act: Change the process for improvement, plan the next cycle.

Six Sigma

By the mid-twentieth century, it had become obvious to the leading industrial companies that the rate of defective products had to be lowered to maintain market competitiveness and customer loyalty. Developed by the American telecommunications company Motorola, the Six Sigma method for quality improvement recognizes that there is a natural variation in process output that can be measured and monitored over time. Controlling and reducing this variation are the keys to business success. Statistical methods are used to calculate acceptable variation. There has to be a strong commitment on the part of management, from top to bottom, to these principles. The Six Sigma method also is based on the belief that improvement to existing processes is always possible and has to be achieved systematically. Analogous to the PDSA cycle, Six Sigma adopts the (Define-Measure-Analyze-Improve-Control (DMAIC) cycle for continuous quality improvement.

Define: Describe and validate the problem, create solutions, create a process map, and create a timeline for completion of the project.

Measure: Identify metrics, develop data collection plan, collect baseline data.

Analyze: Evaluate collected data in the measure phase, determine root causes for the problem and estimate the relative impact of each.

Improve: Discuss, develop, and implement solutions to the root cause(s), and confirm that the intervention is well targeted.

Control: Continue to implement solutions and follow metrics to ensure maintenance and adoption.

Origin of the Term Six Sigma

Sigma (σ) is a Greek letter that is used to note standard deviation in a normally distributed population. Accordingly, one standard deviation from the mean in each direction, that is, ± 1 σ, contains approximately 68% of the population. Similarly, 2 times σ contains 95% and 3 times σ contains 99%. If one considers a process to operate at 1 σ, then one would have to accept a 68% rate of successful product (or a failure rate of 32%). At the 2 σ level of acceptance, the failure rate would be 5% and at 3 σ, it would be 1%. At 6 Sigma, the rate of failure would be 3 in 1 million (or 0.000003). Thus, the Six Sigma process has a goal of a very, very small error rate (Figure 3-5).

Lean Management

Lean management is a business management philosophy that focuses on eliminating waste or non–value added activities. The origins of lean management are in the Japanese automobile maker, Toyota Motor Company. Lean management is analogous to ergonomics; eliminating waste of time, excess work, and unevenness of product are the goals. This goal is achieved by broadly using the principles of "just in time" (i.e., having equipment, personnel, supplies at the right place at the right time, Figures 3-6 and 3-7) and "Jidoka" (a joining of automation and human intelligence that results in a higher level of quality control). According to the Jidoka principle, any person involved in a service or manufacturing of product can stop the process if he or she sees a defect.

Lean management uses tools similar to those in PDSA and Six Sigma, with emphasis on waste elimination. These have been collectively termed the *lean toolbox*. The main instrument is value stream mapping, which is essentially a flow chart with emphasis on identifying value-added activities versus those that are not.

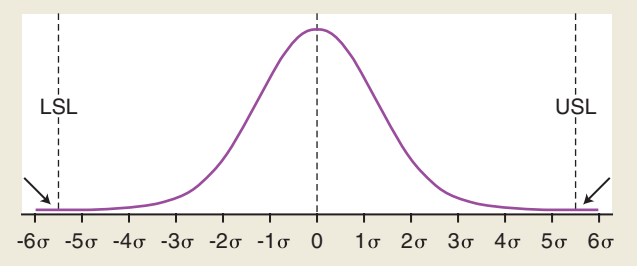

FIGURE 3-5 Normal (Gaussian) distribution. *LSL,* Lower specific limit; USL, upper specific limit.

MINI CLINI

Case Study

Michael Breathewell, an RRT, is the respiratory therapy manager in the respiratory care department of a 300-bed unit in Our Lady of Sacred Lungs Hospital. Over the past 6 months, he has been made aware, through the newly implemented serious event reporting system (SERS), of the time delay in delivery of scheduled inhaled bronchodilator treatments to patients. There is increasing pressure from physicians, nursing, and administration to fix this problem. After careful review of the cases, Michael determines that the problem occurs throughout all shifts and with different RTs and services involved. He believes that the problem may be due to a system issue and not special cause variation.

There are over 200 scheduled treatments given per day at the hospital. Tracking each treatment delay on a daily basis would be a huge job. Therefore, Michael has to select a sample that represents the time delay for the entire population. He asks the hospital biostatistician for help. Based on several assumptions, the biostatistician determined that 16 randomly sampled events were needed to have a fair idea of the average time delay between scheduled treatments and actual delivery.

Next, Michael asks for the help of a quality improvement professional in choosing the appropriate statistical process control chart for studying and monitoring the process of bronchodilator administration. He then begins collecting and graphing the data.

After a 3-month period of observation, he determines that there is an average of 15 minutes of delay between scheduled time and delivery time per patient see (Figure 3-6).

Michael decides to apply the Plan-Do-Study-Act cycle (PDSA) to tackle the issue.

PLAN: Michael calls a brainstorming session with floor respiratory managers and the medical director of respiratory care at this hospital. During the meeting, Michael and the group identify and analyze the problem and map the process. To facilitate the discussion, he uses an Ishikawa fishbone diagram to explore potential causes. Figure 3-6 shows the completed fishbone diagram. The fishbone allows a systematic discussion of possible contributors to the problem by considering factors related to machines, people, material, and process. The attendees overwhelmingly feel that the bulk of the time is spent getting the nebulizer and tubing, setting up the patient, and then returning back to the room. They also research best practices and conduct a literature review to understand reasons for delay in delivering nebulized treatments.

An attendee points out that administration of bronchodilators via metered dose inhalers (MDIs) has been found to be equivalent in efficacy across different diseases and disease severity.[2-4]

After some deliberation, weighing the balancing measures such as cost difference, the group decides to switch to bronchodilator administration via MDIs with a spacer and to follow time delay between scheduled time of bronchodilator delivery and actual time of delivery. The group decides that a 3-month observation should be enough to determine the effect of the intervention and meet monthly to review results. Michael and the team also identify the measures of success, including monitoring time delay between order entry and administration of the medication and employee satisfaction. Michael meets with hospital administration and with the chief financial officer, getting their support and ensuring financial feasibility of the switch.

DO: The group begins to administer scheduled short-acting bronchodilators by MDI with a spacer throughout the hospital floors. At least 16 observations of bronchodilator administration are made randomly throughout the day and recorded on the statistical process chart. Although the literature provides strong support for this intervention, Michael carefully reviews patient outcomes (e.g., treatment failure that results in a higher level of care or intensive care unit admission) to ensure that the switch to MDIs does not have unintended consequences.

STUDY: Michael measures the effect of the intervention and sees a trend toward reduction in delay times after 1 month and is pleased. However, some RTs suggest that further reduction in delays might be possible if patients' MDIs and spacers are kept at the bedside.

ACT: The suggestion to switch to delivery by MDI is discussed with the committee for pharmacy and therapeutics and is approved. MDIs with the patient's name stamp and spacer are kept at the bedside.

At the end of 3 months, Michael studies the process chart (Figure 3-7) and notes that delays have been consistently below the LCL of the original process. He congratulates the entire team and continues to monitor progress. Michael and colleagues plan to refine the intervention through iterative cycles, going back to the plan phase if future results are not as expected or yield unintended consequences.

What Is Quality in Health Care?

As the reader can see, there are common themes in all quality improvement approaches: Identification of process components, increasing efficiency (reducing waste), standardization (reducing common variation), and a teamwork approach in implementing solutions. Broadly speaking, health care delivery systems were slow to adopt these principles, with the possible exception of laboratory medicine. Rising health care costs, however, have brought about a revolution in how health care is delivered in the United States. In line with the *Patient Protection and Affordable Care Act,* the Centers for Medicare and Medicaid Services (CMS) began the Hospital Value-Based Purchasing Program, which rewarded or penalized hospitals based on their performance in the domains of process measures (also called *core measure compliance*), outcomes, patient experience, and efficiency. The Hospital Value-Based Purchasing Program is budget neutral, meaning that superior performance is rewarded and poor performers have to pay a penalty. Funds from the penalties provide the money for the rewards to hospitals that perform well. The federal government also enacted the Hospital Readmissions Reduction Program, which is strictly a penalty

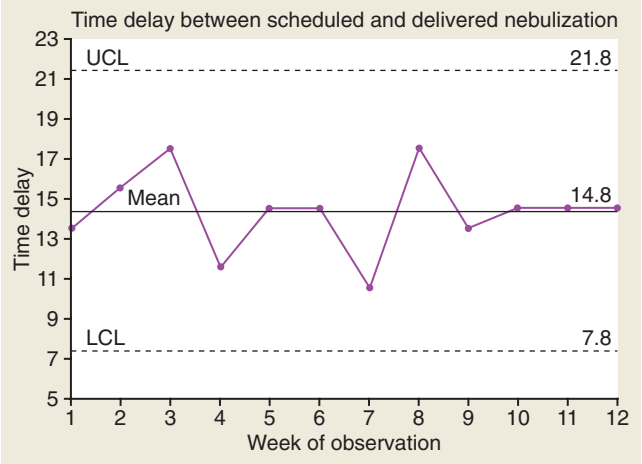

FIGURE 3-6 Time delay between scheduled and delivered nebulization. LCL, Lower control limit; UCL, upper control limit.

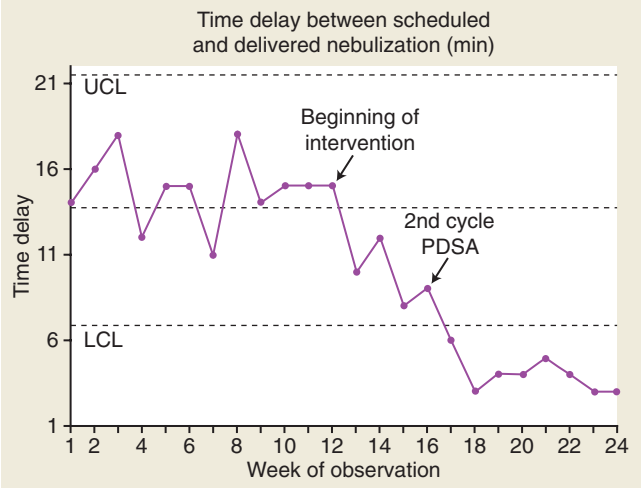

FIGURE 3-7 Time delay between scheduled and delivered nebulization. *LCL,* Lower control limit; *PDSA,* Plan-Do-Study-Act; *UCL,* upper control limit.

program that withholds a certain percentage of entire CMS reimbursements if the hospital has excess readmissions within 30 days of index discharge, compared to the national mean. With these incentives and threats of penalties, the health care industry is now adopting principles of quality improvement quickly.

The National Academy of Medicine (formerly the Institute of Medicine), the health arm of the National Academy of Sciences, suggests the following dimensions in health care quality: Safety, Timeliness, Effectiveness, Efficiency, Equity, Patient-centeredness (STEEP). These elements also define the starting points for quality improvement projects in health care.

Adoption of clinical guidelines and protocols are also important steps toward standardizing care and thereby driving improvement and reducing variation in outcomes (see Chapter 2). This satisfies the effectiveness and efficiency dimensions of health care quality. The patient safety dimension is addressed by adopting the "Jidoka" principle—stopping the process when any team member sees a defect in delivery of the care. Comprehensive and effective handoffs, as discussed later, between RTs are also critical for patient safety. RT-run education programs fulfill the patient centeredness principle. RTs also play a vital role in implementation of the guideline-based RT protocols and disease management programs, which represent a holistic approach to patient care across the continuum of health care settings. Disease management is discussed in the following section, and protocols are discussed in more detail in Chapter 2.

Disease Management

Disease management refers to an organized strategy of delivering care to a large group of individuals with chronic disease to improve outcomes and reduce cost. Disease management has been defined as a systematic population-based approach to identify persons at risk, intervene with specific programs of care, and measure clinical and other outcomes.[5,6] Disease management programs comprise four essential components: (1) an integrated health care system that can provide coordinated care across the full range of patient needs; (2) a comprehensive knowledge base regarding the prevention, diagnosis, and treatment of disease that guides the plan of care; (3) sophisticated clinical and administrative information systems that can help assess patterns of clinical practice; and (4) a commitment to continuous quality improvement. Disease management programs may be developed for chronic conditions such as asthma, diabetes, COPD, and congestive heart failure.

A disease management program for COPD might be adopted by a health care provider, insurance company, or health maintenance organization in defining its practice approach to individuals with COPD. The disease management program might contain algorithms addressing when to suspect COPD, tests to perform (e.g., spirometry, alpha$_1$-antitrypsin level, diffusing capacity), medications to prescribe based on disease severity, management of exacerbations, and indications for rehabilitation. Disease management programs are often outlined in documents containing branched logic algorithms that specify care, similar to respiratory care protocols (see Chapter 2); however, disease management protocols often address large groups and are based on an underlying diagnosis rather than on individual signs and symptoms. Other dimensions of the COPD management program include a data collection activity regarding the number of patients served, the outcomes of care, and, perhaps, the associated costs. In addition, as with quality monitoring in general, ongoing review and periodic updating and revision of the care algorithms are important dimensions of the program.

Monitoring Quality in Respiratory Care

Beyond ensuring that all elements of a high-quality respiratory care program are in place, quality must be monitored to ensure that it is being maintained. Strategies to monitor quality include intrainstitutional monitoring practices, centralized government

monitoring bodies, such as the Centers for Medicare and Medicaid Services (CMS), and independent agencies such as The Joint Commission (TJC).

Intrainstitutional quality assurance often uses skills checks or **competencies**. Competence, or the quality of being competent, can be defined as having suitable or sufficient skill, knowledge, and experience for the purposes of a specific task.[7] Competence for a specific skill is frequently determined by observation of the practitioner's performance of the skill according to a prescribed checklist. Annual competency checks are documented for skills and procedures that carry some degree of patient risk (e.g., arterial puncture, aerosol therapy, bilevel positive airway pressure setup). An example of a skills checklist is shown in Figure 2-5.

Although skills checks have traditionally been done in person or with direct supervision of patient care activities, a new dimension of skills training and certification that is being widely implemented is the use of clinical simulation, using either low-fidelity or high-fidelity simulation trainers. Such simulation training, in which RTs use technology that attempts to reproduce reliably a true patient or true patient scenario, is similar to the flight simulator training that commercial airline pilots undergo to achieve certification to fly various airplanes. Uses of simulation training in respiratory therapy involve intubation, ventilator management, arterial line placement, and optimizing teamwork in acute resuscitation scenarios.[8]

Many health care organizations, including hospitals, subacute care facilities, and outpatient clinics, seek voluntary accreditation as a way to improve their service and assure the public that they maintain high standards. In health care, TJC is a very important organization. TJC (as the Joint Commission on the Accreditation of Healthcare) was formed in 1951 by the American College of Surgeons, the American Hospital Association, and the American Medical Association. Accreditation by TJC is based on satisfying specific standards established by professional and technical advisory committees.

TJC requires a hospital service to have a **quality assurance** plan to provide a system for controlling quality. Nine generally recognized steps for a quality assurance plan are used as the basis for quality assurance programs (Box 3-1).

Current standards of TJC for accreditation emphasize organization-wide efforts for **performance improvement**. Despite increased emphasis on cost containment, quality care remains the first goal of hospitals and respiratory care services. Performance improvement, also commonly called *continuous quality improvement,* is an ongoing process designed to detect and correct factors hindering the provision of quality and cost-effective health care. This process crosses department boundaries and follows the continuum of the patient's care. In 2009, TJC set forth three standards for monitoring performance improvement along with associated elements of performance detailing how the monitoring is to be conducted. These standards are listed in Box 3-2. Meeting quality goals is increasingly being tied to reimbursement rates by the CMS and insurers to hospitals; this phenomenon has been called "pay for performance."[9] Beyond general monitoring goals for respiratory therapy, use of respiratory care protocols creates the need for additional quality monitoring benchmarks regarding correctness, consistency, efficacy, and effectiveness (Box 3-3, Chapter 2).

At the present time, specific methods to monitor the quality of respiratory care protocol programs include conducting care plan audits in real time and ensuring practitioner training by using case study exercises. Evolving innovations include using simulation exercises to enhance and to measure the performance of RTs.

Monitoring correctness of respiratory care plans can be accomplished by using a care plan audit system. Care plan auditors must be therapists who are experienced in providing respiratory care and patient assessment. The auditors must also be practiced in using the institution's protocol system and in writing care plans. With an auditing system, the auditor writes a care plan for a patient and compares it with the care plan written by the therapist evaluator to determine correctness. A specified number of audits should be performed monthly, with results tabulated and reported monthly or quarterly, depending on the size of the hospital. Feedback must be provided to the evaluators whose care plans are being audited to show their proficiency or to indicate areas that require improvement. Figure 2-6 shows a form used at the Cleveland Clinic to provide feedback to evaluators.

Box 3-1 Nine Steps for a Quality Assurance Plan

1. Identify problem
2. Determine cause of problem
3. Rank problem
4. Develop strategy for resolving problem
5. Develop appropriate measurement techniques
6. Implement problem-resolution strategy
7. Analyze and compile results of intervention
8. Report results to appropriate personnel
9. Evaluate intervention outcome

Box 3-3 Quality Monitoring Benchmarks

- Monitoring the correctness of respiratory care plans
- Monitoring the consistency of formulating respiratory care plans among therapist evaluators
- Evaluating the efficacy of algorithms or protocols
- Evaluating the overall effectiveness of the protocol program

Another monitoring method found useful for respiratory therapy consult services is the case study exercise (or simulated patient scenario exercise). Simulated patient exercises can help determine the consistency of respiratory care plans among therapist evaluators. The scores of individual RTs may be tracked over time to identify problems and assess improvement.

Simulated patient exercises may consist of a set of three or four patient scenarios. All RTs working under the protocol system, whether or not they are evaluators, complete an assessment sheet and, following the associated algorithms, write a care plan for each scenario. The assessment sheets and the care plans are compared with the gold standard, or correct assessments and care plans, as determined by the consensus of the education coordinator and the supervisors. Scores are tabulated for the individual RTs, and the number of errors for each therapy is examined. If a particular therapy consistently has a large number of associated errors, the algorithm is reviewed for errors or vagueness. To facilitate administering and grading patient simulation exercise results, a computer-based system that scores the assessments and care plans and provides feedback to the RT has been used.[10] Performance data of individual RTs are maintained in a database to calculate and track aggregate performance statistics.

Peer Review Organizations

In addition to the voluntary accreditation process that health care organizations use to help ensure patients are receiving quality care, the federal government has established an elaborate system of peer review organizations (PROs) to evaluate the quality and appropriateness of care given to Medicare beneficiaries. PROs evaluate care provided to individual patients in real time to assess and ensure compliance with federal guidelines.

In recent years, health care organizations have attempted to improve the quality of patient care while reducing costs by implementing several innovative health care models. Historically, models that were commonly implemented were hospital restructuring and redesign and patient-focused care. Protocols and disease management represent continuing solutions. Accountable care organizations (ACOs)[11] have been proposed as a solution to enhance quality and lessen cost. An ACO can be broadly thought of as an emerging model in which a group of health care providers aligns and agrees together to try to meet quality and care targets and to receive payments as a collective entity, from which individual payments then can be disbursed. The ACO can benefit as a group from its success and can absorb losses as a group related to its failure to meet the targets.

Restructuring and redesign involved changing the basic organization of health care services in an attempt to do more with less, thereby increasing value. Approaches for restructuring have commonly included cross-training employees, using unlicensed assistive staff, and decentralizing services.[12] In one of these approaches, when respiratory therapy departments are decentralized and respiratory care management is eliminated, RTs are deployed to individual nursing units and report to nursing supervisors. When complete decentralization occurs, the responsibilities of equipment purchase and maintenance, continuing education, and quality improvement may be assigned to nursing personnel. Some experience suggests that nurses may be uncomfortable with these additional burdens,[13] so careful planning and stakeholder assessment is needed before decentralization could be implemented.

Although less commonly practiced, another aspect of restructuring and redesign is **cross-training** personnel and using assistive staff. Cross-training among professional health care workers can be attempted by teaching activities normally performed by a specific discipline but not restricted by licensing to personnel of another discipline. Nurses might cross-train RTs to perform phlebotomy, whereas RTs might cross-train nurses to perform metered dose inhaler (MDI) therapy. Although theoretically appealing, this strategy has fallen into disfavor because of the substantial associated challenges in implementation.

Cross-training assistive personnel involves on-the-job training of unlicensed personnel, who may not have an educational background in health care, to perform basic technical functions. These assistive personnel may learn to perform some nursing functions, such as taking vital signs, measuring intake and output, and inserting urinary catheters; laboratory technician activities, such as phlebotomy and simple urinalysis; and respiratory therapy activities, such as incentive spirometry follow-up and O_2 checks. The intent of using cross-trained assistive personnel, whose compensation is lower than that of licensed health care workers, is to enable an institution to reduce the number of nurses, laboratory technicians, and RTs they employ, thereby reducing costs. Although some aspects of hospital restructuring and redesign have been implemented and persist, others (e.g., cross-training and decentralization) have been abandoned.

SAFETY CONSIDERATIONS

Safety is a very important part of ensuring high-quality care. Importantly, patient safety must always be the first consideration in respiratory care. Although the RT usually does not have full control over the patient's environment, efforts must be made to minimize potential hazards associated with respiratory care. The key areas of potential risk for patients, RTs, and co-workers are patient movement and ambulation, electrical hazards, fire hazards, and general safety concerns. Each of these will be discussed as part of attention to providing high-quality, safe care.

Patient Movement and Ambulation

Basic Body Mechanics

Posture involves the relationship of the body parts to each other. A person needs good posture to reduce the risk for injury when lifting patients or heavy equipment. Poor posture may place inappropriate stress on joints and related muscles and tendons. Figure 3-8 illustrates the correct body mechanics for lifting a heavy object. The correct technique calls for a straight spine and use of the leg muscles to lift the object.

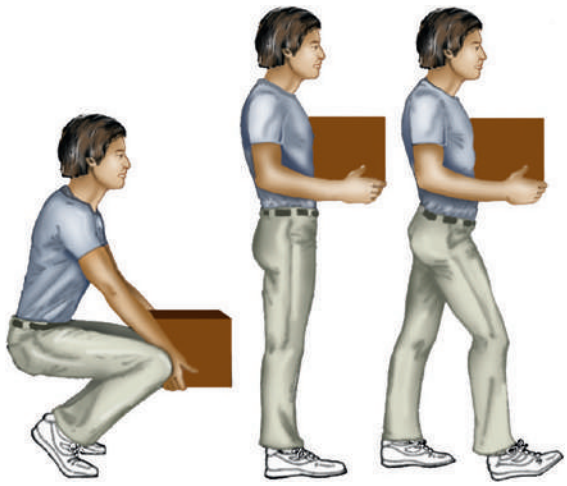

FIGURE 3-8 Body mechanics for lifting and carrying objects.

Moving the Patient in Bed

Conscious people assume positions that are the most comfortable. Bedridden patients with acute or chronic respiratory dysfunction often assume an upright position, with their arms flexed and their thorax leaning forward. This position helps decrease their work of breathing. In other cases, patients may have to assume certain positions for therapeutic reasons such as when postural drainage is applied.

Figure 3-9 shows the correct technique for lateral movement of a bed-bound patient. Figure 3-10 illustrates the ideal method for moving a conscious patient toward the head of a bed. Figure 3-11 shows the proper technique for assisting a patient to the bedside position for dangling his or her legs or transfer to a chair.

Ambulation

Ambulation (walking) helps maintain normal body function. Extended bed rest can cause numerous problems, including bed sores and atelectasis (low lung volumes). Ambulation should begin as soon as the patient is physiologically stable and free of severe pain. Ambulation has been shown to reduce the length of hospital stay after hip surgery and in patients recovering from community-acquired pneumonia.[13,14] RTs may assist to ambulate patients while they are on a mechanical ventilator or while on O_2. Safe patient movement includes the following steps:

1. Place the bed in a low position and lock its wheels.
2. Place all equipment (e.g., intravenous [IV] equipment, nasogastric tube, surgical drainage tubes) close to the patient to prevent dislodgment during ambulation.
3. Move the patient toward the nearest side of bed.
4. Assist the patient to sit up in bed (i.e., arm under nearest shoulder and one under farthest armpit).
5. Place one hand under the patient's farthest knee, and gradually rotate the patient so that his or her legs are dangling off the bed.
6. Let the patient remain in this position until dizziness or lightheadedness lessens (encouraging the patient to look forward rather than at the floor may help).

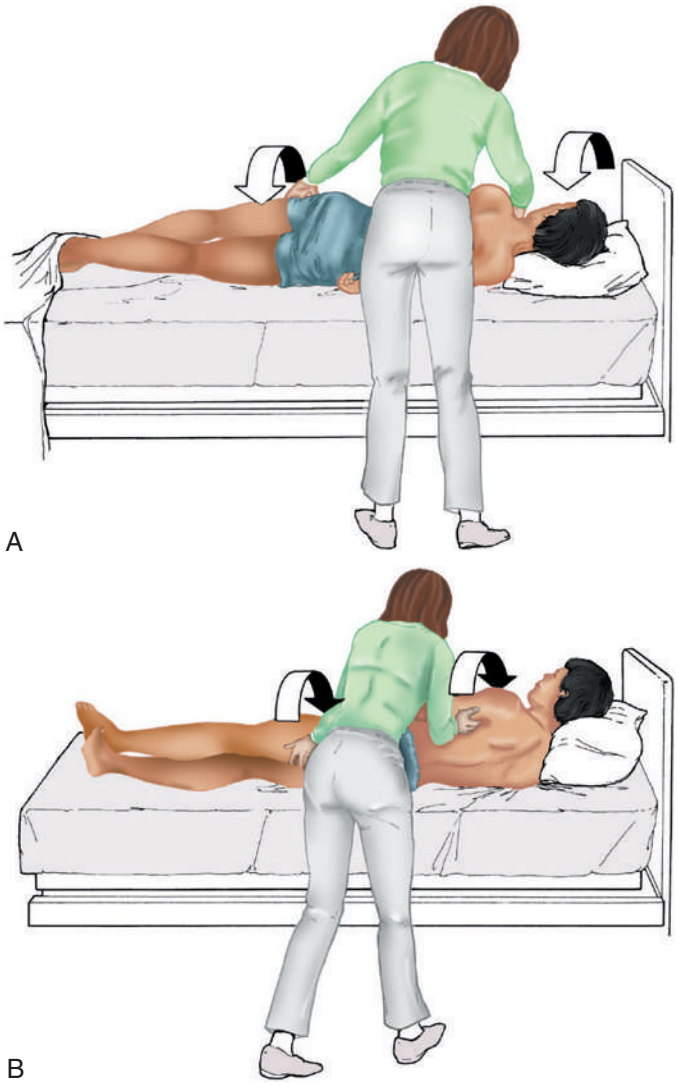

FIGURE 3-9 **A,** Method to pull a bed-bound patient. **B,** Method to push a bed-bound patient.

7. Assist the patient to a standing position.
8. Encourage the patient to breathe easily and unhurriedly during this initial change to a standing posture.
9. Walk with the patient using no, minimal, or moderate support (moderate support requires the assistance of two practitioners, one on each side of the patient).
10. Limit walking to 5 to 10 minutes for the first exercise.

Monitor the patient during ambulation. Note the patient's level of consciousness, color, breathing, strength or weakness, and complaints such as pain or shortness of breath throughout the activity. Ask the patient about his or her comfort level frequently during the ambulation period. Ensure that chairs are present so emergency seats are available if the patient becomes distressed. Ambulation is increased gradually until the patient is ready to be discharged. Each ambulation session is documented in the patient chart and includes the date and time of ambulation, length of ambulation, and degree of patient tolerance.

Electrical Safety

The potential for accidental shocks of patients or personnel in the hospital exists because of the frequent use of electrical equipment. The presence of invasive devices, such as internal catheters and pacemakers, may add to the risk for serious harm from electrical shock. Although this risk is present, it has been significantly reduced in recent years through a combination of education and more rigid standards for wiring, especially in patient care areas. RTs must understand the fundamentals of electrical safety because respiratory care often involves the use of electrical devices.

Fundamentals of Electricity

The ability of humans to create and harness electricity is one of the most important developments in modern times. Because controlled electricity is available on a 24-hour-a-day basis, we can depend on it to power the equipment and appliances that make modern life comfortable and productive. Despite the fact that electricity is one of the most popular sources of power, most people who use it have a poor understanding of it. This lack of knowledge is often a major factor in cases of electrocution.

MINI CLINI

"Tingling" Equipment

PROBLEM: An RT is caring for a patient on a mechanical ventilator that requires both electrical and pneumatic power for operation. When the RT touches the metal housing of the ventilator, a shock is felt. How should the RT handle the situation based on this observation?

DISCUSSION: All therapeutic instruments used in patient care, including mechanical ventilators, should be connected to grounded outlets (three-wire). Because the ground wire is a protection device only and not part of the main circuit, equipment may continue to operate without the clinician being aware that a problem exists. Because the RT felt a tingling sensation when touching the ventilator, this could represent an improper ground and possible serious current leakage. In this situation, the RT should immediately take the equipment out of service and get it replaced (while providing backup ventilation). All electrical equipment used in patient care should be routinely checked for appropriate grounding.

Electricity moves from point *A* to point *B* because of differences in voltage. **Voltage** is the power potential behind the electrical energy. Low-voltage batteries (e.g., 9 V) are sufficient to power a small flashlight but inadequate to power a major appliance such as a microwave oven. Most homes and hospitals are powered with 120-V power sources. Power sources that have high voltage have the potential to generate large amounts of electrical current. The current that moves through an object is directly related to the voltage difference between point *A* and

point *B* and inversely related to the resistance offered by the makeup of the object. Objects with low resistance (e.g., copper wires) allow maximum current to flow through the object. Objects with high resistance (e.g., rubber tubing) allow minimal or no current to flow through the object despite higher levels of voltage.

The simple analogy of water flowing through a piping system is useful to understand electricity. The water pressure level at the source is equivalent to the voltage. Higher water pressure provides the potential for greater water flow or current. The friction (**resistance**) offered by the pipe across the length of the pipe influences the flow exiting the other end. Pipes with lots of friction reduce the water flow (current) greatly. If the friction (resistance) is minimal, the water flow (current) is maximal. Similarly, when voltage is high and resistance is low, electrical current flows easily through the object.

The difference in resistance between two people or two objects explains why the same voltage applied to both can seriously damage one and cause no effect to the other. Two people accidentally touching a "hot" wire with 120 V can experience two completely different sensations. A person with wet skin offers little resistance, and the 120 V passes through the person with high current and can cause serious injury or death. A person with dry skin, which offers high resistance, may not even feel a shock and experiences no injury. The degree of resistance offered by the skin varies from person to person based on the chemistry of the person's skin, the cleanliness of the skin, and the amount of moisture on the surface. For this reason, it is never wise to touch a potentially hot wire even though your skin is dry.

As stated before, voltage is the energy potential from an electrical source, and it is measured with a voltmeter. **Current** is the flow of electricity from a point of higher voltage to one of lower voltage and is reported in **amperes** (amps). Current is measured with an ampmeter. The resistance to electrical current is reported in **ohms**. We can determine the resistance to current for any object by the following equation:

$$\text{Resistance (ohms [}\Omega\text{])} = \text{Voltage (V)}/\text{Current (amps [A])}$$

Current represents the greatest danger to you or your patients when electrical shorts occur. Voltage and resistance are important only because they determine how much current potentially can pass through the body. High voltage provides greater potential for high currents, but if resistance is also very high, current would be minimal or nonexistent. Current represents the potential danger to the patient. The harmful effects of current depend on: (1) the amount of current flowing through the body, (2) the path it takes, and (3) the duration the current is applied. Higher currents (>100 milliamps [mA]) that pass through the chest can cause ventricular fibrillation, diaphragm dysfunction (owing to severe, persistent contraction), and death.

Because current is most important, you should be familiar with the equation used to calculate it:

$$\text{Current (A)} = \text{Voltage (V)}/\text{Resistance (}\Omega\text{)}$$

For example, as long as a person is insulated by normal clothing and shoes and is in a dry environment, a 120-V shock may hardly be felt because the resistance is high in this situation (10,000 Ω). Current can be calculated as:

$$\text{Current (A)} = 120\text{ V}/10{,}000\,\Omega = 0.012\text{ A or }12\text{ mA}$$

Currents of 12 mA would cause a tingling sensation but no physical damage.

However, if the same person is standing without shoes on a wet floor, a much higher current occurs because the resistance is much lower (1000 Ω). The current is then calculated as:

$$\text{Current (A)} = 120\text{ V}/1000\,\Omega = 0.12\text{ A or }120\text{ mA}$$

Because the heart is susceptible to any current level greater than 100 mA, 120 mA represents a potentially fatal shock; this is in sharp contrast to the first example, in which the same voltage caused only a tingling sensation.

A shock hazard exists only if the electrical "circuit" through the body is complete, meaning that two electrical connections to the body are required for a shock to occur. In the previous example, the person standing in water with no shoes has "grounded" himself. The finger touching the hot wire provides the input source while the feet standing in water provide the exit to ground. If the same person is wearing rubber boots, the connection to ground does not exist and the current cannot flow through the individual.

In electrical devices, these two connections typically consist of a "hot" wire and a "neutral" wire. The neutral wire completes the circuit by taking the electrical current to a ground. A **ground** is simply a low-resistance pathway to a point of zero voltage, such as the earth (hence the term *ground*).

Figure 3-12 shows how current can flow through the body. In this case, a piece of electrical equipment is connected to an AC line power via a standard three-prong plug. However, unknown to the practitioner, the cord has a broken ground wire. Normally, current leakage from the equipment would flow back to the ground through the ground wire. However, this pathway is unavailable. Instead, the leakage current finds a path of low resistance through the practitioner to the damp floor (an ideal ground).

Current can readily flow into the body, causing damage to vital organs when the skin is bypassed via conductors such as pacemaker wires or saline-filled intravascular catheters (Figures 3-13 and 3-14). Even urinary catheters can provide a path for current flow. The heart is particularly sensitive to electrical shock. Ventricular fibrillation can occur when currents of 20 μA (20 microamperes, or 20 millionths of 1 ampere) are applied directly to the heart.

Electrical shocks are classified into two types: macroshock and microshock. A **macroshock** exists when a high current (usually >1 mA) is applied externally to the skin. A **microshock** exists when a small, usually imperceptible current (<1 mA) bypasses the skin and follows a direct, low-resistance path into the body. Patients susceptible to microshock hazards are termed *electrically sensitive* or *electrically susceptible*. Table 3-1 summarizes the different effects of these two types of electrical shock.

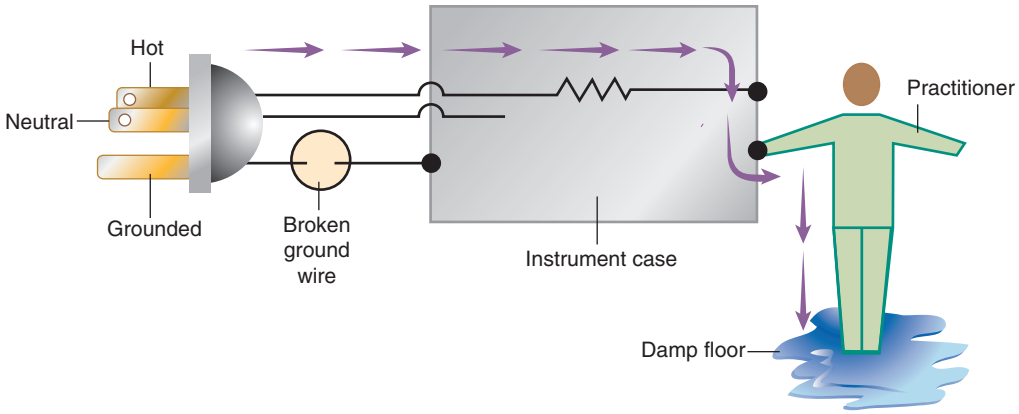

FIGURE 3-12 Hazard created by broken ground wire.

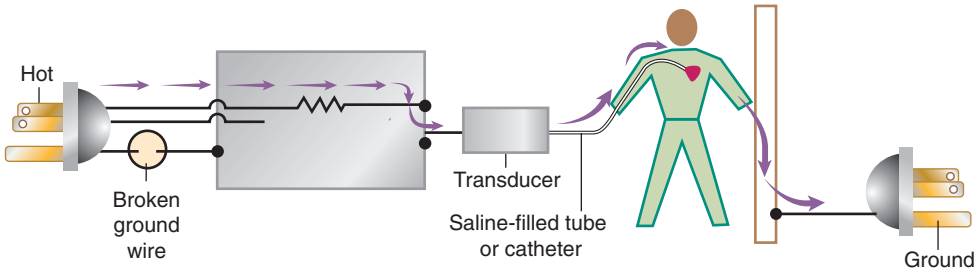

FIGURE 3-13 Possible microshock hazard caused by patient grounding.

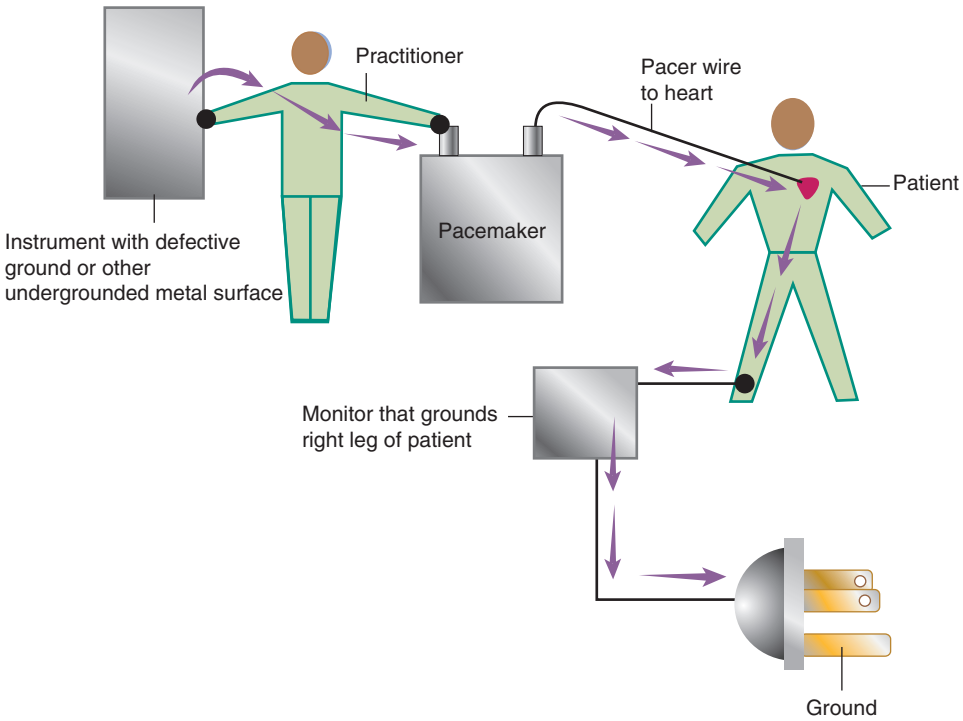

FIGURE 3-14 Possible hazard through use of certain cardiac monitors and a pacemaker.

TABLE 3-1

Effects of Electrical Shock*

Amperes (A)	Milliamperes (mA)	Microamperes (μA)	Effects
Applied to Skin (Macroshock)			
≥6	>6000	>6,000,000	Sustained myocardial contraction followed by normal rhythm; temporary respiratory paralysis; burns, if small area of contact
0.1-3	100-3000	100,000	Ventricular fibrillation; respiratory center intact
0.050	50	50,000	Pain; fainting; exhaustion; mechanical injury; heart and respiratory function intact
0.016	16	16,000	"Let go" current; muscle contraction
0.001	1	1000	Threshold of perception; tingling
Applied to Myocardium (Microshock)			
0.001	0.1	100	Ventricular fibrillation

Duration of exposure and current pathway are major determinants of human response to electrical shock.
*Physiologic effects of AC shocks applied for 1 second to the trunk or directly to the myocardium.

Preventing Shock Hazards

Most shock hazards are caused by inappropriate or inadequate grounding. Shock hazards can be eliminated or minimized if wiring in patient care areas is appropriate and if all equipment brought into the patient care area has been Underwriters Laboratories (UL) approved and checked on a regular basis by a qualified person.

Ground Electrical Equipment Near the Patient

All electrical equipment (e.g., lights, electrical beds, ventilators, monitoring or therapeutic equipment) should be connected to grounded outlets with three-wire cords. In these cases, the third (ground) wire prevents the dangerous buildup of voltage that can occur on the metal frames of some electrical equipment.

Modern electrical devices used in hospitals are designed so their frames are grounded, but their connections to the patient are not. In this manner, all electrical devices in reach of the patient are grounded, but the patient remains isolated from ground. Because the ground wire is simply a protection device and not part of the main circuit, equipment continues to operate normally even if the ground wire is broken. All electrical equipment, particularly devices used with electrically susceptible patients, must be checked for appropriate grounding on a regular basis by a qualified electrical expert.

Fire Hazards

In 1980, approximately 12,000 health care facility fires were officially reported in the United States.[15] During the period of 2006 to 2010, the average annual number of fires in health care facilities was 6240.[14] These health care facilities include hospitals, hospice facilities, nursing homes, mental health facilities, and doctors' offices or clinics. This significant reduction in health care facility fires is primarily due to education and enforcement of strict fire codes.

Approximately 23% of fires in health care facilities occur in hospitals or hospice, and 46% occur in nursing homes; the most common site of origin of the fire is the kitchen.[15] Medical facility fires cause an annual average of 6 civilian deaths, 171 civilian injuries, and approximately $52.1 million in damage.[15]

Hospital fires can be very serious, especially when they occur in patient care areas and when supplemental O_2 is in use. Fires in O_2-enriched atmospheres (OEAs) are larger, more intense, faster burning, and more difficult to extinguish. In addition, some material that would not burn in room air would burn in O_2-enriched air. Hospital fires are also more serious because evacuation of critically ill patients is difficult and slow. For these reasons, hospital fires often cause more injuries and deaths per fire than do residential fires. For a fire to start, three conditions must exist: (1) flammable material must be present, (2) O_2 must be present, and (3) the flammable material must be heated to or above its ignition temperature. When all three conditions are present, a fire starts. Conversely, removing any one of the conditions can stop a fire from starting or extinguish it after it has begun. Fire is a serious hazard around respiratory care patients using supplemental O_2. Although O_2 is nonflammable, it greatly accelerates the rate of combustion. Burning speed increases with an increase in either the concentration or the partial pressure of O_2.

Flammable material should be removed from the vicinity of O_2 use to minimize fire hazards. Flammable materials include cotton, wool, polyester fabrics, bed clothing, paper materials, plastics, and certain lotions or salves such as petroleum jelly. Removal of flammable material is particularly important whenever O_2 enclosures, such as O_2 tents or croupettes, are used.

Ignition sources, such as cigarette lighters, should not be allowed in rooms where O_2 is in use. In addition, the use of electrical equipment capable of generating high-energy sparks, such as exposed switches, must be avoided. All appliances that transmit house current should be kept out of O_2 enclosures. Children should not play with toys that may create a spark when O_2 is in use. RTs must be diligent in educating patients and visitors about the dangers associated with spark-producing items, open flames, and burning cigarettes in the hospital environment, especially in areas with O_2-enriched air.

A frequent source of concern is the presence of static electrical sparks generated by friction. Even in the presence of high O_2 concentrations, the overall hazard from static sparks with the materials in common use is very low. Solitary static sparks

generally do not have sufficient heat energy to raise common materials to their flash points. The minimal risk that may be present can be reduced further by maintaining high relative humidity (>60%).

If you identify a fire in a patient care area, you must know what to do. Each hospital must have a core fire plan that identifies the responsibilities of hospital personnel. The plan should be taught to all hospital personnel and practiced with fire drills to reinforce the education. Requirements may include routinely walking the fire exits and reviewing proper fire extinguisher training. Fire extinguisher training includes following the acronym PASS:

*P*ull the pin. There may be an inspection tag attached.
*A*im the nozzle. Aim low at the bottom of the fire.
*S*queeze the handle. The extinguisher has less than 30 seconds of spray time.
*S*weep the nozzle across the base of the fire.

The core fire plan follows the acronym *RACE:*

*R*escue patients in the immediate area of the fire. The person discovering the fire should perform the rescue.
*A*lert other personnel about the fire so they can assist in the rescue and can relay the location of the fire to officials. This step also involves pulling the fire alarm.
*C*ontain the fire. After rescuing patients, shut doors to prevent the spread of the fire and the smoke. In patient care areas, follow your hospital policy regarding turning off O_2 zone valves.
*E*vacuate other patients and personnel in the areas around the fire who may be in danger if the fire spreads.

RTs are frequently key participants in successful handling of hospital fires. First, they know where the O_2 zone valves are located and how to shut them off. Second, they have the knowledge and skills needed to evacuate patients receiving mechanical ventilation or supplemental O_2 to sustain life. Third, they know how to treat and resuscitate victims of smoke inhalation. For these reasons, RTs should be included in all hospital evacuation planning and practices.

General Safety Concerns

In addition to electrical and fire safety, RTs need to be aware of general safety concerns, including the direct patient environment, disaster preparedness, magnetic resonance imaging (MRI) safety, and medical gas safety. Medical gas safety is discussed in more detail in Chapter 40.

Direct Patient Environment

The immediate environment around the patient can create risk for patient safety. Because RTs use medical equipment and participate in direct patient care, it is necessary for RTs to be cognizant of the patient's immediate environment.

To reduce the risk for patient falls and allow easy access to care, the patient care environment should be as free of impediments to care as possible. Use of respiratory supplies and medical equipment by the RT creates an environment that could impede access to care and create a fall risk. It is the responsibility of the RT to position equipment, tubing, and treatments in a way that does not impede access to care and that reduces risk for falls. In addition, when care is completed, the RT should ensure that the patient has easy access to the patient call system.

Disaster Preparedness

A key component of disaster preparedness involves learning to transport and transfer critically ill patients safely. Another component includes preparing for a loss of electricity, whether it is due to an internal or external disaster. In these emergencies, hospitals have backup generators to power essential equipment. All electrical outlets may not function on the backup generator. Some hospitals designate emergency outlets with a red outlet or red dot on an outlet, whereas others may power an entire wing, such as a medical intensive care unit, with the backup generator power. It is important for the RT to know the specific hospital policy for power failures and other potential disasters.

Magnetic Resonance Imaging Safety

MRI exposes the body to powerful magnetic fields and a small amount of radiofrequency. This powerful magnetic field can create a risk to patients, health care workers, and equipment if metal objects are brought within specified proximity to the field. There are safe proximity areas referred to as *safety zones* or *Gauss lines*. Metal objects can be so forcefully attracted to the magnetic field that they can mimic a missile, causing physical harm. Reports of accidents associated with MRI have involved O_2 cylinders, stethoscopes, scissors, and IV poles. Deaths have been described when O_2 cylinders were pulled into the magnetic area where a patient was lying to undergo an MRI examination. RTs need to become familiar with MRI-compatible ventilators, O_2 supplies, and ancillary equipment. Each radiology department has specific rules and safety precautions that need to be communicated to all patients, caregivers, and health care personnel.

Medical Gas Cylinders

Use of compressed gas cylinders by RTs requires special handling. The physical hazards resulting from improper storage or handling of cylinders include increased risk for fire, explosive release of high-pressure cylinders, and the toxic effect of some gases. It is important to store and transport cylinders in appropriate racks or chained containers. Compressed gas cylinders should never be stored without support.

Storage of medical-grade gases is regulated by National Fire Protection Association Standards 99 Healthcare Facilities Code (2014 edition) and monitored by TJC. Quantities of O_2 or nitrous oxide of 300 cubic feet or less (about 12 E-cylinders) in a patient care area not to exceed 2100 m^2 are required to be secured properly but do not have special storage room requirements.[16] Storing 300 to 3000 cubic feet of O_2 or N_2O requires noncombustible or limited combustible storage rooms with self-closing doors and at least a 30-minute fire rating.[16] Cylinders must be stored 20 feet from any combustibles (5 feet if room is equipped with a sprinkler system).[16] Follow your

hospital policies and procedures when handling, transporting, or storing medical gas cylinders.

COMMUNICATION

Because the delivery of safe, high-quality health care requires interactions among many contributors from different disciplines (e.g., physicians, RTs, nurses, etc.), communication is essential to the quality mission of a health care organization. Strategies to enhance communication are critical to organizational success.

Communication is a dynamic human process involving sharing of information, meanings, and rules. Communication has five basic components: sender, message, channel, receiver, and feedback (Figure 3-15).

The sender is the individual or group who transmits the message. The message is the information or attitude that is communicated by the sender. Messages may be verbal or nonverbal. Verbal messages are voiced or written. Examples of different kinds of messages are lectures, letters, and e-mail memos. Nonverbal communication is any communication that is not voiced or written. Nonverbal communication includes gestures, facial expressions, eye movements and contact, voice tone, space, and touch.

The **channel** of communication is the method used to transmit messages. The most common channels involve sight and hearing, such as written and oral messages. However, other sensory input, such as touch, may be used with visual or **auditory** communication. In addition, communication channels may be formal (memos or letters) or informal (conversation).

The receiver is the target of the communication and can be an individual or a group. One-on-one communication is often more effective because both parties can respond to each other. Communication with a group can be more challenging but is a more efficient way to get information to numerous individuals.

The last essential part of communication is **feedback**. Human communication is a two-way process in which the receiver serves an active role. Feedback from the receiver allows the sender to measure communication success and provide additional information when needed.

Communication in Health Care

Effective communication is the most important aspect of providing safe patient care. The first two 2010 National Patient Safety Goals of TJC are to improve accuracy of patient identification and effectiveness of communicating critical test values among caregivers.[17] All health care personnel must correctly identify patients before initiating care using a two–patient identifier system. The patient identifiers can include any two of the following: name, birth date, and medical record number. Effectively communicating critical test values should include a "read back" scenario verifying the reporter and the receiver of the information and accurate reporting and recording of test values. Each institution may have specific values as critical test values; for example, RTs may be expected to report blood gas values of a pH less than 7.2 or a PaO_2 less than 50 mm Hg. The process of the read back scenario is described in Box 3-4.

Box 3-4 "Read Back" Process to Ensure Accurate Communication of Information

PRESCRIBER/REPORTER

- Orders or critical test results are read and clearly enunciated, using two patient identifiers.
- Avoid abbreviations.
- Ask receiver to "read back" the information if this is not done voluntarily.
- Verify with the receiver that the information is correct.

RECEIVER

- Record the order or value.
- Ask "prescriber/reporter" to repeat if information is not understood.
- "Read back" the information, including two patient identifiers.
- Receive confirmation from the "prescriber/reporter" that the information is correct; if incorrect, repeat the process.

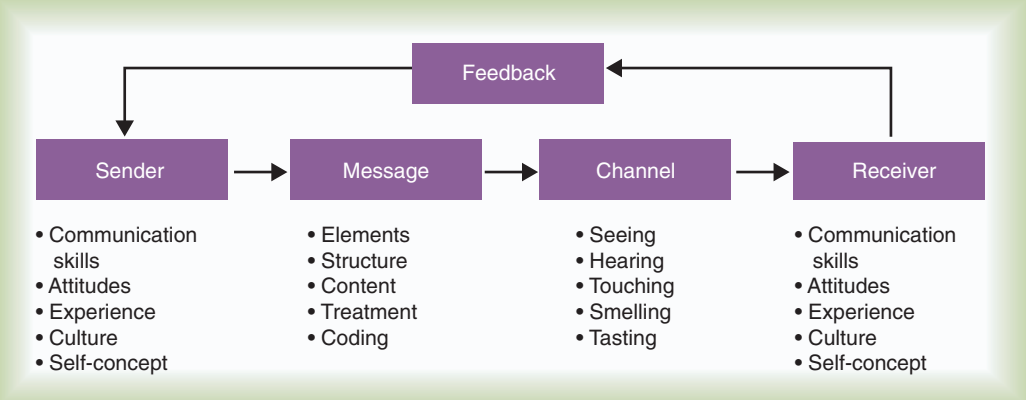

FIGURE 3-15 Elements of human communication. (See text on pp. 49 to 50.)

Another setting for improving communication between RTs regards transitions of care or "hand-off" of care; that is, when one RT is telling a colleague about the care of a patient who will be passed to the incoming RT for care. An effective communication tool in this instance may be an SBAR (*S*ituation, *B*ackground, *A*ssessment, and *R*ecommendation).[18] An example of this would be an RT discussing a patient's intolerance to noninvasive ventilation. The *situation* is the patient is prescribed noninvasive ventilation but is not tolerating the device. The *background* is the patient has COPD and was admitted with a high $PaCO_2$ and would benefit from the noninvasive ventilation. The *assessment* is the patient feels "claustrophobic" in the current full-face mask. Finally, the *recommendation* would be to try a smaller, less-confining mask to improve patient comfort.

As an RT, you will have many opportunities to communicate with patients, other RTs, nurses, physicians, and other members of the health care team. Success as an RT depends on your ability to communicate with these key people. Poor communication skills can limit your ability to treat patients, work well with others, and find satisfaction in your employment.

Factors Affecting Communication

Many factors affect communication in the health care setting (Figure 3-16). The uniquely human or "internal" qualities of sender and receiver (including their prior experiences, attitudes, values, cultural backgrounds, and self-concepts and feelings) play a large role in the communication process.

Generally, the verbal and nonverbal components of communication should enhance and reinforce each other. Other factors that can affect communication include the patient's direct health care environment and their sensory or emotional state. The RT who considers all of these factors will become a better communicator. One example of this would the RT who combines a compassionate-toned verbal message such as, "You're going to be all right now," with a confirming touch of the hand is sending a much stronger message to an anxious patient than the message provided by either component alone. Several key purposes of communication are summarized in Box 3-5.

Improving Communication Skills

To enhance your ability to communicate effectively, focus on improving sending, receiving, and feedback skills. In addition, identify and overcome common barriers to effective communication.

Box 3-5 Purposes of Communication in the Health Care Setting

- To establish rapport with another individual, such as a colleague, a patient, or a member of the patient's family
- To comfort an anxious patient by explaining the unknown
- To obtain information, such as during a patient interview
- To relay pertinent information, as when charting the results of a patient's treatment
- To give instructions, as when teaching a patient how to perform a lung function test
- To persuade others to take action, as when attempting to convince a patient to quit smoking
- To educate and confirm understanding as in a "teach back" scenario

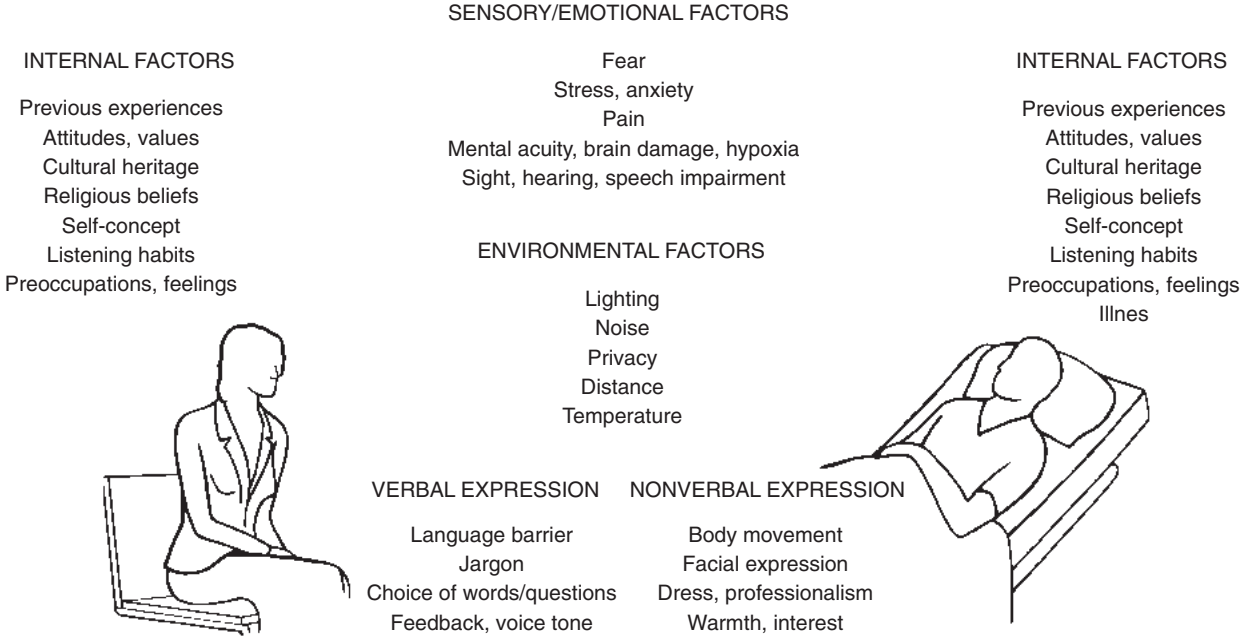

FIGURE 3-16 Factors influencing communication. (Modified from Wilkins RL, Sheldon RL, Krider SJ: Clinical assessment in respiratory care, ed 6, St. Louis, 2010, Mosby.)

MINI CLINI

Patient Communication

PROBLEM: A 73-year-old man with COPD is admitted to the emergency department for acute shortness of breath that is not relieved with rest. The patient has been admitted more than eight times during the past year for various respiratory problems. The patient's physician thinks that this episode may reflect a worsening of his disease process and orders an inhaled bronchodilator via an MDI. After the RT enters the room and introduces herself, the patient becomes quite defensive, stating that he does not need any assistance with treatments and that she should just leave the medication in the room. The RT has not treated the patient in the past and has to decide how to respond to the patient's request.

DISCUSSION: Although this patient exhibited reluctance in allowing the RT to administer the therapy, enough verbal and perhaps nonverbal communication (message) was expressed by the patient (sender) for the RT (receiver) to determine a plan of action. Because human communication is a two-way process, the RT serves an active role for further messages and interaction. This is a key concept for RTs to master because it helps in identifying a patient's problems, evaluating progress, and recommending further respiratory care. The RT must recognize that when an individual verbalizes disagreement with a treatment order and exhibits defensive behavior, the RT must attempt to understand what the patient is saying and must not overreact. The RT could try to put the patient at ease by making eye contact, gesturing effectively, and maintaining a safe distance from the patient when talking. The RT should seek feedback from the patient to ensure that the message was understood as it was intended. In this situation, it may be appropriate for the RT to review and demonstrate MDI use, ask the patient to "teach back" proper inhaler use, and observe the patient self-administer the medication. This process (message) can be repeated until the patient can demonstrate proper technique. Allowing the patient to participate actively in medical care when feasible may serve to help him maintain a sense of control over his disease process.

Practitioner as Sender

Your effectiveness as a sender of messages can be improved in several ways. These suggestions may be applied to the clinical setting as follows:

- *Share information rather than telling.* Health professionals often provide information in an authoritative manner by telling colleagues or patients what to do or say. This approach can cause defensiveness and lead to uncooperative behavior. Conversely, sharing information creates an atmosphere of cooperation and trust.
- *Seek to relate to people rather than control them.* This is of particular significance during communication with patients. Health care professionals often attempt to control patients. Few people like to be controlled. Patients feel much more important if they are treated as an equal partner in the relationship. Explaining procedures to patients and asking their permission to proceed is a way to make them feel a part of the decision making regarding their care.
- *Value disagreement as much as agreement.* When individuals express disagreement, make an attempt to understand what they are saying and do not become defensive. Be prepared for disagreement and be open to the input of others.
- *Use effective nonverbal communication techniques.* The nonverbal communication that you use is just as important as what you say. Nonverbal techniques may include eye contact, effective gesturing, facial expressions, and voice tone. It is important that your nonverbal communication matches what you are saying. It is also important to be cognizant of cultural differences in nonverbal contact. Some cultures may view direct eye contact as inappropriate, whereas in our country most find it an effective communication tool.

Practitioner as Receiver and Listener

Receiver skills are just as important as sender skills. Messages sent are of no value unless they are received as intended. Active listening on the part of the receiver is required. Learning to listen requires a strong commitment and great effort. A few simple principles can help improve your listening skills, as follows:

- *Work at listening.* Listening is often a difficult process. It takes effort to hear what others are saying. Focus your attention on the speaker and on the message.
- *Stop talking.* Practice silent listening and avoid interrupting the speaker during an interaction. Interrupting the patient is a sure way to diminish effective communication.
- *Resist distractions.* It is easy to be distracted by surrounding noises and conversations. This is particularly true in a busy environment such as a hospital. When you are listening, try to tune out other distractions and give your full attention to the person who is speaking.
- *Keep your mind open; be objective.* Being open-minded is often difficult. All people have their own opinions that may influence what they hear. Try to be objective in your listening so that you treat everyone fairly.
- *Hear the speaker out before making an evaluation.* Do not just listen to the first few words of the speaker. This is a common mistake made by listeners. Often, listeners hear the first sentence and tune out the rest, assuming they know what is being said. It is important to listen to the entire message; otherwise, you may miss important information.
- *Maintain composure; control emotions.* Allowing emotions, such as anger or anxiety, to distort your understanding or drawing conclusions before a speaker completes his or her thoughts or arguments is a common error in listening.

- Active listening is a key component in health care communication. Many of the messages being sent are vital to patient care. If you do not listen effectively, important information may be lost and the care of your patients may be jeopardized.

Providing Feedback

To enhance communication with others, effective feedback needs to be provided. Examples of effective feedback mechanisms in oral communication with patients include attending, paraphrasing, requesting clarification, perception checking, and reflecting feelings:

- *Attending*. **Attending** involves the use of gestures and posture that communicates one's attentiveness. Attending also involves confirming remarks, such as, "I see what you mean."
- *Paraphrasing*. Paraphrasing, or repeating the other's response in one's own words, is a technique that is useful in confirming that understanding is occurring between the parties involved in the interaction. However, overuse of paraphrasing can be irritating.
- *Requesting clarification.* Requesting clarification begins with an admission of misunderstanding on the part of the listener, with the intent being to understand the message better through restating or using alternative examples or illustrations. Overuse of this technique, as with paraphrasing, can hamper effective communication, especially if it is used in a condescending or patronizing manner. Requests for clarification should be used only when truly necessary and always should be nonjudgmental in nature.
- *Perception checking.* Perception checking involves confirming or disproving the more subtle components of a communication interaction, such as messages that are implied but not stated. For example, the RT might sense that a patient is unsure of the need for a treatment. In this case, the RT might check this perception by saying, "You don't seem to be sure that you need this treatment. Is that correct?" By verifying or disproving this perception, both the health care professional and the patient understand each other better.
- *Reflecting feelings.* Reflecting feelings involves the use of statements to determine better the emotions of the other party. Nonjudgmental statements, such as, "You seem to be anxious about (this situation)," provide the opportunity for patients to express and reflect on their emotions and can help them confirm or deny their true feelings.

Minimizing Barriers to Communication

There are many potential barriers to effective communication. A skillful communicator tries to identify and eliminate or minimize the influence of these barriers in all interactions. By minimizing the influence of these barriers, the sender can help ensure that the message will be received as intended. Key barriers to effective communication are the following:

- *Use of symbols or words that have different meanings.* Words and symbols (including nonverbal communication) can mean different things to different people. These differences in meaning derive from differences in the background or culture between the sender and receiver and the context of the communication. For example, RTs often use the letters COPD to refer to patients with chronic obstructive pulmonary disease caused by long-term smoking. Patients may hear COPD used in reference to them and be confused about the meaning and interpret COPD to mean a fatal lung disease. Never assume that the patient has the same understanding as you in the interpretation of commonly used symbols or phrases.
- *Different value systems.* Everyone has his or her own value system, and many people do not recognize the values held by others. A large difference among the values held by individuals can interfere with communication. A clinical supervisor may inform students of the penalties for being late with clinical assignments. If a student does not value timeliness, he or she may not take seriously what is being said.
- *Emphasis on status.* A hierarchy of positions and power exists in most health care organizations. If superiority is emphasized by individuals of higher status, communication can be stifled. Everyone has experienced interactions with professionals who make it clear who is in charge. Emphasis on status can be a barrier to communication not only among health care professionals but also between health care professionals and patients.
- *Conflict of interest.* Many people are affected by decisions made in health care organizations. If people are afraid that a decision will take away their advantage or invade their territory, they may try to block communication. An example might be a staff member who is unwilling to share expertise with students. This person may feel that a student is invading his or her territory.
- *Lack of acceptance of differences in points of view, feelings, values, or purposes.* Most of us are aware that people have different opinions, feelings, and values. These differences can thwart effective communication. To overcome this barrier, an effective communicator allows others to express their differences. Encouraging individuals to communicate their feelings and points of view benefits everyone. Most of us think we are always correct. Accepting input from others promotes growth and cooperation.
- *Feelings of personal insecurity.* It is difficult for people to admit feelings of inadequacy. Individuals who are insecure do not offer information for fear they appear ignorant or they may be defensive when criticized, blocking clear communication. Many of us have worked with individuals who are insecure, realizing the difficulty in communicating with them.

To become an effective communicator, identify the purpose of each communication interaction and your role in it. Use specific sending, receiving, and feedback skills in each interaction. Finally, minimize any identified barriers to communication with patients or peers, to ensure that messages are received as intended.

CONFLICT AND CONFLICT RESOLUTION

Conflict is sharp disagreement or opposition among people over interests, ideas, or values. Because no two people are exactly alike in their backgrounds or attitudes, conflict can be found in every organization. Health care professionals experience a great deal of conflict in their jobs. Rapid changes occurring in health care have made everyone's jobs more complex and often more stressful. Because conflict is inevitable, all health care professionals must be able to recognize its sources and help resolve or manage its effect on people and on the organization.

Sources of Conflict

The first step in conflict management is to identify its potential sources. The four primary sources of conflict in organizations are (1) poor communication, (2) structural problems, (3) personal behavior, and (4) role conflict.

Poor Communication

Poor communication is the primary source of conflict in organizations. The previously discussed barriers to communication all are potential sources of conflict. If a supervisor is unwilling to accept different points of view for dealing with a difficult patient, an argument may occur. The importance of good communication cannot be overemphasized.

Structural Problems

The structure of the organization itself can increase the likelihood of conflict. Conflict tends to grow as the size of an organization increases. Conflict is also greater in organizations whose employees are given less control over their work and in organizations in which certain individuals or groups have excessive power. Structural sources of conflict are the most rigid and are often difficult to control.

Personal Behavior

Personal behavior factors are a major source of conflict in organizations. Different personalities, attitudes, and behavioral traits create the possibility of great disagreement among health care professionals and between health care professionals and patients.

Role Conflict

Role conflict is the experience of being pulled in several directions by individuals who have different expectations of a person's job functions. A clinical supervisor is often expected to function both as a staff member and as a student supervisor. Trying to fill both roles simultaneously can cause stress and create interpersonal conflict.

Conflict Resolution

Conflict resolution or management is the process by which people control and channel disagreements within an organization. The following are five basic strategies for handling conflict:

1. Competing
2. Accommodating
3. Avoiding
4. Collaborating
5. Compromising

Competing

Competing is an assertive and uncooperative conflict resolution strategy. Competing is a power-oriented method of resolving conflict. A supervisor who uses rank or other forces to attempt to win is using the competing strategy. This strategy may be useful when an unpopular decision must be made or when one must stand up for his or her rights. However, because it often causes others to be quiet and feel inferior, competing should be used cautiously.

Accommodating

Accommodating is the opposite of competing. Accommodating is being unassertive and cooperative. When people accommodate others involved in conflict, they neglect their own needs to meet the needs of the other party. Accommodation is a useful strategy when it is essential to maintain harmony in the environment. Accommodation is also appropriate when an issue is much more important to one party or the other in a dispute.

Avoiding

Avoiding is both an unassertive and an uncooperative conflict resolution strategy. In avoiding conflict, one or both parties decide not to pursue their concerns. Avoidance may be appropriate if there is no possibility of meeting one's goals. In addition, if one or both of the parties are hostile, avoidance may be a good strategy, at least initially. However, too much avoidance can leave important issues unattended or unresolved.

Collaborating

As a conflict resolution strategy, collaborating is the opposite of avoiding. Collaborating is assertive and cooperative. In collaboration, the involved parties try to find mutually satisfying solutions to their conflict. Collaboration usually takes more time than other methods of conflict management and cannot be applied when the involved parties harbor strong negative feelings about each other.

Compromising

Compromising is a middle-ground strategy that combines assertiveness and cooperation. People who compromise give up more than individuals who compete but give up less than individuals who accommodate. Compromise is best used when a quick resolution is needed that both parties can accept. However, because both parties often feel they are losing, compromise should not be used exclusively.

Deciding which type of conflict resolution strategy to use requires knowledge of the context, the specific underlying problem, and the desires of the involved parties.

RECORDKEEPING

By 2015, the U.S. government would like all medical recordkeeping to be done electronically. The electronic medical record (EMR) is changing the way health care practitioners document care, but the overall content and concept of what we record remains the same (see Chapter 7 for a full discussion of the EMR). A medical record or chart presents a written picture of occurrences and situations pertaining to a patient throughout his or her stay in a health care institution. Medical records are the property of the institution and are strictly confidential. This information is protected under the *Health Insurance Portability and Accountability Act* (HIPAA) of 1996. The content of a patient's medical records, health insurance, or billing are not to be read or discussed by anyone except for the individuals directly caring for the patient in a hospital or medical care facility. In addition, the medical record is a legal document.

MINI CLINI

Legal Aspects of Recordkeeping

PROBLEM: A patient was given a respiratory treatment by a respiratory care student, who forgot to chart that the therapy was given. The student reasoned that because he did not observe any adverse effects during or immediately after the treatment and he knew that the treatment was given, not documenting the treatment in the medical record this one time would be acceptable. What are the problems associated with this student's judgment and subsequent actions?

DISCUSSION: The medical record is a legal document intended to identify types of care given to a patient and serve as a source of information to the physician, RT (including the student), and other health care providers in developing an individualized plan of care. It further serves as a tool for evaluating the effectiveness in reaching the goals of therapy. Hospitals and other health care agencies critically evaluate the medical records of patients to maintain high-quality patient care. Failure to document care rendered, such as a respiratory treatment, hinders the process of providing high-quality care in several ways.

First, information that is important to the physician and other caregivers interested in the patient's respiratory status is missing from the medical record. In this situation, although the student observed a lack of response by the patient during and immediately after the treatment, a delayed effect still could have occurred. Consequently, the physician or RT would have difficulty in establishing the cause of a condition change in the patient related to the respiratory treatment. From a legal perspective, patient care not documented may be viewed as care not rendered, making the hospital or institution vulnerable to charges of patient neglect, which would be difficult to defend in a court of law.

Because the law requires that a record be kept of the patient's care, a patient's chart is also a legal document. For this reason, charting or recordkeeping must be done so that it is meaningful for days, months, or years.

Components of a Traditional Medical Record

Each health care facility has its own specification for the medical records it keeps. Although the forms themselves vary among institutions, most acute care medical records share common sections (Box 3-6). Documentation sheets are designed to report data briefly and to decrease time spent in documentation. Entries can include many measurements, and review of a sequence of entries can reveal trends in patient status.

Legal Aspects of Recordkeeping

Legally, documentation of the care given to a patient means that care was given; no documentation means that care was not given. Hospital accreditation agencies critically evaluate the medical records of patients. If the RT does not document care given (i.e., patient assessment data, interventions, and evaluation of care rendered), the practitioner and the hospital may be accused of patient neglect.

Adequate documentation of care is valuable only in reference to standards and criteria of care. Similar to all departments in health care facilities, respiratory care departments must generate their own standards of patient care. For each standard, criteria must be outlined so that the adequacy of patient care can be measured. Documentation must reflect these standards.

Practical Aspects of Recordkeeping

Recordkeeping is one of the most significant duties that a health care professional performs. Documentation is required for each medication, treatment, or procedure. Accounts of the patient's condition and activities must be charted accurately and in clear terms. Brevity is essential, although a complete account of each patient encounter is needed. The use of standardized terms and abbreviations is acceptable; however, TJC had published a "Do Not Use" abbreviation list developed to reduce potential errors (Table 3-2).[19] Documentation of consultations with the attending physician that include the date and time of the conversation is recommended.

Accounts of care and the patient's condition can be handwritten, but with increasing frequency, EMRs facilitate data entry by selection from menus of choices or direct typing (see section on EMR in Chapter 7). In either case, you must document only what is—not an interpretation or a judgment. Assessments of data must be clearly within one's professional domain. When a practitioner cannot interpret the data obtained, he or she should state so in the record and contact another health care professional for advice or referral and document the referral in the patient's medical record. Other general rules for medical recordkeeping are listed in Box 3-7. In addition to these general rules, each institution has its own policies governing medical recordkeeping.

Box 3-6 General Sections Found in a Patient Medical Record

ADMISSION DATA
Records pertinent patient information (e.g., name, address, religion, nearest of kin), admitting physician, and admission diagnosis

HISTORY AND PHYSICAL EXAMINATION
Records the patient's admitting history and physical examination, as performed by the attending physician or resident

HEALTH MAINTENANCE AND IMMUNIZATIONS
Records the dates of administration

PHYSICIAN'S ORDERS
Records the physician's orders and prescriptions

PROGRESS NOTES
Keeps a continuing account of the patient's progress for the physician

NURSES' NOTES
Describes the nursing care given to the patient, including the patient's complaints (subjective symptoms), the nurses' observations (objective signs), and the patient's response to therapy

MEDICATION RECORD
Notes drugs and IV fluids that are given to the patient

ALLERGIES
Notes reaction, severity, type, and date

VITAL SIGNS FLOWSHEET
Records the patient's temperature, pulse, respirations, and blood pressure over time

I/O SHEET
Records patient's fluid intake (I) and output (O) over time

LABORATORY RESULTS
Summarizes the results of laboratory tests

CONSULTATION NOTE
Records notes by physicians who are called in to examine a patient to make a diagnosis

SURGICAL OR TREATMENT CONSENT
Records the patient's authorization for surgery or treatment

ANESTHESIA AND SURGICAL RECORD
Notes key events before, during, and immediately after surgery

SPECIALIZED THERAPY RECORDS AND PROGRESS NOTES
Records specialized treatments or treatment plans and patient progress for various specialized therapeutic services (e.g., respiratory care, physical therapy)

SPECIALIZED FLOW DATA
Records measurement made over time during specialized procedures (e.g., mechanical ventilation, kidney dialysis)

ADVANCED DIRECTIVES
Records wishes and documents regarding living wills, power of attorney, and do-not-resuscitate orders

TABLE 3-2 The Joint Commission "Do Not Use" List*

Do Not Use	Potential Problem	Use Instead
U (unit)	Mistaken for 0 (zero), the number 4 (four) or cc	Write "unit"
IU (international unit)	Mistaken for IV (intravenous) or the number 10 (ten)	Write "international unit"
Q.E., QD, q.d., qd (daily); Q.O.D., POD, q.o.d, qod (every other day)	Mistaken for each other; period after the Q mistaken for I and the O mistaken for I	Write "daily" or "every other day"
Trailing zero (X.0 mg)†; lack of leading zero (.X mg)	Decimal point is missed	Write "X mg" or "0.X mg"
MS	Can mean morphine sulfate or magnesium sulfate	Write "morphine sulfate"
MSO_4, $MgSO_4$	Confused for one another	Write "magnesium sulfate"
Additional Abbreviations, Acronyms, and Symbols for *Possible* Future Inclusion in the Official "Do Not Use" List		
> (greater than); < (less than)	Misinterpreted as the number 7 (seven) or the letter L; confused for one another	Write "greater than" or "less than"
Abbreviations for drug names	Misinterpreted owing to similar abbreviations for multiple drugs	Write drug names in full
Apothecary units	Unfamiliar to many practitioners; confused with metric units	Use metric units
@	Mistaken for the number "2" (two)	Write "at"
cc	Mistaken for U (units) when poorly written	Write "mL" or "ml" or "milliliters" ("mL" is preferred)
µg	Mistaken for mg (milligrams) resulting in 1000-fold overdose	Write "mcg" or "micrograms"

From Joint Commission on Accreditation of Healthcare Organizations: 2010 JCAHO "Do Not Use" list. http://www.jointcommission.org/hospitals. Accessed September 17, 2014.

*Applies to all orders and all medication-related documentation that is hand-written (including free-text computer entry) or on preprinted forms.

†*Exception:* A "trailing zero" may be used only where required to show the level of precision of the value being reported, such as for laboratory results, imaging studies that report size of lesions, or catheter/tube sizes. It may not be used in medication orders or other medication-related documentation.

Box 3-7 General Rules for Medical Recordkeeping

- Entries on the patient's chart should be printed or handwritten unless the institution is using an electronic medical record. After completing the account in the handwritten record, sign the chart with one initial and your last name and your title (CRT, RRT, Resp Care Student; e.g., S. Smith, CRT). Institutional policy may require that supervisory personnel countersign student entries in the hand-written record.
- Do not use ditto marks.
- Do not erase. Erasures provide reason for question if the chart is used later in a court of law. If a mistake is made, a single line should be drawn through the mistake and the word *error* printed above it. Then continue your charting in a normal manner.
- Record after completing each task for the patient, and sign your name correctly after each entry.
- Be exact in noting the time, effect, and results of all treatments and procedures.
- Chart patient complaints and general behavior. Describe the type, location, onset, and duration of pain. Describe clearly and concisely the character and amount of secretions.
- Leave no blank lines in the charting. Draw a line through the center of an empty line or part of a line. This prevents charting by someone else in an area signed by you.
- Use standard abbreviations. (Follow the "Do Not Use" list.[18])
- Use the present tense. Never use the future tense, as in "Patient to receive treatment after lunch."
- Spell correctly. If you are unsure about the spelling of a word, look it up in a dictionary.
- Document conversations with the patient or other health care providers that you think are important (e.g., you informed the patient's physician or nurse that the patient seems confused or more short of breath).

Problem-Oriented Medical Record

The **problem-oriented medical record (POMR)** is an alternative documentation format used by some health care institutions. The POMR contains four parts: (1) the database, (2) the problem list, (3) the plan, and (4) the progress notes. Whether electronic or written, the precise forms these records take vary among institutions but will share common information.

The database contains routine information about the patient. A general health history, physical examination results, and results of diagnostic tests are included.

In the POMR, a problem is something that interferes with a patient's physical or psychologic health or ability to function. The patient's problems are identified and listed on the basis of the information provided by the database. The list of problems is dynamic; new problems are added as they develop, and problems are removed as they are resolved.

The POMR progress notes contain the findings (subjective and objective data), assessment, plans, and orders of the physicians, nurses, and other practitioners involved in the care of the patient. The format used is often referred to as **SOAP** (*S* = subjective information, *O* = objective information, *A* = assessment, *P* = plan of care). Figure 3-17 shows a representative SOAP form for respiratory care progress notes. Box 3-8 provides a handwritten example of a SOAP entry. Table 3-3 lists common objective data gathered by RTs and examples of applicable assessments and plans. In many institutions, all caregivers chart on the same form, using the SOAP format.

TABLE 3-3

Examples of Objective Data, Assessments, and Plans Typical for Documentation Using SOAP Notes

Objective Data	Assessment	Plan
Sputum Production		
Thick, purulent	Respiratory infection	Humidity therapy, antibiotics
Auscultation		
Expiratory wheezing	Bronchospasm	Bronchodilator
Stridor	Upper airway obstruction	Racemic epinephrine, possible intubation
Late-inspiratory crackles	Atelectasis	Lung expansion therapy
Breathing Pattern		
Prolonged expiratory time	Bronchospasm	Bronchodilators
Prolonged inspiratory time	Upper airway obstruction	Racemic epinephrine; consider need for intubation
Rapid and shallow	Restrictive lung disease	Notify physician, perform additional assessment, consider lung expansion therapy
Vital Signs		
Acute tachycardia/tachypnea	Acute respiratory failure	Obtain ABGs, chest x-ray films; call physician
Abnormal sensorium	Acute hypoxia	Assess patient further; oxygen therapy
ABGs		
PaO_2 40-60 mm Hg	Moderate hypoxemia	Give O_2 via cannula or mask
PaO_2 < 40 mm Hg	Severe hypoxemia	Give high concentration O_2 as needed and consider positive pressure ventilation with PEEP or CPAP
Chest Radiograph		
Low lung volumes or infiltrates	Atelectasis	Lung expansion therapy
Air in pleural space	Pneumothorax	Insert chest tube

ABGs, Arterial blood gas analysis; *CPAP,* continuous positive airway pressure; *PEEP,* positive end-expiratory pressure.

FIGURE 3-17 Example of a SOAP form for respiratory care progress notes. (From Des Jardins T, Burton GG: Clinical manifestations and assessment of respiratory disease, ed 6, St. Louis, 2011, Mosby.)

Box 3-8 Example of SOAP Entry

PROBLEM 1
Difficult breathing.

SUBJECTIVE
"I can't catch my breath."

OBJECTIVE
Awake; alert; oriented to time, place, and person; sitting upright in bed with arms leaning over the bedside stand; pale, dry skin; respirations 26 breaths/min and shallow; pulse 98 beats/min, regular and faint to palpation; blood pressure 112/68 mm Hg, left arm, sitting position; body temperature 101°F; bronchial breath sounds in lower posterior lung fields; occasionally expectorating small volumes of mucopurulent sputum. Chest x-ray film shows left lower lung infiltrate.

ASSESSMENT
Retained mucus and possible infection.

PLAN
Therapeutic: Assist with coughing and deep breathing at least every 2 hours; postural drainage and percussion every 4 hours; assist with ambulation as per physician orders and patient tolerance.
Diagnostic: Continue to monitor lung sounds before and after each treatment.
Education: Teach patient to cough and deep breathe and evaluate return demonstration.

RULE OF THUMB

Charting Progress Notes Using the SOAP Format

SOAP stands for Subjective, Objective, Assessment, Plan.

- Subjective information obtained from the patient, his or her family members, or a similar source
- Objective information based on caregivers' observations of the patient, the physical examination, or diagnostic or laboratory tests such as arterial blood gases or pulmonary function tests
- Assessment, which refers to the analysis of the patient's problem
- Plan of action to be taken to resolve the problem

SUMMARY CHECKLIST

- The quality of a service or product refers to the sum of its properties that serve to satisfy the needs of its consumer.
- Quality improvement is everyone's job.
- Statistical process control and run charts are tools that allow continuous monitoring of quality of service.
- Quality improvement projects involve different phases: Planning the project, implementing the project, analyzing the results, and changing course of action based on analysis.
- Competency is defined as having suitable or sufficient skills, knowledge, and experience for the purposes of the specific task.
- Annual competency checks need to be documented for skills and procedures that pose potential risk to patient safety.
- The Joint Commission (TJC) is an independent, non-for-profit organization that strives to continuously improve quality and safety of health care services by setting high standards and evaluating health care organizations for adherence.
- TJC requires hospitals to have quality assurance plans and encourages performance improvement efforts.
- Hospital accreditation by TJC is based on satisfying specific standards established by professional and technical advisory committees.
- Good posture is needed when lifting patients or heavy equipment to avoid injury.
- Electrical current (flow) is the dangerous element of electricity. Current is directly related to voltage and inversely related to resistance.
- A microshock is a small, imperceptible current (<1 mA) that enters the body through external wires or catheters; microshocks can cause ventricular fibrillation.
- To avoid electrical hazards, always ground equipment and use only equipment that has been checked for proper wiring.
- Fires in health care facilities most often start in the kitchen, but when they occur in patient care areas, loss of life and serious injuries are likely.
- Maintain a safe and clutter-free direct patient care environment.
- Store and transport medical grade gases in a safe and effective manner.
- Communication skills play a key role in the ability to identify a patient's problems, to evaluate the patient's progress, to make recommendations for respiratory care, and to achieve desired patient outcomes.
- Individuals' prior experiences, attitudes, values, cultural backgrounds, self-concepts, and feelings play a large role in the communication process.
- To enhance communication ability, focus on improving sending, receiving, and feedback skills; in addition, be able to identify and overcome common barriers to effective communication.
- Choose the best strategy for handling conflict considering knowledge of the context, the specific underlying problem, and the desires of the involved parties.
- The EMR is transforming the way we document care but not the concept and content of what is documented.
- A medical record is a confidential document that summarizes the care received by a patient; legally, a failure to document care means that care was not given.
- Following accepted standards, each medication, treatment, or procedure provided to the patient, including his or her condition and response to therapy, must be documented in accurate and clear terms.
- When entering notes in a POMR, use a SOAP format.

CHAPTER 4

Principles of Infection Prevention and Control

MICHELE MESSAM AND THOMAS G. FRASER

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Define health care–associated infections and state how often they occur.
- Describe why infection prevention is important in respiratory care.
- Identify and describe the three elements that must be present for transmission of infection within a health care setting.
- List the factors associated with an increased risk for a patient acquiring a hospital-acquired infection.
- State the three major routes for transmission of human sources of pathogens in the health care environment.
- Describe strategies to control the spread of infection in the hospital.
- Describe how to select and apply chemical disinfectants for processing respiratory care equipment.
- Describe equipment-handling procedures that help prevent the spread of pathogens.
- State when to use personal protective equipment during patient care.
- Describe surveillance with regard to infection control.

CHAPTER OUTLINE

KEY TERMS

antiseptic
bactericidal
bacteriostatic
cohorting
contact precautions
disinfection
droplet nuclei
droplet precautions
fomites
health care–associated infection
Healthcare Infection Control Practices Advisory Committee

high-efficiency particulate air/aerosol filters
hospital-acquired infections
Occupational Safety and Health Administration
respiratory hygiene/cough etiquette
sporicidal
standard precautions
sterilization
surveillance
virucidal

Patients are at risk for developing infections during their hospital stay. A recent study estimated that 4% of hospitalized patients in the United States develop a health care–associated infection.[1] To help better understand preventive measures, infections can be categorized by where they originate. Those that develop outside the hospital are called *community onset.* Those that develop in the hospital are called *hospital-onset* or *nosocomial* infections. However, in the current era, patients can receive care in many different settings—the home, the hospital, a skilled nursing facility, or an outpatient treatment center. Patients who are at home but getting care in a nonhospital setting can develop community-onset infections that are related to health care and are not community acquired. The term **health care–associated infection** (HAI) refers to infections that develop in a patient during the course of medical treatment. This classification system is not arbitrary, because there are unique risks for HAIs such as the presence of an endotracheal tube or a central venous catheter. HAIs also can be related to certain pathogens that are more likely to be resistant to one or more classes of antimicrobial agents. For example, *Pseudomonas aeruginosa* is commonly seen as a cause of HAI pneumonia; however, it is not routinely seen as a cause of community-acquired disease.

Efforts to decrease **hospital-acquired infection** and HAIs are commonly organized and coordinated by a hospital's Infection Prevention (IP) program. IP programs are charged with reducing the risk for HAIs and thereby protecting patients, employees, and visitors. They do this by providing guidance to their organizations so that they can break the chain of events leading to HAIs. Guidance and prevention efforts are directed at overall organizational structure and systems ("this is what we do as an institution to prevent infection") and at the individual caregiver level ("this is what I do to prevent infection").

Protecting patients and health care professionals against HAIs requires strict adherence to IP procedures. These procedures aim to eliminate the sources of infectious agents, create barriers to their transmission, and monitor and evaluate the effectiveness of control. IP departments coordinate activities and provide guidance to their institutions. Decreasing the risk for HAIs is a major and ongoing responsibility of all health care workers, including respiratory therapists (RTs). To fulfill this responsibility, RTs must be able to select and consistently apply a full spectrum of daily competencies. This chapter provides the foundation needed to assume this important responsibility.

SPREAD OF INFECTION

Three elements must be present for transmission of infection within a health care setting: (1) a *source* (or reservoir) of pathogens, (2) a *susceptible host,* and (3) a *route* of transmission for the pathogen (Figure 4-1).[2]

Sources of Infectious Agents

Humans (patients, personnel, or visitors) are the primary source for infectious agents in the health care setting, but inanimate objects (e.g., contaminated medical equipment, linen, medications) also have been implicated in transmission. Patients quickly contaminate their local hospital environment, particularly high-touch surfaces, such as call lights, bed rails, tray tables, and bathrooms. People also may serve as their own source of infection, via endogenous flora. This latter process is called *autogenous infection*.

Susceptible Hosts

Susceptibility and resistance to infection vary greatly. Host factors in the acute setting that predispose to HAI can be considered modifiable and nonmodifiable. Host factors, such as poorly controlled diabetes mellitus, extremes of age, and underlying acquired (human immunodeficiency virus [HIV] infection) or iatrogenic (through chemotherapy or anti–tumor necrosis factor inhibitors) immunodeficiency, can enhance susceptibility to infection and are not readily modifiable in the acute setting. Surgical incisions and radiation therapy impair defenses of the skin and organ space. Medical devices, such as urinary tract catheters, central venous catheters, and endotracheal tubes, increase the risk for infection by impeding local host defenses and providing a surface for the development of biofilms. The need for the medical device may be unavoidable. However, the risk for infection associated with it can be modified by employing appropriate techniques for insertion, maintenance, and removal.

Modes of Transmission

The three major routes for transmission of human pathogens in the health care environment are *contact* (direct and indirect), *respiratory droplets,* and *airborne droplet nuclei* (respirable particles <5 μm). Table 4-1 provides examples of the common transmission routes for selected microorganisms.[3]

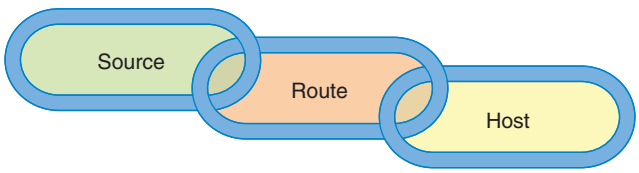

FIGURE 4-1 Elements that must be present for infection to spread.

TABLE 4-1

Routes of Infectious Disease Transmission

Mode	Type	Examples
Contact	Direct	Hepatitis A
		HIV
		Staphylococcus
		Enteric bacteria
	Indirect	*Pseudomonas aeruginosa*
		Enteric bacteria
		Hepatitis B and C
		HIV
Droplet		*Haemophilus influenzae* (type B) pneumonia and epiglottitis
		Neisseria meningitidis pneumonia
		Diphtheria
		Pertussis
		Streptococcal pneumonia
		Influenza
		Mumps
		Rubella
		Adenovirus
		Rhinovirus
Vehicle	Water-borne	Shigellosis
		Cholera
	Food-borne	Salmonellosis
		Hepatitis A
Airborne	Aerosols	Legionellosis
	Droplet nuclei	Tuberculosis
		Varicella
		Measles
		Smallpox
Vector-borne	Ticks and mites	Rickettsia
		Lyme disease
	Mosquitoes	Malaria
	Fleas	Bubonic plague

HIV, Human immunodeficiency virus.

Contact Transmission

Contact transmission is the most common route of transmission and is divided into two subgroups: direct and indirect. *Direct contact transmission* occurs when a pathogen is transferred directly from one person to another. Direct contact transmission occurs less frequently than indirect contact in the health care environment but is more efficient. An example of direct contact transmission would be development of respiratory syncytial virus bronchiolitis in a bone marrow transplant recipient owing to transmission of the virus from an ill health care worker who did not perform appropriate hand hygiene before providing care.

Indirect contact transmission is the most frequent mode of transmission in the health care environment and involves transfer of a pathogen through a contaminated intermediate object or person. The most common indirect contact transmission in health care involves unwashed hands of health care personnel that touch an infected or a colonized body site on one patient, or a contaminated inanimate object, and subsequently touch another patient. Inanimate objects that may serve to transfer pathogens from one person to another are called **fomites.** Indirect contact transmission involving fomites can occur when instruments have been inadequately cleaned between patients before disinfection or sterilization.

Droplet Transmission

Droplet transmission is a form of contact transmission, but the mechanism of transfer of the pathogen is distinct and additional prevention measures are required. Organisms that are transmitted by respiratory droplets include influenza and *Neisseria meningitidis*. Respiratory droplets are generated when an infected individual discharges large contaminated liquid droplets into the air by coughing, sneezing, or talking. Respiratory droplets are also generated during procedures such as suctioning, bronchoscopy, and cough induction. Transmission occurs when infectious droplets are propelled (usually ≤3 feet through the air) and are deposited on another person's mouth or nose. Using the distance of 3 feet or less as a minimum threshold for donning a mask has been effective in preventing transmission of infectious agents. However, experimental studies with smallpox and investigations of outbreaks of severe acute respiratory syndrome (SARS) suggest that droplets from infected patients rarely are able to reach a person 6 feet away.[4] A distance of 3 feet or less around the patient is considered a short distance and is not used as a criterion for deciding when a mask should be donned to protect from exposure. **Healthcare Infection Control Practices Advisory Committee** (HICPAC) guidelines state it may be prudent to don a mask when within 6 to 10 feet of a patient or on entry into the room of a patient who is on droplet isolation.[3]

Airborne Transmission

Airborne transmission occurs via the spread of airborne **droplet nuclei.** These are small particles (≤5 μm) of evaporated droplets containing infectious microorganisms that can remain suspended in air for long periods. Microorganisms carried in this manner may be dispersed widely by air currents because of their small size and inhaled by susceptible hosts over a longer distance from the source patient compared with droplet transmission. Examples of pathogens transmitted via the airborne route include *Mycobacterium tuberculosis,* varicella-zoster virus (chickenpox), and rubeola virus (measles).[4]

Special air handling and ventilation and respiratory protection are required to prevent airborne transmission because microorganisms may remain suspended in air and be widely dispersed by air currents before contacting a susceptible host. In addition to airborne infection isolation rooms, personal respiratory protection with National Institute for Occupational Safety and Health (NIOSH)–approved N-95 or higher respirators is required to prevent airborne transmission.[3] A surgical mask, used for droplet precautions, is insufficient.

Miscellaneous Types of Aerosol Transmission

The separation of organisms that are transmitted by aerosols into the categories of droplet and airborne is based on the usual

manner in which disease is transmitted. In-depth investigations of outbreaks have demonstrated that the line between these two categories of transmission is sometimes blurry. In certain circumstances, such as during endotracheal intubation and aerosol-generating procedures, there is some evidence that organisms such as influenza and SARS can be transmitted via droplet nuclei. Similarly, norovirus, the most common cause of infectious diarrhea transmitted mainly by contact, probably also can be transmitted by swallowing aerosolized virus from vomitus. Based on these examples, aerosol transmission of droplet nuclei can be further refined as follows[3]:

- *Obligate transmission:* Under natural conditions, disease occurs after transmission of the microorganism only through airborne (droplet nuclei) aerosols. An example of obligate transmission is tuberculosis.
- *Preferential transmission:* Natural infection results from transmission through multiple routes, but airborne transmission predominates. Measles is an example of preferential airborne transmission.
- *Opportunistic transmission:* Microorganisms that cause disease through other routes—droplet or contact—but under certain environmental conditions may be transmitted via airborne transmission. An example of this is SARS transmission via an aerosol plume that originated from sewage in the Amoy Gardens housing complex in the Kowloon section of Hong Kong in 2003.[4]

Awareness of these nuances of transmission informs health care workers to wear the appropriate personal protective equipment depending on the clinical circumstances. For example, during a bronchoscopy for a patient infected with influenza, the possibility of opportunistic airborne transmission of the virus would cause one to consider wearing an N95 mask as opposed to a regular surgical mask.

Other Sources of Infection Not Involving Person-to-Person Transmission

Common vehicle transmission occurs via exposure to pathogens in contaminated food, water, or medications (e.g., heparin solution). Vector-borne transmission of infectious diseases from insects and rats and other vermin occurs but is of less significance in U.S. health care facilities.

INFECTION PREVENTION STRATEGIES

Creating a Safe Culture

From an organizational perspective, a crucial first step to decrease the risk for HAIs is the creation by leadership, at all levels, of a culture of safety in which there is a shared commitment to patient and health care worker safety. Creating a culture of safety is also the responsibility of each individual health care worker. It is important that each person is empowered and willing to speak up and "stop the line" if the person has a concern that a patient or employee is in an unsafe situation.

Organizations also endorse best practices for infection prevention by ensuring that the bedside caregiver has the appropriate time, equipment, and training to provide the best possible care. Competent health care workers execute appropriate practice, such as attention to hand hygiene and adherence to infection prevention bundles of care on a daily basis with every patient. Failure to perform these basics is a deviation from good practice and cannot be tolerated. The presence of appropriate systems to deliver care and a committed workforce consistently executing best practice are necessary for an organization to reliably prevent infections.[6]

Maintaining a Healthy Workforce

The day-to-day care of hospitalized patients relies on people. A sick health care worker not only has difficulty executing assignments but could also serve as a source of infection for vulnerable patients. There are multiple different components to maintaining a healthy workforce. The standard and transmission-based precautions described later not only prevent transmission of pathogens from patient to patient but also protect health care workers. Other efforts employed to protect health care workers are employee immunization and chemoprophylaxis. Certain immunizations are recommended for susceptible health care personnel to decrease the risk for infection and the potential for transmission to patients and co-workers within the health care facility.[5] The **Occupational Safety and Health Administration** (OSHA) mandates that employers offer hepatitis B vaccination. Vaccinations of health care workers in the absence of evidence of immunity against varicella, rubella, and measles should be strongly encouraged. In addition, health care personnel should receive the adult acellular pertussis vaccine, particularly those who care for young infants and children. Health care personnel without medical contraindications should receive an annual influenza vaccination.[5] Health care worker influenza vaccination is the single most effective way to prevent health care–associated influenza. A vaccinated population decreases the risk for presenteeism (health care workers being at work when sick). The importance of receiving an influenza vaccine is reflected in the recent requirement that health care facilities publicly report vaccination rates of their employees, licensed independent practitioners, volunteers, and adult students.[7] To improve health care worker vaccination adherence, many organizations have made receiving a flu vaccine mandatory.

Uncommonly, health care workers are recommended to take antibiotics in addition to standard and transmission-based precautions and vaccination, to prevent disease. Examples of these situations include postexposure prophylaxis after close contact with a patient with meningococcal meningitis or exposure to blood or body fluid of a patient with HIV. One specific situation in which vaccination and chemoprophylaxis are combined is exposure to a patient with *Bordetella pertussis* (whooping cough). Infants can develop severe complications from whooping cough, including death. If health care workers have had close contact with an active case of whooping cough, and have contact with infants younger than 1 year of age or women in the third trimester of pregnancy, they should receive prophylaxis in addition to having their vaccination status updated.[3,5]

RULE OF THUMB

All health care workers with patient contact should undergo immunization for hepatitis B and varicella (if not immune), pertussis booster, and annual influenza vaccination.

Eliminating the Source of Pathogens

Elimination of all pathogens from any working environment is impossible. Nonetheless, standard infection prevention procedures always include efforts to eliminate pathogens, and recommended practices for cleaning and disinfecting noncritical surfaces in patient care areas should be followed. Procedures designed to remove environmental pathogens fall into two major categories: *general sanitation measures* and *specialized equipment processing.*

General sanitation measures help keep the overall environment clean. General sanitation aims to reduce the number of pathogens to a safe level. This reduction is achieved through sanitary laundry management, food preparation, and housekeeping. Environmental control of the air (using specialized ventilation systems) and water complements these efforts.

The goal of specialized equipment processing is to decontaminate equipment capable of spreading infection. Equipment processing involves cleaning, disinfection, and sterilization (when necessary). Methods that kill bacteria are **bactericidal,** whereas methods and techniques that inhibit the growth of bacteria are **bacteriostatic.** Methods that destroy spores are **sporicidal,** and methods that destroy viruses are **virucidal.**

Interrupting Transmission

General sanitation measures and equipment processing have limits. To prevent the spread of infections between patients and to keep themselves healthy, health care personnel must take measures to stop infection. Best practices to limit transmission of pathogens in the hospital have been put forth by HICPAC and the Centers for Disease Control and Prevention (CDC). These recommendations include standard precautions and transmission-based precautions.[3]

Standard Precautions

The term **standard precautions** refers to the simplest level of infection control based on the recognition that all blood, body fluids, secretions, and excretions (with the exception of sweat) may contain transmissible infectious agents. Standard precautions are intended to be applied to the care of all patients in all health care settings all the time. This is the primary strategy for the prevention of health care–associated transmission of infections among patients and health care personnel. To reduce risk for infection, a health care worker should employ personal protective equipment (PPE). PPE refers to various barriers used alone or in combination to protect mucous membranes, skin, and clothing from contact with infectious agents. Gloves, gowns, masks, eye protection, and face shields should be employed depending on the anticipated exposure.

The application of standard precautions by health care personnel during patient care depends on the nature of the interaction and the potential for blood, body fluid, or pathogen contact. For some patient care situations, only gloves are required. In other cases, gloves, gowns, and face shield may be required. Box 4-1 describes standard precautions, including hand hygiene; use of gloves, masks, and eye protection; equipment handling; and patient placement.

Hand Hygiene

The importance of hand hygiene to reduce the transmission of infectious agents cannot be overemphasized and is an essential element of standard precautions.[8] Hand hygiene includes handwashing with either plain or **antiseptic**-containing soap and water for at least 15 seconds or the use of alcohol-based products (gels, rinses, and foams). In the absence of visible soiling of hands, approved alcohol-based products are preferred over antimicrobial or plain soap and water because of their superior microbicidal activity, reduced drying of skin, and convenience. The quality of performing hand hygiene can be affected by the type and length of fingernails and by wearing jewelry. Artificial fingernails and extenders should not be worn by health care workers because of their association with infections.[8] Figure 4-2 illustrates the proper technique for handwashing.

Gloves

Gloves protect both patients and health care workers. Gloves protect patients from exposure to pathogens that may be carried on the hands of health care workers. Gloves protect caregivers from contamination when contacting blood, body fluids, secretions, excretions, mucous membranes, and nonintact skin of patients and when handling or touching visibly or potentially contaminated patient care equipment and environmental surfaces.[8]

Caregivers should wear sterile gloves whenever performing invasive procedures. A single pair of nonsterile disposable gloves (e.g., latex, vinyl, nitrile) may be used for routine patient care. Hand hygiene always should be performed before donning gloves. Gloves should be changed between each patient contact and after any direct contact with infectious material, even if in the middle of a procedure. After removing the gloves, caregivers always must clean their hands. Gloves may have small, invisible defects or may be torn during use. The hands also can be contaminated during removal of the gloves. For these reasons, the wearing of gloves should never be used as a substitute for hand hygiene.

Mouth, Nose, Eye, and Face Protection

Face protection is an important component of standard precautions because the mucous membranes of the eyes, nose, and mouth are particularly vulnerable to some types of pathogens. Masks protect mucosal surfaces against splashes or sprays, but should not be confused with particulate respirators that are recommended for protection from small particles (as described subsequently for airborne isolation [AI]). The wearing of masks,

Box 4-1 Standard Precautions

HAND HYGIENE
- Perform hand hygiene before and after patient contacts, immediately after removing gloves, and when otherwise indicated to avoid cross contamination.
- Perform hand hygiene after touching blood, body fluids, secretions, excretions, and contaminated items, even if wearing gloves.
- Perform hand hygiene between tasks and procedures on the same patient if cross contamination of different body sites is possible (e.g., tracheostomy care after assistance with a bedpan).
- Use an approved alcohol-based product for routine hand hygiene. If hands are visibly soiled, use soap and water.

GLOVES
- Perform hand hygiene before and after removing gloves.
- Wear clean gloves when touching blood, body fluids, secretions, excretions, and contaminated items.
- Don clean gloves just before touching mucous membranes and nonintact skin.
- Change gloves between tasks and procedures on the same patient after contact with infectious material.
- Remove gloves promptly after use, before touching noncontaminated items and environmental surfaces, and before going to another patient.

MASKS, EYE PROTECTION, FACE SHIELDS
- Wear a mask and eye protection or a face shield to protect mucous membranes of the eyes, nose, and mouth during procedures and patient care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, and excretions.

GOWNS
- Wear a clean gown to protect skin and prevent soiling of clothing during procedures and patient care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, or excretions.
- Remove a soiled gown as promptly as possible and perform hand hygiene to avoid transfer of microorganisms to other patients or environments.

PATIENT CARE EQUIPMENT
- Handle used patient care equipment soiled with blood, body fluids, secretions, and excretions in a manner that prevents skin and mucous membrane exposures, contamination of clothing, and transfer of microorganisms to other patients and environments.
- Do not use reusable equipment to care for another patient unless it has been cleaned and reprocessed appropriately.
- Discard single-use items properly.

OCCUPATIONAL HEALTH AND BLOOD-BORNE PATHOGENS
- Exercise extreme caution when handling needles, scalpels, and other sharp instruments or devices; when cleaning used instruments; and when disposing of used needles.
- Never recap used needles, handle them using both hands, or point toward any part of the body.
- Do not remove used needles from disposable syringes by hand, and do not bend, break, or otherwise manipulate used needles by hand.
- Place used disposable syringes and needles, scalpel blades, and other sharp items in appropriate puncture-resistant containers; place reusable syringes and needles in a puncture-resistant container for transport to the reprocessing area.
- Use mouthpieces, resuscitation bags, or other ventilation devices as an alternative to mouth-to-mouth resuscitation methods in areas where the need for resuscitation is predictable.

PATIENT PLACEMENT
- Place patients who contaminate the environment or who do not (or cannot be expected to) assist in maintaining appropriate hygiene or environmental control in a private room.
- If a private room is unavailable, consult with infection preventionist regarding patient placement.

eye protection, and face shields in specified circumstances when exposures are likely to occur (e.g., bronchoscopy suite) is mandated by the OSHA Bloodborne Pathogen Standard.

Respiratory Protection

Respiratory protection (use of NIOSH-approved N-95 or higher level respirator) is intended for diseases (e.g., *M. tuberculosis*) that could be transmitted through the airborne route.[3] The term *respiratory protection* has a regulatory context that includes components of a program required by OSHA to protect workers: (1) medical clearance to wear a respirator, (2) provision and use of appropriate NIOSH-approved fit-tested respirators, and (3) education in respirator use.

Gowns, Aprons, and Protective Apparel

Isolation gowns and other apparel (aprons, leg coverings, boots, or shoe covers) also provide barrier protection and can prevent the contamination of clothing and exposed body areas from blood and body fluid contact and transmissible pathogens (e.g., respiratory syncytial virus and *Clostridium difficile*). Selection of protective apparel is dictated by the nature of the interaction of the health care worker with the patient, including anticipated degree of body contact with infectious material.[3] In most instances, gowns are worn only if contact with blood and body fluid is likely. Clinical coats and jackets worn over clothing are not considered protective apparel. Isolation gowns always should be donned with gloves and other protective equipment as indicated. As with gloves and masks, a gown should be worn only once and then discarded. In most situations, aseptically clean, freshly laundered, or disposable gowns are satisfactory.

Cough Etiquette

The emergence of novel respiratory viruses such as SARS and Middle East respiratory syndrome (MERS) along with pandemic H1N1 influenza have reinforced the need for a strategy

for preventing transmission of respiratory infections at the first point of contact within a health care setting (e.g., physician's office), termed **respiratory hygiene/cough etiquette.** This concept is a component of standard precautions.[3] The elements of respiratory hygiene/cough etiquette include (1) education of health care personnel, patients, and visitors; (2) posted signs in language appropriate to the population served with instructions for patients and accompanying family members or friends; (3) source control measures (covering the mouth and nose with a tissue when coughing or placing a surgical mask on a coughing person when possible); (4) hand hygiene after contact with respiratory secretions; and (5) spatial separation (≥3 feet from persons with respiratory infections in common waiting areas).

Transmission-Based Precautions

Transmission-based precautions are for patients who are known or suspected to be infected with pathogens that require additional control measures to prevent transmission. There are three categories of transmission-based precautions based on the predominant manner in which the pathogen is transmitted: contact

FIGURE 4-2 Steps for handwashing. **A,** Thorough wetting of hands. **B,** Washing around wrist and forearm. **C,** Scrubbing palm of hand. **D,** Washing between digits on back of hand.

Continued

FIGURE 4-2, cont'd **E,** Washing around the cuticle. **F,** Drying hands with clean towel. **G,** Using towel to turn off faucet.

precautions, droplet precautions, and airborne infection isolation (see earlier section on Modes of Transmission). Whether used singularly or in combination, these precautions are always used in addition to standard precautions.[3]

Contact precautions are intended to reduce the risk for transmission by direct or indirect contact with the patient or the patient's environment. Contact precautions require health care personnel and visitors to wear gowns and gloves for all interactions that may involve contact with the patient or the patient's environment. Contact precautions are most commonly employed to decrease the spread of multidrug-resistant organisms such as *C. difficile*. Contact precautions are described in Box 4-2.

Droplet precautions are used to prevent a form of contact transmission that occurs when droplets are propelled short distances (≤3 feet through the air). Droplets are often generated with coughing, sneezing, suctioning, bronchoscopy, and cough induction. Health care personnel and visitors should don a mask during all interactions that may involve contact with such patients. Droplet precautions are employed for patients with

Box 4-2 Contact Precautions (Used *in Addition to* Standard Precautions)

- Place the patient in a private room; if a private room is unavailable, cohorting is acceptable.
- Perform hand hygiene and don gown and gloves to enter room whether or not direct patient contact is anticipated. Wear clean gloves when entering the room.
- Remove gown and gloves before leaving the patient's environment and perform hand hygiene.
- After glove removal and hand hygiene, ensure that hands do not touch potentially contaminated environmental surfaces or items in the patient's room.
- Limit transport of the patient from the room to essential purposes only.
- When possible, dedicate the use of noncritical patient care equipment to a single patient or patient cohort.
- If use of common equipment or items cannot be avoided, ensure that it is adequately cleaned and disinfected before use on another patient.

MINI CLINI

Isolation Methods

PROBLEM: A serious influenza outbreak occurs in a local long-term care facility. You are called to the emergency department (ED) because four of the sickest patients are being admitted together to your hospital for treatment. Currently, no private rooms are available for these patients. Outline the key isolation methods you would apply to help prevent the spread of influenza in your institution.

DISCUSSION: Influenza spreads via the droplet route. Both standard and droplet precautions must be applied for these patients. When transporting these patients out of the ED, you must be sure they wear surgical masks. Because private rooms are unavailable, these patients need to be grouped together. If this is not feasible, the patients must be separated from other patients by at least 3 feet. Special air handling and ventilation are unnecessary, and the door may remain open. In addition to following standard precautions, all caregivers and visitors should wear surgical masks when within 3 feet of these patients (or entering the room). All remaining patients at the long-term care facility should be immunized with the flu vaccine (if not already) and be given antiviral prophylaxis.

Box 4-3 Droplet Precautions (Used *in Addition to* Standard Precautions)

- Place the patient in a private room; if a private room is unavailable, cohorting is acceptable.
- Special air handling and ventilation are unnecessary, and the door may remain open.

MASK

- Perform hand hygiene and put on a surgical mask before entering the room.
- Remove mask before exiting the room and perform hand hygiene.
- Limit movement and transport of the patient from the room to essential purposes only.
- If transport or movement is necessary, minimize droplet transmission by having the patient wear a surgical mask.

Box 4-4 Guidelines for Cough-Inducing and Aerosol-Generating Procedures

- Cough-inducing procedures include endotracheal intubation and suctioning, diagnostic sputum induction, aerosol treatments (e.g., pentamidine therapy), and bronchoscopy.
- Cough-inducing procedures should not be performed on patients who may have infectious tuberculosis, unless the procedures are essential and can be performed with appropriate precautions.
- All cough-inducing procedures performed on patients who may have infectious tuberculosis should be performed using booths or special enclosures; if this is not feasible, a room that meets the ventilation requirements for airborne infection isolation can be used.
- After completion of cough-inducing procedures, patients who may have infectious tuberculosis should remain in their isolation rooms or enclosures until coughing subsides. They should be required to cover their mouths and noses with tissues when coughing.
- Before the enclosure or room is used for another patient, enough time should be allowed to pass for at least 99% of airborne contaminants to be removed (this time varies according to the efficiency of the ventilation or filtration system).

Box 4-5 Airborne Precautions (Used *in Addition to* Standard Precautions)

- Place the patient in a private negative-pressure room that has 6 to 12 air changes per hour and either safe external air discharge or HEPA filtration of recirculated air.
- Keep the room door closed and the patient in the room.
- If a private room is unavailable, cohorting is acceptable.
- Perform hand hygiene and don respiratory protection when entering the room of a patient with known or suspected infectious pulmonary tuberculosis.
- Remove respiratory protection and perform hand hygiene after leaving the room.
- Susceptible persons should not enter the room of patients known or suspected to have measles (rubeola) or varicella (chickenpox) if other immune caregivers are available; individuals who are immune to measles or varicella need not wear respiratory protection.
- Limit transport of the patient from the room to essential purposes only.
- If transport or movement is necessary, minimize patient dispersal of droplet nuclei by having the patient wear a surgical mask.

presumed or confirmed infection with organisms known to be transmitted by respiratory droplets such as influenza. Droplet precautions are described in Box 4-3. Precautions for use when performing cough-inducing and aerosol-producing procedures are described in Box 4-4. Airborne infection isolation (AII) refers to isolation techniques intended to reduce the risk for selected infectious agents transmitted by "small droplets" of aerosol particles (e.g., *M. tuberculosis*).[5] Persons who enter an AII room must wear respiratory protection (an NIOSH-approved N-95 or higher respirator). Patients should be placed in a single-patient AII room that is equipped with special air handling and ventilation capacity that meets the American Institute of Architects/Facility Guidelines Institute standards (monitored negative pressure relative to surrounding area, minimum of two outdoor air changes per hour, minimum of 12 total air changes per hour for new construction or 6 air changes per hour for existing buildings, and air exhausted directly to the outside).[9] In settings where AII cannot be implemented because of limited resources, physical separation, mask patients, and respiratory protection for health care personnel should be implemented to reduce the likelihood of airborne transmission. Box 4-5 describes airborne precautions that should be used in addition to standard precautions.

Protective Environment

A specialized engineering approach to protect highly immunocompromised patients is a protective environment. A protective environment is used for patients with allogeneic hematologic stem cell transplants to minimize fungal spore counts in the air.[3] The rationale for such controls has been studies showing outbreaks of aspergillosis associated with construction. Air quality for patients with hematologic stem cell transplants is improved through a combination of environmental controls that include (1) high efficiency particulate air (HEPA) filtration of incoming air, (2) directed room airflow, (3) positive room air pressure relative to the corridor, (4) well-sealed rooms to prevent infiltration of outside air, (5) ventilation to provide 12 or more air changes per hour, (6) strategies to reduce dust, and (7) prohibition of dried and fresh flowers and potted plants in rooms.

Transport of Infected Patients

By limiting the transport of patients with contagious disease, the risk for cross infection can be reduced. However, infected patients sometimes do need to be transported and, when that occurs, the patient needs to wear appropriate barrier protection (mask, gown, impervious dressings) consistent with the route and risk for transmission.[3] Health care personnel receiving the patient need to be notified of the patient's impending arrival and what infection control measures are required.

RULE OF THUMB

Apply standard precautions when caring for all patients.

1. Wash your hands after touching blood, body fluids, or contaminated items (even if gloves were worn).
2. Wear fresh, clean gloves for all tasks and procedures involving potential contact with blood, body fluids, or contaminated items.
3. Exercise extreme caution when handling "sharps."
4. Handle soiled equipment in a manner that prevents skin and mucous membrane exposures, contamination of clothing, and transfer of microorganisms to other patients and environments.[5]

Medical Devices and Bundles

A large percentage of HAIs are device-related infections, including ventilator-associated pneumonia (VAP), catheter-related bloodstream infection, and catheter-associated urinary tract infection. The best way to decrease host susceptibility to a device-related infection is first to limit device use and second to ensure that devices are placed and maintained appropriately. Prevention bundles—defined as the use of multiple different evidence-based best practices to prevent device-related infection—have been shown to decrease the incidence of HAIs significantly.[10,11] Exactly how much each component of a bundle contributes to a reduction in infection is often difficult to determine. There are bundles for placement of central vascular catheters, placement and maintenance of urinary catheters, and for the management of patients on ventilators. There are several different permutations of VAP bundles described. Common components to most include maintaining the head of the bed above 30 degrees, routine mouth care with chlorhexidine, and minimizing sedation (daily sedation vacation).[11] Other practices commonly included in VAP bundles are venous thromboembolism prophylaxis and stress ulcer prophylaxis, even though these practices do not have a direct effect on the risk for pneumonia. Institutions should be committed to these processes of care, and individual health care workers should be familiar with these practices and execute them on a routine basis.[11–13] Compliance with bundles can be tracked over time as part of process improvement projects. Each individual component can be tracked, or all components can be tracked in an all or none, total appropriateness of care manner.

MINI CLINI

Spread of Infection

PROBLEM: You work in the neonatal intensive care unit (NICU) of a large urban hospital. Over the last 2 days, many infants in the unit have developed serious *Staphylococcus aureus* infections. Identify the most likely source and route of transmission and suggest ways to prevent spread of this serious infection.

DISCUSSION: In hospitals, *S. aureus* commonly colonizes the skin of both health care professionals and visitors. Neonates are very susceptible hosts because of their poor immunity. *Staphylococcus* infections spread mainly via direct contact transmission (see Table 4-1). To help prevent the spread of this infection to the newborn infants, you should try to disrupt the transmission route. Meticulous attention to hand hygiene and use of gloves would help. In addition, you could isolate the infected neonates from uninfected infants (**cohorting**) and, in an effort to identify patients who may be colonized, begin *S. aureus* screening of the umbilicus and nares of all infants in the NICU and all new admissions.

DISINFECTION AND STERILIZATION

Medical instruments are used in tens of millions of procedures in the United States every year. When properly performed, cleaning, disinfection, and sterilization procedures can reduce the risk for infection associated with the use of invasive and noninvasive medical instruments. Although a detailed review of disinfection and sterilization is beyond the scope of this chapter, overall principles are discussed, particularly as they pertain to the use of bronchoscopes. The interested reader is referred to detailed guidance available from the CDC.[14] Table 4-2 lists definitions of the steps involved in equipment reprocessing.

Spaulding Approach to Disinfection and Sterilization of Patient Care Equipment

In 1968, Spaulding published his approach to disinfection and sterilization, which was based on the degree of risk for infection

involved in the use of the item in patient care.[15] The three categories he described were critical, semicritical, and noncritical (Table 4-3). *Critical* items are categorized based on the high risk for infection if such an item is contaminated with pathogens, including bacterial spores (e.g., items that enter sterile tissue or the vascular system). Critical devices enter normally sterile tissues. Most of these items should be purchased sterile or be sterilized with steam if possible. *Semicritical* items come into contact with mucous membranes or nonintact skin; this includes most respiratory equipment. These items should be free of all microorganisms before use (bacterial spores may be present). Semicritical items require at least high-level disinfection using chemical disinfectants. *Noncritical* items come into contact with intact skin (an effective barrier to most microbes) but not mucous membranes. Most noncritical reusable devices may be decontaminated where they are used (e.g., bedpans, patient bed rails).

Bronchoscopes routinely become contaminated with high levels of organisms during a procedure because of the body cavities in which they are used. The benefits of these medical devices are numerous; however, proper reprocessing is crucial because numerous outbreaks and pseudo-outbreaks owing to improper procedures have been described. Individuals responsible for bronchoscope reprocessing should receive initial and annual training, and their competency should be ensured. The five key components to bronchoscope reprocessing are cleaning, disinfecting, rinsing, drying, and storage (Box 4-6).[14] Automated bronchoscope reprocessors (ABRs) offer many advantages over manual disinfection because they automate several of these steps. Regardless of whether disinfection is done manually or with an ABR, personnel responsible for this task need to ensure reprocessing is done per device manufacturer and reprocessor guidelines with products registered with U.S. Environmental Protection Agency (EPA) or cleared by the U.S. Food and Drug Administration (FDA). Health care workers should wear appropriate PPE while cleaning, disinfecting, or sterilizing medical equipment to protect themselves from potentially infectious material and chemical products used in the process.

Cleaning

Medical equipment must be cleaned and maintained according to the manufacturer's instructions. Cleaning is the first step in all equipment processing, including those undergoing low-level or high-level disinfection and sterilization. Cleaning involves removing all dirt and organic material from equipment, usually by washing (see Table 4-3).[14] Failure to clean

TABLE 4-2

Equipment Processing Definitions

Term	Definition
Cleaning	Removal of all foreign material (e.g., soil, organic material) from objects
Disinfection (general term)	Inactivation of most pathogenic organisms, excluding spores
Disinfection, low level	Inactivation of most bacteria, some viruses, and fungi, without destruction of resistant microorganisms such as *Mycobacterium tuberculosis* or bacterial spores
Disinfection, intermediate level	Inactivation of all vegetative bacteria, most viruses, most fungi, and *M. tuberculosis,* without destruction of bacterial spores
Disinfection, high level	Inactivation of all microorganisms *except* bacterial spores (with sufficient exposure times, spores may also be destroyed)
Sterilization	Complete destruction of all forms of microbial life

TABLE 4-3

Processing of Medical Equipment According to Infection Risk Categories

Category	Description	Examples	Processing
Critical	Devices introduced into the bloodstream or other parts of the body	Surgical devices Intravascular catheters Implants Heart-lung bypass components Dialysis components Bronchoscope forceps/brushes	Sterilization
Semicritical	Devices that directly or indirectly contact mucous membranes	Bronchoscopes Oral, nasal, and tracheal airways Ventilator circuits/humidifiers Pulmonary function testing mouthpieces and tubing Nebulizers and their reservoirs Resuscitation bags Laryngoscope blades/stylets Pressure, gas, or temperature probes	High-level disinfection
Noncritical	Devices that touch only intact skin or do not contact patient	Face masks Blood pressure cuffs Ventilators	Detergent washing Low- to intermediate-level disinfection

Modified from Chatburn RL, Kallstrom TJ, Bajasouzian S: A comparison of acetic acid with a quaternary ammonium compound for disinfection of hand-held nebulizers. Respir Care 34:98–109, 1989.

Box 4-6 Key Components of Bronchoscope Sterilization or Disinfection

Clean: Mechanically clean external surfaces, including brushing internal channels and flushing each internal channel with water and a detergent or enzymatic cleaner.

1. *Disinfect:* Immerse bronchoscope in high-level disinfectant and perfuse disinfectant into the suction/biopsy channel and air/water channel and expose for at least 20 minutes (or FDA-cleared exposure time).
2. *Rinse:* The bronchoscope and all channels should be rinsed with sterile water, filtered water, or tap water.
3. *Dry:* Rinse insertion tube and inner channels with alcohol, and dry with forced air after disinfection and before storage.
4. *Store:* The bronchoscope should be stored in a way that prevents recontamination (e.g., hung vertically in an enclosed cabinet, the bronchoscope should not touch any surface of the cabinet).

Data from Rutala WA, Weber DJ, and the Healthcare Infection Control Practices Advisory Committee (HICPAC), Centers for Disease Control and Prevention: Guidelines for sterilization and disinfection in healthcare facilities, Atlanta, 2008. http://www.edu.gov./hicpac/.pdf/guidelines.

equipment properly can render all subsequent processing efforts ineffective. Cleaning should occur in a designated facility with separate dirty and clean areas. Before being cleaned, the equipment should be disassembled per manufacturer's recommendations and examined for worn parts. Disassembly helps ensure good exposure to the cleaning agent.

Because water alone cannot dissolve organic matter, detergents or enzymatic cleaners and brushes should be used to clean all internal and external surfaces of equipment. Enzymatic cleaners are neutral detergents with enzymes added that help remove organic (proteinaceous) material from equipment. Some EPA-registered products combine a germicide with a detergent, providing the dual action of cleaning and disinfection. This product type is generally appropriate for use on noncritical items. Noncritical items, such as stethoscopes, intravenous pumps, and ventilator surfaces, must be cleaned and low-level disinfected using an appropriate EPA-registered product before use on another patient.

Although careful cleaning removes most pathogens from the equipment, it cannot eliminate the risk for infection. For this reason, semicritical and critical medical equipment must then undergo either high-level disinfection or sterilization.

Disinfection

Disinfection describes a process used on medical equipment that destroys the vegetative form of all pathogenic organisms on an inanimate object, except bacterial spores. By definition, *disinfection* differs from *sterilization* by its lack of sporicidal activity.[14] However, a few disinfectants kill spores with prolonged exposure times (hours) and are called *chemical sterilants*. Disinfection can involve either physical or chemical methods. The most common physical method of disinfection is *pasteurization*. Many chemical methods are used to disinfect respiratory care equipment.

Chemical Disinfection

Chemical disinfection involves the application of chemical solutions to contaminated surfaces or equipment. The EPA groups disinfectants based on whether the product label claims "limited," "general," or "hospital" disinfection.[14] Numerous disinfectants are used alone or in combination in the health care setting, including alcohol, chlorine and chlorine products, glutaraldehyde, iodophors, phenolics, quaternary ammonium compounds, peracetic acid, and hydrogen peroxide. In most cases, a given product is designed for a specific purpose and should be used in a certain manner; the label should be read carefully. Table 4-4, excerpted from the CDC guideline for sterilization and disinfection, summarizes common chemical disinfectants and their activity against various pathogens.[14] Health care facilities should select disinfectant agents that best meet their overall needs. Product manufacturer's recommendations for the amount, dilution, and contact time of disinfectants should be followed. A comprehensive overview of disinfectants in the hospital can be found in the updated CDC guidelines for disinfection and sterilization in health care facilities.[14]

For high-level disinfection to be effective, cleaned equipment must be completely immersed in the disinfectant solution. The FDA provides a list of cleared chemical disinfectants that can be used for high-level disinfection of medical devices. Cleared agents include 2.4% or greater glutaraldehyde, 0.55% orthophthaldehyde (OPA), 0.95% glutaraldehyde with 1.64% phenylphenate, 7.35% hydrogen peroxide with 0.23% peracetic acid, 1.0% hydrogen peroxide with 0.08% peracetic acid, and 7.5% hydrogen peroxide.[16] The choice of agent used in high-level disinfection is dictated by the device manufacturer.

After a set "contact" time, the equipment is removed, rinsed in sterile water (to remove toxic residues), and thoroughly dried. Equipment must be handled and stored carefully, to prevent recontamination during subsequent reassembly, packaging, and storage.

Sterilization

Sterilization destroys all microorganisms on the surface of an article or in a fluid, which prevents transmission of pathogens associated with the use of that item. Both physical and chemical means can achieve sterilization. Physical methods include various forms of heat (steam) and ionizing radiation. Chemical methods of sterilization include low-temperature sterilization technologies such as ethylene oxide (EtO) gas. Table 4-5, excerpted from the CDC guideline for sterilization and disinfection, compares and contrasts the major methods of sterilization.[14]

Medical devices that have contact with sterile body tissues or fluids are critical items and should be sterile before use. If the object is heat resistant, steam sterilization is usually recommended. However, increases in the use of medical devices that are heat and moisture sensitive have necessitated the development of low-temperature sterilization technology. These include, but are not limited to, EtO, hydrogen peroxide gas plasma, and peracetic acid. A review of the commonly used sterilization technologies with a summary of advantages and

glut, Glutaraldehyde; HLD, high level-disinfectant; *HP,* hydrogen peroxide; *NA,* not applicable; *OPA,* orthophthalaldehyde (FDA cleared as a high-level disinfectant, included for comparison with other chemical agents used for high-level disinfection); *PA,* peracetic acid; *PA/HP,* peracetic acid and hydrogen peroxide; *TWA,* time-weighted average for a conventional 8-hour workday.

[a]Number of days a product can be reused as determined by reuse protocol.

[b]Time a product can remain in storage (unused).

[c]No U.S. Environmental Protection Agency regulations, but some states and local authorities have additional restrictions.

[d]Minimum effective concentration is the lowest concentration of active ingredients at which the product is still effective.

[e]Conc soln, concentrated solution.

[f]The ceiling limit recommended by the American Conference of Governmental Industrial Hygienists is 0.05 ppm.

[g]Per cycle cost profile considers cost of the processing solution (suggested list price to health care facilities in August 2001) and assumes maximum use life (e.g., 21 days for hydrogen peroxide, 14 days for glutaraldehyde), five reprocessing cycles per day, 1-gallon basin for manual processing, and 4-gallon tank for automated processing.

+, Least expensive; ++++, most expensive.

MINI CLINI

Selection of a Disinfectant

PROBLEM: You work in the pulmonary function laboratory of a community hospital. Immediately after performing spirometry on a patient, you learn that he has been admitted and tests positive for pulmonary tuberculosis. You also remember him coughing into the spirometry tubing. You have four more patients scheduled for spirometry testing, beginning in 45 minutes. How should you process the spirometry tubing to prevent transmission of the tuberculosis?

DISCUSSION: Ideally, you would have a backup set of tubing to deal with this type of problem. If not, you need to disinfect or sterilize the tubing quickly. Because permanent spirometry tubing is made from heat-labile plastics, you cannot use steam (damage). Ethylene oxide (EtO) gas is an option, but aeration would take too long. Instead, you should select a broad-spectrum, quick-acting disinfectant solution that works well in the presence of organic matter and does not damage rubber or plastic. Glutaraldehyde is a good choice, with a minimum exposure time of 20 minutes. A stabilized hydrogen peroxide–based compound or a 1:50 sodium hypochlorite solution also might be considered.

disadvantages can be found in the updated CDC guidelines for disinfection and sterilization in health care facilities.[14] Following is an overview of a few of these technologies.

Steam Sterilization

Moist heat in the form of steam under pressure is the most common, most efficient, and easiest sterilization method. Steam sterilization is the application of steam under pressure. Steam sterilization is efficient, quick, cheap, clean, and reliable. Equipment always must be thoroughly cleaned before sterilization because materials that remain on the surfaces of equipment interfere with the effectiveness of the sterilization process. Clean equipment is wrapped in muslin, linen, or paper or placed in specially designed rigid containers, all of which are easily penetrated by steam. Items must be properly packed in the autoclave to ensure exposure. The higher the temperature and pressure of the sterilizer, the shorter is the time needed for sterilization. The combination most commonly used for autoclaving is 15 psi at 121°C for a minimum of 30 minutes. After sterilization, the packaging prevents recontamination during handling and storage. Numerous quality control monitors (mechanical, chemical, and biological) are employed to ensure adequate sterilization has taken place.

TABLE 4-5

Advantages and Disadvantages of Accepted Methods for Equipment Sterilization

Sterilization Method	Advantages	Disadvantages
Steam	Nontoxic to patient, staff, environment Cycle easy to control and monitor Rapidly microbial Least affected by organic/inorganic soils among sterilization processes listed Rapid cycle time Penetrates medical packing, device lumens	Deleterious for heat-sensitive instruments Microsurgical instruments damaged by repeated exposure May leave instruments wet, causing them to rust Potential for burns
Hydrogen peroxide gas plasma	Safe for the environment Leaves no toxic residuals Cycle time is 28-75 min (varies with model type) and no aeration necessary Used for heat- and moisture-sensitive items because process temperature <50°C Simple to operate, install (208 V outlet), and monitor Compatible with most medical devices Requires electrical outlet only	Cellulose (paper), linens, and liquids cannot be processed Sterilization chamber size from 1.8-9.4 ft^3 total volume (varies with model type) Some endoscopes or medical devices with long or narrow lumens cannot be processed at this time in the United States (see manufacturer's recommendations for internal diameter and length restrictions) Requires synthetic packaging (polypropylene wraps, polyolefin pouches) and special container tray Hydrogen peroxide may be toxic at levels >1 ppm TWA
100% Ethylene oxide (EtO)	Penetrates packaging materials, device lumens Single-dose cartridge and negative pressure chamber minimizes potential for gas leak and EtO exposure Simple to operate and monitor Compatible with most medical materials	Requires aeration time to remove EtO residue Sterilization chamber size 4.0-7.9 ft^3 total volume (varies with model type) EtO is toxic, a carcinogen, and flammable EtO emission regulation by states but catalytic cell removes 99.9% of EtO and converts it to CO_2 and H_2O EtO cartridges should be stored in flammable liquid storage cabinet Lengthy cycle/aeration time
EtO mixtures: 8.6% EtO/91.4% HCFC; 10% EtO/90% HCFC; 8.5% EtO/91.5% CO_2	Penetrates medical packaging and many plastics Compatible with most medical materials Cycle easy to control and monitor	Some states (e.g., California, New York, Michigan) require EtO emission reduction of 90%-99.9% CFC (inert gas that eliminates explosive hazard) banned in 1995 Potential hazards to staff and patients Lengthy cycle/alteration time EtO is toxic, a carcinogen, and flammable
Peracetic acid	Rapid cycle time (30-45 min) Low temperature (50°-55°C) liquid immersion sterilization Environmentally friendly by-products Sterilant flows through endoscope, which facilitates salt, protein, and microbe removal	Point-of-use system, no sterile storage Biologic indicator may be unsuitable for routine monitoring Used for immersible instruments only Some material incompatibility (e.g., aluminum anodized coating becomes dull) One scope or a small number of instruments processed in a cycle Potential for serious eye and skin damage (concentrated solution) with contact

Data from Rutala WA, Weber DJ, and the Healthcare Infection Control Practices Advisory Committee (HICPAC), Centers for Disease Control and Prevention: Guidelines for sterilization and disinfection in healthcare facilities, Atlanta, 2008, http://www.edu.gov./hicpac/.pdf/guidelines.
CFC, Chlorofluorocarbon; *HCFC,* hydrochlorofluorocarbon; TWA, time-weighted average.

Immediate Use Sterilization

Immediate-use (previously referred to as *flash* sterilization) "steam sterilization" is a modification of conventional steam sterilization in which the item is placed in an open tray or a specially designed container to allow for rapid penetration of steam.[14] It is considered an acceptable practice for processing cleaned patient care items that cannot be packaged, sterilized, and stored before use. Its use only for reasons of convenience (e.g., to save time) should be discouraged.

Low-Temperature Sterilization Technologies

Low-temperature (<60°C) sterilants are needed for sterilizing temperature-sensitive and moisture-sensitive medical devices and equipment. Low-temperature sterilant technology includes EtO, hydrogen peroxide gas plasma, ozone, vaporized hydrogen peroxide, and peracetic acid.[14] We review the most commonly used process—EtO.

EtO is a colorless, toxic gas and potent sterilizing agent. Because it is active at ambient temperatures and is harmless to rubber and plastics, EtO is a good sterilant for items that cannot be autoclaved. Similar to steam, EtO penetrates most packaging materials, permitting prewrapping. Were it not for its many hazards, EtO would be the ideal sterilant.[16] Acute exposure to EtO gas can cause airway inflammation, nausea, diarrhea, headache, dizziness, and seizures. Chronic exposure to the gas is associated with respiratory infections, anemia, and altered behavior. Residual EtO left on processed equipment can cause tissue inflammation and hemolysis. When combined with

water, EtO forms ethylene glycol, which also can irritate tissues. Other potential problems include carcinogenic, mutagenic, and teratogenic effects. EtO concentrations greater than 3% are explosive.

EtO requires special attention to general safety precautions, equipment preparation, and sterilization cycle parameters. In addition, because of its toxicity, residual EtO must be removed from equipment after sterilization via a process called *aeration*. EtO is used to sterilize critical (and sometimes semicritical) items that cannot be steam sterilized.

EQUIPMENT HANDLING PROCEDURES

Equipment handling procedures that help prevent the spread of pathogens include maintenance of in-use equipment, processing of reusable equipment, application of one-patient-use disposables, and fluid and medication precautions.

Maintenance of In-Use Equipment

In-use respiratory care equipment that can spread pathogens includes nebulizers, ventilator circuits, bag-valve-mask devices (manual resuscitators), and suction equipment. Oxygen therapy and pulmonary function equipment are also implicated as potential sources of HAIs.

Nebulizers

Small-volume medication nebulizers (SVNs) also can produce bacterial aerosols. SVNs have been associated with health care–associated pneumonia, including Legionnaires disease, resulting from either contaminated medications or contaminated tap water used to rinse the reservoir. Procedures designed to prevent nebulizers from spreading pathogens are presented in Box 4-7.

Box 4-7 Procedures to Minimize Infection Risk With Nebulizers

LARGE-VOLUME NEBULIZERS AND MIST TENTS

- Always fill nebulizers with sterile distilled water.
- Fill fluid reservoirs immediately before use; do not add fluid to replenish partially filled reservoirs. If fluid is to be added, discard the remaining old fluid first.
- Drain tubing condensate away from the patient and discard as contaminated waste; do not allow condensate to drain back into reservoir.
- Sterilize or high-level disinfect large-volume nebulizers between patients and after every 24 hours of use on the same patient.
- Use mist tent nebulizer and reservoirs that have undergone sterilization or high-level disinfection, and replace them between patients.
- Do not use large-volume room air humidifiers that create aerosols unless they can be sterilized or subjected to high-level disinfection at least daily and filled only with sterile water.

SMALL-VOLUME NEBULIZERS

- Between treatments on the same patient, disinfect, rinse with sterile water, and air dry small-volume nebulizers.
- Between patients, replace small-volume nebulizers with sterile or high-level disinfected units.
- Use only sterile fluids for nebulization, and dispense these fluids aseptically.
- When possible, use single-use medication vials; if using multidose vials, handle, dispense, and store them according to manufacturer's instructions and checking expiration dates.

Ventilators and Ventilator Circuits

The internal workings of ventilators are uncommon sources for infection; this is partly a result of the widespread use of **high-efficiency particulate air/aerosol (HEPA) filters**, which have an efficiency rate of 99.97%, and the use of sheathed suction catheters, which help reduce endotracheal tube contamination. An inspiratory HEPA filter (placed between the machinery and the external circuit, proximal to any humidifier) can eliminate bacteria from the driving gas and prevent retrograde contamination back into the machine. An expiratory filter using a heated thermistor to prevent condensation performs the same function and still protects the internal ventilator components. Expiratory filters also prevent pathogens from being expelled into the surroundings from the patient's expired air.

The external ventilator circuitry poses the most significant contamination risk, particularly in systems using heated humidifiers. The humidifiers themselves are rarely the problem. Bubble or wick designs produce little or no aerosol and pose minimal infection risk. In addition, heating the humidifier reduces or eliminates growth of most bacterial pathogens. However, because tap water or distilled water may harbor heat-resistant pathogens, sterile water should still be used to fill bubble-type humidifiers.

The primary problem stems from contaminated condensate in the inspiratory limb of the ventilator circuit. Most often, the source of this contamination is the patient. Spillage of contaminated condensate into the patient circuit and the patient occurs when moving the tubing or the patient, increasing the risk for self-infection. In addition, microorganisms in this condensate can be transmitted to other patients via the hands of the health care worker handling the fluid, if he or she is negligent. This is another reason why it is crucial for RTs to practice hand hygiene before and after contact with every ventilated patient. Contact with the patient's ventilator is considered contact with the patient's body.

One way to address this problem is by reducing or eliminating circuit condensation. This reduction or elimination is easily achieved using heated wire circuits or a *heat-and-moisture exchanger (HME)*. Available guidance does not recommend daily changing of HMEs. These devices should be inspected daily and replaced if contaminated with patient secretions or if flow resistance has increased. HMEs can be used safely for 48 hours, and with some patient populations they may be able to be used for up to 7 days.[17]

Based on current knowledge, both the CDC and the American Association for Respiratory Care (AARC) have developed guidelines addressing ventilator-associated infection control. Box 4-8 provides general procedures for minimizing HAIs

Box 4-8 Procedures to Minimize Infection Risk With Mechanical Ventilators

- Do not routinely sterilize or disinfect the internal workings of ventilators.
- Do not routinely change ventilator circuit more often than every 48 to 72 hours with HME.
- Sterilize or high-level disinfect reusable breathing circuits and humidifiers.
- Periodically drain tubing condensate away from patient and discard.
- Wash hands after draining tubing condensate or handling the fluid.
- Do not place bacterial filters distal to humidifier reservoirs.
- Use sterile water to fill bubble humidifiers.
- Use sterile, distilled water to fill wick humidifiers.
- Change HMEs according to manufacturer's recommendation and when you observe evidence of gross contamination or mechanical dysfunction.
- Do not routinely change HME breathing circuits while in use.

HME, Heat-and-moisture exchanger.

associated with ventilator use. Mechanical ventilation exposes the patient to the risk for VAP, and the frequency of circuit changes and the relationship to VAP have been investigated.[11] Current guidelines suggest that ventilator circuits should not be changed routinely for infection control purposes; however, they should be changed when visibly soiled or malfunctioning.[18]

Bag-Mask Devices

Bag-mask devices are a source for colonizing both the airways of intubated patients and the hands of medical personnel.[19] Nondisposable bag-mask devices should be sterilized or high-level disinfected between patients. In addition, the exterior surface of any bag-mask device should be cleaned of visible debris and disinfected at least once a day.

Suction Systems

Tracheal suctioning increases the risk for infection. Proper hand hygiene and gloving help minimize this risk. Although much has been made of the infection prevention advantages of sheathed suction systems over open tracheal suction systems, evidence is mixed as to whether it is clearly superior. However, guidance recommends in-line suctioning as part of VAP reduction program.[18] There is no need to change a closed system suction catheter daily. To minimize the risk for cross contamination during suctioning with an open system, a fresh, sterile, single-use catheter should be used on each patient. In addition, only sterile fluid should be used to remove secretions from the catheter. Last, both the suction collection tubing and collection canister should be changed between patients except in short-term care units, where only the collection tubing needs to be changed.

Oxygen Therapy Apparatus

O_2 therapy devices pose much less risk than other in-use equipment but are still a potential infection hazard. In-use nondisposable O_2 humidifiers have a contamination rate of 33%. Conversely, prefilled, sterile disposable humidifiers present a negligible infection risk.[20] On the basis of this knowledge, procedures that can help prevent O_2 therapy apparatus from spreading pathogens are outlined in Box 4-9.

Box 4-9 Procedures to Minimize Infection Risk With Oxygen Therapy Apparatus

- Humidifiers are not needed with flows less than 4 L/min.
- When needed and whenever possible, prefilled, sterile disposable humidifiers should be used.
- With reusable humidifiers, fluid reservoirs should be filled immediately before use with sterile distilled water.
- Fluid must not be added to replenish partially filled reservoirs. If fluid is to be added, discard the remaining old fluid first, then clean and dry reservoir before refilling.
- The tubing and oxygen delivery device should be changed between patients; prefilled, sterile, disposable humidifiers do not need to be changed between patients in high-use areas such as the recovery room.
- Prefilled, disposable humidifiers can be used safely for 30 days.

Pulmonary Function Equipment

The inner parts of pulmonary function testing equipment are not a major source for spread of infection. However, contamination of external tubing, connectors, rebreathing valves, and mouthpieces can occur during testing. These components should be cleaned and subjected to high-level disinfection or sterilization between patients.[21,22] The common practice of using HEPA filters to isolate the spirometer from the patient makes sense logically but has yet to be proved either effective or necessary in preventing HAI.

Other Respiratory Care Devices

Use of other respiratory care equipment, including O_2 analyzers, the hand-held bedside spirometer, and circuit probes, has been linked with hospital outbreaks of gram-negative bacterial infections.[21] The most likely transmission route is direct patient-to-patient contact via either the device itself or the contaminated hands of caregivers. The best way to control this problem is with proper hand hygiene and sterilization or high-level disinfection of the devices between patients.

Processing Reusable Equipment

Improperly processed reusable equipment is another potential source for pathogens. General principles for cleaning, disinfection, and sterilization were provided previously. This section presents specific guidelines for processing reusable respiratory care equipment and a special section on bronchoscope disinfection.

Respiratory Care Equipment

Several factors must be considered in selecting a processing method for reusable respiratory care equipment (Box 4-10).

4-1 Care of the Ventilator Circuit and Its Relationship to Ventilator-Associated Pneumonia

AARC Clinical Practice Guideline (Excerpts)*

INTRODUCTION

A concern related to the care of a mechanically ventilated patient is the development of VAP. For many years, this concern focused on the ventilator circuit and humidifier. The circuit and humidifier have been changed on a regular basis in an attempt to decrease the VAP rate. However, as the evidence evolved, it became apparent that the origin of VAP is more likely from sites other than the ventilator circuit, and the prevailing practice has become one of changing circuits less frequently. If this practice is safe, it would offer substantial cost savings. Other issues related to the components of the circuit and VAP also have become more important. Humidification systems can be either active or passive. Increasingly, in-line suction is used and this becomes part of the ventilator circuit.

QUESTIONS

A systematic review of the literature was conducted with the intention of making recommendations for change frequency of the ventilator circuit and additional components of the circuit. Specifically, the Writing Committee wrote these evidence-based clinical practice guidelines to address the following questions:

1. Do ventilator circuits need to be changed at regular intervals?
2. What is the economic impact of decreasing the frequency of ventilator circuit changes?
3. What are the issues related to circuit type?
4. Does the choice of active versus passive humidification affect ventilator circuit change frequency?
5. Do passive humidifiers need to be changed at regular intervals?
6. Do in-line suction catheters need to be changed at regular intervals?
7. Are there specific populations for which the recommendations should be altered?

RECOMMENDATIONS

Recommendation #1

Ventilator circuits should not be changed routinely for infection control purposes. The available evidence suggests no patient harm and considerable cost savings associated with extended ventilator circuit change intervals. The maximum duration of time that circuits can be used safely is unknown. (Evidence Grade A)

Recommendation #2

Evidence is lacking related to VAP and issues of heated versus unheated circuits, type of heated humidifier, method for filling the humidifier, and technique for clearing condensate from the ventilator circuit. It is prudent to avoid excessive accumulation of condensate in the circuit. Care should be taken to avoid accidental drainage of condensate into the patient's airway and to avoid contamination of caregivers during ventilator disconnection or during disposal of condensate. Care should be taken to avoid breaking the ventilator circuit, which could contaminate the interior of the circuit. (Evidence Grade D)

Recommendation #3

Although the available evidence suggests a lower VAP rate with passive humidification than with active humidification, other issues related to the use of passive humidifiers (e.g., resistance, dead space volume, airway occlusion risk) preclude a recommendation for the general use of these devices. The decision to use a passive humidifier should not be based solely on infection control considerations. (Evidence Grade A)

Recommendation #4

Passive humidifiers do not need to be changed daily for reasons of infection control or technical performance. They can be safely used for at least 48 hours, and with some patient populations, some devices may be able to be used for up to 1 week. (Evidence Grade A)

Recommendation #5

The use of closed suction catheters should be considered part of a VAP prevention strategy. When closed suction catheters are used, they do not need to be changed daily for infection control purposes. The maximum time that closed suction catheters can be used safely is unknown. (Evidence Grade A)

Recommendation #6

Clinicians (e.g., respiratory therapists, nurses, and physicians) caring for mechanically ventilated patients should be aware of risk factors for VAP (e.g., nebulizer therapy, manual ventilation, and patient transport). (Evidence Grade B)

EVIDENCE GRADES

Grade A: Scientific evidence provided by randomized, well-designed, well-conducted, controlled trials with statistically significant results that consistently support the guideline recommendation; supported by Level 1 or 2 evidence

Grade B: Scientific evidence provided by well-designed, well-conducted observational studies with statistically significant results that consistently support the guideline recommendation; supported by Level 3 or 4 evidence

Grade C: Scientific evidence from bench studies, animal studies, and case studies; supported by Level 5 evidence

Grade D: Expert opinion provides the basis for the guideline recommendation, but scientific evidence either provided inconsistent results or was lacking

**For the complete guidelines, see AARC Clinical Practice Guidelines, Care of the ventilator circuit and its relation to ventilator-associated pneumonia. Respir Care 48:569–879, 2003.*

Box 4-10 Factors to Consider in Processing Reusable Equipment

- Infection risk (critical, semicritical, noncritical)
- Material and equipment configuration
- Available hospital disinfection resources
- Relative cost (labor and materials)

When a device's risk category is known, its composition must be matched to the resources available for hospital disinfection and sterilization. In this manner, each reusable device undergoes the most effective and least costly processing approach available.

MINI CLINI

Selection of Equipment Processing Methods

PROBLEM: A patient is discharged from the intensive care unit after extubation from mechanical ventilatory support. The following contaminated nondisposable items are returned to the respiratory care department for processing: the ventilator, the ventilator circuit and humidifier, a resuscitation bag, a mechanical (vane-type) respirometer, and a laryngoscope with blades. Outline what processing you would select for each item and why.

DISCUSSION: First, the circuit, humidifier, and resuscitation bag should be disassembled and cleaned using a detergent or enzymatic cleaner combined with a low-level or intermediate-level disinfectant. Because the ventilator, respirometer, and laryngoscope and blades cannot be immersed in water, they should immediately undergo surface disinfection, using an appropriate EPA-registered product.

After cleaning and initial disinfection, you should sort the items according to risk category and heat sensitivity. No items from this patient pose a critical infection risk. The ventilator circuit, humidifier, resuscitation bag, respirometer, and laryngoscope are semicritical items, whereas the ventilator itself is a noncritical item. The ventilator circuit, humidifier, and resuscitation bag are also plastic and probably heat labile. The respirometer and laryngoscope are heat stable.

When possible, semicritical items should be sterilized between patients; the heat-stable items should be autoclaved, and heat-labile items should undergo EtO sterilization. The ventilator (a noncritical item) need undergo only low-level to intermediate-level surface disinfection. The inner parts of the ventilator need not be sterilized or disinfected between patients.

HAIs associated with bronchoscopes have been most commonly reported with *M. tuberculosis,* nontuberculosis mycobacteria, and *P. aeruginosa*.[22] The most common reasons for transmission include failure to adhere to recommended cleaning and disinfection procedures, failure of automated endoscope reprocessors, and flaws in design. Flexible endoscopes are particularly difficult to disinfect, and meticulous cleaning must precede any sterilization or high-level disinfection process.

Disposable Equipment

An important alternative to reprocessing equipment continually is employing single-patient-use disposable devices. In the past, only O_2 therapy devices (i.e., masks, cannulas), suction apparatus (i.e., catheters, tubing), and some supplies were disposable. Today, manufacturers provide a range of disposable devices, including humidifiers, nebulizers, incentive spirometers, ventilator circuits, bag-valve-masks, and monitoring transducers.

Three major issues are involved in using disposable devices: *cost, quality,* and *reuse*. Cost issues boil down to straightforward dollar comparisons between purchasing and processing reusable devices versus stocking and distributing disposable devices. Good comparisons take into account direct and indirect costs (e.g., personnel, inventory, maintenance) and risk factors. Most recent findings support the cost-effectiveness of disposable devices over reusable devices in respiratory care.

Cost savings notwithstanding, many quality issues persist. Although disposable devices generally perform well, poor quality control remains a problem.[20] Respiratory care managers need to evaluate carefully disposable devices being considered for bulk purchase before actual clinical use. To ensure reliability, this evaluation should include physical testing of multiple units of each model being assessed. Finally, bedside clinicians need to inspect carefully and confirm the operation of any disposable device before use.

Reusing high-cost, high-volume disposable equipment saves hospitals money. The practice of reusing devices labeled by the manufacturer for "single-use only" raises significant safety concerns and issues of negligence. The FDA provides stringent regulations for reprocessing and reusing single-use devices.[23] A reused single-use device must comply with the same regulatory requirements of the original manufactured device, including, but not limited to, submitting documents for premarket notification or approval, submitting adverse event reports, and meeting manufacturing and labeling requirements. The U.S. Centers for Medicare and Medicaid Services recommends that the reprocessing of single-use devices be performed by an FDA-approved third-party reprocessor and not by hospitals.

Fluids and Medications Precautions

Unit dosing has decreased but has not eliminated the infection hazard associated with medications. Box 4-11 outlines several simple procedures designed to help prevent cross contamination while using fluids and medications.

Handling Contaminated Articles and Equipment

Contaminated items, whether reusable or disposable, should be enclosed in an impervious bag before removal from a patient's room. Bagging helps prevent accidental exposure of both personnel and the environment to contaminated articles. A single bag is satisfactory if (1) the bag is strong and impervious, and

Box 4-11 Fluids and Medications Precautions

- Sterile fluids should always be used for tracheal suctioning and to fill nebulizers and bubble humidifiers. These fluids should be dispensed aseptically.
- Sterile water should be used when rinsing equipment. If tap water must be used, either an alcohol rinse must follow or the equipment must thoroughly air dry before use.
- If a large stock bottle of sterile fluid must be reused, the container must be resealed and dated after opening. Remaining fluid should be discarded within 24 hours.
- When multidose medication vials are being used, they must be handled, dispensed, and stored according to manufacturer's instructions (on the label or package insert). Medication must not be used after its expiration date.

(2) the contaminated items can be bagged without contaminating the outer surface of the bag. Otherwise, the contaminated items should be double-bagged. Bags used for contaminated articles or waste materials should be clearly labeled or color-coded for this purpose.

After bagging, reusable patient care equipment must be returned to the applicable processing area. Contaminated reusable equipment should remain bagged until ready for decontamination or sterilization. When contaminated waste is being discarded, both OSHA procedures and any applicable local, state, or federal regulations must be followed.

Handling Laboratory Specimens

When gathering laboratory specimens (e.g., sputum), extreme care needs to be taken to prevent contamination of the external surface of the container. If the outside of the container is contaminated, the caregiver must either disinfect it or place it in an impervious bag. To minimize the likelihood of laboratory specimens leaking during transport, they always should be placed in a sturdy container with a secure lid. When gathering a specimen from a patient on isolation precautions, the container must be placed in an appropriately labeled, impervious bag before it is removed from the room.

SURVEILLANCE FOR HOSPITAL-ACQUIRED INFECTIONS

Surveillance is an ongoing process of monitoring patients and health care personnel for acquisition of infection, colonization of pathogens, or both. It is one of the five key recommended components of an infection prevention program; the others are *investigation, prevention, control,* and *reporting*.[2] Surveillance is a tool to provide HAI data on patients to provide outcome measurements either to ensure there is no ongoing problem or detect problems and intervene to prevent transmission of pathogens in the health care environment.

Generally, an infection prevention committee establishes surveillance policies and an infection preventionist or epidemiologist administers them. The surveillance program may be centralized or decentralized (to the various service departments). The following principles should be a part of any infection prevention surveillance program[2]: (1) use of standard definitions for HAIs; (2) use of microbiology-based data (when available), including resistance patterns for pathogens of significance (e.g., *S. aureus*); (3) establishment of risk stratification for infection risk when available (e.g., ventilator days, device days); (4) monitoring of results prospectively and identifying trends that indicate unusual rates of infection or transmission within the facility; and (5) provision of feedback to stakeholders within the institution (e.g., surgical site infection rates reported back to individual surgeons). It is also common for infection prevention programs to oversee hand hygiene and standard precautions adherence observations.

Most hospitals perform surveillance for device-related infections: central line-associated bloodstream infections (CLABSI), catheter-associated urinary tract infections (CAUTI), and VAPs. It is also commonplace to track certain organisms, including *C. difficile* infection and methicillin-resistant *S. aureus* infection. Surveillance is performed by applying National Healthcare Safety Network (NHSN) definitions. Increasingly, there are regulatory mandates for the public reporting of surveillance results.

Traditionally, VAP was tracked and a standardized definition was employed. The VAP surveillance definition has significant limitations, including a lack of sensitivity and specificity that limits its usefulness.[11] Recently, a new construct for evaluating the development of complications in ventilated adult patients has been developed and publicized by NHSN.[24] Instead of following patients only for the development of VAP, surveillance is performed to look for ventilator-associated events (VAE). VAEs are broken down into three tiers: ventilator-associated conditions (VAC), infection-related ventilator-associated conditions (IVAC), and possible and probable VAP (Figure 4-3). VAE surveillance starts with the identification of a VAC defined as an increase in the daily minimum positive end expiratory pressure (PEEP) or daily minimum fraction of inspired oxygen (FiO_2) for 2 calendar days or longer after a period of stability. An IVAC is considered present if a VAC has been identified and there is an elevated temperature or white blood cell count and new antibiotics have been started and administered for 4 or more days. Possible VAP is identified in a patient with an IVAC who has purulent sputum by Gram stain or a positive sputum culture. Probable VAP is an IVAC in a patient with purulent sputum by Gram stain and a positive semiquantitative or quantitative sputum culture. The cultures need to be positive for a known respiratory pathogen. VAE surveillance is a new paradigm in surveillance in that it tries to examine the overall safety of ventilator therapy and not focus just on infection-related outcomes. Conduct of this surveillance requires a partnership among infection prevention, critical care physicians, and respiratory therapists.

The surveillance activities of an infection prevention program are most effective when they generate actionable data that are communicated to the bedside caregiver in a timely fashion. These data can become the springboard for continuous

Device-associated Module
VAE

Figure 1: Ventilator-Associated Events (VAE) Surveillance Algorithm*

Patient has a baseline period of stability or improvement on the ventilator, defined by ≥2 calendar days of stable or decreasing daily minimum* FiO_2 or PEEP values. The baseline period is defined as the 2 calendar days immediately preceding the first day of increased daily minimum PEEP or FiO_2.
*Daily minimum defined by lowest value of FiO_2 or PEEP during a calendar day that is maintained for at least 1 hour.

After a period of stability or improvement on the ventilator, the patient has at least one of the following indicators of worsening oxygenation:
1) Increase in daily minimum* FiO_2 of ≥0.20 (20 points) over the daily minimum FiO_2 in the baseline period, sustained for ≥2 calendar days.
2) Increase in daily minimum* PEEP values of ≥3 cmH_2O over the daily minimum PEEP in the baseline period,† sustained for ≥2 calendar days.
*Daily minimum defined by lowest value of FiO_2 or PEEP during a calendar day that is maintained for at least 1 hour.
†Daily minimum PEEP values of 0-5 cmH_2O are considered equivalent for the purposes of VAE surveillance.

Ventilator-Associated Condition (VAC)

On or after calendar day 3 of mechanical ventilation and within 2 calendar days before or after the onset of worsening oxygenation, the patient meets both of the following criteria:

1) Temperature >38 °C or <36°C, **OR** white blood cell count ≥12,000 cells/mm^3 or ≤4,000 cells/mm^3.
AND
2) A new antimicrobial agent(s) (see Appendix for eligible antimicrobial agents) is started, and is continued for ≥4 calendar days.

Infection-Related Ventilator-Associated Complication (IVAC)

On or after calendar day 3 of mechanical ventilation and within 2 calendar days before or after the onset of worsening oxygenation, ONE of the following criteria is met (**taking into account organism exclusions specified in the protocol**):

1) Criterion 1: Positive culture of one of the following specimens, meeting quantitative or semi-quantitative thresholds as outlined in protocol, without requirement for purulent respiratory secretions:
   - Endotracheal aspirate, ≥10^5 CFU/ml or corresponding semi-quantitative result
   - Bronchoalveolar lavage, ≥10^4 CFU/ml or corresponding semi-quantitative result
   - Lung tissue, ≥10^4 CFU/g or corresponding semi-quantitative result
   - Protected specimen brush, ≥10^3 CFU/ml or corresponding semi-quantitative result
2) Criterion 2: Purulent respiratory secretions (defined as secretions from the lungs, bronchi, or trachea that contain ≥25 neutrophils and ≤10 squamous epithelial cells per low power field [lpf, x100])† plus a positive culture of one of the following specimens (qualitative culture, or quantitative/semi-quantitative culture without sufficient growth to meet criterion #1):
   - Sputum
   - Endotracheal aspirate
   - Bronchoalveolar lavage
   - Lung tissue
   - Protected specimen brush

   † If the laboratory reports semi-quantitative results, those results must correspond to the above quantitative thresholds. See additional instructions for using the purulent respiratory secretions criterion in the VAE Protocol.
3) Criterion 3: One of the following positive tests:
   - Pleural fluid culture (where specimen was obtained during thoracentesis or initial placement of chest tube and NOT from an indwelling chest tube)
   - Lung histopathology, defined as: 1) abscess formation or foci of consolidation with intense neutrophil accumulation in bronchioles and alveoli; 2) evidence of lung parenchyma invasion by fungi (hyphae, pseudohyphae or yeast forms); 3) evidence of infection with the viral pathogens listed below based on results of immunohistochemical assays, cytology, or microscopy performed on lung tissue
   - Diagnostic test for *Legionella* species
   - Diagnostic test on respiratory secretions for influenza virus, respiratory syncytial virus, adenovirus, parainfluenza virus, rhinovirus human metapneumovirus coronavirus

Possible Ventilator-Associated Pneumonia (PVAP)

*According to Centers for Disease Control (CDC).

FIGURE 4-3 Ventilator-associated events (VAE) surveillance algorithm.

improvement in the delivery of care. Infection preventionists must communicate the results of surveillance activities to bedside caregivers in a meaningful way so that continuous improvements in care occur based on local data. Health care workers need to be willing to accept surveillance data in the way it is intended, not as a punitive grade, but as a tool to encourage reflection on current processes for delivering care. All health care workers should be aware of the rates of adherence in their area to bundles, hand hygiene, and HAI and should seek out their infection preventionist with any questions, observations, and suggestions on how care could be improved.

SUMMARY CHECKLIST

- The five major routes for transmission of pathogens are contact, droplet, airborne, common vehicle, and vector-borne.
- Infection prevention procedures involve (1) eliminating the sources of infectious agents, (2) creating barriers to their transmission, and (3) monitoring and evaluating the effectiveness of control.
- Failure to clean equipment properly can render all subsequent processing efforts ineffective.
- Physical or chemical disinfection destroys the vegetative form of pathogenic organisms but cannot kill bacterial spores.
- Glutaraldehyde (20 minutes) is the most common option for high-level disinfection of semicritical respiratory care equipment.
- EtO is best suited for sterilization of critical moisture-sensitive or heat-sensitive items; heat-stable critical items should be steam-sterilized.
- Among respiratory care equipment, large-volume nebulizers have the greatest potential to spread infection.
- Ventilator circuits should be changed when visibly soiled or malfunctioning.
- HMEs may be used up to 96 hours before they need to be changed.
- Single-use items should be reused only if there is hard documented evidence that reprocessing poses no threat to the patient, it does not alter the function of the device, and FDA guidelines are followed. The use of a third-party reprocessor is recommended.
- Sterile fluids always must be used for tracheal suctioning and filling nebulizers and humidifiers.
- Hands need to be thoroughly cleaned after any patient contact, even when gloves are used.
- Standard precautions must be used in caring for all patients, regardless of their diagnosis or infection status.
- The use of gloves is part of routine basic care when there is skin contact with a patient.
- Masks, goggles, or a face shield must be worn during any procedure that can generate splashes or sprays of blood, body fluids, secretions, or excretions.
- RTs must be familiar with the overall infection prevention program, including surveillance policies and procedures.

CHAPTER 5

Ethical and Legal Implications of Practice

ANTHONY L. DEWITT

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Summarize the philosophical foundations of ethics.
- Explain what constitutes an ethical dilemma and how such dilemmas arise in health care.
- Describe how professional codes of ethics apply to ethical decision making.
- Explain how traditional ethical principles are useful in resolving ethical dilemmas.
- Describe the information that should be gathered before making an ethical decision.
- Explain how the systems of civil and criminal law differ.
- Describe what constitutes professional malpractice and negligence.
- Explain how a respiratory therapist can become liable for wrongful acts.
- List the elements that constitute a practice act.
- Explain how licensing affects legal responsibility and liability.
- Describe how changes in health care delivery have shaped the ethical and legal aspects of practice.
- Summarize the basic elements of the *Health Insurance Portability and Accountability Act* of 1996 (HIPAA).
- Describe the role of advance directives and living wills in health care.

CHAPTER OUTLINE

tort
veracity
virtue ethics

An effective respiratory therapist (RT) must possess excellent clinical skills and an understanding of the business of health care. The health care industry, similar to all industries, must deliver services in an atmosphere in which ethical and legal considerations are an integral part of the organizational culture. RTs regularly encounter circumstances that require them to make choices or take actions that have ethical and legal implications. In society, ethics and law help maintain order, stability, and accountability. In professional practices, ethics guide RTs in carrying out their duties in a morally defensible way. Law establishes the minimum legal standards to which practitioners must adhere. Although not always the case, ethical practice may require a standard above that of legal practice. The tension between these two competing values can sometimes be problematic.

The force behind law is threefold: (1) state statutes regulate individual conduct by imposing criminal and sometimes civil penalties on those whose actions are considered to be against public policy by the legislative branch of government. The sanctions range from reparations and fines to imprisonment; (2) state statutes and professional boards regulate the practice of therapists and set minimum standards for competent practice as well as requirements for continuing education. Violation of licensing statutes and regulations can result in fines or discipline or revoking of the individual practitioner's license; and (3) the common law of civil liability for negligent and intentional acts imposes a duty to pay compensation to individuals who are injured. Civil judgments are usually monetary—they do not affect personal liberty.

Sanctions for ethical misconduct range from a loss of professional standing to expulsion from the profession or professional societies. In some cases, ethical misconduct and legal misbehavior may result from the same incident. The distinction between illegal acts and unethical behavior is not always obvious but is straightforward. *An illegal act violates the standards of conduct set down for all citizens (e.g., domestic assault), whereas ethical misconduct usually relates to violations of professional and ethical norms established by the profession as a whole.* A given act may fit any one of the following categories, depending on the circumstances and the ethical orientation of the person involved: ethical and legal, unethical but legal, ethical but illegal, or unethical and illegal.

For example, a therapist who spends 30 minutes after clocking out visiting with a patient because the patient has no family is performing an act that is both ethical and legal. If the purpose of the visit, however, is to encourage the patient to offer her monetary gratuities for this extra visitation, the act would be *legal but unethical* because it seeks to exploit the emotional vulnerability of a patient. If the same patient, however, was a prisoner subject to a restriction on their right to visitation by the state, and the therapist knowingly violated the prohibition against visitation in violation of a state statute, the act *would not be unethical* (because the act does not violate the standards of the profession) *but may well be illegal* under state law. Finally, if the purpose of the visit was to rummage through a demented patient's valuables for the purpose of taking their credit card and checkbook, the act would be *both unethical* (because it would be exploiting the patient's mental vulnerabilities in violation of professional norms) *and illegal* (because it would be theft in violation of state criminal laws).

This chapter provides a foundation of principles related to the ethical and legal practice of respiratory care.

PHILOSOPHICAL FOUNDATIONS OF ETHICS

Although an in-depth discussion of philosophy is beyond the scope of this chapter, you should realize that ethics has its origins in philosophy. *Philosophy* may be defined as the love of wisdom and the pursuit of knowledge concerning humankind, nature, and reality.[1] *Ethics* is one of the disciplines of philosophy, which include ontology (the nature of reality), metaphysics (the nature of the universe), epistemology (the nature of knowledge), **axiology** (the nature, types, and criteria of values), logic, and aesthetics. Ethics is primarily concerned with the question of how we should act. Although ethics may share common origins with the disciplines of law, theology, and economics, as an applied practice, ethics is clearly different from these disciplines.[1] Ethics can be described philosophically as a moral principle that supplements the golden rule and can be

summed up by a commitment to "respect the humanity in persons."[2]

ETHICAL DILEMMAS OF PRACTICE

The growth of respiratory care has paralleled the development of advanced medical technology and treatment protocols. At the same time, during the 1970s and through the 1990s, the medical community has experienced rising expectations about acceptable standards of care. This is due to an ever-growing and sophisticated patient population fueled by medical benefit packages from the government and employers. In the latter part of the 1990s, managed care strategies and other cost-containment methods adopted by most third-party payers slowed the growth of the health care industry. The ethical and legal issues faced by practitioners, although changed in many cases, continued to grow. In the earlier period, RTs faced ethical dilemmas and legal issues associated with patient expectations, staffing, and quality of care, among others. RTs continue to face ethical dilemmas and legal issues; however, such dilemmas may now include the rationing of care, dealing with conflicts associated with third party–imposed standards of care, and delivery of the appropriate standard of care in the face of cost constraints and corporate influence. Staffing issues continue to be a problem and are at the root of many of the ethical and legal concerns faced by RTs. As respiratory care continues to mature as a profession, these challenges are likely to increase. The twenty-first century has brought one particular challenge, although not new to health care or to RTs: a heightened awareness of the patient's right to privacy. The *Health Insurance Portability and Accountability Act* of 1996 (HIPAA), discussed later in this chapter, is now a major consideration for RTs as they perform their jobs. It also has brought new opportunities in the form of the *Patient Protection and Affordable Care Act* of 2010 (PPACA). The PPACA has improved access to health care and increased reimbursement for patient care services, as well as creating disease management opportunities for RTs.

RTs work in complex health care settings. As a result, there is a large range of ethical dilemmas that may face the RT on a regular basis. The clinical aspects and the management aspects of health care are full of possibilities for ethical dilemmas. In addition, the ethical orientation of the RT plays a role in recognition and identification of ethical dilemmas. The health care industry continues to be in a period of dynamic change, bringing many new challenges. New technologic and management methodologies are continuously being introduced to accomplish the missions and goals of health care organizations. Over the past decade, there has been an almost complete change from a relatively open fee-for-service system to one in which care is managed in some fashion and the fees are in some form of capitated payment. These changes often pose serious ethical dilemmas.

For example, managed care uses a concept known as "restrictive gatekeeping." Restrictive gatekeeping requires patients to obtain prior approval from their third-party payer, usually an insurance company, before hospitalization and before certain procedures. When the hospital admission or procedure is approved, specific requirements or limitations are usually associated with the patient's care. As a result, health care workers, including RTs, may find themselves engaged in clinical processes that are dictated more by the third-party payers than by patient needs. Under these circumstances, health care workers may feel frustrated and helpless if they believe a patient needs care beyond that approved by the third-party payer. Ethics may impose a duty on professionals to interact with and press for change with the third party.

The rationing of care continues to be a side effect of staffing patterns created by managed care. Although all businesses must carefully balance staffing patterns against productivity, managed care has brought this concept home in a major way to health care facilities. An RT working in an understaffed department may decide that Patient A can really forego therapy because the department is short staffed and Patient A is really not going to get better anyway. Although this may sound at first like a case of simple neglect of duty, it is also an ethical dilemma. Unless this behavior is endorsed by a treatment protocol approved by the medical director and medical staff, it may violate professional norms and be unethical to effectively prefer one patient over another on the basis of factors beyond the patient's control.

The approaches used to address ethical issues in health care range from the specific to the general. Specific guidance in resolving ethical dilemmas is usually provided by a professional code of ethics. General approaches involve the use of ethical theories and principles to reach a decision.[3]

CODES OF ETHICS

A *code of ethics* is an essential part of any profession that claims to be self-regulating. The adoption of a code of ethics is one way in which an occupational group establishes itself as a profession. A code may try to limit competition, restrict advertisement, or promote a particular image in addition to setting forth rules for conduct.[4]

The first American medical code of ethics (established in 1847) was as much concerned with separating orthodox practitioners from nontraditional ones as it was with regulating behavior. Even modern codes tend to be vague regarding what is prescribed and what is to be avoided.

The American Association for Respiratory Care (AARC) has adopted a Statement of Ethics and Professional Conduct. The current code appears in Box 5-1. This code represents a set of general principles and rules that have been developed to help ensure that the health needs of the public are provided in a safe, effective, and caring manner. Codes for different professions might differ from the code governing respiratory care because they may seek different goals. However, all codes of ethics seek to establish parameters of behavior for members of the chosen profession. Professional codes of ethics often represent overly simplistic or prohibitive notions of how to deal with open misbehavior or flagrant abuses of authority.

The most difficult ethical decisions arise from situations in which two or more right choices are incompatible, in which the

Box 5-1 American Association for Respiratory Care Statement of Ethics and Professional Conduct (Revised July, 2004)

In the conduct of professional activities, the respiratory therapist shall be bound by the following ethical and professional principles. Respiratory therapists shall:

- Demonstrate behavior that reflects integrity, supports objectivity, and fosters trust in the profession and its professionals. Actively maintain and continually improve their professional competence and represent it accurately.
- Perform only those procedures or functions in which they are individually competent and that are within the scope of accepted and responsible practice.
- Respect and protect the legal and personal rights of patients they treat, including the right to informed consent and refusal of treatment.
- Divulge no confidential information regarding any patient or family unless disclosure is required for responsible performance of duty or required by law.
- Provide care without discrimination on any basis, with respect for the rights and dignity of all individuals.
- Promote disease prevention and wellness.
- Refuse to participate in illegal or unethical acts and refuse to conceal illegal, unethical, or incompetent acts of others.
- Follow sound scientific procedures and ethical principles in research.
- Comply with state or federal laws that govern and relate to their practice.
- Avoid any form of conduct that creates a conflict of interest and shall follow the principles of ethical business behavior.
- Promote health care delivery through improvement of the access, efficacy, and cost of patient care.
- Encourage and promote appropriate stewardship of resources.

choices represent different priorities, or in which limited resources exist to achieve a desired end. Ethicists readily admit that reducing these issues to simple formulations is not an easy task. The number and complexity of ethical dilemmas continue to grow as the complexity of life and health care increases. For health care, difficult ethical dilemmas continue to involve concerns about the practical limits on financial resources, the growing emphasis on individual autonomy, and more research advances such as cloning and stem cell research. Resolution of these more complex problems requires a more general approach than that provided by a code of ethics. This more general perspective is provided by ethical theories and principles.

In addition to the moral obligations that ethical duties impose on RTs, ethical obligations are often cited in legal proceedings as a tool of cross-examination. If an RT expresses opinions or is accused of actions that would violate the ethical duties of the profession, the RT's ignorance of ethical standards during cross-examination can have a powerful effect on a jury.

ETHICAL THEORIES AND PRINCIPLES

Ethical theories and principles provide the foundation for all ethical behavior. Contemporary ethical principles have evolved from many sources, including Aristotle's and Aquinas' natural law, Judeo-Christian morality, Kant's universal duties, and the values characterizing modern democracy.[5,6] Although controversy exists, most ethicists agree that autonomy, veracity, nonmaleficence, beneficence, confidentiality, justice, and role fidelity are the primary guiding principles in contemporary ethical decision making.[1,5]

Each of these ethical principles, as applied to professional practice, consists of two components: a *professional duty* and a

MINI CLINI

Conflicting Obligations

PROBLEM: Mary Smith, a registered RT with 18 years' experience, has worked for a large regional medical center for the past 10 years. She is generally happy with her work but is concerned about the financial stability of the hospital. As a result, she has signed on with a temporary agency to ensure that she will have work if the hospital decides to initiate a reduction in force. On one of her scheduled days off, Mary Smith agrees to work a shift for the temporary agency at another hospital. Two hours before her shift is scheduled to begin, she receives a telephone message from the medical center where she is employed. Her supervisor asks Mary Smith to report to work at the medical center because the only experienced therapist on the shift has been in an automobile accident. Mary Smith is torn between her obligation to the medical center where she has worked for 10 years and the agency.

DISCUSSION: Professionalism and ethics generally require a commitment to one's duties. In this situation, Mary Smith must consider not only her duty but also the consequences of each decision that she might make. In either case, there is the possibility that her decision will leave a staffing shortage at one of the hospitals.

DISCUSSION QUESTIONS: Should Mary Smith cancel her shift with the agency, although she has agreed to give the agency a 4-hour notice except in an emergency? Should she work the shift at the agency as scheduled, using the rationale that she did not create the staffing problem at the medical center? Should she call her supervisor, explain the situation, and ask for help in making the right decision, realizing that the final decision would still be hers? Should she call her supervisor and tell the supervisor that she is ill and cannot come in and report to the agency job?

GUIDANCE: Generally, a therapist's loyalty should be to the primary institution that employs her. In this situation the hospital has invested time, money, and benefits, as well as training, in the therapist, and the therapist owes the institution a duty of loyalty. Saying "I didn't create the problem" does not solve the problem; it merely passes the buck. The agency may be annoyed at the change of plans, but likely has others to call. The same does not appear to be true of the hospital. Calling the supervisor makes the problem a shared problem, and that is probably not fair to the supervisor because the supervisor did not seek outside employment. Thus this situation requires the therapist to consider her duty of loyalty to her employer and do the right thing.

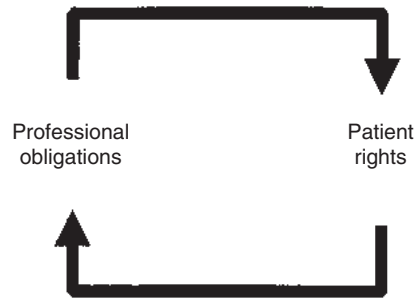

FIGURE 5-1 Reciprocal relationship between professional obligations and patient rights.

patient right (Figure 5-1). The principle of autonomy obliges health care professionals to uphold the freedom of will and freedom of action of others. The principle of beneficence obliges health care professionals to further the interests of others, either by promoting their good or by actively preventing their harm. The principle of justice obliges health care professionals to ensure that others receive what they rightfully deserve or legitimately claim.

Expressed in each duty is a reciprocal patient right. Reciprocal patient rights include the right to autonomous choice, the right not to be harmed, and the right to fair and equitable treatment. More specific rules can be generated from these general principles of rights and obligations, such as those included in a code of ethics.

Autonomy

The principle of **autonomy** acknowledges the personal liberty of patients and their right to decide their own course of treatment and follow through on a plan on which they freely agree. It is from this principle that rules about **informed consent** are derived. Under the principle of autonomy, the use by an RT of deceit or coercion to get a patient to reverse the decision to refuse a treatment is considered unethical. Likewise, it is unethical and illegal to threaten a patient who is unwilling to sign a consent form.

Veracity

The principle of **veracity** (accuracy or truthfulness) is often linked to autonomy, especially in the area of informed consent. Generally, veracity binds the health care provider and the patient to tell the whole truth about the choices inherent in medical care. This means providing not only information about the benefits of a particular course of action but also what might go wrong and what kinds of frequent complications occur. The nature of the health care delivery process is such that both parties involved are best served in an environment of trust and mutual sharing of all information. Problems with the veracity principle revolve around such issues as benevolent deception. In actions of **benevolent deception**, the truth is withheld from the patient for, supposedly, his or her own good.

When the physician decides to withhold the truth from a conscious, well-oriented adult, the decision affects the interactions between health care providers and the patient and has a chilling effect on the rapport that is so necessary for good care. In a poll conducted by the Louis Harris group, 94% of Americans surveyed indicated that they wanted to know everything about their cases, even the dismal facts. Other than with pediatrics and rare cases in which there is evidence that the truth would lead to a harm (e.g., suicide), the truth, provided in as pleasant a manner as possible, is probably the best policy.[7]

Truth telling also can involve documentation and medical recordkeeping. This type of dilemma is occurring more frequently under strict managed care reimbursement protocols.

MINI CLINI

Patient Rights

PROBLEM: An RT working at a hospital receives a physician order to administer an aerosolized bronchodilator treatment to a 26-year-old female patient with asthma admitted for suspected pneumonia. The patient refuses the treatment on entering the room, stating that she is having a "bad day" today and does not want to be bothered by anyone. The patient is regarded as being competent and fully capable of making health care decisions for herself. How should the RT handle this situation?

DISCUSSION: The RT must acknowledge and respect the patient's right to decide freely whether or not to allow the respiratory care treatment. According to the principles of ethical theory and conduct, health care professionals have an obligation to promote patient autonomy by permitting freedom of will and freedom of action. It is also important that neither coercion nor deceit be used to get a patient to reverse his or her decision to refuse a treatment. According to the American Hospital Association statement called "The Patient Care Partnership," the patient has the right to refuse treatment and to be informed of the medical consequences of her action.

The RT could talk to the patient and explore what the term "bad day" meant to her. It might be that she is not feeling well because of breathing problems from her asthma condition and worsening symptoms of possible pneumonia. The RT has an important role in ensuring that the patient understands the benefits of the respiratory treatment and the health consequences of refusal so that the patient can make a well-informed decision. If the RT approaches the patient in a professional, nonthreatening manner, she may feel more at ease and be willing to discuss in greater depth why she does not want to take the treatment. It is common for a patient to refuse therapy initially only to change his or her mind after discussion with the RT. Should the patient still refuse the treatment after discussion with the RT, the RT should remain nonjudgmental, even if he or she disagrees with the patient's decision. Appropriate documentation in the medical record and physician notification should then occur.

Nonmaleficence

The principle of **nonmaleficence** requires that health care providers avoid harming patients and prevent harm actively where

possible. It is sometimes difficult to uphold this principle in modern medicine because in many cases, drugs and procedures have secondary effects that may be harmful in varying degrees. Procedures carry risks for complications, not all of which can be predicted. For example, an RT might ask whether it is ethical to give a high dose of steroids to an asthmatic patient, knowing the many harmful consequences of these drugs. One solution to these dilemmas is based on the understanding that many helping actions inevitably have both a good and a bad effect, or *double effect*. The key is the *first intent*. If the first intent is good, the harmful effect is viewed as an unintended result. The **double effect** brings us to the essence of the definition of the word *dilemma*. The word comes from the Greek terms *di,* meaning "two," and *lemma,* meaning "assumption" or "proposition."[8]

Consideration of intent alone, however, does not settle the issue. Nonmaleficience and veracity cannot always be separated; effects must be explained, even if this may lead the patient to pass up the intended benefits of the treatment.

Beneficence

The principle of **beneficence** raises the "do no harm" requirement to an even higher level. Beneficence requires that health care providers go beyond doing no harm and contribute actively to the health and well-being of their patients. Many quality-of-life issues are included within this dictum. Practitioners of medicine today possess the technology to keep some individuals alive well beyond any likelihood of meaningful recovery. This technology presents dilemmas for practitioners who have the ability to prolong life but not the ability to restore any uniquely human qualities.

One approach in this situation is for the RT to tell the patient that the physician will interpret the studies and provide a full report at the next office visit. All final discussion of results must ultimately go through the physician.

Some individuals interpret the principle of beneficence to mean that they must do everything to promote a patient's life, regardless of how useful the life might be to that individual. Other professionals in the same situation might believe they are allowing the principle to be better served by doing nothing and allowing death to occur without taking heroic measures to prevent it. In an attempt to allow patients to participate in resolving this dilemma, legal avenues, called **advance directives**, have been developed.[9] Advance directives allow a patient to give direction to health care providers about treatment choices in circumstances in which the patient may no longer be able to provide that direction. The two types of advance directives available at the present time and widely used are the *living will* and the *durable power of attorney for health care.* A durable power of attorney for health care allows the patient to identify another person to carry out his or her wishes with respect to health care, whereas a **living will** states a patient's health care preferences in writing. As a result of the *Patient Self-Determination Act* of 1990, most states require that all health care agencies receiving federal reimbursement under Medicare/Medicaid legislation provide adult clients with information on advance directives.[9,10]

MINI CLINI

Veracity

PROBLEM: Jon performs pulmonary function testing, including blood gases, for his hospital. Many of the patients he sees are attempting to qualify or requalify for continuous reimbursement for home oxygen use. To qualify, the patient's PaO_2 must be less than 60 mm Hg on room air at rest. Patient A, who has home O_2 therapy, is attempting to requalify, although her condition has improved from what it was 1 year earlier. Her blood gas results show a PaO_2 of 63 mm Hg. The patient's husband asks Jon if there is anything he can do, while relating how greatly his wife benefits from the O_2. Jon tells the husband that there is nothing he can do and assists the husband in taking the patient out to her car. At the car, the husband pulls out his wallet, shows it to Jon, and repeats the question.

DISCUSSION POINTS: RTs have an obligation to carry out their duties in the most competent and professional manner possible. Failure to do so may constitute both an ethical dilemma and a legal issue. Similarly, RTs have a duty to be truthful with third parties who may rely on their clinical results.

DISCUSSION QUESTIONS: What is the potential ethical dilemma in this situation? What ethical principles are involved here? What other ways could Jon have chosen to handle this situation?

GUIDANCE: The ethical dilemma here is whether to accept cash to change a blood gas result, and there should be no question about the right answer. It is never okay to accept money from patients for doing your job. It creates a situation in which a clinician feels obligated to perform additional or, in this case, unlawful acts for the patient. That is a slippery slope, and once a therapist starts down that path, there is frequently no turning back. Falsification of medical records can result in both civil and criminal liability. Accepting money to change the test result could be viewed as receiving a kickback under the federal Anti-Kickback statute, which carries criminal penalties. It could be viewed as an unlawful and unethical act by the state board, and result in license discipline. Worse, it erodes the trust of other professionals—including physicians and nurses—in the scientific objectivity and professional status of all the other therapists who will be tarred with the same brush.

This Mini Clini involves the ethical principles of veracity and the duty of candor to third parties. Therapists have fought hard for professional recognition, and selling test results undermines the entire profession. The ethical principle of veracity is among the most important of the ethical principles because it has the potential to do the most damage if it is violated.

Confidentiality

The principle of **confidentiality** is founded in the Hippocratic Oath; it was later reiterated by the World Medical Association in 1949. It obliges health care providers to "respect the secrets which are confided even after the patient has died."[11] Confidentiality, as with the other axioms of ethics, often must be balanced against other principles, such as beneficence. Notably, state laws require a breach of confidence under certain

conditions (e.g., reporting gunshot wounds or child abuse) in which risk to other parties may result from not disclosing events or results.

The main ethical issue surrounding confidentiality is whether more harm is done by occasionally violating its mandate or by always upholding it regardless of the consequences. This limitation to confidentiality is known as the *harm principle*. This principle requires that practitioners refrain from acts or omissions in which foreseeable harm to others could result, especially when the others are vulnerable to risk. This principle would require that confidentiality be maintained for a patient with acquired immunodeficiency syndrome (AIDS) in matters involving his or her landlord. In this case, confidentiality is justified because the landlord is not particularly vulnerable. However, if the patient was planning to marry, the harm principle would require that confidentiality be broken because of the special vulnerability of the future spouse.

Confidentiality is usually considered a qualified, rather than an absolute, ethical principle in most health care provider–patient relationships. These qualifications are often written into codes of ethics. The American Medical Association Code of Ethics, Section 9, provides the following guidelines: "A physician may not reveal the confidences entrusted to him in the course of medical attendance or the deficiencies he may observe in the character of patients, unless he is required to do so by law or unless it becomes necessary in order to protect the welfare of the community or a vulnerable individual." Under the requirements of public health and community welfare, there is often a legal requirement to report such things as child abuse, poisonings, industrial accidents, communicable diseases, blood transfusion reactions, narcotic use, and injuries caused with knives or guns.[12] In many states, child abuse statutes protect the health care practitioner from liability in reporting even if the report should prove false as long as the report was made in good faith. Failure to report a case of child abuse can leave the practitioner legally liable for additional injuries that the child may sustain after being returned to the hostile environment.

Breaches of confidentiality more often result from careless slips of the tongue than from decision making or purposeful actions. Trading gossip about patients is unprofessional, unethical, and, in certain cases, illegal. Risks for inadvertent disclosure increase markedly when RTs may exchange information on social networks such as Facebook and LinkedIn. Such information should never be placed in such social media networks, because doing so violates the rights of individual patients.

RULE OF THUMB

Patient information should be discussed **only** in private and with persons who have a legitimate reason and need to know.

Because of the widespread use of computerized databases, confidential information, previously highly protected, is now relatively easy to obtain. Clinical data are available for close scrutiny by the clerical staff, laboratory personnel, and other health care providers. The widespread use of these data systems also threatens patient confidentiality. In an attempt to reduce this threat, most clinical databases are restricted to use by only the health care workers who have a need to know. In addition to being unethical, an RT who reads the file of a patient whom he or she is not treating would likely be in violation of institutional policy. The accompanying Mini Clini below provides an example.

MINI CLINI

Confidentiality

PROBLEM: Mary, an RT, is working the evening shift at a large urban medical center when she receives a telephone call from a friend telling her that her next door neighbor has been admitted to the medical center. Mary's first thought is to check the neighbor's file on the computer system to see why her neighbor has been hospitalized.

DISCUSSION POINT: Mary knows that the medical center has a policy that employees are to access only the charts for which they have a reason to do so.

DISCUSSION QUESTIONS: Should Mary access this chart via the computer system? If she does, what kind of violation will she be committing—ethical, legal, or both? What ethical principles, if any, would apply here? What is the harm in simply checking the computer on this patient? Is anyone likely to know if Mary accesses this patient's information?

GUIDANCE: The answer here is straightforward. She should absolutely not access the computer. The policy is there to keep the facility compliant with HIPPA and with state laws regarding privacy. Mary runs the risk for being fired because this action violates hospital policy. What harm does looking at the computer do? It erodes the confidentiality that patients expect. The far greater harm will be to Mary's reputation and future employability. If Mary does this, she will certainly be found out because the electronic medical record system has an "audit trail" that indicates who accessed the record and when. Mary will face hospital discipline for the policy violation (likely termination) and she may face criminal charges or civil administrative penalties under state and federal law for breaches of patient confidentiality. This action also places Mary at risk for a civil lawsuit for invasion of privacy.

The only exception to the rule of confidentiality regarding Mary's neighbor is if Mary is assigned to provide care to her as a treating RT. Only then does she have a need to know what is in the chart and what is wrong with her neighbor. But even then, the wiser course, because of the close relationship, would be for Mary to ask that she be excused from this case and that someone else handle the clinical duties for the patient.

Why? If the patient has an illness that carries any stigma with it (human immunodeficiency virus [HIV] infection, pediculosis capitis, etc.), the patient will likely be very embarrassed if her neighbor knows about it. And, if the patient's other neighbors learn about the condition from another source, Mary will be suspected. This will have consequences at work. For this reason, Mary should steer clear of this patient's medical record.

Despite medical and sociologic advances, potential violations of the individual's right to privacy in certain populations, such as patients with AIDS, pose a special risk because disclosure may result in economic, psychologic, or physical harm to the patient. RTs should adhere to the dictum found in the Hippocratic Oath: "What I may see or hear in the course of the treatment or even outside of treatment of the patient in regard to the life of men, which on no account one must spread abroad, I will keep to myself, holding such things to be shameful to be spoken about."[13]

Justice

The principle of **justice** involves the fair distribution of care. Rising health care expectations, coupled with the decreased availability of care because of cost, is making this principle an important one for health care workers. Population trends and the financial shortfalls in programs such as Medicaid and Medicare will contribute to the continuing importance of this principle.

The United States is rapidly approaching the point at which a balance must be found between health care expenses and the revenue available to pay for them. Efforts to achieve this balance may lead to some form of rationing of the delivery of health care services. This type of justice is properly referred to as **distributive justice**.

A second form of justice seen in health care is **compensatory justice**. This form of justice calls for the recovery for damages that were incurred as a result of the action of others. Damage awards in civil cases of medical malpractice or negligence are examples of compensatory justice. Compensatory justice often has been cited as playing a major role in increasing the cost of health care. However, the Congressional Budget Office estimates that less than 2% of the cost of health care is related to medical malpractice. Studies by Zurich Insurance Company,[14] Harvard University, and Dartmouth College showed little to no impact on the cost of health care and generally debunk the myth that physicians always practice defensive medicine. The Harvard study showed that patients were not compensated in the presence of actual malpractice more frequently than physicians were held accountable in the absence of actual malpractice. Other studies generally confirm that the civil justice system does a good job of protecting the rights of health care workers and patients in negligence litigation. There is a general bias, fueled in part by media reports, against medical liability. Nationally, 75% of medical negligence cases that go to trial are won by the medical provider.

Role Duty

Because no single individual can be solely responsible for providing all of a patient's health care needs, modern health care is necessarily a team effort. There are more than 100 allied health professions, and allied health workers (excluding nursing and physicians) provide approximately 60% of all patient care. Each of the allied health professions has its own practice niche, defined by tradition or by licensure law. Practitioners have a duty to understand the limits of their role and to practice with fidelity. For example, because of differences in *role duty,* an RT might be ethically obliged not to tell a patient's family how critical the situation is, instead having the attending physician do so.[3] The previous Mini Clinis addressed role duty, and the accompanying Mini Clini presents another example of the ethics of role duty.

ETHICAL VIEWPOINTS AND DECISION MAKING

In deciding ethical issues, some practitioners try to strictly interpret one or more of the aforementioned ethical principles. Other practitioners seek to decide the issue solely on a case-by-case basis, considering only the potential good (or bad) consequences. Still other practitioners would appeal to the image of a "good practitioner," asking themselves what a virtuous person would do in a similar circumstance. Finally, many practitioners acknowledge that they largely follow their intuition for making ethical decisions. These different viewpoints represent the four dominant theories underlying modern ethics.[5,15] The viewpoint that relies on rules and principles is called **formalism**, or duty-oriented reasoning. The viewpoint in which decisions are based on the assessment of consequences is called **consequentialism**. The viewpoint that asks what a virtuous person would do in a similar circumstance is called **virtue ethics**. When intuition is involved in the decision-making process, the approach is called **intuitionism**.

Formalism

Formalist thought asserts that certain features of an act determine its moral rightness. In this framework, ethical standards of right and wrong are described in terms of rules or principles. These rules function apart from the consequences of a particular act. An act is considered morally justifiable only if it upholds the rules or principles that apply.

The major objection to this duty-oriented approach lies in its potential for inconsistency. Critics of formalist reasoning insist that no principle or rule can be framed that does not have exceptions. These critics claim that no principle or rule can be framed that does not conflict with other rules.

Consequentialism

For the consequentialist, an act is judged to be right or wrong based on its consequences. Each possible act is assessed in terms of the relative amount of good (over evil) that it would cause. The most common application of consequentialism judges acts according to the *principle of utility*. The principle of utility, in its simplest form, aims to promote the greatest general good for most people.

Critics of this approach claim that it has two fundamental flaws. First, the analyzing and weighing the amount of good over evil that might occur is not always possible. Second, reliance on the principle of utility to the exclusion of all else can result in actions that are incompatible with ordinary judgments about right and wrong. A classic example of this problem can be seen in the true World War II case of the battle for

MINI CLINI

Role Duty

PROBLEM: Sue, an RT, receives a request to perform a blood gas analysis for a patient on a ventilator because, as reported by the nurse, the patient's oxygen saturation is only 61%. The patient has an order to obtain blood gas values as needed. As the nurse and RT look at the blood gas results, they both are surprised because the saturation is now 93%. The nurse suggests repeating the blood gas examination. The RT is about to comply until she notes the oximeter display on which the nurse is relying shows the patient with an O_2 saturation of 93% and a pulse rate of 61 beats/min.

DISCUSSION POINT: Teamwork and role delineation are both essential components of good patient care. Each practitioner also has an obligation to perform his or her duties in the most competent and professional manner possible.

DISCUSSION QUESTIONS: What kind of issue or dilemma exists here—legal, ethical, or both? What should the RT do at this point? Should an incident report be written and, if so, by whom?

GUIDANCE: The dilemma here is to explain the nurse's mistake in a way that does not jeopardize the working relationship with the nurse, while at the same time protecting the patient and the facility. Clearly a second blood gas value should not be obtained. Placement of the oximeter should be checked, and, if the oximeter is functioning properly, then it should be believed.

There are both legal and ethical components to the problem. The nurse had a good-faith belief that blood gas levels were required based on her understanding of the pulse oximeter. Her belief was wrong but reasonable. It is easily corrected with some training, and it is far better to discover this problem with an error that does not harm a patient as opposed to an error in which patient harm might have resulted.

The first issue is to explain the way the oximeter works and the meaning of the readings. Many nurses fail to understand the oxyhemoglobin dissociation curve, and as a result, interpret data from oximeters incorrectly. A therapist's job is to educate both patients and other caregivers and to do so in a professional and nonjudgmental manner.

The second issue is to evaluate the level of risk. There is very limited legal risk in this situation because the patient simply was not harmed by the error. The ethical duty of veracity and the duty of loyalty to the employer create a tension, however, regarding the filing of an incident report. Incident reports are necessary to protect the institution.

The nurse may be very reluctant to write an incident report about this event because it makes her look bad. Sadly, in some institutions incident reports are used incorrectly as a disciplinary tool instead of as a method of reporting errors from which systems can be improved. So the nurse may not wish to write an incident report, but the therapist must insist in this case. In the current era ensuring high-quality care is so important that hospitals must establish a culture in which reporting errors is encouraged and, in fact, expected as every caregiver's obligation to use the experience of errors and "near miss" errors to improve care.

Why must a report be filed regarding the current event? First, the incident carried with it a strong presumption that risk to patients was present because the nurse did not understand the limits of the technology. Second, although a bad outcome was averted, at least one unnecessary blood gas level was obtained and a second was advocated. Third, the therapist is involved because she should have checked the oximeter before doing the first blood gas measurement to determine that the equipment was operating within specifications. So there is error on both sides of the issue. Even if the nurse does not write an incident report, the incident report should be written by the therapist and the mistake disclosed to the physician. Teamwork and a commitment to high-quality care for patients requires honesty and full disclosure. Hospitals must ensure that reporting such events causes a focus on the process of care and opportunities to improve rather than on punishing the caregivers involved.

North Africa. In this scenario, there were two groups of soldiers but only enough antibiotics for one group. One group required the medication for syphilis contracted in the local brothels; the other group needed antibiotics for wounds sustained in battle. The dilemma arose as to who should receive the antibiotics. Formalist or duty-oriented reasoning would base the decision about who should receive the antibiotics on some concept of justice, such as giving priority to the sickest or to the individuals most in need. However, the actual decision in this case was a consequentialist one, based not on the desire to distribute the drug justly but rather on the need to obtain a quick victory with as few casualties as possible. The scarce medication was given to the soldiers who were "wounded" in the brothels rather than in battle because these soldiers could be restored quickly and returned to the frontlines to aid the war effort.

Mixed Approaches

Mixed approaches to moral reasoning try to capitalize on the strengths of two major lines of ethical thought. One approach, called **rule utilitarianism**, is a variation of consequentialism. Under this framework, the question is not which act has the greatest utility but which rule would promote the greatest good if it were generally followed.

The rule utilitarian would agree with the formalist that truth telling is a necessary ethical principle but for a different reason. To the rule utilitarian, truth telling is a needed principle not because it has any underlying moral rightness but because it promotes the greatest good in professional-patient relationships. Specifically, if truth telling were not followed consistently, trusting relationships between patients and health care professionals would be impossible.

MINI CLINI

Role Duty

PROBLEM: Courtney is the lone RT on duty on the midnight shift in a small, 65-bed rural hospital. She likes working at the small hospital and knows most of the patients and their conditions by memory. The night is quiet and uneventful until 2:00 AM, when a code is called for a patient in the intensive care unit (ICU). Courtney immediately heads for the ICU while mentally noting the condition of the patient on whom the code has been called. She remembers that the patient is 78 years old and has COPD. Just as she nears the ICU, a second code is called for a patient in a room just outside of the ICU. Courtney quickly jogs her memory and remembers that this patient is a 25-year-old woman with diabetes who has just given birth to a baby girl.

DISCUSSION POINT: The lone RT can attend to only one code, although she has an obligation to provide the best care possible to all patients. There is no protocol of which the RT is aware that would provide guidance about which patient she should help first. At the time the second code is called, she is at an equal distance from both patients.

DISCUSSION QUESTIONS: Is this RT facing an ethical dilemma? If so, what guiding principle or principles should be relied on to determine the best course of action? Which patient should the RT help first?

GUIDANCE: The ethical dilemma here is one that arises more frequently than most clinicians realize. Fortunately, however, because it is not new there are certain principles that can be used to help guide decision making.

First of all, there is no "right" answer. The life of a 78-year-old man is no less valuable than the life of a 25-year-old woman. They are both equal under the law and from an ethical point of view. But the therapist cannot be in two places at once. So, irrespective of whether it is fair, a choice must be made. Triage is the principle that guides the approach to these situations. According to the 2014 Unabridged *Webster's Third New International Dictionary,* the term *triage* comes from the French verb *trier,* meaning to separate, sift, or select. In this situation, the therapist has to sift through two choices. Triage originated from the need to treat multiple wounded soldiers with limited resources. Wounded soldiers were initially assigned into three categories: (1) those who would likely live without medical aid, (2) those who would likely die no matter what was done, and (3) those for whom immediate treatment would likely be lifesaving.

Between the two patients, there is a strong likelihood that no matter what is done for the 78- year-old patient, that patient will expire given his diagnosis and comorbidities. The young woman likely has the greatest chance for survival, so that lifesaving care will likely benefit her more than the 78-year-old patient. These are the factors that could be used to make the decision, but ultimately, the decision belongs to the therapist. No one can say whether one choice is better than the other. Ethics rarely involves the choice between good and evil, it usually involves a choice between good and better, or better and best. Because the lines are so gray, it is easy to cross them.

The rule utilitarian approach is probably the most appealing and useful to health care professionals. This approach is appealing because it addresses both human rights and obligations and the consequences of actions. Rule utilitarianism seems best able to account for the modern realities of human experience that so often affect the day-to-day practice of health care. However, although it has some value as an ethical framework, it has the disadvantage of being quite variable among caregivers. Where caregivers have different values and different educational levels, ethical decision making using this tool frequently is inconsistent.

Virtue Ethics

A theory of virtue ethics has evolved based in part on the limits of both formalism and consequentialism. Virtue ethics is founded not in rules or consequences but in personal attributes of character or virtue. Under this formulation, the first question is not, "How do I act in this situation?" but rather, "How should I carry out my life if I am to live well?" or "How would the good RT act?"

Virtue-oriented theory holds that professions have historical traditions. Individuals entering a profession enter into a relationship not only with current practitioners but also with the practitioners who have come before them. With these traditions comes a history of character standards set by the individuals who have previously distinguished themselves in that profession.

According to this perspective, the established practices of a profession can give guidance, without an appeal to either the specific moral principles or the consequences of an act.[3] When the professional is faced with an ethical dilemma, he or she need only envision what the "good practitioner" would do in a similar circumstance. It is hard to imagine the good RT stealing from the patient, charging for services not provided, or smothering a patient with a pillow.

Rapidly changing fields such as respiratory care pose some problems for virtue ethics. What might be considered good ethical conduct at one time might be deemed wrong the next time. An example of this change over time is an RT who is asked not only to disconnect a brain-dead patient from a ventilator but also to remove the feeding tubes and intravenous lines.

In addition to the difficulty with changing values in virtue ethics, it provides no specific directions to aid decision making. The heavy reliance of virtue ethics on experience rather than on reason makes creative solutions less likely. Finally, practitioners often find themselves in conflicting role situations for which virtue ethics has no answers. A good example is an RT who practices the virtue of being a good team player but is confronted with the need to "blow the whistle" on a negligent or incompetent team member.[3] Despite these limitations, virtue ethics is probably the way most practitioners make their ethical decisions.

Intuitionism

Intuitionism is an ethical viewpoint that holds that there are certain self-evident truths, usually based on moral maxims such

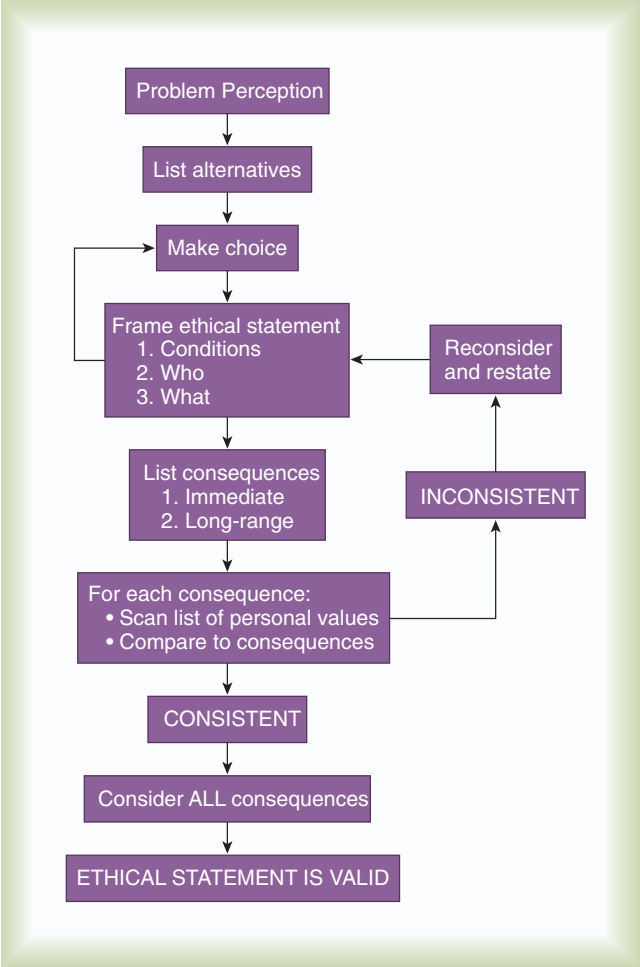

FIGURE 5-2 Comprehensive ethical decision-making model. (Redrawn from Brody H: Ethical decisions in medicine, ed 2, Boston, 1981, Little, Brown.)

as "treat others fairly." The easiest way to understand intuitionism is to think of as many timeless maxims as you can, which form the basis for intuitionism. These maxims may range from "do not kill" to "look before you cross the street."[6] As a decision-making tool, intuitionism is not helpful, mostly because it depends on the intuitional abilities of the specific caregiver.

Comprehensive Decision-Making Models

To aid in the process of decision making in bioethics, several comprehensive models have been developed. Figure 5-2 depicts one example of a comprehensive decision-making model that combines the best elements of formalism, consequentialism, and virtue ethics. As is evident in this approach, the ethical problem is framed in terms of the conditions and who is affected. Initially, an action is chosen based on its predicted consequences. The potential consequences of this decision are compared with the human values underlying the problem. The short test of this comparison is a simple restatement of the golden rule, that is, "Would I be satisfied to have this action performed on me?" The initial decision is considered ethical if, and only if, it passes this test of human values. A simpler but nonetheless comprehensive model is used by many ethicists. The model uses eight key steps (Box 5-2).

Box 5-2 Ethical Decision-Making Model

1. Identify the problem or issue.
2. Identify the individuals involved.
3. Identify the ethical principle or principles that apply.
4. Identify who should make the decision.
5. Identify the role of the practitioner.
6. Consider the alternatives (long-term and short-term consequences).
7. Make the decision (including the decision not to act).
8. Follow the decision to observe its consequences.

With or without these models, RTs are often at a double disadvantage in ethical decision making because RTs not only must live with their own decisions but also must support (and act on) the decisions of their physician colleagues. Unless excellent communication exists, misunderstandings can occur. Such misunderstandings may be an essential factor in the high job stress, burnout, and attrition in respiratory care.

Classes in ethics, decision making, and communication skills are crucial components of the preparation of RTs for the often confusing and frustrating practice in today's medical settings. The specialty requires practitioners who can go beyond simple assertions of right or wrong and provide justifications that are both right and reasoned. Many hospitals have ethics boards or committees to review and set policy and to assist in making informed ethical decisions. In addition to administrators and medical staff members, these committees may include a member of the lay public, a chaplain, and one or more experts in bioethics.

A major factor in the disciplinary decisions of professional boards is frequently whether the acts of the RT conformed to the ethical standards of the profession. Nearly every respiratory care practice act has ethical principles embedded in the statute and codified in state regulations. Every RT should be aware of what the particular state dictates in terms of ethical practice.

RULE OF THUMB

Never attempt to make ethical decisions for others. You can only make them for yourself.

LEGAL ISSUES AFFECTING RESPIRATORY CARE

Not all decisions can be made in the confines of the medical community. The patient comes from outside this community of professionals, and with expectations different from those of the professionals who will care for her. Sometimes there is a conflict in the expectations and the results. Other times, there

are medical errors or acts by professionals that fail to meet professional standards. When the result of those errors is patient injury or death, the possibility of professional liability results.

Recently, some hospitals and health care organizations have adopted a model that attempts to subvert the medical liability process. It involves the rapid investigation of sentinel events, and, where errors are made, the disclosure of those errors to the patient followed by an immediate apology. In those instances where there is compensable injury, immediate compensation is offered. This process has reduced medical liability costs for some providers.*

Unfortunately for professionals, in the absence of a system designed to address errors within the professional community, these problems often go to the courts. The problem of professional liability in the delivery of health care is significant. Professional liability may contribute to increasing health care costs. Limits on medical liability have been key factors in recent legislation; however, these limits often suffer from constitutional flaws.†

Practitioners are caught in the middle. On one hand, they are required to keep costs down by avoiding overuse of technology and therapeutics. On the other hand, they are faced with a level of consumerism that holds them accountable when medical errors result from scarcity of resources. The costs, losses, frustration, and distraction brought about by the current level of legal intervention in health care practice are a concern, but a manageable one. Very few cases actually wind up going to court, and most therapists will practice their entire career without ever seeing the inside of a courtroom.

Systems of Law

Under our legal system, the law is divided into two broad classes: *public law* and *civil law.* Public law deals with the relationships of private parties and the government. Civil law is concerned with the recognition and enforcement of the rights and duties of private individuals and organizations.

Public (Criminal and Administrative) Law

The two major divisions of public law are *criminal law* and *administrative law.* Criminal law deals with acts or offenses against the welfare or safety of the public. Offenses against criminal law are punishable by fines, imprisonment, or both. In these cases, the accuser is the state, and the person prosecuted is the **defendant**.

Administrative law is the second major branch of public law. Administrative law consists of the countless regulations set by government agencies. Health care facilities face a large number of administrative and agency rules that affect almost every aspect of operation. RTs are obligated to abide by these rules and regulations.

Civil Law

Private or civil law protects private citizens and organizations from others who might seek to take unfair and unlawful advantage of them. If an individual believes that his or her rights have been compromised, the individual can seek redress in the civil courts. In these cases, the individual bringing the complaint is known as the **plaintiff**, and the individual accused of wrong is the **defendant**. Civil courts, usually in the form of juries, decide between the two parties with regard to the degree of wrong and the level of reparation required. The category of civil law best related to respiratory care is tort law.

Tort Law. A **tort** is a civil wrong, other than a breach of contract, committed against an individual or property, for which a court provides a remedy in the form of an action for damages. Causes for the complaints may range from assault and battery to invasion of privacy. The basic functions of torts are to keep the peace between individuals and to substitute a compensatory remedy for personal injury instead of allowing individuals to seek vengeance.

There are three basic forms of torts: *negligent torts, intentional torts,* and torts in which liability is assessed regardless of fault (as in the case of manufacturers of defective products). The basic difference between negligent and intentional torts is the element of intent. An intentional tort always involves a willful act that violates another's interest. A negligent tort does not have to involve any action at all. Instead, a negligent tort can consist of an omission of an action or a failure to carry out a professional duty.

Professional Negligence. **Negligence**, in its simplest terms, is the failure to perform one's duties competently. For example, to clarify negligence to juries in Missouri, the state's jury instructions state:

The term *negligent* or *negligence* as used in this [these] instruction[s] means the failure to use that degree of skill and learning ordinarily used under the same or similar circumstances by the members of defendant's profession.‡

Negligence may involve acts of commission or omission. The tort of negligence is concerned with the compensation of an individual for loss or damages arising from the unreasonable behavior of another. The normal standard for the claim, for

‡Missouri Approved Instruction 11.06 (1990 Revision).

example, in an automobile accident, is the duty imposed on individuals not to cause risk or harm to others, the standard being what a reasonable and prudent person should have foreseen and avoided. Professional negligence is different because the duty is defined by other professionals, and for that reason, requires expert testimony to establish.

In negligence cases, the breach of duty often involves the matter of foreseeability. Cases in which the patient falls, is burned, is given the wrong medication, or is harmed by defects in an apparatus often revolve around the duty of the health care provider to anticipate the harm. Duty is imposed by law. Courts tell us the following about duty:

> *For purposes of determining whether a duty exists, this Court has defined foreseeability as the presence of some probability or likelihood of harm sufficiently serious that ordinary persons would take precautions to avoid it. [citation omitted] The existence of a mere possibility is insufficient. Id. The test is not the balance of probabilities, but of the existence of some probability of sufficient moment to induce the reasonable mind to take the precautions which would avoid it.*
>
> ***Lopez v. Three Rivers Elec. Co-op., 26 S.W.3d 151, 156 (Mo. 2000)***

For the tort of negligence to be a valid claim, the four conditions listed in Box 5-3 must be met.

The assessment of what is reasonable and prudent for an RT can be determined by guidelines established by a professional group (e.g., the AARC), by direct expert testimony, or by circumstantial evidence. The legal principle ***res ipsa loquitur*** (the thing speaks for itself) may apply where a court determines under the facts that the circumstantial evidence rises to a level to permit its assertion. *Res ipsa loquitur* is sometimes invoked to show that the harm would not ordinarily have happened if the individuals in control had used appropriate care. In these cases, negligence is established by inference.

For a claim of *res ipsa loquitur* to be supported, three basic conditions must be met: (1) The harm was such that it would not normally occur without someone's negligence. (2) The action responsible for the injury was under the control of the defendant. (3) The injury did not result from any contributing negligence or voluntarily assumed risk on the part of the injured party. An example of *res ipsa loquitur* might be the failure to recognize that a patient's right main stem bronchus had been intubated with a resultant pneumothorax. For negligence to occur, the breach in duty also must cause damage or injury to the individual. The injured party must file the lawsuit within the time frame set by the statute of limitations. The term *injury,* in this sense, may include not only physical harm but also mental anguish and other invasions of the patient's rights and privileges. The claim must be established by a preponderance of the evidence to prevail. Essentially this means that a jury must be convinced that it is more likely than not that negligence occurred.

Box 5-3 Elements of Negligence

- The practitioner owes a duty to the patient.
- The practitioner breaches that duty.
- The breach of duty was the cause of damages.
- Damage or harm came to the patient.

For the tort of negligence to cause liability, the breach of duty must be shown to be the cause of the injury. *Causation* revolves around whether the acts of negligence were the cause in fact and the legal cause of the damages. *Causation in fact* means simply that the negligent act of the caregiver caused the damages. *Proximate causation* or *legal causation* usually turns on foreseeability and whether it is fair to impose damages on a defendant.

Factual causation usually is a question for the jury. It is best illustrated in the context of a motor vehicle accident. If a car runs a stop sign but does not hit anyone, the driver may well be negligent, but no one could sue because the driver did not cause any harm. If there is a collision, there is harm flowing directly from the failure to stop. For that reason, the mere failure to provide the appropriate standard of care is insufficient to necessitate payment of damages unless injury occurs as a result of the action or omission. In most states, the act of negligence does not have to be the only cause; it only has to be one cause. Sometimes this is referred to in jury instructions as a requirement that the defendant's actions "caused or contributed to cause" the injury. Ordering O_2 turned off on a severely hypoxemic patient might be the direct cause of the patient's injury, but the therapist's acting on that order instead of questioning it could be thought of as a contributing cause.

Proximate causation turns on foreseeability. It tends to be a retrospective analysis. If an RT fails to check a ventilator as required, it is foreseeable that the patient could develop a compromised airway and sustain brain damage or die. The RT's failure would be both the factual and the legal cause of the injury. Proximate causation also comes into play, however, when there are multiple wrongdoers. For example, a nurse requests a therapist's help to place a patient on the bedside commode. The therapist is unaware that the patient's systolic blood pressure is 60 mm Hg by Doppler. The patient bears down, experiences a cardiac arrest, and dies. Although the actions of the therapist in helping to move the patient to the commode are the cause in fact, the therapist might escape liability because it was not foreseeable that helping the nurse move the patient would result in the patient's death.

Most medical negligence lawsuits are defended by claiming that no matter what the medical error was, it was not the cause in fact of the patient's death. This is frequently possible because only a very limited number of patients actually get autopsies. There may be no demonstrative evidence or pathology report detailing what caused the patient's death.

For example, in a situation in which the leads were reversed in a patient receiving a dual-chamber pacemaker, the heart, on autopsy, showed focal areas of inflammation. The defendant had a pathologist testify that the most likely cause of death was not the failure to place the pacemaker leads in the correct position, but rather, a particularly virulent virus (never identified) that caused rhythm disturbances and death. In nearly

every case, one of the primary defenses will always be a lack of medical causation.

Damages are another factor in negligence lawsuits. There are three kinds of damages: economic, noneconomic, and punitive. Economic damages are awarded for economic loss. For example, a working wife and mother killed in a vehicular accident leaves a family without a caregiver for the children and without the $45,000 a year salary she earned. Her economic damages include both the salary figure (adjusted for inflation and wage increases over her work life) and the cost of replacing the home care she rendered to her family.

Noneconomic damages include pain, suffering, disability, disfigurement, and loss of the enjoyment of life. Although economic damages can be guided by hard numbers, juries are often left to decide the value of a person's pain or suffering. Many states have limited the amounts that can be awarded for these elements of damage, as noted earlier, but in some states those caps have been overturned.

Punitive damages are damages that are awarded to punish wrongful conduct and discourage future unlawful conduct. Punitive damages are quite rare in medical negligence cases except where alcohol or drug use by caregivers is involved or where there is overwhelming negligence that is equivalent to intentional conduct. Some states also limit these damages.

Malpractice. **Malpractice**, as a form of negligence, can involve professional misconduct, unreasonable lack of skill or fidelity in professional duties, evil practice, or unethical conduct. There are three classifications of malpractice: (1) *Criminal* malpractice includes crimes such as assault and battery or euthanasia (handled in criminal court). (2) *Civil* malpractice includes negligence or practice below a reasonable standard (handled in civil court). (3) *Ethical* malpractice includes violations of professional ethics and may result in censure or disciplinary actions by licensure boards.

Intentional Torts. An intentional tort is a wrong perpetrated by someone who intends to do the act and, possibly, intends to do the harm. In contrast, in negligence, the professional fails to exercise adequate care in doing what is otherwise permissible. The acts must be intentionally performed to produce the harm or must be performed with the belief that the result was likely to follow. These torts are more serious than the tort of negligence, in that the defendant intended to commit the wrong. Consequently, punitive and actual damages may be awarded. Examples of intentional torts are acts that involve fraud, defamation of character, invasion of privacy, deceit, infliction of mental distress, and assault and battery.

In the hospital, the unwarranted discussion of the patient's condition, diagnosis, or treatment for purposes other than the exchange of information is always deemed suspect in regard to defamation of character. Under the general title of defamation of character are the torts of libel and slander. **Slander** is the verbal defamation of an individual by false words by which his or her reputation is damaged. **Libel** is printed defamation by written words, cartoons, and such representations to cause the individual to be avoided or held in contempt. Libel and slander do not exist unless they are seen or heard by a third person. If the practitioner directed such remarks only to the individual involved, it would not be slanderous; if the remark was made in the presence of a third party, it might constitute slander. Torts involving defamation are subject to short statutes of limitation and are generally disfavored in the law. The First Amendment to the Constitution may even provide a shield against slander or libel in many cases.

Caution to avoid unauthorized disclosure of patient information is especially critical in cases involving diseases such as AIDS, which often carries a high degree of medical and social stigma. Patients have the legal right to expect that all information about their illness will be held in strict confidence. Several states now have civil liability and criminal penalties for the release of confidential HIV test results in which the breach of confidence results in economic, psychologic, or bodily harm to the patient.

An **assault** is an intentional act that places another person in fear of immediate bodily harm. Threatening to injure someone through some overt act (e.g., swinging a bat at a person, even if it misses) is considered an act of assault. **Battery** represents unprivileged, nonconsensual physical contact with another person. In the classic act of assault and battery, one individual threatens injury through some overt act (throws a punch) and injures another through an overt act (connects with the punch).

Although battery is an unusual charge against a clinician (because of the nature of the work), it creates special problems. The major element of battery is physical contact without consent. When a practitioner performs a procedure without the patient's consent, this contact may be considered battery. In most instances, there is an implied consent, created when the patient seeks care from the physician. This implied consent allows the performance of ordinary procedures without written consent. In all cases of unusual, difficult, or dangerous procedures, such as surgery, the courts require written consent. For this reason, to avoid being accused of battery, RTs should always explain all procedures involving physical contact to their patients before they proceed. If a patient refuses something like a blood gas test, in the absence of some other factor that makes it unreasonable to do so, the patient's refusal should be honored.

There are two general defenses against intentional torts. The first defense is that there was a lack of intent to harm and that only clinicians who engage in intentional conduct are liable. For example, if a practitioner fainted during a procedure and caused the patient injury, he or she would not be liable because the action was involuntary. The second defense is that the patient gave consent for the procedure. If the patient consented to the action, knowing the risks involved, the practitioner would not be liable. Consent by the patient for both nonroutine and routine procedures should be obtained in writing before care is rendered.

Strict Liability. **Strict liability** is a theory in tort law that can be used to impose liability without fault, even in situations in which injury occurs under conditions of reasonable care. The most common cases of strict liability are cases involving the use of dangerous products or techniques. Courts have imposed this

principle on medical equipment manufacturers and on hospitals. However, strict liability generally has not been extended to professional services.

Breach of Contract. **Breach of contract** is a more unusual legal claim than negligence. This claim is based on the theory that when a health care professional renders care, an implicit or explicit professional-patient "contract" is established. Essentially, the contract binds the health care professional to place the patient's welfare as the foremost concern, to act only in the patient's behalf, to protect the patient's life, to preserve the patient's health, to relieve suffering, and to protect privacy. When the patient is injured as a result of the services rendered under this contract, the patient may claim that the failure of the health care professional to perform the service competently is a breach of the contract. Most state laws do not permit this kind of action, and those that do require high standards for proof.

RTs are responsible for their actions, as are members of all other professions. When these actions result in the injury of another, the injured party may turn to the courts for redress. If the RT, while acting for the physician, injures the patient through some negligent act, the patient may sue both the RT and the physician.

Civil Suits. Civil action can be brought for many reasons, such as to challenge a law or to prevent an activity. However, as in the case of malpractice suits, most civil suits seek monetary damages. The following scenario is an example of a situation that might involve the RT. The physician intends to order 0.5 ml of a bronchodilator for a 3-year-old asthmatic patient but inadvertently prescribes 5.0 ml of the drug. Because of the overdose given by the RT, the child dies.

A clearly articulated legal principle in negligence is that the duty owed to the patient is commensurate with the patient's needs. In short, the more vulnerable the patient, the greater is the caregiver's duty to protect. When the order is unclear or seems inappropriate under this principle, clinicians have an obligation to clarify rather than risk harm.

The suit could be brought against the physician for negligence for ordering the overdose, against the nurses and RT for failing to recognize that the dose was incorrect for the child, and, possibly, against the pharmacist for failing to gain adequate information as to the nature of the patient so that an appropriate dosage could be calculated. The plaintiff would base the secondary charges against the nurses and allied health practitioners on the theory that liability would be incurred by the individuals who missed an opportunity to correct the first wrongdoer's mistake. The hospital's risk management department and legal counsel can sometimes provide direction and counsel to the RT in the case of a civil suit. If the hospital in which the RT works does not provide malpractice insurance for the RT, then he or she should carry his or her own policy of malpractice insurance.

Professional liability insurance is available through the AARC's preferred provider, and it provides RTs with an attorney not only to represent them in the case of a malpractice lawsuit but also in those rare instances in which a professional board questions the conduct of the RT. Should a judgment result, it protects the RT not only from the plaintiff but also from any settling defendant who attempts to point the finger at the RT. It is crucial that the RT adhere to professional legal advice and not try to "go it alone" in a malpractice case. Sometimes well-meaning but poorly informed risk professionals tell therapists that having their own insurance is likely to get them sued. This is simply untrue.

There is no central registry or online resource where an attorney can look up an individual and determine if she has malpractice insurance. As therapists exercise greater discretion about what treatments to give and under what circumstances, that discretion is likely to increase rather than decrease their malpractice liability risk. It is the negligent act that determines who will be sued, not the insurance status of that individual. Decisions about whom to sue are made early, before any opportunity is developed for discovery, and the presence or absence of insurance is unlikely to have any impact on the person suing. Whether the person being sued has malpractice insurance can have a huge impact, because the defendant may stand to risk losing her home and everything she has worked for in the event of an unsuccessful defense. For this reason, malpractice insurance is an essential element of every RT's professional responsibility. No therapist should practice without it.

Avoiding Lawsuits

There is no foolproof formula for avoiding lawsuits; the right to bring suit is protected by the United States Constitution and guarded by the U.S. legal system. But the simplest and most effective way of avoiding lawsuits is both providing excellent care that meets professional standards and documenting that care carefully. Documenting the care that was given is a skill that every RT should develop, because it is what prevents, in most cases, lawsuits for professional negligence.

Practitioners should always deliver care in a professional manner and document care in a way that proves professional standards were met. For example, in the case of routine ventilator care, frequent documentation of tube position and suctioning is vital to show that the patient's airway was protected and that therapists were aware of the patient's condition. Documentation of an Allen's test before an arterial blood gas measurement shows attention to detail and documents that the patient's circulation was assessed. Knowing both what to do and how to document it are critical to avoiding litigation.

A key step to avoid litigation is being aware of and conforming to all professional standards regarding the care that is being delivered. All professionals should adhere to the legal requirements of professional licensure, and institutions should have policies and procedures that require the licensure status be verified upon employment and regularly thereafter.

Being aware of professional standards also includes keeping pace with institutional practice policies and procedures and the facility's own internal standards of care.

Moreover, risk management is a job requirement for every clinician. It should be an ongoing component of departmental operation and professional development and should always address documentation standards and risk management.

Even if everyone does every possible thing right, there is no guarantee that the plaintiff or her attorney will understand this if the patient meets an untimely or unexpected death because of things outside the control of the clinicians. Just as there are "professionals" with medical degrees who will testify that everything was done properly when standards of care were violated, so too are there people who are willing to say anything on behalf of a plaintiff in a lawsuit. Once a professional meets the baseline requirements of an expert witness (skill and expertise in the field and exposure to the facts of the case sufficient to form an opinion), in most cases his or her opinion will become evidence in the case. For this reason, malpractice insurance as well as having a good legal team to defend the case are the best safeguards a clinician has to protect against liability.

Not all cases wind up in court. Sometimes, when the parties are willing, a lawsuit can be avoided with mediation. However, when any potential legal claim or lawsuit surfaces, decisions about how to proceed should be made only with full input of institutional risk management and legal counsel experienced in professional negligence defense.

In recent years, the experience of several large hospital systems has suggested that active risk management practices and appropriate guest relations policies are two of the most effective tools to prevent malpractice litigation. Unhappy patients are identified quickly, and corrective action is implemented immediately. Good guest relations programs encourage listening that often results in better clinical decision making, preventing the malpractice that is at the heart of every medical malpractice lawsuit. The best way to avoid a malpractice suit is to develop a good, sound relationship with the patient that communicates to the patient that he or she is important and valued.

Health Insurance Portability and Accountability Act of 1996

In August 1996, the U.S. Congress enacted HIPAA, which required, among other things, the establishment of Standards for Privacy of Individually Identifiable Health Information. These standards, which have become known as simply the Privacy Rule, added a major dimension to the need to treat medical records and information as confidential. The Privacy Rule was developed, with public comment and input, in the years after enactment of HIPAA. The final rule was issued in March 2002. Updates to the Privacy Rule are likely to continue, making it imperative that the practitioner remain up to date with the latest requirements of the rule. The primary goal of the rule was to strike a balance between protecting individuals' health information and not impeding the exchange of information needed to provide quality health care and protect the public's health and well-being.[16]

The Privacy Rule applies to all health care providers, health plan providers (with some exceptions, such as small employer plans with fewer than 50 participants administered solely by the employer), and health care clearinghouses. An example of a health care clearinghouse is an entity that processes insurance claims for payment. Some of the exceptions are complex and beyond the scope of this chapter. The practitioner in clinical practice need not be concerned with particular exceptions because, in most cases, basic patient confidentially requires a standard at least equal to the strictest interpretation of the Privacy Rule.[16]

The basic goal of the Privacy Rule is to protect all "individually identifiable health information," commonly referred to as *protected health information*. Protected information includes any record or information that would or could identify or reveal (1) an individual's past, present, or future physical or mental health or condition; (2) the provision of health care to the individual; or (3) the past, present, or future payment for the provision of health care to the individual. Protected health information includes information in any format, which may include patient charts (electronic or paper), faxes, e-mails, or other records. The Privacy Rule provides avenues for the normal and appropriate conduct of health care treatment and business for all "covered entities," individuals, and organizations that have a legitimate need to access and use the information. Consent of the individual is not required for these covered entities.[16]

Medical Supervision

RTs are required by their scope of practice to work under competent medical supervision. This requirement creates not only a professional relationship but also a legal one. If the RT is employed by the physician, the physician is liable for the RT's actions. If the RT is employed by the hospital, the hospital is liable for the RT's actions. Under the laws of some states, the supervising physician may still be liable even if the RT is employed by the hospital where the legal theory involves a failure to supervise. The legal basis for this liability is rooted in centuries-old common law. When tradesmen had apprentices and masters had servants, the negligence of the apprentice or servant was applied to the master who controlled the action of the servants. Under modern law, an employer is deemed a master, and an employee is deemed a servant. This principle, sometimes called *vicarious liability,* is premised on this centuries-old concept expressed in Latin as ***respondeat superior*** ("let the master answer").

Under the doctrine of medical supervision, the physician assumes responsibility for the wrongful actions of the RT as long as such negligence occurred in the course of the employer-employee relationship. For this liability to apply, two conditions must be met: (1) the act must be within the scope of employment, and (2) the injury caused must be the result of an act of negligence. If the RT acted outside of his or her scope of practice, as outlined by licensure laws or by institutional regulations, the court would have to decide whether the physician would still be liable. If the RT, while in the patient's room to deliver an aerosol treatment, went beyond the normal scope of practice and adjusted cervical traction, causing injury, it is doubtful that the physician could be held fully responsible. However, under the principle of *respondeat superior,* the hospital, as a corporate entity, could be held responsible for the actions of its employees.

MINI CLINI

Health Insurance Portability and Accountability Act

PROBLEM: You, the RT, are in Ms. Smith's room tending to her respiratory equipment when the telephone rings. Ms. Smith and some of her family members are well known to you because of her many previous hospitalizations. During this hospitalization, Ms. Smith's condition has progressively worsened and today has been a particularly bad day for her. At this point, she is having serious difficulty moving and even talking. As the telephone rings, she looks at you and in a barely audible voice asks you to please answer the telephone. You do so, and the person on the other end identifies herself as Ms. Smith's granddaughter. You tell Ms. Smith that her granddaughter is on the telephone, but Ms. Smith simply looks away. You tell the granddaughter that Ms. Smith cannot talk right now and to call back later. The granddaughter asks you why Ms. Smith cannot talk, along with a series of specific questions about her condition.

DISCUSSION: As the RT, how should you handle this situation?

1. What HIPAA guidelines, if any, are applicable in this case?
2. Because you know Ms. Smith and her family, is it permissible to answer the granddaughter's questions?
3. To avoid alarming the granddaughter, should you say Ms. Smith is asleep or in the bathroom?

GUIDANCE: The first question is whether HIPAA applies. HIPAA pertains to "the individual's past, present or future physical or mental health or condition."* HIPAA requires that protected health care information never be disclosed to those who are not authorized to receive it, and the rule requires a written authorization of who can receive protected health information by the patient. Until you verify that the person on the other end of the phone is authorized in writing to receive information, you cannot disclose anything. You also may have no way of knowing whether this really is the daughter of the patient, even if you think you recognize the voice. The hospital has specific policies regarding the release of information, and you must follow those to protect yourself from any allegation of wrongdoing.

Simply because you know Mrs. Smith and her family, it is not sufficient to disclose information. Information must be given only to those on the written authorization. Verbal authorizations are not permitted because (1) you have no way to prove that it happened and (2) the patient may later change his or her mind or forget who was authorized. Thus, until you know that the person is authorized in writing to receive the information, you may not disclose protected health information.*

Even though it may be difficult to tell a family member of a patient that you cannot share information over the phone, that is the answer that you must give. You may not say that Mrs. Smith is in the bathroom because it is not true. There is no ethical exception that permits lying to family members. Lying erodes trust in the health care system.

*See, for example, "What information is protected" on the Department of Health and Human Services website: http://www.hhs.gov/ocr/privacy/hipaa/understanding/summary/index.html.

Historically, RTs have not been named individually as defendants in malpractice cases because the law generally has not focused on their role as specialized health care providers separate from the health care facility. Either the hospital or the physician is usually named as the defendant for the acts of the practitioner. RTs in these cases have been viewed simply as employees, merely carrying out the orders of a superior. However, with the increased application of state licensure regulations governing respiratory care, and especially with the development of respiratory care protocols giving RTs more autonomy, this relative protection from liability is changing rapidly. As RTs are given more discretion and are permitted to exercise independent judgment, their decision making is likely to be more frequently called into question in court.

Scope of Practice

One measure of professionalism is the extent to which the group is willing to direct its own development and regulate its own activities. This self-direction is carried out mainly through professional associations and state licensure boards, which attempt to ensure that professionals exhibit minimum levels of competence.

Basic Elements of a Practice Act. Some practice acts emphasize one area over another, but most acts address the following elements:

- Scope of professional practice
- Requirements and qualifications for licensure
- Exemptions
- Grounds for administrative action
- Creation of examination board and processes
- Penalties and sanctions for unauthorized practice

Licensure Laws and Regulations. In licensure legislation, there is always a clause specifying a scope of practice. The scope-of-practice statutes give general guidelines and parameters for the clinician's practice. Deviation from these statutes could be a source of legal problems as the specialty seeks to add new duties. Practitioners must know the limits of their scope of care and seek amendments to the licensure regulations as they expand their practice. Ideally, the original language of a licensure law should be broad enough to account for changes in practice without requiring continual amendment. Continuing education and regular review of the practice act are essential to ensure compliance with both the statute and evolving rules of the practice act.

Providing Emergency Care Without Physician Direction. One unique area that allows practice without the direction of a competent physician is that of rendering emergency medical care to injured persons. Good Samaritan laws protect citizens from civil liability for any errors they make while attempting to give emergency aid. Most states have legislated Good Samaritan statutes to encourage individuals to give needed emergency medical assistance. It is necessary for this aid to be given in good faith and free of gross negligence or willful misconduct. However, it is unlikely that the RT would be protected for giving aid that went beyond the expected skills of the individual or aid that went beyond that which could be defined

as first aid, such as performing a tracheostomy. Good Samaritan rules generally apply only to roadside accidents and emergency situations outside the hospital, although this is not always the case. The doctrine has sometimes been used by physicians inside a health care organization who respond to an emergency on a patient who is not their own. However, in California, the statute for RTs specifically extends protection only where the acts of the RT are "outside both the place and the course of employment."[‖]

INTERACTION OF ETHICS AND THE LAW

A good example of the interaction of ethics and the law in respiratory care is the diversification of the field into home care and durable medical equipment supply. This diversification has led to new relationships between these elements of the health care system and has created the potential for unethical and unlawful activity. If a practitioner accepts some payment, such as a finder's fee or percentage of the total lease costs for referring patients to a particular home care company or equipment service, he or she should be prepared to face charges of unethical and perhaps illegal practice.

Several federal and many state statutes address the legality of these types of transactions. Generally, these statutes say that anyone who knowingly or willfully solicits, receives, offers, or pays directly or indirectly any payment in return for Medicare business is guilty of a criminal offense. Violation of these statutes carries the potential for prison, a substantial fine, or both. In addition, violation of the statutes by an organization can result in exclusion from Medicare and other federal health care programs.

In recent years, hospitals have been encouraged to appoint a corporate compliance officer (CCO) to oversee the hospital's business practices and ensure that the hospital conforms to the law. In most hospitals with a working compliance plan, the CCO is freely available to discuss legal or ethical issues arising in the course of care. Appointed by the board of directors and reporting both to the hospital administration and to the board, the CCO often can address legal issues quickly and competently. Most hospitals use a toll-free anonymous number to allow employees who wish to remain anonymous to report wrongful activity. If the practitioner is aware of others who are engaged in these practices, he or she should report these activities to the appropriate state or federal health care agency. To aid the clinician in maintaining an ethical stance on these new issues, the AARC has established a position statement about ethical performance of respiratory home care.

PROFESSIONAL LICENSURE ISSUES

Because nearly every state has now passed some form of licensure for respiratory care practitioners, more RTs are being disciplined for various offenses related to the practice of respiratory care. Most RTs serve their entire professional careers and never have a problem with their professional boards. There are four significant things that RTs can be aware of now that would help prevent problems with their professional boards later.

Licensure Statute

All RTs should know in detail the requirements of their respiratory care practice act. They should know what is expected of them in terms of obtaining licensure and in the requirements to remain licensed. After receiving licenses, many professionals never look at their statute and never evaluate what actions are mandated by the rules and regulations enacted by their board. Some states by statute require that RTs report certain behavior.

Section 3758.5. Reporting Violations

If a licensee has knowledge that another person may be in violation of, or has violated, any of the statutes or regulations administered by the board, the licensee shall report this information to the board in writing and shall cooperate with the board in furnishing information or assistance as may be required.

California Respiratory Care Practice Act

Some states also require that employers make reports not only on individuals terminated for cause but also on the supervisors of the RTs.

Section 3758.6. Report on Supervisor

1. In addition to the reporting required under Section 3758, an employer shall also report to the board the name, professional licensure type and number, and title of the person supervising the licensee who has been suspended or terminated for cause, as defined in subdivision (b) of Section 3758. If the supervisor is a licensee under this chapter, the board shall investigate whether due care was exercised by that supervisor in accordance with this chapter. If the supervisor is a health professional, licensed by another licensing board under this division, the employer shall report the name of that supervisor and any and all information pertaining to the suspension or termination for cause of the person licensed under this chapter to the appropriate licensing board.
2. The failure of an employer to make a report required by this section is punishable by an administrative fine not to exceed $10,000 per violation.

The second thing all RTs should do to protect themselves against licensure issues is to purchase an insurance policy that covers professional discipline. Most policies available for purchase by RTs provide for coverage of both malpractice liability and professional discipline.

Understanding the Causes of Discipline

A review of professional discipline cases available from publicly available sources, including the California Board for

[‖]Cal. Bus. & Prof. Code § 3706.

Respiratory Care, reveals that the most frequent causes of professional discipline are as follows:

- Substance abuse
- Domestic violence
- Sexual abuse
- Gross incompetence

Even in cases in which the cause of discipline is rooted in domestic violence or sexual abuse of another person, some form of substance abuse is often a contributing factor. Alcohol violations (driving while intoxicated, driving while impaired) are often the most frequent violation that brings an RT face to face with his or her professional board. RTs with alcoholism or a significant drug habit are almost certain to come before their professional board. Sometimes employers and supervisors take the position that as long as such a problem does not affect a person's work at the facility, they should not address it. However, even in cases in which an RT does not use drugs or alcohol at work, the disease process is affecting their judgment and decision making and should be addressed. A supervisor who fails to report a substance abuser of any kind is asking for legal trouble, in the form of either a damages lawsuit or a visit from the professional board. Academic RTs should be especially vigilant with students and should insist on substance abuse counseling for any student who appears to have such a problem.

Sometimes human resources personnel and administrators do not see the value in addressing these kinds of problems and may counsel against discipline for impaired workers. Sometimes supervisors ignore the behaviors that should be red flags. Sometimes the human resources department may have made exceptions for other workers and fears that these exceptions may permit an inference of discrimination. None of these excuses sounds good to a jury.

Any good attorney will tell you that it is far better to defend a wrongful termination lawsuit than a wrongful death lawsuit. If you are wrong about the termination, the employee can be rehired. There is no remedy for the patient when an employee's substance abuse leads to that patient's death.

Engaging Counsel

If approached by the professional board, an RT should never talk to investigators without an attorney present. Every investigation is by its nature oppressive and burdensome, and an attorney ensures that the RT's rights are respected and protected. Often in cases in which an RT has violated the professional code or engaged in conduct that merits discipline, an attorney can help negotiate a better resolution than the RT could without the help of a professional.

RESPIRATORY THERAPISTS WHO SPEAK OUT ABOUT WRONGDOING

RTs are in a unique position to help protect patients from multiple harms. Sometimes they have a duty to speak out about problems or issues in the department. Usually working with a CCO is the most effective way to effect change inside an organization. However, sometimes the person who speaks out and identifies a problem still faces retaliation. Several federal laws protect RTs who, because of their respect for ethical issues, speak out about wrongdoing.

Patient Protection and Affordable Care Act

In 2010, Congress passed the PPACA in an attempt to reform health care. Challenges to the PPACA are still finding their way through the state and federal courts, and results to date have been mixed. One thing that the statute did was improve whistleblower protections for hospital workers. Section 1558 of the PPACA amends the *Fair Labor Standards Act* of 1938 (FLSA) by adding Section 18C, which provides that an employer cannot discriminate "against any employee with respect to his or her compensation, terms, conditions, or other privileges of employment" because the employee, among other things:

1. Provided, caused to be provided, or is about to provide or cause to be provided to the employer, the Federal Government, or the attorney general of a State information relating to the violation of, or any act or omission the employee reasonably believes to be a violation of, any provision of this title;
2. Actually did or is about to assist, participate, or testify in a proceeding about such violation; or
3. Objected to or refused to participate in any activity or task that the employee "reasonably believed" to be in violation of the statute or any rule or regulation promulgated under the statute.

Any employee who believes that he or she has been discharged or discriminated against in violation of Section 18C of the FLSA is entitled to seek relief using the same procedures provided in 15 U.S.C. §2087(b), which contains the extensive whistleblower protections contained in the *Consumer Product Safety Improvement Act* of 2008. These procedures include filing a complaint concerning discrimination or retaliation with the Department of Labor, going through an administrative process to determine whether the employee's conduct protected by Section 18C was "a contributing factor in the unfavorable personnel action" alleged by the employee, and providing for the filing of a civil action in federal court after exhaustion of the administrative remedies provided by the statute.

Section 1558 explicitly limits application of Section 18C only to violations of the statute's central provisions related to medical care in hospital and clinic settings. Employees who report fraud, waste, or violations in traditional health care settings fall under the protections afforded by Section 1558. In most cases, an employee needs legal advice to pursue remedies under this section of the FLSA.

National Labor Relations Act

Although the *National Labor Relations Act* (NLRA) is usually thought of as a "union" statute, the NLRA provides protections to hospital workers whether they are organized into a union or not. Specifically, the NLRA provides for protection where a worker engages in actions for the benefit of all employees. For example, when an RT approaches the supervisor on behalf of

all the workers on the second shift to request that shift differentials be increased, that RT—who is engaged in what is called "protected concerted activity"—cannot be discharged for acting on behalf of the other RTs in the department. When an RT is discharged for such an offense, the RT has 180 days in which to make a complaint to the local office of the National Labor Relations Board. No attorney is necessary to make such a complaint.

False Claims Act

Buried in the banking section of the United States Code is a little-known statute called the *False Claims Act* (FCA) (31 USC §3729). The statute forbids making false claims against the government and provides for severe sanctions for people who do. Someone making a false claim against a government health care program can be made to repay three times the amount of the false claim plus a civil penalty of $5500 to $11,000 per false claim. Similar to the whistleblower protections built into the PPACA, the FCA contains language that prevents retaliation against an employee who gathers information or supports a government case against his or her employer. Remedies may include reinstatement and back pay.

Perhaps the most powerful part of the statute is the part that permits an employee with knowledge of fraud or false billing to file a lawsuit against the company or organization engaging in fraud. For example, when an emergency medical technician (EMT) knows that his employer is giving away free ambulance services to nursing homes in exchange for the Medicare business of the nursing homes, the EMT could file an FCA case against the employer.

The government investigates such lawsuits and frequently intervenes in them. Where the government intervenes, the employee who blows the whistle stands to receive an award of up to 25% of the amount the government recovers. In recent years, the United States has recovered greater than $3 billion in fraudulently paid claims, most of which came from employees who blew the whistle on the fraud of their employers or competitors.

HEALTH CARE AND CHANGE

The health care industry is experiencing rapid change relating to how services are funded and how patients and health care workers interact. These changes are occurring at the same time that ethical considerations are reemerging as significant components of how health care should be structured and delivered. Managed care affects the ethical decision-making process. Although the effect is not negative, it forces health care workers to take a new look at ethical dilemmas to arrive at both the best ethical outcome and the best managed care outcome. Patients no longer freely choose who will deliver health care services to them. Health care practitioners must consider not only the best services to deliver to patients but also the best managed care outcome.

If ethical reasoning is to be of any value, it must account for the reality of human experience and take into account changes in the health care system. Specific considerations include (1) factual premises and beliefs, such as the definition of death; (2) legal concepts, such as tort laws; (3) externally imposed mandates or expectations, such as hospital accreditation standards; and (4) the best managed care outcome. In many instances, such considerations uphold our moral convictions and provide support for a given action. The real challenge to RTs arises when moral principles dictate one course of action and factual knowledge, legal concepts, or external expectations dictate another.

Socrates demanded that professionals acknowledge the social context of their activities and recognize their obligations toward the segment of society that they profess to serve. As our analysis of ethical reasoning and the law has made clear, only by identifying, justifying, and prioritizing basic principles of human values can the RT resolve the difficult questions of professional behavior consistently. To the extent that clearly articulated principles guide our choices and actions, all involved will be well served.

RULE OF THUMB

The letters RCP are used to indicate respiratory care practitioner. They also suggest three important characteristics of the RT when confronted with ethical dilemmas:
*R*espect
*C*ompassion
*P*rofessionalism

Health Care Advance Directives

In recognition of the right of competent adults to exercise choices concerning their health care, all 50 states and the District of Columbia have adopted some form of health care advance directives. Although the federal government acknowledged the need for advance directives with the 1991 *Patient Self-Determination Act* by requiring that all hospitals receiving Medicaid or Medicare funds ascertain whether patients have or wish to have advance directives, the advance directive instruments are state regulated.

SUMMARY CHECKLIST

- Ethical dilemmas occur when there are two equally desirable or equally undesirable choices. Ethical dilemmas may involve situations that are either legal or illegal.
- Ethical dilemmas in respiratory care involve scope of practice, confidentiality, working within levels of professional responsibility, professional development issues, staffing patterns, or recordkeeping.
- Professional codes of ethics are general guidelines established to identify ideal behavioral parameters by members of a professional group. These codes are often simplistic and tend to deal with behavior over which there is little disagreement.
- Traditional ethical principles are rooted in philosophical thought and include autonomy, beneficence,

confidentiality, role fidelity, justice, nonmaleficence, and veracity. These principles are used in the ethical decision-making process.

- There are two basic ethical theories: formalism and consequentialism. The most commonly used ethical decision-making model is the mixed approach. The mixed approach combines components of formalism, consequentialism, and modern decision-making theory.
- The basic information that must be identified before a reasoned ethical decision is made includes the problem or issue, the individuals involved, and the ethical principle or principles that apply; a determination of who should make the decision; and the role of the practitioner.
- Public law deals with the relationships of private parties and the government. Civil law is concerned with the recognition and enforcement of the rights and duties of private individuals and organizations.
- Professional malpractice is negligence in which a professional has failed to provide the care expected, resulting in harm to someone. Examples of situations that RTs might encounter include attempting procedures beyond the practitioner's skill level, failure to perform a duty as assigned, or failure to perform the duty correctly.
- Like members of other professions, RTs are responsible for their actions. If their actions result in injury to others, the injured party or parties are entitled to seek redress in the courts.
- A professional license provides a framework under which a licensee carries out his or her duties. Because licensure acts define who can perform specified duties, it is expected that the duties will be performed in a responsible manner and the professional will be responsible for his or her actions. The purpose of licensure is to provide for the public's safety. Practitioners must carry out their duties with an eye toward defending themselves in the case of legal action.
- Patients today are better educated and hold higher expectations from health care practitioners. Many patients are assuming responsibility for their own health care, placing the health care practitioner into the role of consultant.

CHAPTER 6

Physical Principles of Respiratory Care

DANIEL F. FISHER

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the properties that characterize the three states of matter.
- Describe how heat transfer occurs among substances.
- Identify the three common temperature scales and explain how to use them.
- Describe how substances undergo change of state.
- Describe how water vapor capacity, absolute humidity, and relative humidity are related.
- Describe how to predict gas behavior under changing conditions, including at extremes of temperature and pressure.
- Describe the principles that govern the flow of fluids.

CHAPTER OUTLINE

KEY TERMS

absolute humidity
adhesion
ATPS
Avogadro's law
BTPS
Coanda effect
cohesion
condensation
conduction
convection
critical temperature
Dalton's law
dew point
evaporation
flow resistance
Graham's law
Henry's law
jet entrainment
kinetic energy
laminar flow
Laplace's law
latent heat of fusion
latent heat of vaporization
law of continuity
laws of thermodynamics
melting point
Pascal's principle
Poiseuille's law
potential energy
radiation
relative humidity (RH)
solubility coefficient
specific gravity
STPD
strain-gauge pressure transducers
surface tension
thermal conductivity
thermodynamics
turbulent flow
vaporization
viscosity
water vapor pressure

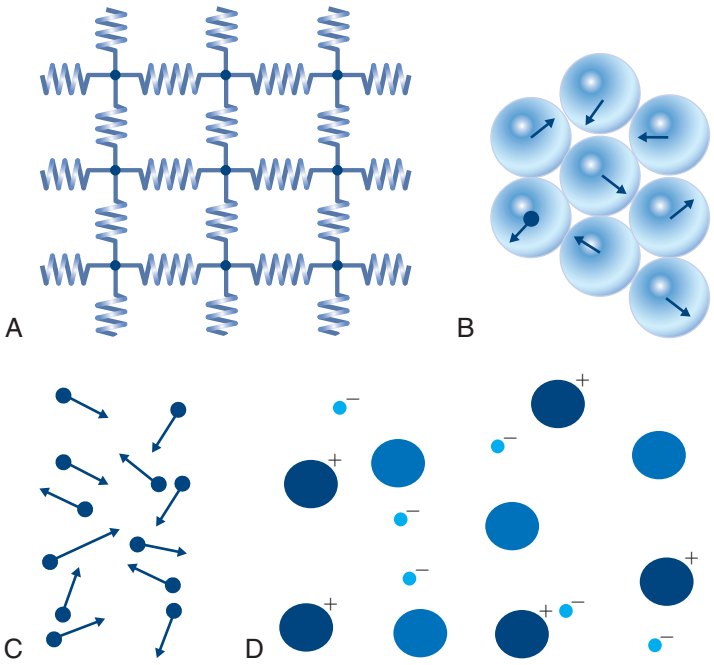

FIGURE 6-1 Simplified models of the four states of matter. **A,** Solid (rigid network of interconnected springs). **B,** Liquid (freely moving spheres with no space among them). **C,** Gas (small rapidly moving particles with a lot of space among them). **D,** Plasma (small rapidly moving charged particles with a lot of space among them).

STATES OF MATTER

There are three primary states of matter: solid, liquid, and gas. Figure 6-1, *A to C* depicts simplified models of these states of matter.

Solids have a fixed volume and shape. The molecules that make up the solid have the shortest distance to travel until they collide with one another. This motion has been referred to as a "jiggle." Solids have a high degree of internal order; their atoms or molecules are limited to back-and-forth motion about a central position, as if held together by springs (see Figure 6-1, *A*). Solids maintain their shape because their atoms are kept in place by strong mutual attractive forces, called *van der Waals forces.*[1]

Liquids have a fixed volume, but adapt to the shape of their container. If a liquid is not held within a container, the shape is determined by numerous internal and external forces. Liquid molecules exhibit mutual attraction. However, because these forces are much weaker in liquids than in solids, liquid molecules can move about freely (see Figure 6-1, *B*). This freedom of motion explains why liquids take the shape of their containers and are capable of flow. However, similar to solids, liquids are dense and cannot be compressed easily.

In a *gas,* molecular attractive forces are very weak. Gas molecules, which lack restriction to their movement, exhibit rapid, random motion with frequent collisions (see Figure 6-1, *C*). Gases have no inherent boundaries and are easily compressed and expanded. Similar to liquids, gases can flow. For this reason, both liquids and gases are considered fluids. Gases have no fixed volume or shape. Both of these qualities depend on local conditions for the gas.

Plasma has been referred to as a fourth state of matter. Plasma is a combination of neutral atoms, free electrons, and atomic nuclei. Plasmas can react to electromagnetic forces and flow freely similar to a liquid or a gas (see Figure 6-1, *D*). Although mentioned here for the sake of completeness, plasmas are not discussed further because at this time they are not known to be relevant to the practice of respiratory care.

Internal Energy of Matter

The atoms that make up all matter are in constant motion at normal temperature.[2] This motion is resulting from *internal energy*. There are two major types of internal energy: (1) **potential energy**, and (2) **kinetic energy**. Potential energy is referred to as the energy of position—that is, object balanced on a shelf. Potential energy is a result of the strong attractive forces between molecules. These intermolecular forces are why solids are rigid and liquids have viscosity and cohesiveness. These same intermolecular forces are not as strong in gases. Kinetic energy is the energy of motion, such as a falling object. Most internal energy in gases is in the form of kinetic energy.

Laws of Thermodynamics

The term **thermodynamics** can refer to either the science studying the properties of matter at various temperatures or the kinetics (speed) of reactions of matter at various temperatures. From the study of physics, we take special notice of the **laws of thermodynamics**. The laws describe how fundamental physical quantities (temperature, energy, and entropy) behave under various circumstances and forbid certain phenomena (such as perpetual motion). A basic knowledge of these principles is helpful in understanding many aspects of respiratory care. Of particular interest is the first law of thermodynamics, one version of which states that an increase in the internal energy of a closed system can be the result only of work performed on the system. Work can be viewed as the process of transferring energy to or from a system. The increase in internal energy of a system can be observed as an increase in heat (as with a humidifier) or pressure (as during mechanical ventilation).

Heat Transfer

When two objects exist at different temperatures, the first law of thermodynamics tells us that heat will move from the hotter object to the cooler object until the objects' temperatures are equal. This is an example of transitioning from a higher state of energy to a lower state. Two objects with the same temperature exist in thermal equilibrium. Heat can be transferred in four ways: (1) *conduction,* (2) *convection,* (3) *radiation,* and (4) *evaporation and condensation*.

Conduction

Heat transfer in solids occurs mainly via conduction. **Conduction** is the transfer of energy by direct contact between hot and cold molecules. How well heat transfers by conduction depends

TABLE 6-1

Thermal Conductivities in (cal/sec)/(cm² °C/cm)

Material	Thermal Conductivity (k)
Silver	1.01
Copper	0.99
Aluminum	0.50
Iron	0.163
Lead	0.083
Ice	0.005
Glass	0.0025
Concrete	0.002
Water at 20° C	0.0014
Asbestos	0.0004
Hydrogen at 0° C	0.0004
Helium at 0° C	0.0003
Snow (dry)	0.00026
Fiberglass	0.00015
Cork board	0.00011
Wool felt	0.0001
Air at 0° C	0.000057

From Nave CR, Nave BC: Physics for the health sciences, ed 3, Philadelphia, 1985, WB Saunders.

on both the number and the force of molecular collisions between adjoining objects.

Heat transfer between objects is quantified by using a measure called **thermal conductivity**. Table 6-1 lists the thermal conductivities of selected substances in centimeter-gram-second (cgs) system units. As is evident, solids (especially metals) tend to have high thermal conductivity. This is why metals feel cold to the touch even when at room temperature. In this case, the high thermal conductivity of metal quickly draws heat away from the skin, creating a feeling of "cold." In contrast, with fewer molecular collisions than in solids and liquids, gases exhibit low thermal conductivity.

Convection

Heat transfer in both liquids and gases occurs mainly by convection. **Convection** involves the mixing of fluid molecules at different temperatures. Although air is a poor heat conductor (see Table 6-1), it can efficiently transfer heat by convection. To do so, the air is first warmed in one location and then circulated to carry the heat elsewhere; this is the principle behind forced-air heating in houses and convection heating in infant incubators. Fluid movements carrying heat energy are called *convection currents.*

Radiation

Radiation is another mechanism for heat transfer. Conduction and convection require direct contact between two substances, whereas radiant heat transfer occurs without direct physical contact. Heat transfer by radiation occurs even in a vacuum, such as when the sun warms the earth.

The concept of radiant energy is similar to that of light. Radiant energy given off by objects at room temperature is mainly in the infrared range, which is invisible to the human eye. Objects such as an electrical stove burner or a kerosene heater radiate some of their energy as visible light. In the clinical setting, radiant heat energy is commonly used to keep newborn infants warm.

Evaporation and Condensation

Vaporization is the change of state from liquid to gas. Vaporization requires heat energy. According to the first law of thermodynamics, this heat energy must come from the surroundings. In one form of vaporization, called **evaporation**, heat is taken from the air surrounding the liquid, cooling the air. In warm weather or during strenuous exercise, the body takes advantage of this principle of *evaporative cooling* by producing sweat. The liquid sweat evaporates and cools the skin.

Condensation is the opposite of evaporation. In condensation, gases become liquids. Because vaporization takes heat from the air around a liquid (cooling), condensation must give heat back to the surroundings (warming). A refrigerator (or air conditioner) works on the principle of repeated vaporization cycles. The food cools as it passes energy through the walls of the refrigerator into pipes containing condensed refrigerant. The refrigerant warms, vaporizes, and expands. Then a compressor condenses the refrigerant again, releasing heat that is carried away to the atmosphere by a radiator. The condensed refrigerant is then passed by the food and the cycle repeats. The whole system is basically a heat pump transferring thermal energy from the food to the atmosphere. The next section expands on the concept of change of state and provides more detail on the processes of vaporization and condensation.

Temperature

Temperature and kinetic energy are closely related.[2] Temperature is a measurement of heat. Heat is the result of molecules colliding with one another. The temperature of a gas, with most of its internal energy spent keeping molecules in motion, is directly proportional to its kinetic energy. In contrast, the temperatures of solids and liquids represent only part of their total internal energy.

Absolute Zero

In concept, absolute zero is the lowest possible temperature that can be achieved. That is the temperature at which there is no kinetic energy. Because there is no energy, the molecules cease to vibrate and the object has no heat that can be measured. This temperature is defined to be absolute zero. Although researchers have come close to attaining absolute zero, no one has actually achieved it; this is due to the third law of thermodynamics, which states absolute zero is impossible to achieve.

Temperature Scales

Multiple scales can be used to measure temperature. The Fahrenheit and Celsius scales are based on properties of water (freezing and boiling). A third scale, the Kelvin scale, is based on molecular motion. Absolute zero provides a logical zero point on which to build a temperature scale. The International System of Units (SI) units for temperature is measured in Kelvin (K)

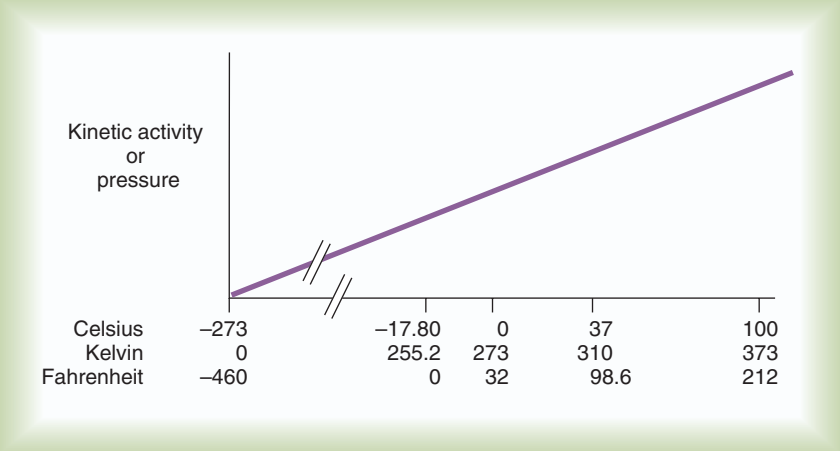

FIGURE 6-2 Linear relationship between gas molecular activity, or pressure, and temperature. The graph shows comparable readings on three scales for five temperature points.

with a zero point equal to absolute zero (0° K).[3-7] Because the Kelvin scale has 100 degrees between the freezing and boiling points of water, it is a centigrade, or 100-step, temperature scale. The Kelvin scale has the unique quality of being based on the triple-point definition for water (the temperature at which all three phases of water exist). This temperature happens to be approximately 273° K (0.0° C).[5-7]

The cgs temperature system is based on Celsius (C) units. Similar to the Kelvin scale, the Celsius scale is a centigrade scale (100 degrees between the freezing and boiling points of water). However, 0° C is not absolute zero but instead is the freezing point of water.

In Celsius units, kinetic molecular activity stops at approximately −273° C. Therefore 0° K equals −273° C, and 0° C equals 273° K. To convert degrees Celsius to degrees Kelvin, simply add 273:

$$°K = °C + 273$$

For example:

$$25° C = 25 + 273 = 298° K$$

Conversely, to convert degrees Kelvin to Celsius, you simply subtract 273. For example:

$$310° K = 310 - 273 = 37° C$$

The Fahrenheit scale is the primary temperature scale in the foot, pound, and second (fps) or British system of measurement. Absolute zero on the Fahrenheit scale equals −460° F.

To convert degrees Fahrenheit to degrees Celsius, use the following formula:

$$°C = (°F - 32)/1.8$$

For example:

$$°F = 98.6$$
$$°C = (98.6 - 32)/1.8$$
$$°C = 37$$

To convert degrees Celsius to degrees Fahrenheit, simply reverse this formula:

$$°F = (1.8 \times °C) + 32$$

For example:

$$°C = 100$$
$$°F = (1.8 \times 100) + 32$$
$$°F = 212$$

Figure 6-2 shows the relationship between the kinetic activity of matter and temperature on all three common temperature scales. For ease of reference, four key points are defined: (1) the zero point of each scale, (2) the freezing point of water (0° C), (3) body temperature (37° C), and (4) the boiling point of water (100° C).

CHANGE OF STATE

All matter can change state. Because respiratory therapists work extensively with both liquids and gases, they must have a good understanding of the key characteristics of these states and the basic processes underlying their phase changes.

Liquid-Solid Phase Changes (Melting and Freezing)

When a solid is heated, its molecular kinetic energy increases. This added internal energy increases molecular vibrations. If enough heat is applied, these vibrations eventually weaken the intermolecular attractive forces. At some point, molecules break free of their rigid structure, and the solid changes into a liquid.

Melting

The changeover from the solid to liquid state is called *melting*. The temperature at which this changeover occurs is the **melting point**.[2] The range of melting points is considerable. For example, water (ice) has a melting point of 0° C, carbon has a melting

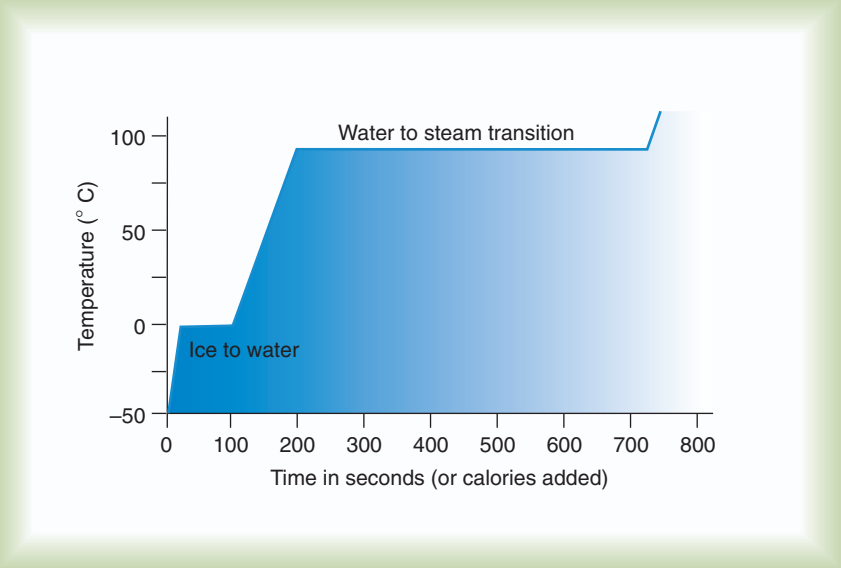

FIGURE 6-3 Temperature as a function of time for 1 g of water heated at the rate of 1 cal/sec. (Modified from Nave CR, Nave BC: Physics for the health sciences, ed 3, Philadelphia, 1985, WB Saunders.)

point of greater than 3500° C, and helium has a melting point of less than −272° C.

Figure 6-3 depicts the phase change caused by heating water. At the left origin of −50° C, water is solid ice. As the ice is heated, its temperature increases. At its melting point of 0° C, ice begins to change into liquid water. However, the full change to liquid water requires additional heat. This additional heat energy changes the state of water but does not immediately change its temperature.

The extra heat needed to change a solid to a liquid is the **latent heat of fusion**. In cgs units, the latent heat of fusion is defined as the number of calories required to change 1 g of a solid into a liquid without changing its temperature. The latent heat of fusion of ice is 80 cal/g, whereas the latent heat of fusion of oxygen is 3.3 cal/g. This change of state, compared with simply heating a solid, requires enormous energy.

Freezing

Freezing is the opposite of melting. Because melting requires large amounts of externally applied energy, you would expect freezing to return this energy to the surroundings, and this is exactly what occurs. During freezing, heat energy is transferred from a liquid back to the environment, usually by exposure to cold.

As the kinetic energy of a substance decreases, its molecules begin to regain the stable structure of a solid. According to the first law of thermodynamics,[4] the energy required to freeze a substance must equal that needed to melt it. The freezing and melting points of a substance are the same.

Sublimation is the term used for the phase transition from a solid to a vapor without becoming a liquid as an intermediary form. An example of sublimation is dry ice (frozen carbon dioxide). Dry ice sublimates from its solid form into gaseous CO_2 without first melting and becoming liquid CO_2. This sublimation occurs because the vapor pressure is low enough for the intermediate liquid not to appear.

Properties of Liquids

Liquids exhibit flow and assume the shape of their container. Liquids also exert pressure, which varies with depth and density. Variations in liquid pressure within a container produce an upward supporting force, called *buoyancy*.

Although melting weakens intermolecular bonding forces, liquid molecules still attract one another. The persistence of these cohesive forces among liquid molecules helps explain the physical properties of viscosity, capillary action, and surface tension.

Pressure in Liquids

Liquids exert pressure, which has the dimensions of force per unit area. The *pressure* exerted by a liquid depends on both its *height* (depth) and *weight density* (weight per unit volume), which is shown in equation form:

$$P_L = h \times d_w$$

where P_L is the static pressure exerted by the liquid, h is the height of the liquid column, and d_w is the liquid's weight density.

For example, to compute the pressure at the bottom of a 33.9-ft (1034-cm)-high column of water (density = 1 g/cm^3), you would use this equation:

$$\begin{aligned} P_L &= h \times d_w \\ &= 1034\ \text{cm} \times (1\ \text{g/cm}^3) \\ &= 1034\ \text{g/cm}^2 \end{aligned}$$

The answer (1034 g/cm^2) also equals 1 atmosphere of pressure (atm), or approximately 14.7 lb/in^2. This figure does not account for the additional atmospheric pressure (P_B) acting on the top

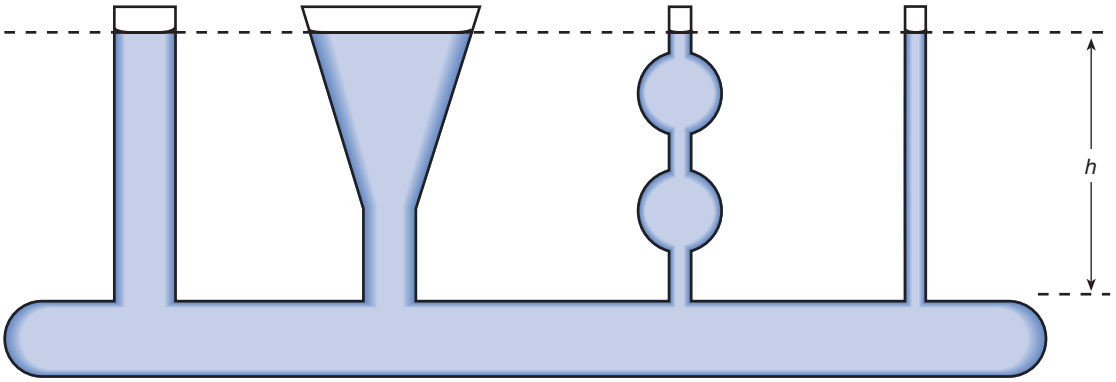

FIGURE 6-4 Pascal's principle. Liquid pressure depends only on the height (h) and not on the shape of the vessel or the total volume of liquid. (Modified from Nave CR, Nave BC: Physics for the health sciences, ed 3, Philadelphia, 1985, WB Saunders.)

of the liquid. The total pressure at the bottom of the column equals the sum of the atmospheric and liquid pressures. In this case, the total pressure is 2068 g/cm^2, equal to 29.4 lb/in^2, or 2 atm.

As shown in Figure 6-4, the pressure of a given liquid is the same at any specific depth (h), regardless of the container's shape. This is because the pressure of a liquid acts equally in all directions. This concept is called **Pascal's principle**.

Buoyancy (Archimedes' Principle)

Thousands of years ago, Archimedes showed that an object submersed in water appeared to weigh less than in air. This effect, called *buoyancy,* explains why certain objects float in water. Liquids exert buoyant force because the pressure below a submerged object always exceeds the pressure above it. This difference in liquid pressure creates an upward or supporting force. According to Archimedes' principle, this buoyant force must equal the weight of the fluid displaced by the object. The buoyant force (B) may be calculated as follows:

$$B = d_w \times V$$

where d_w is weight density (weight/unit volume) and V is volume of displaced fluid. If the weight density of an object is *less* than that of water (1 g/cm^3), it will displace a weight of water greater than its own weight. In this case, the upward buoyant force will overcome gravity, and the object will float. Conversely, if an object's weight density exceeds the weight of water, the object will sink.

Clinically, Archimedes' principle is used to measure the specific gravity of certain liquids. The term **specific gravity** refers to the ratio of the density of one fluid compared with the density of another reference substance, which is typically water. Figure 6-5 shows the use of a hydrometer to measure the specific gravity of urine. The specific gravity of gases also can be measured. In this case, O_2 or hydrogen is used as the standard instead of water.

Gases also exert buoyant force, although much less than that provided by liquids. Buoyancy helps keep solid particles suspended in gases. These suspensions, called *aerosols,* play an important role in respiratory care. More detail on the characteristics and use of aerosols is provided in Chapters 38 and 39.

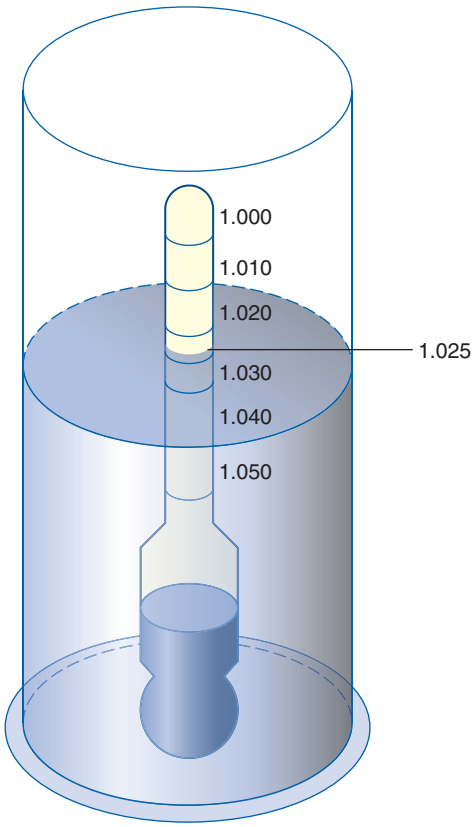

FIGURE 6-5 Using a hydrometer to measure the specific gravity of a urine specimen. The scale value of 1.025 indicates that this urine sample has a weight density 1.025 times greater than that of water.

Viscosity

Viscosity is the force opposing a fluid's flow and is similar to friction in solids. The viscosity of a fluid is directly proportional to the cohesive forces between its molecules. The stronger these cohesive forces are, the greater the fluid's viscosity. The greater

a fluid's viscosity, the greater is its resistance to deformation and the greater its opposition to flow.

The understanding of viscosity leads to the concept that fluids move in discrete cylindrical layers, called *streamlines.* This pattern of motion is called **laminar flow**. Laminar flow is viewed as concentric layers of fluid flowing parallel to the tube wall at velocities that increase toward the center. As shown in Figure 6-6, frictional forces between the streamlines and the tube wall impede movement of the outer layers of a fluid. Each layer, moving toward the center of the tube, hinders the motion of the next inner layer less and less.

The difference in the velocity among these concentric layers is called the *shear rate* and is simply a measure of how easily these layers separate. Shear rate depends on two factors: (1) the pressure pushing or driving the fluid, called the *shear stress,* and (2) the viscosity of the fluid. Shear rate is directly proportional to shear stress and inversely proportional to viscosity.

In uniform fluids such as water or oil, viscosity varies with temperature. Because higher temperatures weaken the cohesive forces between molecules, heating a uniform fluid reduces its viscosity. Conversely, cooling a fluid increases its viscosity. This is why a car's engine is so hard to start on a cold winter morning. The oil becomes so viscous that it impedes movement of the engine's parts.

Blood, in contrast to water or oil, is a complex fluid that contains not only liquid (plasma, which is 90% water) but also cells in suspension. For this reason, blood has a viscosity approximately five times greater than the viscosity of water. The greater the viscosity of a fluid, the more energy is needed to make it flow. The heart works harder to pump blood than it would if it were pumping water. The heart must perform even more work when blood viscosity increases, as occurs in *polycythemia* (an increase in red blood cell concentration in the blood).

Cohesion and Adhesion

The attractive force between like molecules is called **cohesion**. The attractive force between unlike molecules is called **adhesion**. These forces can be observed at work by placing a liquid in a small-diameter tube. As shown in Figure 6-7, the top of the liquid forms a curved surface, or *meniscus*. When the liquid is water, the meniscus is concave because the water molecules at the surface adhere to the glass more strongly than they cohere to each other (see Figure 6-7, *A*). In contrast, a mercury meniscus is convex (see Figure 6-7, *B*). In this case, the cohesive forces pulling the mercury atoms together exceed the adhesive forces trying to attract the mercury to the glass.

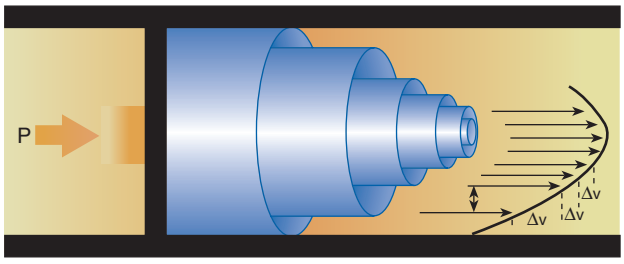

FIGURE 6-6 Effects of shear stress or pressure *(P)* on shear rate (velocity gradient *[v]*) in a Newtonian fluid. (Modified from Winters WL, Brest AN, editors: The microcirculation, Springfield, IL, 1969, Charles C Thomas.)

Surface Tension

Surface tension is a force per unit length (equivalent to surface energy density with units of $Nm^{-1} = Jm^{-2}$) exerted by like molecules at the surface of a liquid. A small drop of fluid provides a good illustration of this force. As shown in Figure 6-8, cohesive forces affect molecules inside the drop equally from all

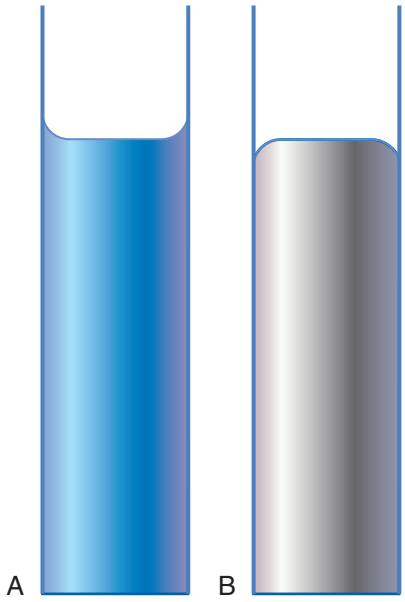

FIGURE 6-7 The shape of the meniscus depends on the relative strengths of adhesion and cohesion. **A,** Water: Adhesion stronger than cohesion. **B,** Mercury: Cohesion stronger than adhesion.

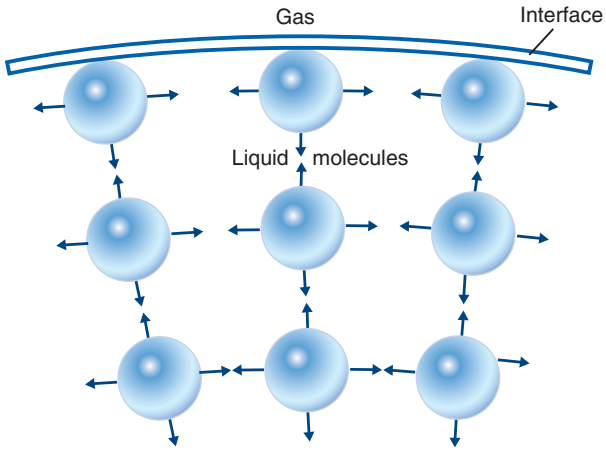

FIGURE 6-8 The force of surface tension in a drop of liquid. Cohesive force *(arrows)* attracts molecules inside the drop to one another. Cohesion can pull the outermost molecules inward only, creating a centrally directed force that tends to contract the liquid into a sphere.

directions. However, only inward forces affect molecules on the surface. This imbalance in forces causes the surface film to contract into the smallest possible surface area, usually a sphere or curve (meniscus). This phenomenon explains why liquid droplets and bubbles retain a spherical shape.

Surface tension is quantified by measurement of the force needed to produce a "tear" in a fluid surface layer. Table 6-2 lists the surface tensions of selected liquids in dynes per centimeter (cgs). For a given liquid, surface tension varies inversely with temperature: The higher the temperature, the lower is the surface tension. Surface tension plays an important role in determining the relative sizes of connected alveoli (Figure 6-9). To understand this, consider a spherical bubble of air in a liquid (analogous to an alveolus). According to **Laplace's law**, the pressure inside the bubble varies directly with the surface tension of the liquid and inversely with its radius. Internal surface tension (T) will attempt to contract the bubble but is opposed by the resulting pressure inside the bubble (P). To increase the radius by an amount dR, we must perform work, dW (where d represents an infinitesimal change as used in calculus). The work, $dW = PdV = TdA$, where dV is the change in volume and dA is the change in surface area. Because the area of a sphere is $4\pi R^2$, $dA = d(4\pi R^2)$. From calculus, the differential of the expression $4\pi R^2$ is $8\pi RdR$. The volume of a sphere is $4\pi R^3/3$, so $dV = d(4\pi R^3/3)$. Again taking the differential of this expression gives $dV = 4\pi R^2 dR$. Returning to dW, we now see that because $PdV = TdA$, it follows that $P(4\pi R^2 dR) = T(8\pi RdR)$. Rearranging and solving for P with simple algebra we get the common expression for the law of Laplace:

$$P = \frac{2T}{R}$$

For a structure such as a soap bubble, which has two liquid-air surfaces (and hence twice the surface tension) the equation is:

$$P = \frac{4T}{R}$$

Figure 6-9 suggests that if two alveoli of different sizes are connected, the smaller one will tend to empty into the larger one. However, this does not happen because, in reality, the two alveoli would have different surface tensions. This is because of the thin layer of surfactant inside the alveoli that counteracts the surface tension. As the radius of the alveoli decreases, its internal surface area also increases but the volume of surfactant stays the same. Hence the thickness of the layer of surfactant increases, which decreases the surface tension. Therefore all other factors being equal, the two alveoli will reach equilibrium, at which point they have the same radius. Abnormalities in alveolar surface tension occur in certain clinical conditions, such as *prematurity.* These abnormalities may result in collapse of alveoli secondary to high surface tension.

TABLE 6-2

Examples of Surface Tension

Substance	Temperature (°C)	Surface Tension (dynes/cm)
Water	20	73
Water	37	70
Whole blood	37	58
Plasma	37	73
Ethyl alcohol	20	22
Mercury	17	547

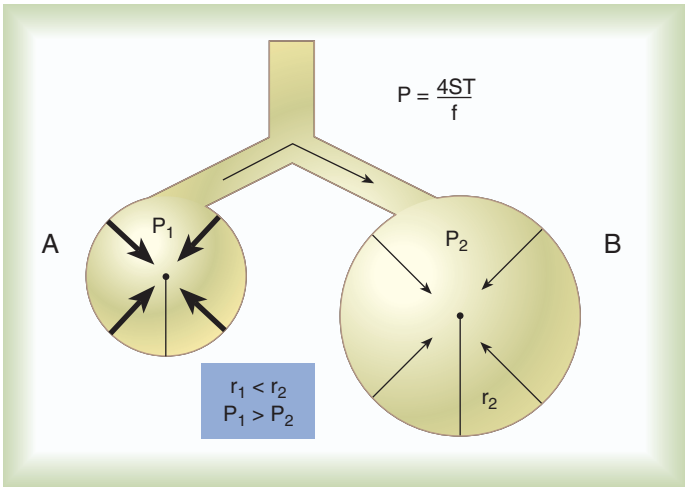

FIGURE 6-9 Laplace relationship. Two bubbles in a liquid matrix (models of alveoli). They have different sizes but the same surface tension. Bubble *A,* with the smaller radius, has the greater inward or deflating pressure and is more prone to collapse than the larger bubble, *B.* Because the two bubbles are connected, bubble *A* would tend to deflate and empty into bubble *B.* Conversely, because of the greater surface tension of bubble *A,* it would be harder to inflate than bubble *B.*

Capillary Action

Capillary action is a phenomenon in which a liquid in a small tube moves upward, against gravity. Capillary action involves both adhesive and surface tension forces. As shown in Figure 6-10, *A*, the adhesion of water molecules to the walls of a thin tube causes an upward force on the edges of the liquid and produces a concave meniscus.

Because surface tension acts to maintain the smallest possible liquid-gas interface, instead of just the edges of the liquid moving up, the whole surface is pulled upward. The strength of this force depends on the amount of liquid that contacts the tube's surface. Because a small capillary tube creates a more concave meniscus and a greater area of contact, liquid rises higher in tubes with smaller cross-sectional areas (see Figure 6-10, *B*).

Capillary action is the basis for blood samples obtained by use of a capillary tube. The absorbent wicks used in some gas humidifiers are also an application of this principle, as are certain types of surgical dressings.

Liquid-Vapor Phase Changes

Only after ice completely melts does additional heat increase the temperature of the newly formed liquid (see Figure 6-3). As

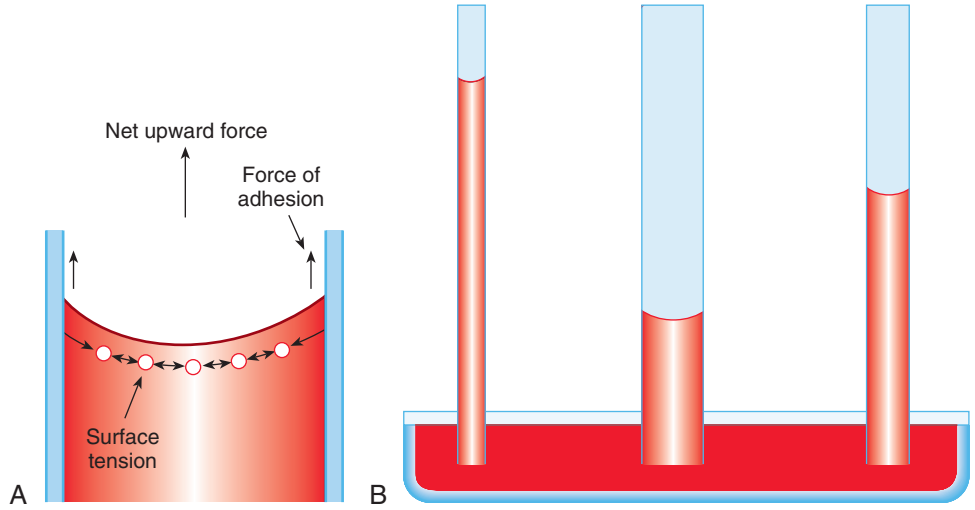

FIGURE 6-10 Capillary action. **A,** Adhesion and surface tension contribute to capillary action (capillarity). **B,** The liquid rises highest in the smallest tube. (Modified from Nave CR, Nave BC: Physics for the health sciences, ed 3, Philadelphia, 1985, WB Saunders.)

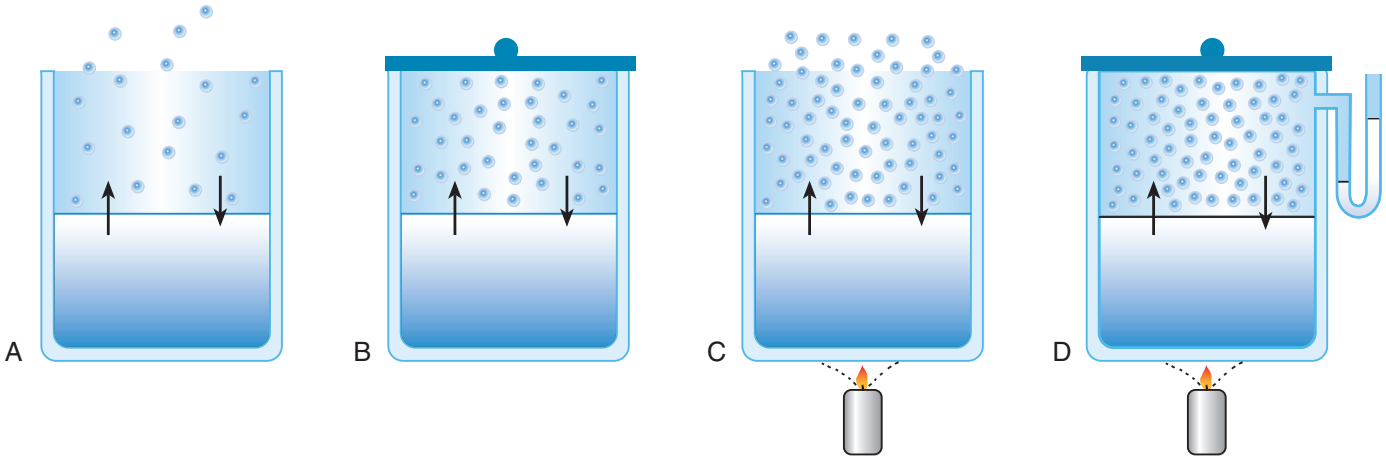

FIGURE 6-11 Factors influencing vaporization of water. See text for details.

the water temperature reaches 100°C, a new change of state begins—from liquid to vapor. This change of state is called *vaporization.* There are two different forms of vaporization: *boiling* and *evaporation.*

Boiling

The *boiling point* of a liquid is the temperature at which its vapor pressure exceeds atmospheric pressure. When a liquid boils, its molecules must have enough kinetic energy to force themselves into the atmosphere against the opposing pressure. Because the weight of the atmosphere retards the escape of vapor molecules, the greater the ambient pressure, the greater is the boiling point. Conversely, when atmospheric pressure is low, liquid molecules escape more easily and boiling occurs at lower temperatures. This is why cooking times must be increased at higher altitudes.

Although boiling is associated with high temperatures, the boiling points of most liquefied gases are very low. At 1 atm, O_2 boils at −183°C.

Energy is also needed to vaporize liquids, as with other phase changes. The energy required to vaporize a liquid is the **latent heat of vaporization**. In cgs units, the latent heat of vaporization is the number of calories required to vaporize 1 g of a liquid at its normal boiling point.

Melting weakens attractive forces between molecules, whereas vaporization eliminates them. Elimination of these forces converts essentially all of the internal energy of a substance into kinetic energy. For this reason, vaporization requires substantially more energy than melting. As shown in Figure 6-3, almost seven times more energy is needed to convert water to steam (540 cal/g) than is needed to melt ice.

Evaporation, Vapor Pressure, and Humidity

Boiling is only one type of vaporization. A liquid also can change into a gas at temperatures lower than its boiling point through a process called *evaporation.* Water is a good example (Figure 6-11). When at a temperature lower than its boiling point, water enters the atmosphere via evaporation. The liquid

molecules are in constant motion, as in the gas phase. Although this kinetic energy is less intense than in the gaseous state, it allows some molecules near the surface to escape into the surrounding air as water vapor (see Figure 6-11, *A*).

After water is converted to a vapor, it acts like any gas. Not to be confused with visible particulate water, such as mist or fog, this invisible gaseous form of water is called *molecular water.* Molecular water obeys the same physical principles as other gases and exerts a pressure called **water vapor pressure**. This pressure needs to be considered when calculating gas exchange (Chapter 13).

Evaporation requires heat. The heat energy required for evaporation comes from the air next to the water surface. As the surrounding air loses heat energy, it cools. This is the *principle of evaporative cooling,* which was previously described.

If the container is covered, water vapor molecules continue to enter the air until it can hold no more water (see Figure 6-11, *B*). At this point, the air over the water is saturated with water vapor. However, vaporization does not stop when saturation occurs. Instead, for every molecule escaping into the air, another returns to the water reservoir. These conditions are referred to as a *state of equilibrium.*

Influence of Temperature. No other factor influences evaporation more than temperature. Temperature affects evaporation in two ways. First, the warmer the air, the more vapor it can hold. Specifically, the capacity of air to hold water vapor increases with temperature. The warmer the air contacting a water surface, the faster is the rate of evaporation.

Second, if water is heated, its kinetic energy is increased, and more molecules are helped to escape from its surface (see Figure 6-11, *C*). Last, if the container of heated water is covered, the air again becomes saturated (see Figure 6-11, *D*). However, the heated saturated air, compared with the unheated air (see Figure 6-11, *B*), now contains more vapor molecules and exerts a higher vapor pressure (as shown by the manometer in Figure 6-11, *D*). The temperature of a gas affects both its capacity to hold molecular water and the water vapor pressure.

The relationship between water vapor pressure and temperature is shown graphically in Figure 6-12. The left vertical axis plots water vapor pressure in both millimeters of mercury (mm Hg) and (kilopascals (kPa). The horizontal axis plots temperatures between 0° and 70°C. This graph shows that the greater the temperature, the greater is the saturated water vapor pressure *(bold red dots).* Table 6-3 lists actual water vapor pressures in saturated air in the clinical range of temperatures (20° to 37°C).

Humidity. Water vapor pressure represents the kinetic activity of water molecules in air. For the actual amount or weight of water vapor in a gas to be determined, the water vapor content or absolute humidity must be measured.

Absolute humidity can be measured by weighing the water vapor extracted from air using a drying agent. The common unit of measure for absolute humidity is milligrams of water vapor per liter of gas (mg/L). Absolute humidity values for saturated air at various temperatures are plotted against the right vertical axis of Figure 6-12. The middle column of Table 6-3 lists these absolute humidity values for saturated air between 20° and 37°C.

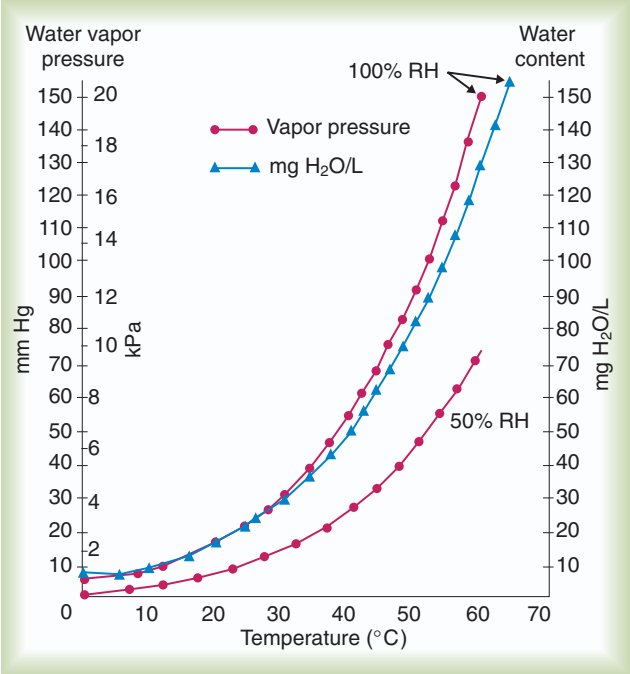

FIGURE 6-12 Water vapor pressure (P_{H_2O}) and absolute humidity (mg H_2O/L) curves for gas that is fully saturated (relative humidity [RH] = 100%) and gas that is half saturated (RH = 50%).

TABLE 6-3

Vapor Pressure and Absolute Humidity for Air Saturated with Water Vapor

Temperature (°C)	Vapor Pressure (mm Hg)	Water Vapor Content (mg/L)	ATPS to BTPS Correction Factor*
20	17.50	17.30	1.102
21	18.62	18.35	1.096
22	19.80	19.42	1.091
23	21.10	20.58	1.085
24	22.40	21.78	1.080
25	23.80	23.04	1.075
26	25.20	24.36	1.068

ATPS, Ambient temperature and pressure saturated; *BTPS,* body temperature and pressure saturated.
*Correction factors are based on 760 mm Hg pressure.

A gas does not need to be fully saturated with water vapor. If a gas is only half saturated with water vapor, its water vapor pressure and absolute humidity are only half that in the fully

saturated state. Air that is fully saturated with water vapor at 37° C, and 760 mm Hg has a water vapor pressure of 47 mm Hg and an absolute humidity of 43.8 mg/L (see Table 6-3). However, if the same volume of air were only 50% saturated with water vapor, its water vapor pressure would be 0.50 × 47 mm Hg, or 23.5 mm Hg and its absolute humidity would be 0.50 × 43.8 mg/L, or 21.9 mg/L.

When a gas is not fully saturated, its water vapor content can be expressed in relative terms using a measure called **relative humidity (RH)**. The RH of a gas is the ratio of its actual water vapor content to its saturated capacity at a given temperature. RH is expressed as a percentage and is derived with the following simple formula:

$$\text{RH}(\%) = \frac{\text{content}}{\text{capacity}} \times 100\%$$

For example, saturated air at a room temperature of 20° C has the capacity to hold 17.3 mg/L of water vapor (see Table 6-3). If the absolute humidity is 12 mg/L, the RH is calculated as follows:

$$\text{RH} = 12\ \text{mg/L} / 17.3\ \text{mg/L} \times 100\%$$
$$\text{RH} = 0.69 \times 100\%$$
$$\text{RH} = 69\%$$

Actual water vapor content does not have to be measured for RH to be computed. Instruments called *hygrometers* allow measurement of RH using a wide variety of ingenuous mechanisms based on the effects of humidity on, for example, temperature through evaporation (psychrometers), the length of a human hair, or electrical capacitance and resistance.

When the water vapor content of a volume of gas equals its capacity, the RH is 100%. When the RH is 100%, a gas is fully saturated with water vapor. Under these conditions, even slight cooling of the gas causes its water vapor to turn back into the liquid state, a process called *condensation.*

Condensed moisture deposits on any available surface, such as on the walls of a container or delivery tubing or on particles suspended in the gas. Condensation returns heat to and warms the surrounding environment, whereas vaporization of water cools the adjacent air.

If air that is at an RH of 90% is cooled, its capacity to hold water vapor decreases. Although the water vapor capacity of the air decreases, its content remains constant. With a lower capacity but the same content, the RH of the air must increase. Continued cooling decreases the air's water vapor capacity until it eventually equals the water vapor content (RH = 100%). When content equals capacity, the air is fully saturated and can hold no more water vapor.

Because RH never exceeds 100%, any further decrease in temperature causes condensation. The temperature at which condensation begins is called the **dew point**. Cooling a saturated gas below its dew point causes increasingly more water vapor to condense into liquid water droplets.

Figure 6-13 provides a useful analogy of the relationship among water vapor content, capacity, and RH. The various-sized glasses represent the capacity of a gas to hold water vapor. The larger the glass, the greater is its capacity. The water in the glasses represents the actual water vapor content. A glass that is half full is at 50% capacity, or 50% RH. A full glass represents the saturated state, which is equivalent to 100% RH.

Figure 6-13, *A*, shows what happens when a saturated gas is heated. Warming a gas increases its capacity to hold water vapor but does not change its content. This is equivalent to pouring the contents of the full glass on the *left* in Figure 6-13, *A* into

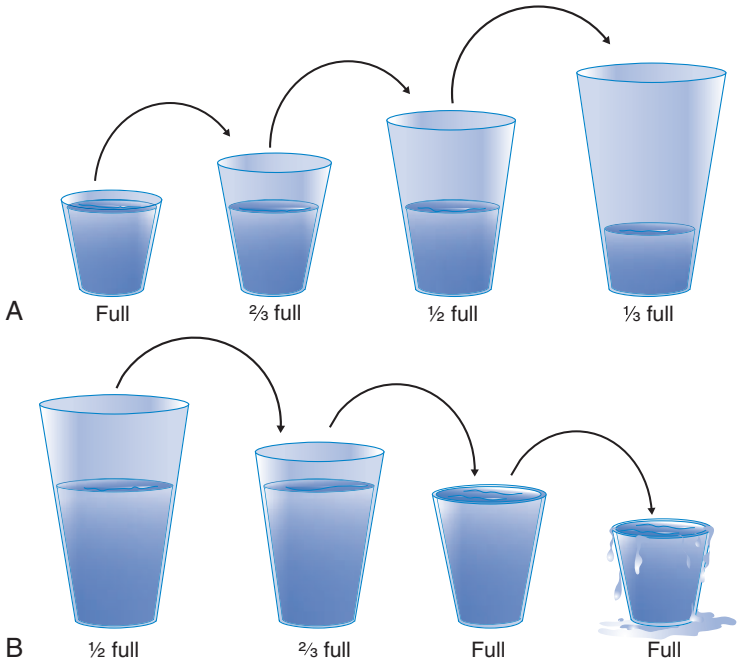

FIGURE 6-13 Relative humidity analogy. **A,** The effect of increasing capacity without changing content, as when heating a saturated gas. **B,** The effect of decreasing capacity, as when cooling a gas. See text for details.

progressively larger glasses. The amount of water does not change, but as the glasses get larger, they become less full. We started with a full glass (100% RH) but end up with one that is only one-third full (33% RH).

A decrease in capacity would have the opposite effect. In Figure 6-13, *B*, we start with a large glass, which is half full (50% RH). The capacity of the glass is decreased by pouring the water into progressively smaller glasses (equivalent to decreasing the gas temperature). Eventually, the water volume is enough to fill a smaller glass (100% RH). What happens if we try to empty this full glass into an even smaller one? Because the smaller glass has less capacity, the excess content must spill over. This spillover is analogous to the condensation occurring when a saturated gas cools below its dew point. However, although condensation has removed the excess moisture from the air, the smaller glass is still full (100% RH).

MINI CLINI

Condensation and Evaporation

A good clinical example of condensation and evaporation is the hygroscopic condenser humidifier, a form of artificial nose (Figure 6-14). These devices consist of layers of water-absorbent material encased in plastic. When a patient exhales into an artificial nose, the warm, saturated expired gas cools, causing condensation on the absorbent surfaces. As condensation occurs, heat is generated in the device. When the patient inhales through the device, the inspired gases are warmed and the previously condensed water evaporates, aiding in airway humidification. Chapter 38 provides more detail on humidification devices, including the artificial nose.

In clinical practice, two additional measures of humidity are used: *percent body humidity* (BH) and *humidity deficit*. The BH of a gas is the ratio of its actual water vapor content to the water vapor capacity in saturated gas at body temperature (37° C). The BH is the same as RH except that the capacity (or denominator) is fixed at 43.8 mg/L:

$$\text{BH}(\%) = \frac{\text{content}\,(\text{mg/L})}{43.8} \times 100\%$$

The humidity deficit associated with a BH less than 100% represents the amount of water vapor the body must add to the inspired gas to achieve saturation at body temperature (37° C).

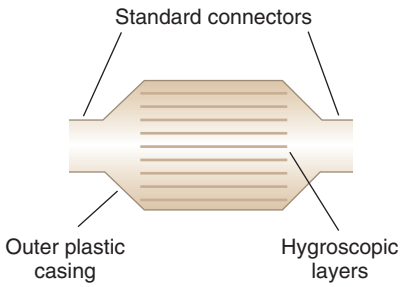

FIGURE 6-14 Hygroscopic condenser humidifier.

To compute the humidity deficit, simply subtract the actual water vapor content from its capacity at 37° C (43.8 mg/L).

Influence of Pressure. High temperatures increase vaporization, whereas high pressures impede this process. Water molecules trying to escape from a liquid surface must push their way out against the opposing air molecules. If the surrounding air pressure is high, there are more opposing air molecules and vaporization decreases. Alternatively, low atmospheric pressures increases vaporization.

Influence of Surface Area. The greater the available surface area of the gas in contact with air, the greater is the rate of liquid evaporation. This statement can be easily proved by comparing how quickly equal volumes of water evaporate under dry conditions from a flat plate versus from a tall, narrow glass. The water spread over a flat plate evaporates more quickly compared with the same amount of liquid in a tall, narrow glass. This principle is applied to the design of certain humidifiers to increase their ability to put water vapor in the passing gas.

Properties of Gases

Gases share many properties with liquids. Specifically, gases exert pressure, are capable of flow, and exhibit the property of viscosity. However, in contrast to liquids, gases are readily compressed and expanded and fill the spaces available to them through diffusion.

Kinetic Activity of Gases

Because the intermolecular forces of attraction of a gas are so weak, most of the internal energy of a gas is kinetic energy. *Kinetic theory* says that gas molecules travel about randomly at very high speeds and with frequent collisions.

The velocity of gas molecules is directly proportional to temperature. As a gas is warmed, its kinetic activity increases, its molecular collisions increase, and its pressure increases. Conversely, when a gas is cooled, molecular activity decreases, particle velocity and collision frequency decrease, and the pressure decreases.

Molar Volume and Gas Density

A major principle governing chemistry is **Avogadro's law**. This law states that the 1-g atomic weight of any substance contains exactly the same number of atoms, molecules, or ions. This number, 6.023×10^{23}, is *Avogadro's constant.* In SI units, this quantity of matter equals 1 mole.

Molar Volume. Avogadro's law states that equal volumes of gases under the same conditions must contain the same number of molecules. At a constant temperature and pressure, 1 mole of a gas should occupy the same volume as 1 mole of any other gas. This ideal volume is termed the *molar volume.*

At standard temperature (0.0° C) and pressure (760 mm Hg), dry (**STPD**); the ideal molar volume of any gas is 22.4 L. In reality, there are small deviations from this ideal. For example, although the molar volumes of both O_2 and nitrogen are 22.4 L at STPD, the molar volume of CO_2 is closer to 22.3 L. These values are used to calculate gas densities and convert dissolved gas volumes into moles per liter.

Density. Density is the ratio of the mass of a substance to its volume. A dense substance has heavy (high atomic weight) particles packed closely together. Uranium is a good example of a dense substance. Conversely, a low-density substance has a low concentration of light atomic particles per unit volume. Hydrogen gas is a good example of a low-density substance.

In clinical practice, weight is often substituted for mass, and weight density (weight per unit volume [d_w]) is actually measured. Solid or liquid weight density is commonly measured in grams per cubic centimeter. For gases, the most common unit is grams per liter. Because weight density equals weight divided by volume, the density of any gas at STPD can be computed easily by dividing its molecular weight (gmw) by the universal molar volume of 22.4 L (22.3 for CO_2). Box 6-1 provides examples of gas density calculations.

For the density of a gas mixture to be calculated, the percentage or fraction of each gas in the mixture must be known. To calculate the density of air at STPD, the following equation is used:

$$d_w \text{ air} = (FN \times \text{gmw N}) + (FO_2 \times \text{gmw } O_2)/22.4 \text{ L}$$
$$d_w \text{ air} = (0.79 \times 28) + (0.21 \times 32)/22.4$$
$$d_w \text{ air} = 1.29 \text{ g/L}$$

FN and FO_2 equal the fractional concentrations of N and O_2 in air.

Gaseous Diffusion

Diffusion is the process whereby molecules move from areas of high concentration to areas of lower concentration. *Kinetic energy* is the driving force behind diffusion. Because gases have high kinetic energy, they diffuse most rapidly. However, diffusion also occurs in liquids and can occur in solids. Gas diffusion rates are quantified using **Graham's law**. Mathematically, the rate of diffusion of a gas (D) is inversely proportional to the square root of its gram molecular weight:

$$D_{gas} \propto \frac{1}{\sqrt{gmw}}$$

According to this principle, light gases diffuse rapidly whereas heavy gases diffuse more slowly. Because diffusion is based on kinetic activity, anything that increases molecular activity quickens diffusion. Heating and mechanical agitation speed diffusion.

Gas Pressure

Whether free in the atmosphere, enclosed in a container, or dissolved in a liquid such as blood, all gases exert pressure. In physiology, the term *tension* is often used to refer to the pressure exerted by gases when dissolved in liquids. The pressure or tension of a gas depends mainly on its kinetic activity. In addition, gravity affects gas pressure. Gravity increases gas density, increasing the rate of molecular collisions and gas tension; this explains why atmospheric pressure decreases with altitude.

Pressure is a measure of force per unit area. The SI unit of pressure is the N/m^2, or Pascal (Pa). Pressure in the cgs system is measured in dynes/cm^2, whereas pounds per square inch (lb/in^2 or psi) is the British foot-pound-second (fps) pressure unit. Pressure can also be measured indirectly as the height of a column of liquid, as is commonly done to determine atmospheric pressure.

Measuring Atmospheric Pressure. Atmospheric pressure is measured with a barometer. A barometer consists of an evacuated glass tube approximately 1 m long. This tube is closed at the top end, with its lower, open end immersed in a mercury reservoir (Figure 6-15). The pressure of the atmosphere on the mercury reservoir forces the mercury up the vacuum tube a distance equivalent to the force exerted. In this manner, the height of the mercury column represents the downward force of atmospheric pressure and is measured in either inches (British) or millimeters (metric). Barometer pressure is reported with readings such as 30.4 inches of mercury (Hg) or 772 mm Hg; this means that the atmospheric pressure is great enough to support a column of mercury 30.4 inches or 772 mm in height.

Alternatively, the term *torr* may be used in pressure readings. Torr is short for Torricelli, the seventeenth-century inventor of the mercury barometer. At sea level, 1 torr equals 1 mm Hg. A pressure reading of 772 torr is the same as 772 mm Hg.

Box 6-1 Examples of Gas Densities d_w at Standard Temperature and Pressure, Dry

$d_w O_2$ = gmw/22.4 = 32/22.4 = 1.43 g/L
$d_w N_2$ = gmw/22.4 = 28/22.4 = 1.25 g/L
d_w He = gmw/22.4 = 4/22.4 = 0.179 g/L
$d_w CO_2$ = gmw/22.4 = 44/22.4 = 1.97 g/L

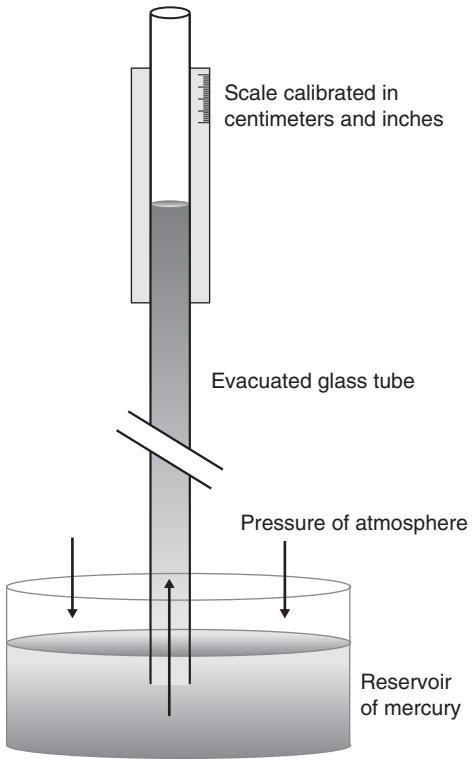

FIGURE 6-15 Major components of a mercury barometer.

The height of a column of mercury is not a true measure of pressure. Height is a linear measure, whereas pressure represents force per unit area. The pressure exerted by a liquid is directly proportional to its depth (or height) times its density:

$$\text{Pressure} = \text{Height} \times \text{Density}$$

At sea level, the average atmospheric pressure supports a column of mercury 76 cm (760 mm) or 29.9 inches in height. If we also know that mercury has a density of 13.6 g/cm^3 (0.491 lb/in^3), the average atmospheric pressure (P_B) is calculated as follows:

$$\text{cgs units: } P_B = 76\ \text{cm} \times 13.6\ \text{g/cm}^3 = 1034\ \text{g/cm}^2$$
$$\text{fps units: } P_B = 29.9\ \text{in} \times 0.491\ \text{lb/in}^3 = 14.7\ \text{lb/in}^2$$

These two measures, 1034 g/cm^2 and 14.7 lb/in^2, are considered standards in the cgs and British fps systems, each being equivalent to 1 atm.[4-7]

Similar to any solid material, a barometer's housing reacts to temperature changes by expanding and contracting. In addition, the mercury column acts like a large thermometer. Both pressure and temperature affect the mercury level of a barometer. For accuracy, the reading must be corrected for temperature changes.

Clinical Pressure Measurements. Mercury is the most common fluid used in pressure measurements both in barometers and at the bedside. Because of the high density (13.6 g/cm^3) of mercury, it assumes a height that is easy to read for most pressures in the clinical range. Water columns also can be used to measure pressure (in centimeters of water [cm H_2O]) but only low pressures. Because water is 13.6 times less dense than mercury, 1 atm would support a water column 33.9 feet high or about as tall as a two-story building.

Both mercury and water columns are still used in clinical practice, especially when vascular pressures are being measured. However, these traditional tools are rapidly being replaced by mechanical or electronic pressure-measuring devices. Even so, these new instruments must be calibrated against a mercury or water column before making measurements.

The simplest mechanical pressure gauge is the *aneroid barometer,* which is common in homes. An aneroid barometer consists of a sealed evacuated metal box with a flexible, spring-supported top that responds to external pressure changes (Figure 6-16). This motion activates a geared pointer, which provides a scale reading analogous to pressure.

This same concept underlies the simple mechanical manometers used to measure blood or airway pressure at the bedside (Figure 6-17). However, rather than the pressure acting externally on the sealed chamber, the inside is connected to the pressure source. In this manner, the flexible chamber wall expands and contracts as pressure increases or decreases.

A flexible chamber also can be used to measure pressure electronically. These devices are called **strain-gauge pressure transducers**. In these devices, pressure changes expand and contract a flexible metal diaphragm connected to electrical wires (Figure 6-18). The physical strain on the diaphragm changes the amount of electricity flowing through the wires. By measuring this change in electrical voltage, we are indirectly measuring changes in pressure. Most modern medical devices use small, solid-state, piezoelectric pressure sensors. These devices work on the principle that certain materials generate an electric charge in response to applied mechanical stress.

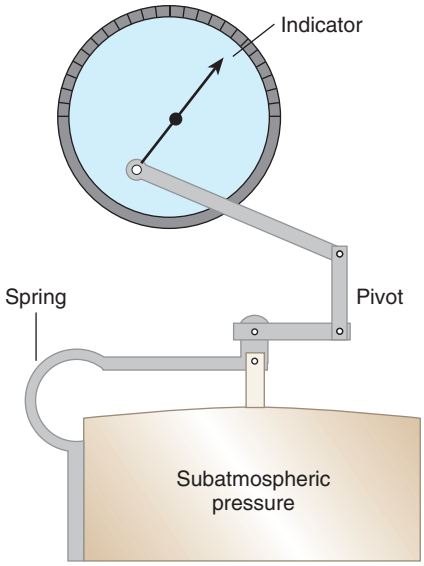

FIGURE 6-16 Aneroid barometer.

FIGURE 6-17 Mechanical manometer used to measure a patient's airway pressure.

Although millimeters of mercury and centimeters of water are still the most common pressure units used at the bedside, they do not represent the SI standard. The SI unit of pressure is the kPa; 1 kPa equals approximately 10.2 cm H_2O or 7.5 torr. To convert between these pressure units accurately, use the factors provided in the rear inside cover of this book.

RULE OF THUMB

One kilopascal equals approximately 10.2 cm H_2O. A pressure of 10 kPa equals approximately 100 cm H_2O. Conversely, a pressure of 60 cm H_2O equals approximately 6 kPa.

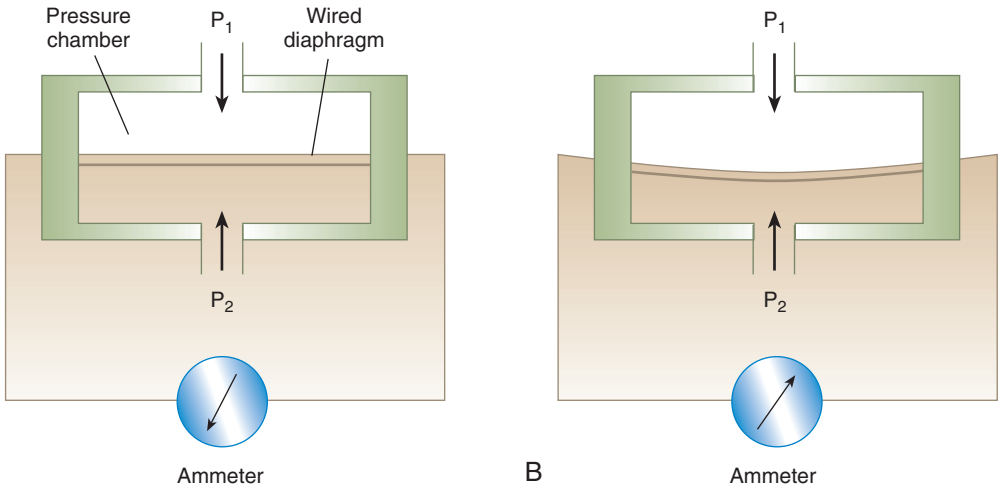

FIGURE 6-18 Strain-gauge pressure transducer. **A,** No pressure is applied. **B,** Pressure is applied to the transducer. An ammeter shows a change in electrical current proportional to the magnitude of pressure applied.

Partial Pressures (Dalton's Law)

Many gases exist together as mixtures. Air is a good example of a gas mixture, consisting mainly of O_2 and N. A gas mixture, similar to a solitary gas, exerts pressure. The pressure exerted by a gas mixture must equal the sum of the kinetic activity of all its component gases. The pressure exerted by a single gas in a mixture is called its *partial pressure.*

Dalton's law describes the relationship between the partial pressure and the total pressure in a gas mixture. According to this law, the total pressure of a mixture of gases must equal the sum of the partial pressures of all component gases. The principle states that the partial pressure of a component gas must be proportional to its percentage in the mixture.[8]

A gas making up 25% of a mixture would exert 25% of the total pressure. For consistency, the percentage of a gas in a mixture is usually expressed in decimal form, using the term *fractional concentration*. A gas that is 25% of a mixture has a fractional concentration of 0.25. For example, air consists of approximately 21% O_2 and 79% N. To compute the partial pressure of each component, simply multiply the fractional concentration of each component by the total pressure. Assuming a normal atmospheric pressure of 760 torr, the individual partial pressure is computed as follows:

$$\text{Partial pressure} = \text{Fractional concentration} \times \text{Total pressure}$$

$$PO_2 = 0.21 \times 760 \text{ torr} = 160 \text{ torr}$$

$$PN = 0.79 \times 760 \text{ torr} = 60 \text{ torr}$$

As predicted by Dalton's law, the sum of these partial pressures equals the total pressure of the gas mixture.

What if the total pressure changed? Barometric pressure changes, in addition to minor fluctuations caused by weather, are mainly a function of altitude. Considering only O_2, we know that its fractional concentration, or fractional inspired O_2 (FiO_2), remains constant at approximately 0.21. At a P_B of 760 torr, the PO_2 is equal to 0.21 × 760, or 160 torr. At 25,000 feet, the FiO_2 of air is still 0.21. However, the P_B is only 282 torr, and the resulting PO_2 is 0.21 × 282, or 59 torr, just more than one-third of that available at sea level. Because the PO_2 (not its percentage) determines physiologic activity, high altitudes can impair O_2 uptake by the lungs. Mountain climbers must sometimes use supplemental O_2 at high altitudes for this reason. By increasing the amount of O_2 more than 0.21, we can raise its partial pressure and increase uptake by the lungs. For a practical application of this principle, see the accompanying Mini Clini.

MINI CLINI

Why Are Oxygen Masks Needed on Airplanes?

PROBLEM: People who have traveled by air are familiar with the safety instructions given by the crew before flight. Instructions are included on how to use the O masks. When and why are these masks needed?

DISCUSSION: At a typical cruising altitude of 30,000 feet, the P_B outside the airplane cabin is approximately 226 torr. The inspired partial pressure of O_2 (PiO_2) is calculated as follows:

$$PiO_2 = 0.21 \times 226 \text{ torr} = 47 \text{ torr}$$

If the cabin were to depressurize, travelers inside would be exposed to this low PiO_2. At this PiO_2, most people become unconscious within seconds and eventually die of lack of O_2 (anoxia).

To overcome this problem, emergency O_2 masks are available when the cabin depressurizes. These masks, assuming a tight fit, probably provide approximately 70% O_2, or an FiO_2 of 0.70. The PiO_2 of a person wearing a mask under these conditions is calculated as follows:

$$PiO_2 = 0.70 \times 226 \text{ torr} = 158 \text{ torr}$$

This PiO_2 (about the same as at sea level) is sufficient to keep the passengers alive until the crew can bring the plane down to a safe altitude.

In contrast, high atmospheric pressures increase the partial pressure of inspired O_2 (PiO_2) in an air mixture. Pressures above atmospheric are called *hyperbaric pressures*.[9] Hyperbaric pressures commonly occur only in underwater diving and in special hyperbaric chambers.[9] For example, at a depth of 66 feet under the sea, water exerts a pressure of 3 atm, or 2280 mm Hg (3 × 760). At this depth, the O_2 in an air mixture breathed by a diver exerts a PO_2 of 0.21 × 2280, or approximately 479 mm Hg. This is nearly three times the PO_2 at sea level.

The same conditions can be created on dry land in a *hyperbaric chamber*. Hyperbaric chambers are used for controlled depressurization of deep-sea divers and to treat certain types of diving accidents. Clinically, hyperbaric chambers and O_2 are used together to treat various conditions, including carbon monoxide poisoning and gangrene. Chapter 41 provides more details on this use of high-pressure O_2.

Solubility of Gases in Liquids (Henry's Law)

Gases can dissolve in liquids. Carbonated water and soda are good examples of a gas (CO_2) dissolved in a liquid (water). **Henry's law** states that at a constant temperature, the amount of a given gas that dissolves in a given type and volume of liquid is directly proportional to the partial pressure of that gas in equilibrium with that liquid. For O_2 dissolved in blood, the equation is

$$C_{dO_2} = kP_{O_2}$$

where C_{dO_2} is the concentration of O_2 of dissolved O_2 in the blood at standard temperature and pressure dry conditions (milliliters per deciliter of blood, equivalent to mL/100 mL, also called volume percent), k is the constant of proportionality, or **solubility coefficient** (for blood k = 0.0031 mL/mm Hg/dL blood at 37° C). Note that this term shows up in the equation for the total O_2 content of blood (see Chapter 12). For example, if the PaO_2 is 100 mm Hg, the concentration of dissolved O_2 is:

$$C_{dO_2} = 0.0031 \times 100 = 0.3 \text{ mL/dL}$$

Temperature plays a major role in gas solubility. High temperatures decrease solubility, and low temperatures increase solubility. This is why an open can of soda may still fizz if left in the refrigerator but quickly goes flat when left out at room temperature. The effect of temperature on solubility is a result of changes in kinetic activity. As a liquid is warmed, the kinetic activity of any dissolved gas molecules is increased. This increase in kinetic activity increases the escaping tendency of the molecules and partial pressure. As an increasing number of gas molecules escape, the amount left in a solution decreases rapidly. For a practical application of this principle, see the accompanying Mini Clini, which discusses blood gases and patient temperature.

GAS BEHAVIOR UNDER CHANGING CONDITIONS

Gases, with large distances between their molecules, are easily compressed and expanded. When a gas is pressurized, the molecules are squeezed closer together. If a gas-filled container could be enlarged, the gas would expand to occupy the new volume. Figure 6-19 illustrates the concepts of gas compression and expansion.

MINI CLINI

Blood Gases Versus Patient Temperature

PROBLEM: Respiratory therapists (RTs) frequently need to sample and measure the partial pressures of O_2 and CO_2 in patients' arterial blood. These samples are called *arterial blood gas* (ABG) samples. Typically, ABG samples are measured in analyzers kept at a normal body temperature of 37° C. However, not all patients have normal body temperatures. Many are feverish (hyperpyrexia), and some have low body temperatures (hypothermia). What effect does this have on the measurements?

DISCUSSION: The direct relationship between temperature and partial pressure causes higher arterial PO_2 and PCO_2 readings at higher temperatures. At 37° C, the arterial PO_2 in a normal adult is approximately 100 torr. However, at 47° C, the PO_2 would be nearly twice as high. A smaller increase from 37° to 39° C increases the arterial PO_2 less markedly from 100 torr to approximately 110 torr. Likewise, an increase in temperature increases the arterial PCO_2. Arterial PCO_2 values increase approximately 5% per degree Celsius. An increase in temperature from 37° to 39° C increases the PCO_2 by approximately 10%, from 40 torr to 44 torr.

The reverse is also true. Decreased temperatures decrease the arterial partial pressures of O_2 and CO_2. Correction equations are available to help compute these corrections; however, they correct only for the relationship between temperature and pressure and do not take into account metabolic and cardiovascular changes that accompany a change in a patient's temperature. For this reason, the use of corrected PO_2 and PCO_2 readings remains controversial.

Gas Laws

Several laws help define the relationships among gas pressure, temperature, mass, and volume (Table 6-4). Using these laws,[10,11] the behaviors of gases under changing conditions can be predicted. Underlying all these laws are three basic assumptions: (1) No energy is lost during molecular collisions, (2) the volume of the molecules themselves is negligible, and (3) no forces of mutual attraction exist between these molecules. These three assumptions describe the behavior of an "ideal gas." Under normal conditions, most gases exhibit ideal behavior.

Effect of Water Vapor

In clinical practice, most gas law calculations must take into account the presence of water vapor. Water vapor, similar to any gas, occupies space. The dry volume of a gas at a constant pressure and temperature is always smaller than its saturated volume. The opposite is also true. Correcting from the dry state to the saturated state always yields a larger gas volume.

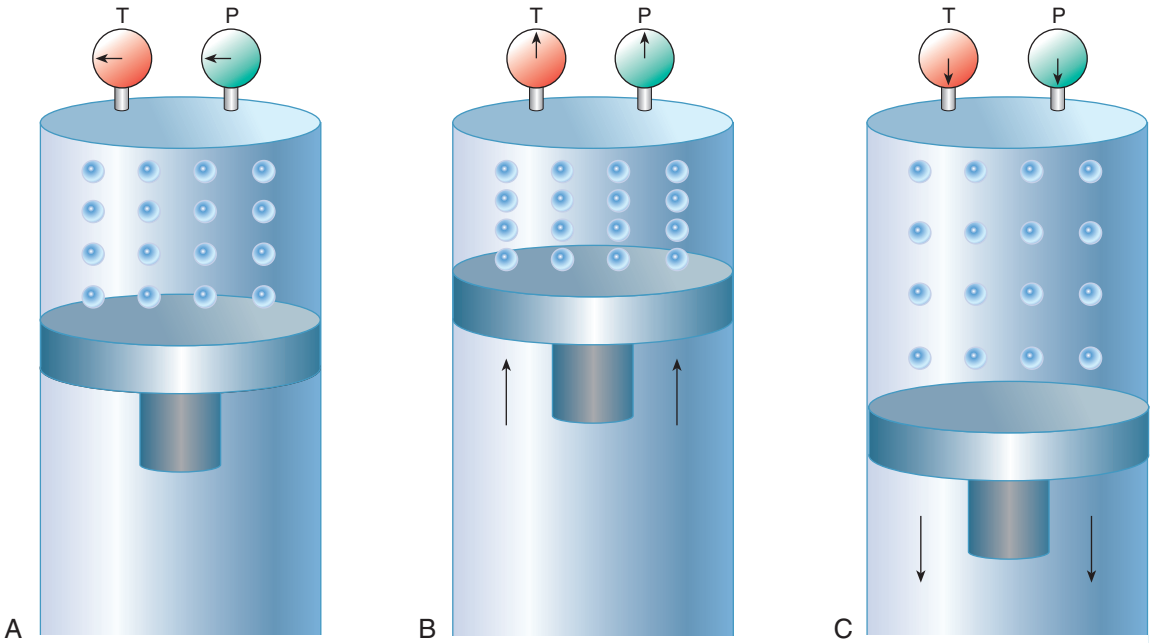

FIGURE 6-19 A mass of gas in the resting state exerts a given pressure *(P)* at a given temperature *(T)* in cylinder **A.** In cylinder **B,** as the piston compresses the gas, the molecules are crowded closer together, and the increased energy of molecular collisions increases both the temperature and the pressure. Conversely, as the gas expands in cylinder **C,** molecular interaction decreases and the temperature and pressure decrease.

TABLE 6-4

Laws Describing Gas Behavior Under Changing Conditions

Gas Law	Basic Relationship	Constants	Description	Working Formula*	Clinical Applications
Boyle's law	$P \times V = k$	Temperature, mass	Volume of a gas varies inversely with its pressure	$P_1V_1 = P_2V_2$	Ventilation (see Chapter 11) Body plethysmography (see Chapter 19) Compressed volume (see Chapter 38)
Charles' law	$\frac{V}{T} = k$	Pressure, mass	Volume of gas varies directly with changes in its temperature (°K)	$\frac{V_1}{T_1} = \frac{V_2}{T_2}$	ATPS to BTPS corrections (see this chapter)
Gay-Lussac's law	$\frac{P}{T} = k$	Volume, mass	Pressure exerted by a gas varies directly with its absolute temperature	$\frac{P_1}{T_1} = \frac{P_2}{T_2}$	Cylinder pressures (see Chapter 38)
Combined gas law	$PV = nRT$	—	Interaction of above (none held constant)	$\frac{P_1V_1}{nT_1} = \frac{P_2V_2}{nT_2}$	Complex interactions of variables

*Use the working formulas to calculate the new value of a parameter when a gas undergoes a change in P, V, n, or T. For example, to solve for a new volume (V_2) using Boyle's law, you would simply rearrange its working equation as follows:

$$V_2 = V_1 \times P_1/P_2$$

n, Mass; *P,* pressure; *R,* the gas constant (a combined constant of proportionality); *T,* temperature (°K); *V,* volume.

The pressure exerted by water vapor is independent of the other gases with which it mixes, depending only on the temperature and RH. The addition of water vapor to a gas mixture always lowers the partial pressures of the other gases present. This fact becomes relevant when discussing the partial pressure of gases in the lung, where the gases are saturated with water vapor at body temperature.

Corrected Pressure Computations

To compute the new or corrected partial pressure of a gas after saturation with water vapor, the following formula is applied:

$$P_C = F_{gas} \times (P_T - P_{H_2O})$$

P_C is the corrected gas pressure, F_{gas} is the fractional concentration of the gas in the gas mixture, P_T is the total gas pressure of

the mixture, and P_{H_2O} is the water vapor pressure at the given temperature (see Table 6-3). If only a single gas is present, F_{gas} equals 1, and the formula can be simplified:

$$P_C = (P_T - P_{H_2O})$$

Correction Factors

Correction factors can be used to convert gas volumes from one set of conditions to another. Such computations are common in pulmonary function laboratories. But they are also common to mechanical ventilators. For example, suppose you set a tidal volume on a ventilator to 500 mL. If the ventilator's output control valve metered out 500 mL, and if the gas was heated and humidified to body conditions (fully saturated at 37° C), then the gas volume would increase because of the heat and addition of water vapor. But how much would it increase? To find out, we need to use conversion equations. As it turns out, the volume increases to 562 (assuming ambient barometric pressure of 760 mm Hg) which is a significant increase of 12%. The current standard of care for mechanical ventilation places emphasis on accurately dosing tidal volume to approximately 6 mL/kg. To maintain the desired accuracy, most intensive care unit ventilator manufacturers correct the set tidal volume to convert from ambient temperature and pressure dry conditions (ATPD) to body temperature and pressure saturated conditions (BTPS), which in this case would mean decreasing the volume exiting the control valves by 62 mL. Such conversions are important for research when evaluating the performance of mechanical ventilators in terms of volume delivery accuracy. In that case, the experiment generally involves measuring gas at (ATPD) and then converting to BTPS to make a fair comparison to the ventilator's display (which is corrected to BTPS).

In gas volume conversions, the four most common computations are as follows (P_B in millimeters of mercury and temperature in °C):

1. Correction from ambient temperature and pressure dry (**ATPD**) to body temperature and pressure saturated (**BTPS**), as is done in some mechanical ventilators.

$$\text{Correction factor} = \frac{P_B}{P_B - 47} \times \frac{310}{273 + T}$$

2. Correction from ambient temperature and pressure saturated (**ATPS**) to body temperature and pressure saturated (**BTPS**).

$$\text{Correction factor} = \frac{P_B - P_{H_2O}}{P_B - 47} \times \frac{310}{273 + T}$$

3. Correction from ATPS to standard temperature and pressure dry, **STPD** (0° C and 760 torr)

$$\text{Correction factor} = \frac{P_B - P_{H_2O}}{760} \times \frac{273}{273 + T}$$

4. Correction from STPD to BTPS:

$$\text{Correction factor} = \frac{760}{P_B - 47} \times \frac{310}{273 + T}$$

In each case, the new volume equals the original volume times the correction factor.

Properties of Gases at Extremes of Temperature and Pressure

Most gases exhibit ideal behavior under normal conditions. However, gases can deviate from these expectations, especially at the extremes of pressure and temperature. The accompanying Mini Clini (page 6-19) provides two good clinical examples of how gas behavior can deviate from the ideal.

Weak attractive forces (van der Waals forces) between gas molecules oppose their kinetic activity. Both temperature and pressure affect these forces. At high temperatures, the increased kinetic activity of gas molecules far overshadows these forces. However, at very low temperatures, kinetic activity lessens and these forces become more important. Likewise, very low pressures permit gas molecules to move freely about with little mutual attraction. In contrast, high pressures crowd molecules together, increasing the influence of these forces.

The actual space occupied by gas molecules also can influence their behavior. At low pressure, the total mass of matter in a gas is a negligible fraction of the total volume. However, at very high pressures, molecular density becomes important, altering the expected relationship between pressure and volume.

Critical Temperature and Pressure

For every liquid, there is a temperature above which the kinetic activity of its molecules is so great that the attractive forces cannot keep them in a liquid state. This temperature is called the **critical temperature**. The critical temperature is the highest temperature at which a substance can exist as a liquid. The pressure needed to maintain equilibrium between the liquid and gas phases of a substance at this critical temperature is the *critical pressure*. Together, the critical temperature and pressure represent the critical point of a substance.

The critical temperature of water is 374° C. At this temperature, a pressure of 218 atm is needed to maintain equilibrium between the liquid and gaseous forms of water. No pressure can return water vapor to its liquid form at a temperature greater than 374° C.

Compared with liquids, gases have much lower critical points. Table 6-5 lists the critical points of four gases used in clinical practice: O_2, helium, CO_2, and nitrous oxide. The critical temperatures of O_2 and He are well below the normal room temperature of 20° C (68° F).

TABLE 6-5

Critical Points of Three Gases

Gas	°C	°F	Atmosphere
Helium (He)	–267.9	–450.2	2.3
Oxygen (O_2)	–118.8	–181.1	49.7
Carbon dioxide (CO_2)	31.1	87.9	73.0
Nitrous oxide (N_2O)	36.5	97.7	71.8

MINI CLINI

Variations from Ideal Gas Behavior: Expansion Cooling and Adiabatic Compression

Boyle's law describes gas behavior under constant temperature, or isothermal conditions.[10] During isothermal conditions, the temperature of an ideal gas should not change with either expansion or contraction. For example, if an ideal gas were to escape rapidly from a high-pressure cylinder into the atmosphere, its temperature should not change. The rapid expansion of real gases causes substantial cooling. This phenomenon of expansion cooling is called the *Joule-Thompson effect.*

A rapidly expanding gas cools because the attractive force between its molecules is broken. Because the energy needed to break these forces must come from the gas itself, the temperature of the gas must decrease. This decrease in temperature, depending on the pressure drop that occurs, can be large enough to liquefy the gas. This is the primary method used to liquefy air for the production of O_2.

Isothermal processes keep gas temperature constant. The internal energy will remain constant. In an *adiabatic process,* the container is insulated, resulting in no heat transfer into or out from the system. If the volume increases, the internal energy decreases to perform the work and thus the temperature decreases. If the volume is increased the internal energy is also increased, resulting in a higher temperature. Adiabatic processes are used in liquefying gases.

Lung simulators are often constructed from rigid-walled containers such that the compressibility of the gas in the container represents the compliance of the lungs (particularly useful for neonatal lung simulators). Such containers are often filled with very fine strands of copper (called copper wool) to absorb the heat generated when the gas is compressed, approximating isothermal conditions. However, this is not essential and adiabatic conditions can be assumed instead. The volume of the container (V in liters) required to simulate a given compliance (C in cm H_2O/L) is given by the equations:

$$V = 1.35 \times P_B \times C_I \text{ (isothermanal)}$$
$$V = 1.9 \times P_B \times C_A \text{ (adiabatic)}$$

The derivation of these equations is described elsewhere.[12]

The concept of critical temperature can be applied to distinguish between a true gas and a vapor. A true gas, such as O_2, has a critical temperature so low that at room temperature and pressure it cannot exist as a liquid. In contrast, a vapor is the gaseous state of a substance coexisting with its liquid or solid state at room temperature and pressure. This is why molecular water is referred to as *water vapor.*

The concept of critical temperature and pressure also helps explain how gases are liquefied. A gas can be liquefied by being cooled to below its boiling point. Alternatively, a gas can be liquefied by being cooled to less than its critical temperature and then being compressed. The more a gas is cooled below its critical temperature, the less pressure will be needed to liquefy it. However, under no circumstances can pressure alone liquefy a gas existing above its critical temperature.

According to these principles, any gas with a critical temperature above ambient should be able to be liquefied simply by having pressure applied. Both CO_2 and N_2O have critical temperatures above normal room temperature (see Table 6-5). Both gases can be liquefied by simple compression and stored as liquids at room temperature without cooling. However, both liquefied gases still need to be stored under pressure, usually in strong metal cylinders.

Liquid O_2 is produced by separating it from a liquefied air mixture at a temperature below its boiling point (−183°C or −297°F). After it is separated from air, the O_2 must be maintained as a liquid by being stored in insulated containers below its boiling point. As long as the temperature does not exceed −183°C, the O_2 remains liquid at atmospheric pressure. If higher temperatures are needed, higher pressures must be used. If at any time the liquid O_2 exceeds its critical temperature of −118.8°C, it converts immediately to a gas.

FLUID DYNAMICS

So far, liquids and gases have been presented under static, or nonmoving, conditions. However, both liquids and gases can flow. Flow is the bulk movement of a substance through space. The study of fluids in motion is called *hydrodynamics.* Because many respiratory care devices use hydrodynamic principles, the RT must have a good understanding of the basic concepts governing fluids in motion.

Pressures in Flowing Fluids

As we have seen, the pressure of a static liquid depends solely on the depth and density of the fluid. In contrast, the pressure exerted by a liquid in motion depends on the nature of the flow itself. As shown in Figure 6-20, *A*, the pressure exerted by a static fluid is the same at all points along a horizontal tube, depending only on the height (h) of the liquid column. However, when the fluid flows out through the bottom tube, the pressure progressively decreases all along the tube length (see Figure 6-20, *B*). In addition, the decrease in pressure between each of the equally spaced vertical tubes is the same.

The decrease in fluid pressure along the tube reflects a cumulative energy loss, as predicted by the second law of thermodynamics.[4] Available energy decreases because frictional forces (flow resistance) oppose fluid flow. Frictional resistance to flow exists both within the fluid itself (viscosity) and between the fluid and the tube wall. Generally, the greater the viscosity of the fluid and the smaller the cross-sectional area of the tube, the greater is the decrease in pressure along the tube.

For any given tube length, **flow resistance** is defined as the constant of proportionality for an assumed linear relation between the pressure difference between the two points along the tube and the flow. The constant of proportionality (R) is simply the slope of the straight line relation:

$$R = \frac{\Delta(P_1 - P_2)}{\Delta \dot{V}}$$

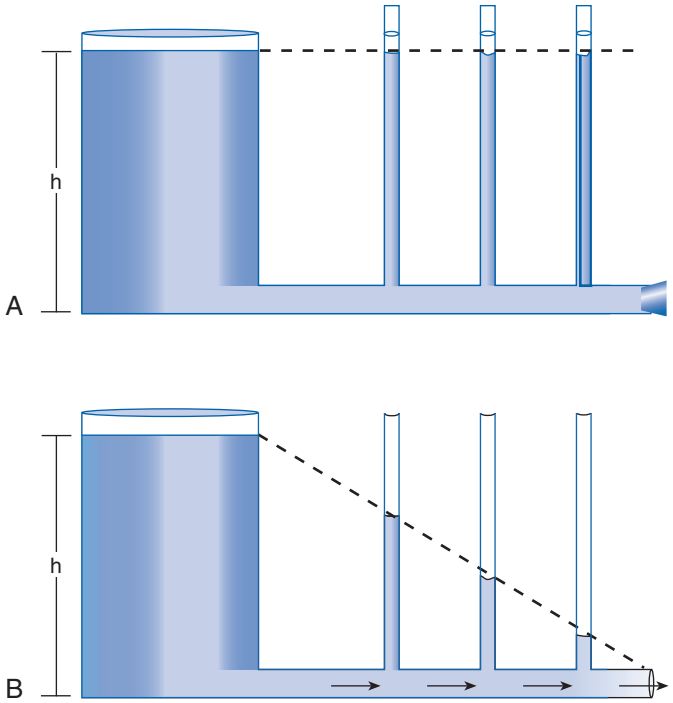

FIGURE 6-20 **A,** The pressure is the same at all points along the horizontal tube when there is no flow. **B,** A progressive decrease in pressure occurs as the fluid flows. (Modified from Nave CR, Nave BC: Physics for the health sciences, ed 3, Philadelphia, 1985, WB Saunders.)

where R is resistance (cm H_2O/L/sec, the most common units in pulmonary physiology), P_1 is the pressure (cm H_2O) at the upstream point (point 1), P_2 is the pressure at the downstream point (point 2), and $\dot{V}$ is the flow (L/sec). This equation has wide application in pulmonary physiology and respiratory care. The accompanying Mini Clini provides a good example of such application.

MINI CLINI

Differential Pressure Pneumotachometer

PROBLEM: It is often necessary to measure and record changes in airflow as a patient breathes. How can we apply the formula for resistance to measure and record airflow?

DISCUSSION: Airflow can be measured using a device called a *pneumotachometer*. One of the simplest designs is the differential pressure pneumotachometer. A differential pressure pneumotachometer incorporates a flow tube with a known and constant resistance. If the formula for resistance is rearranged to solve for flow, it appears as follows:

$$\Delta\dot{V} = k \times \Delta(P_1 - P_1)$$

Patterns of Flow

The pressure difference that results from flow also varies with the pattern of flow. There are three primary patterns

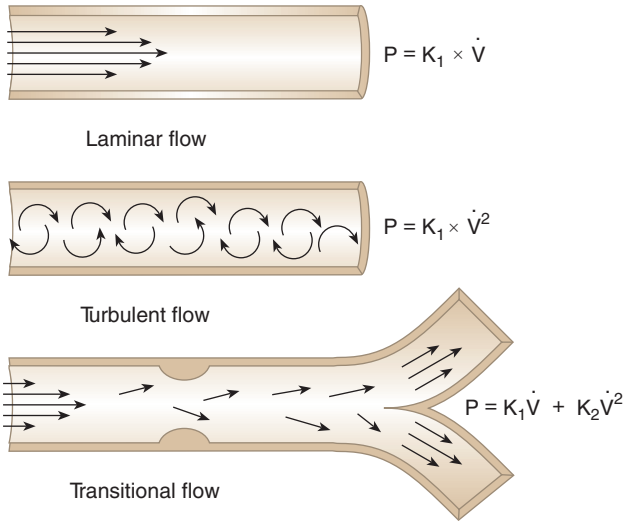

FIGURE 6-21 Three patterns of flow—laminar, turbulent, and transitional. (Modified from Moser KM, Spragg RG: Respiratory emergencies, ed 2, St Louis, 1982, Mosby.)

of flow through tubes: laminar, turbulent, and transitional (Figure 6-21).

Laminar Flow

As discussed earlier, during laminar flow, a fluid moves in discrete cylindrical layers or streamlines (see Figure 6-6). The difference in pressure required to produce a given flow, under conditions of laminar flow through a smooth tube of fixed size, is defined by **Poiseuille's law**[12]:

$$P_1 - P_2 = \frac{8nL\dot{V}}{\pi r^4}$$

where P_1 is the pressure (dyne/cm^2; equal to 0.001 cm H_2O) at the upstream point (point 1), P_2 is the pressure at the downstream point (point 2), n is viscosity (dyne • sec/cm^2, called poise), L is length (cm), r is radius (cm) and $\dot{V}$ is the flow (cm^3/min = mL/min). The viscosity of air is approximately 1.9×10^{-4} poises; for water it is approximately 8.90×10^{-3} poises. A pressure of 1 cm H_2O is about 980 dyne/cm^2.

Occasionally flow resistance is expressed in terms of the Poiseuille equation as:

$$R = \frac{\Delta P}{\dot{V}} = \frac{8nL}{\pi r^4}$$

which indicates that resistance is very sensitive to changes in tube radius (e.g., doubling the tube radius decreases the resistance by a factor or $2^4 = 8$). Another way to view this is that increasing the tube radius by 19% will increase the flow by 100% (i.e., double the flow; $1.19^4 = 2.0$).

Turbulent Flow

Under certain conditions, the pattern of flow through a tube changes significantly, with a loss of regular streamlines. Instead, fluid molecules form irregular eddy currents in a chaotic pattern called **turbulent flow** (see Figure 6-21). This changeover from

laminar to turbulent flow depends on several factors, including fluid density (d), viscosity (n), linear velocity (v), and tube radius (r). In combination, these factors determine **Reynold's number** (Re).

$$Re = \frac{\rho v d_h}{\mu}$$

where ρ is the density of the fluid (kg/m^3), v is the velocity of the fluid (m/sec), d_h is the diameter of the tube (m), and μ is the dynamic viscosity of the fluid [kg/(m • sec)]. Flow is considered to be laminar when Re is less than 2000, transient when it is between 2000 and 3000, and turbulent when it is above 3000. The equation shows that conditions favoring turbulent flow include increased fluid velocity, increased fluid density, increased tube diameter, and decreased fluid viscosity. In the presence of irregular tube walls, turbulent flow can occur when Re is less than 2000.

Flow through a tube with constant resistance is directly proportional to the pressure difference ($P_1 - P_2$) across the tube. By measuring this pressure difference we can measure flow. To ensure linearity between pressure and flow, the pneumotachometer is usually designed so that the flow pattern through the tube remains laminar, which simplifies calibration and use by having only one constant value for k.[13] The pneumotachometer is calibrated by measuring ($P_1 - P_2$) at different flows, plotting flow on the vertical axis and ($P_1 - P_2$) on the horizontal axis. Then, using linear regression, the calibration factor k is derived (this is essentially drawing a straight line through the data points and calculating the slope). When using the pneumotachometer, the pressure difference is multiplied by k to get the flow. This technique is at the heart of many pulmonary function laboratory procedures and is also used by some mechanical ventilators that have flow sensors at the airway opening portion of the patient circuit.

When flow becomes turbulent, Poiseuille's law no longer applies. Instead, the pressure difference across a tube is defined as follows:

$$P_1 - P_2 = \frac{fL\dot{V}^2}{4\pi^2 r^5}$$

where ΔP is the driving pressure, f is a friction factor based on the density and viscosity of the fluid and the tube wall roughness, L is the tube length, and $\dot{V}$ is the fluid flow.

Figure 6-22 compares the relationship between pressure and flow under laminar and turbulent conditions. As can be seen, when flow is laminar (Poiseuille's law), the relationship between driving pressure and flow is linear. However, when flow becomes turbulent, driving pressure varies with the square of the flow ($\dot{V}^2$). To double flow under laminar conditions, it is necessary to only double the driving pressure. To double flow under turbulent conditions, the driving pressure would be increased fourfold.

Transitional Flow

Transitional flow is a mixture of laminar and turbulent flow. Flow in the respiratory tract is mainly transitional. When flow is transitional, the total driving pressure equals the sum of the pressures resulting from laminar and turbulent flow:

$$P_1 - P_2 = (k_1 \times \dot{V}) + (k_2 \times \dot{V}^2)$$

where k_1 and k_2 are factors indicating the respective contribution of laminar and turbulent flow to overall driving pressure. When flow is mainly laminar, the pressure varies linearly with the flow. When flow is mainly turbulent, driving pressure varies exponentially with the flow. With all else equal, pressures generated during laminar flow are most affected by fluid viscosity, whereas fluid density is the key factor when flow is turbulent.

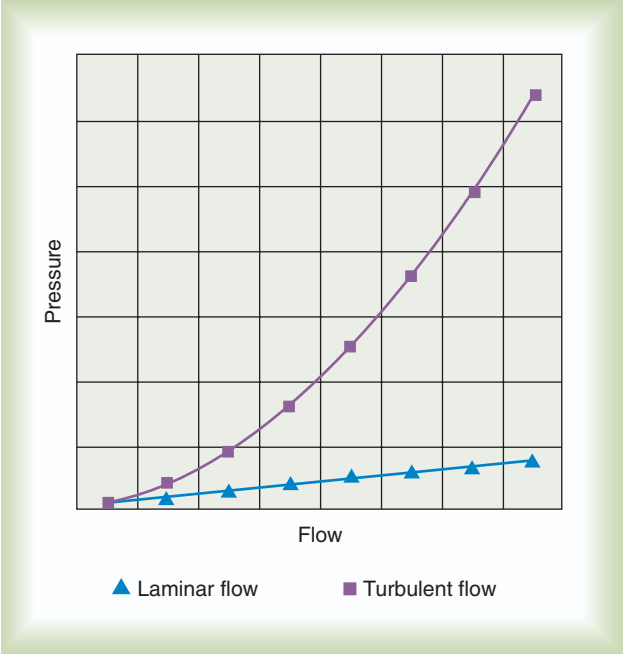

FIGURE 6-22 Relationship between driving pressure and flow under laminar and turbulent conditions.

Flow, Velocity, and Cross-Sectional Area

Clinically, the most common units of measurement describing flow are liters per minute (L/min) or liters per second (L/sec). In contrast, velocity is a measure of linear distance traveled by the fluid per unit of time. Centimeters per second (cm/sec) is a common velocity unit used in pulmonary physiology.

Although fluid flow and velocity are different measures, the two concepts are closely related. The key factor relating velocity to flow is the cross-sectional area of the conducting system. Figure 6-23 shows this relationship.

Throughout the tube, the fluid flows at a constant rate of 5 L/min. At *point A*, with a cross-sectional area of 5.08 cm^2, the velocity of the fluid is 16.4 cm/sec. At *point B*, the cross-sectional area of the tube decreases to 2.54 cm^2, half its prior value. At this point, the velocity of the fluid doubles to 32.8 cm/sec. At *point C*, the passage divides into eight smaller tubes. Although each tube is smaller than its "parent," together they provide a

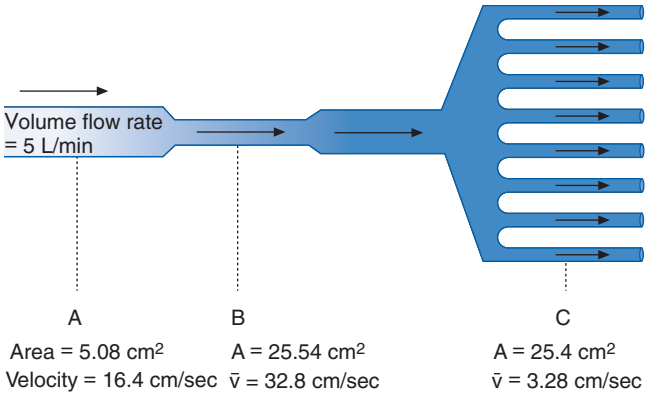

FIGURE 6-23 Fluid velocity, at a constant flow, varies inversely with the cross-sectional area of the tube. (Modified from Nave CR, Nave BC: Physics for the health sciences, ed 3, Philadelphia, 1985, WB Saunders.)

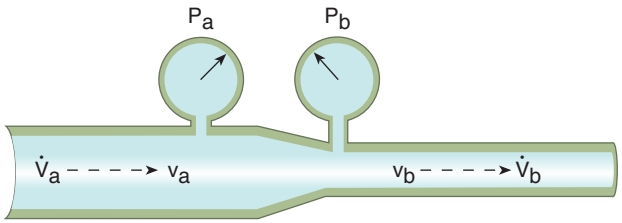

FIGURE 6-24 According to the Bernoulli theorem, lateral pressure of a flowing fluid must vary inversely with its velocity. $\dot{V}_a$, flow in tube "a"; v_a, velocity in tube "a"; v_b, velocity in tube "b"; $\dot{V}_b$, flow in tube "b"; P_a, lateral wall pressure in tube "a"; P_b, lateral wall pressure after restriction (see text).

10-fold increase in the cross-sectional area available for flow compared with *point B*. The velocity of the fluid decreases proportionately, from 32.8 cm/sec to 3.28 cm/sec.

These observations show that the velocity of a fluid moving through a tube at a constant flow varies inversely with the available cross-sectional area. This relationship is called the **law of continuity**. Mathematically, the equation is as follows:

$$(A_1 \times v_1) + (A_2 \times v_2) + (A_n \times v_n) = k$$

where A is the cross-sectional area of the tube; v is the velocity of the fluid; 1, 2, and n are different points in the tube; and k is a constant value.

Although the principle holds true only for incompressible liquids, the qualitative features are similar for gas flow. This principle also underlies the application of nozzles or jets in fluid streams. Nozzles and jets are simply narrow passages in a tube designed to increase fluid velocity. A garden-hose nozzle is a good example of this principle in action. Clinically, jets are used in many types of respiratory care equipment, including pneumatic nebulizers (see Chapter 39) and gas entrainment or mixing devices (see Chapter 41).

Bernoulli Principle

In a steady flow, the sum of all forms of energy in a fluid is the same at all points along the path of flow. Consequently, the sum of kinetic energy, potential energy, and internal energy remains constant. The Bernoulli principle states that an increase in the velocity of the fluid results in a decrease in the sum of its static pressure, potential energy, and internal energy.[11] The Bernoulli equation is:

$$p + \frac{1}{2}\rho v^2 + \rho g y = \text{constant}$$

where p = pressure at some point in a tube, ρ = fluid density, v = fluid velocity, g = acceleration due to gravity, and y = elevation of the pressure point above a reference plane. Figure 6-24 shows this relationship. Fluid is flowing through a tube at a point with a certain velocity (v_a) and a lateral pressure (P_a). According to the law of continuity, as the fluid moves into the narrow or constricted portion of the tube, its velocity must increase ($v_b > v_a$). According to the Bernoulli theorem, the higher velocity at point b should result in a lower lateral pressure at that point ($P_b < P_a$). As a fluid flows through the constriction, its velocity increases and its lateral pressure decreases.

This equation also helps demonstrate how heliox therapy works. The equation implies that the lower the density, the higher is the velocity (and hence flow) for the same inspiratory effort (driving pressure) or the lower is the pressure for the same velocity—either way that is a good effect for someone struggling to breathe.

Fluid Entrainment

Jet entrainment is the design principle used in simple O_2 masks with variable FiO_2 settings, although they are often mistakenly called *Venturi masks*. In this case, a pressurized gas, usually O_2, serves as the primary flow source. This pressurized gas passes through a nozzle or jet, beyond which is an air entrainment port (Figure 6-25, *A*). In this case, air entrainment occurs as a consequence of fluid viscosity. The viscous shearing force that exists between moving and static layers of gas causes the nonmoving gas (room air) to be dragged into the moving stream of O_2.[14] The amount of air entrained depends on both the diameter of the jet orifice and the size of the air entrainment ports. For a fixed jet size, the larger the entrainment ports, the greater is the volume of air entrained, the higher is the total flow, and the lower is the FiO_2 (see Figure 6-25, *B*). The entrained volume can still be altered, with fixed entrainment ports, by changing the jet diameter (see Figure 6-25, *C*). A large jet results in a lower gas velocity and less entrainment, whereas a small jet boosts velocity, entrained volume, and total flow.

Fluidics and the Coanda Effect

Fluidics is a branch of engineering that applies hydrodynamic principles in flow circuits for purposes such as switching, pressure and flow sensing, and amplification. Because fluidic devices have no moving parts, they are very dependable and require little maintenance.

The primary principle underlying most fluidic circuitry is a phenomenon called *wall attachment,* or the **Coanda effect**. This

effect is observed mainly when a fluid flows through a small orifice with properly contoured downstream surfaces.[15] We know that a jet or nozzle entrains any surrounding fluid, such as air, into the primary flow stream (Figure 6-26, *A*). If a carefully contoured curved wall is added to one side of the jet (see Figure 6-26, *B*), the pressure near the wall becomes negative relative to atmospheric pressure. The atmospheric pressure on the other side of the gas stream pushes it against the wall, where it remains "locked" until interrupted by some counterforce. By carefully extending the wall contour, we can deflect the fluid stream through a full 180-degree turn.

Various fluidic devices can be designed using this principle, including on/off switches, pressure and flow sensors, and flow amplifiers. These individual components can be combined into *integrated fluidic logic circuits,* which function much like electronic circuit boards but without the need for electrical power.

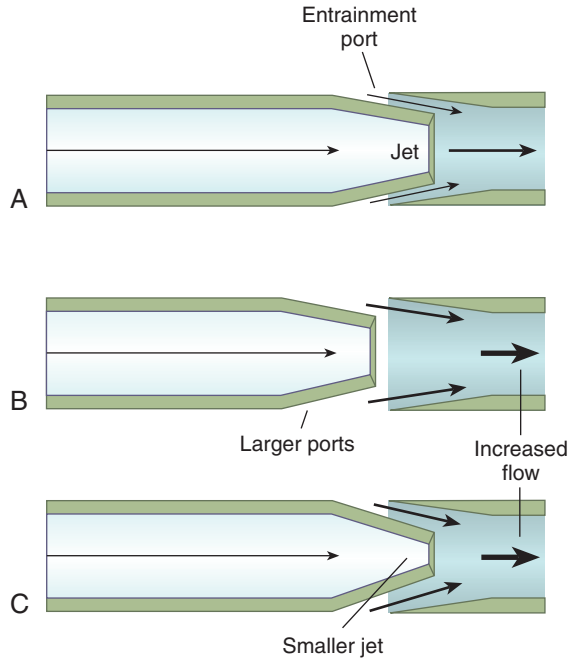

FIGURE 6-25 Air injector. **A,** Basic design. **B,** Greater entrainment and total flow occurs with larger entrainment ports. **C,** Alternatively, a smaller jet increases source gas velocity and entrains more air.

SUMMARY CHECKLIST

- Gases have no inherent boundary, are readily compressed and expanded, and can flow.
- Three temperature scales are in common use: Kelvin (SI), Celsius (cgs), and Fahrenheit (fps); conversion among these scale units can be done by using simple formulas.
- Transfer of heat energy can occur by conduction, convection, radiation, and evaporation.
- Liquids exert pressure and exhibit the properties of flow, buoyant force, viscosity, capillary action, and surface tension.
- The pressure exerted by a liquid depends on both its height (depth) and weight density.
- Surface tension forces increase the pressure inside a liquid drop or bubble; this pressure varies directly with the surface tension of the liquid and varies inversely with the radius.
- A liquid can vaporize by either boiling or evaporation; in evaporation, the required heat energy is taken from the air surrounding the liquid, cooling the air.
- Vaporization causing cooling and condensation causes warming of the surroundings.
- The capacity of air to hold water vapor increases with temperature.
- Relative humidity (RH) is the ratio of water vapor content (absolute humidity) to saturated water vapor capacity; for a constant content, cooling increases RH and warming decreases RH.
- The rate of diffusion of a gas is inversely proportional to its molecular weight.
- The total pressure of a mixture of gases must equal the sum of the partial pressures of all component gases.
- The volume of a gas that dissolves in a liquid equals its solubility coefficient times its partial pressure; high temperatures decrease gas solubility, and low temperatures increase gas solubility.
- Volume and pressure of a gas vary directly with temperature; however, with constant temperature, gas volume and pressure vary inversely.
- The critical temperature of a substance is the highest temperature at which it can exist as a liquid; gases with critical temperatures higher than room temperature can be stored under pressure as liquids without cooling.
- Under conditions of laminar flow, the difference in pressure required to produce a given flow is defined by Poiseuille's law.

CHAPTER 7

E-Medicine in Respiratory Care

NARCISO E. RODRIGUEZ, ALBERT J. HEUER, AND MADHU SASIDHAR

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Define electronic health records and their major uses in respiratory care.
- State the differences between the electronic health records and the electronic medical record.
- Identify the value of E-medicine applications in informatics and clinical decision support.
- Describe E-medicine applications in clinical care and management.
- Evaluate the trustworthiness and accuracy of health information sources.
- Describe major uses of E-medicine applications in health care administration.
- Outline steps to maintain security and confidentiality of electronic health records.
- Describe major E-medicine applications in respiratory care education and training.

CHAPTER OUTLINE

KEY TERMS

benchmarking
business intelligence
clinical decision support
clinical simulation
computerized physician order entry
continuing respiratory care education
continuous quality improvement
electronic health record
electronic medical record
enterprise software packages
E-medicine
health informatics
Health Information Technology for Economic and Clinical Health Act
information retrieval
key performance indicators
learning management systems
picture archiving and communication systems
point-of-care testing
root-cause analysis
telemedicine
telemonitoring
value-based purchasing

E-Medicine is the term that relates to the use of computerized or digital technology to enhance efficiency and effectiveness of health care in general and more specifically in patient care. E-Medicine was initially used to describe the use of basic computer applications in clinical care, record-keeping, and health education. However, because of significant and wide-spread technologic advancements, the term *E-medicine* now refers to a wide array of hardware and software applications used in essentially every facet of health care. As a vital part of the patient care team, respiratory therapists (RTs) need to have an understanding of, and be proficient in, many aspects of E-medicine. This chapter describes digital applications related to electronic health records, direct clinical care, disease management, health care administration, health information sources, and training and education.

THE ELECTRONIC HEALTH RECORD AND THE ELECTRONIC MEDICAL RECORD

A transformation has taken place in the recent past whereby medical records formerly maintained primarily in paper form are now almost exclusively computerized and are maintained as part of the patient's **electronic health record** (EHR). A closely related but different term is the **electronic medical record** (EMR), which represents the computerized record produced every time the patient (or consumer) uses health services. The EHR is the sum of all EMRs produced by a patient during the different encounters with various health care entities throughout a lifetime. Unlike the EHR, which is owned by the patient, the EMR (the "chart") is owned by the hospital or health care delivery organization.[1] The terms EHR and EMR are so closely related that for simplicity we will use the term EHR to describe both concepts for the rest of this chapter.

Nonclinical information is also now electronic, such as patient demographics (e.g., age, gender, religion) and health insurance, as well as clinical information, including the patient's history and physical examination information, progress notes, physician orders, laboratory and other testing results, vital signs trending, and other information formerly found only in the hard-copy chart. This information is now readily available to authorized clinicians via secured personal computers and mobile devices. In addition to being able to access existing medical information, new records can be more readily entered making most EHRs more current than paper records. Medical imaging and laboratory tests generally become a part of the EHR immediately as the results are finalized. The net impact of these factors is that the EHR has helped make disease diagnosis quicker and more accurate by facilitating the efficient access of medical records.[2,3] EHRs are also proving to be a significant asset in the realm of patient treatment. When coupled with other computerized tools such as clinical decision support applications, EHRs have enhanced treatment and disease management, as discussed in more detail later. The core functions of EHRs are shown in Box 7-1.

Box 7-1 Core Functions of Electronic Health Records

- Medical records
- Results reporting
- Computerized physician order entry
- Clinical decision support
- Electronic communication
- Channels between health care providers and patients
- Patient-entered data

EHRs are more than a repository for medical records and patient-related information. EHRs are also a rich source of information that can be used in a variety of applications, including quality improvement and regulatory compliance, as detailed later in this chapter. EHRs also can serve as a vital source of data for conducting research, as discussed in Chapter 7 of this text.

Computerized Physician Order Entry

A subset of EHRs is the **computerized physician order entry** (CPOE) system. Through CPOEs, orders can be electronically transmitted to the EHR, saving time and reducing transcription errors resulting from handwriting clarity issues. Built in stop-gaps and prescribing templates alert physicians about potential dosing problems and drug interaction concerns. The interfacing of CPOE systems with other hospital computer systems also alerts RTs and other clinicians of new, expired, or changed orders. Thus the CPOE has helped facilitate patient care and reduce medical errors.[4] All of these factors combined make both EHR and CPOE systems value-added features for health care organizations, clinicians, and patients alike. Indeed, EHRs and other computerized applications are helping transform medicine and enhancing both efficiency and effectiveness in essentially all aspects of health care and respiratory care.[5]

Enterprise Software Packages

An issue that had plagued health care organizations and our health care system involves the use of separate software packages for individual organizational functions, including but not limited to EHRs. In the past, the need for one such system to interface or "talk" to another was dealt with on an as-needed basis through ad-hoc software "patches." Over time these separate software packages, which were originally designed to stand alone or provide a specific or limited number of functions, became inefficient and much less able to meet the increasingly sophisticated and numerous requirements of health care organizations, including hospitals and departments within them. At about the same time that this problem was reaching critical proportions, the U.S. government (as part of a larger legislative initiative) passed the ***Health Information Technology for Economic and Clinical Health Act***, or the HITECH Act, as part of a national strategy for building a national health information infrastructure (Figure 7-1). Among other things, HITECH began providing incentives to hospitals, physicians, and other

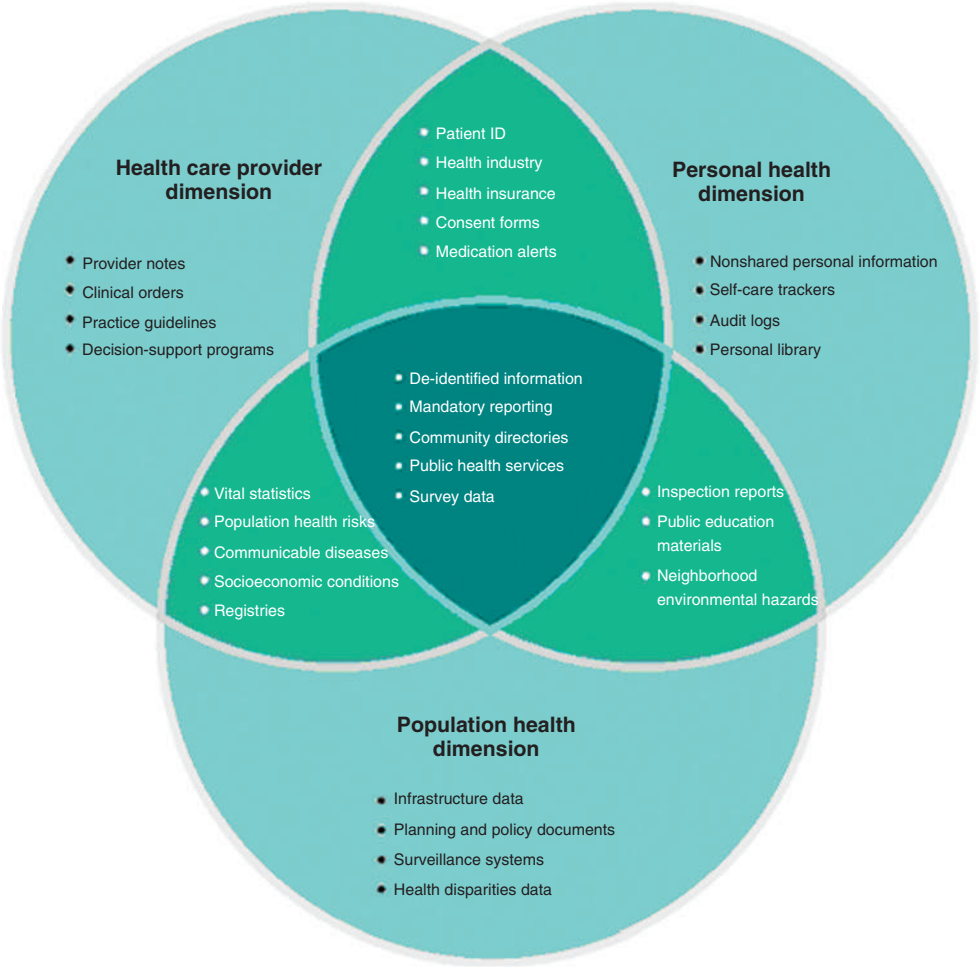

FIGURE 7-1 Electronic health records: dimensions of the national health information structure. (From U.S. Department of Health and Human Services. health service providers who demonstrated that they are meaningfully using their EHRs by meeting predefined standards for a number of objectives. These objectives relate to the submission of patient data to authorized third-party surveillance registries, making clinical data more easily available to patients via secure Internet sources, including vital sign changes and office visit summaries, as well as interfacing multiple functions together, such as EHRs with CPOE.[6-8]

To address these issues, hospitals and other health care providers often now use a single comprehensive software system or **enterprise software package** designed to provide integrated functionality to enhance both efficiency and effectiveness, as well as comply with the HITECH Act. A variety of such software packages are available to health care organizations (Table 7-1). These include McKesson, Cerner, Epic, Meditech, Siemens, which are major vendors of integrated software for health care organizations.[7] In addition to serving as a secure repository for EHRs, these software packages provide integrated functionality for the use of EHR data for a multitude of purposes. Some purposes are for data input, such as what occurs when a

physician enters an order into a CPOE or an RT documents therapy given. Other purposes are for the retrieval, review, and interpretation of existing records, such as those used to provide direct patient care, or for nondirect care functions, such as billing, process improvement, regulatory reporting, or other similar functions discussed later in this chapter.[4] In addition, enterprise software systems that interface the EHRs with functions relevant to respiratory care and other clinical departments are almost universally in use.

APPLICATIONS IN PATIENT CARE

Applications in Diagnostics

Because the EHR contains an abundance of important clinical information, the RT needs to be able to promptly access and interpret key elements of it to assist the patient care team in accurately diagnosing the patient's condition. This may involve hemodynamic monitoring, blood gas and point-of-care testing, medical imaging applications, and pulmonary function testing (PFT), among others.

Hemodynamic Monitoring

In hemodynamic monitoring computers calculate cardiac output (CO), monitor intravascular fluid volume, and provide cardiac parameters and indices using both invasive and noninvasive applications. However, invasive methods using a pulmonary artery catheter (see Chapter 51) have a multitude of complications, including the risk for infection and death.

As a result, the rapid evolution of E-medicine has allowed for the development of safer noninvasive continuous cardiac output monitoring applications in perioperative and intensive care medicine. Some of these applications include thoracic electrical bioimpedance, thoracic bioreactance, vascular unloading technique, pulse wave transit time, and radial artery applanation tonometry. According to clinical studies, these technologies are capable of providing cardiac output readings noninvasively and continuously with minimal complications. Like most new technologies, their performance and accuracy needs further validation. These new applications might prove to be innovative tools for the assessment of advanced hemodynamic monitoring without the drawbacks of invasive techniques.[8] However, further discussion of these techniques is beyond the scope of this chapter.

Blood Gas Laboratories and Point-of-Care Applications

The accuracy and precision of blood gas data influence clinical decisions and patient safety. Computerized blood gas analyzers and computer-assisted quality assurance measures in a blood gas laboratory are crucial functions in a respiratory care department. Quality assurance data are necessary for accreditation of blood gas laboratories by the College of American Pathologists (CAP), the Clinical Laboratory Improvement Amendments (CLIA), and The Joint Commission (TJC). Blood gas laboratory applications interface analyzers with the patient's EHR to make blood gas results immediately available at the point of care and alert the clinician of critical results. Additionally, this interfacing enables the storage, retrieval, billing, and quality assurance of the blood gas analyzer data.

Point-of-care testing (POCT) refers to blood gas analysis performed at or near the site of a patient, in a setting that is different from a normal hospital clinical laboratory. POCT testing reduces the time required to produce blood gas test results (turnaround time) and thus improves clinical care and decision making for the clinician. POCT applications integrate seamlessly with the EHR allowing for immediate reporting of results and flagging of critical values. POCT applications can be used in a variety of clinical settings, including the operating room, critical care unit, emergency department (ED), maternity unit, and outpatient clinic.[9]

Medical Imaging and Picture Archiving and Communication Systems

Chest imaging (see Chapter 21), is critical in the practice of pulmonary and critical care medicine. Likewise, remote access of a patient's imaging studies has become an important element in the delivery of care. Clinical integration of all these imaging modalities with the EHR is essential for the RT and other clinicians to help in the diagnosis of the pulmonary patient and to improve patient care and safety. A **picture archiving and communication system** (PACS) is an application that allows for imaging storage, portability, communication, and clinical integration of all imaging modalities with the EHR.[10] Technologic advances in E-medicine and computer applications have allowed for PACS enterprise systems to flourish. In addition to the advantages mentioned earlier, current PACS applications have enhanced medical treatment and research by providing a variety of digital tools for the manipulation and interpretation of radiologic images, including three-dimensional imaging and three-dimensional printing technology.

Pulmonary Function Testing and Interpretation

Essentially all of the older volume displacement and spirograph pulmonary function test (PFT) systems have been replaced by those that use computer interfaces to measure and interpret the results. Similarly, most hospitals interface their PFT systems with the EHR, which allows clinicians to access reports and graphics from multiple workstations and remote devices.

Interpretation of Pulmonary Function Tests

Computer algorithms use standard reference predicted values to aid in the interpretation of PFTs, including spirometry, lung volume, diffusing capacity, and bronchodilator response. The algorithms compare the patterns of the patient's measured values with reference values based on age, height, gender, and race. The computer classifies the patterns of the patient's measured values as either normal or abnormal with degrees of severity. However, qualified interpreters must consider the effect of patient effort and other factors on the computer-assisted interpretation of PFTs.

The American Thoracic Society has recommended pulmonary function reference standards based on the National Health and Nutrition Examination Survey. These standards for prediction of normal PFT values may differ from other reference values. This difference can confound the interpretation of successive PFTs in an individual patient when clinicians focus on the computer-assisted interpretation of percent-of-predicted values, rather than the actual observed values.[11] Clinicians should have a clear understanding of which reference values were used for each test and interpret PFT results accordingly.

MINI CLINIC

Computer-Assisted Interpretations of Pulmonary Function Tests in an Individual Patient

PROBLEM: A patient with alpha$_1$-antitrypsin deficiency has repeat PFTs, including a diffusing capacity of the lung for carbon monoxide (DLCO). Based on a computer-assisted interpretation, there appears to be a remarkable decrease in the percent-of-predicted value for DLCO. It was previously normal; now it is 68% of predicted, indicative of emphysema. An effective therapy, pooled human plasma alpha$_1$-antitrypsin, is available but expensive. What additional information should the clinician evaluate?

DISCUSSION: The clinician should determine (1) the actual observed DLCO values of the previous and repeat test and (2) whether the computer-assisted interpretations are based on different reference values among the tests. If the computer-assisted percent-of-predicted values for each test were based on different sets of reference values, it could account for the change in DLCO. Further investigation of the results is warranted.

Applications in Treatment

Many current devices, therapies, and protocols developed in the last decade rely on technologic advances generated by E-medicine applications. These applications can be used in acute or nonacute settings by RTs to provide support and care for the pulmonary patient.

Applications in the Acute Care Setting

Mechanical Ventilators. Conventional mechanical ventilators use microprocessors to deliver and monitor modes of ventilation.[12] A "mode" of ventilation is a predetermined pattern of patient-ventilator interaction. Modes can be quite complex, as explained in detail in Chapter 45. Newer modes, such as neurally adjusted ventilatory assist (NAVA), aim to enhance the patient-ventilator synchrony via automation that is highly responsive to the patient.[13]

Microprocessors perform additional functions. They provide for graphic outputs and touch screens and interfaces; they also control ventilator alarms and archive the history of set and measured values, which can be uploaded to a computer. Current conventional ventilators allow for updating and adding new modes of ventilation via software updates, rather than purchasing new ventilators.

Protocols for ventilator weaning and management of certain respiratory conditions (e.g., acute respiratory distress syndrome) coupled with the trending capabilities of today's microprocessor ventilators can improve patients' outcomes and decrease length of stay. Complete, accurate, and consistent documentation of ventilator settings is key to achieve these goals. However, manual ventilator charting is frequently incomplete, inaccurate, and inconsistent, particularly regarding nomenclature.[14] Computerized ventilator charting applications have the potential to improve the quality and consistency of ventilator charting, especially when fully integrated with the patient's EHR. Automated ventilator charting, verified by RTs, takes ventilator charting a step further, with the potential to improve completeness, accuracy, consistency, and efficiency.[15] Figure 7-2 is an example of a computer screen for automated charting.

Therapist-Driven Protocols. Evidence-based, therapist-driven protocols can improve health outcomes.[16] Under medical supervision and based on patient assessment, RTs use protocols to allocate and titrate respiratory care. Consistency and timeliness of implementation are keys to the effectiveness of protocols. Automation of protocols at the point of care can help RTs address these concerns. An automated protocol for discontinuation of the mechanical ventilation program on hand-held devices can decrease the time to the first spontaneous breathing trial and the length of stay in the intensive care unit (ICU) compared with a protocol without automation.[17] These protocols allow the RTs to enter information about each mechanically ventilated patient via a hand-held device throughout the shift. When the patients meet preset criteria, the computer application prompts the RTs to conduct a spontaneous breathing trial to help determine the patient's readiness for ventilator discontinuation.

Applications in Nonacute Care Settings and Chronic Diseases

Management of chronic diseases presents a serious challenge to the U.S. health care system. As of 2012, approximately half of all adults—117 million people—have one or more chronic health conditions. One of four adults has two or more chronic health conditions.[18] Of the top 10 causes of death in 2010, 7 were chronic diseases. Two of these chronic diseases—heart disease and cancer—together accounted for nearly 48% of all deaths.[19] Chronic disease is present in 8 of 10 Americans on Medicare, and 84% of all health care spending in 2006 was for the 50% of the population who have one or more chronic medical conditions.[20] As baby boomers continue to age, the proportion of the U.S. population 65 years old and older is expected to double. There is much interest in optimizing chronic disease management through advances in E-medicine technologies to improve health outcomes in a cost-effective manner. This is particularly noteworthy given the focus by the U.S. government on reducing short-term (within 30 days) hospital readmissions. Hospitals have begun being penalized for

excessive short-term readmissions for their patients with certain conditions, including chronic obstructive pulmonary disease (COPD). To address this initiative, hospitals and other health care providers have developed an array of protocols to address the main reasons for such readmissions. These protocols often emphasize patient and family education and follow-up and often use computer applications to help accomplish this.[21,22]

Asthma. E-Medicine applications for asthma include interactive Internet applications, such as games for children, web applications linked to cell phones for personalized or automated voice or text messaging, and other telemonitoring applications. Many of these applications use monitored patient data to tailor the adjustment to the plan of care. Some provide for personalized goals, calendars, and reminders. Educational tools include audiovisuals, games, and quizzes. In patients with persistent asthma, evidence from research studies shows that these E-medicine applications can result in an improvement in asthma knowledge, self-management skills, peak flow rates, and adherence to inhaled corticosteroid controller medications and fewer symptoms, missed school days, nighttime awakenings, activity limitations, ED visits, and hospitalizations.[23-26] These applications are generally well received by patients.[24]

Chronic Obstructive Pulmonary Disease. Increasingly, COPD is being managed in the home. Web-based telemonitoring systems, smartphones, and mobile phones with computer applications extend the reach of health care providers into the home. E-Medicine applications for patients with COPD facilitates education, self-management, and timely feedback from health care providers (Figure 7-3). Patients generally have a positive attitude about the role of this technology, and the quality of the transmitted data is generally good.[27] Improved

FIGURE 7-3 Telehealth Homepod. (Courtesy Tele Health Ltd. Dublin, Ireland.)

outcomes include earlier identification of deteriorating symptoms, better response to exacerbations, increased rate of sustained exercise after pulmonary rehabilitation and decreased ED visits and hospitalizations.[27-29] Additionally, E-medicine applications can help detect comorbidities, such as sleep apnea.[27]

Applications in Disease Prevention

As explained earlier, through HITECH, the federal government has committed unprecedented resources to supporting the adoption and use of EHRs.[30] HITECH's goal is not adoption alone but "meaningful use" of EHRs—that is, their use by providers to achieve significant improvements in care. Payments by third-party payers to health service providers are specifically

tied to the achievement of advances in health care processes and outcomes. Disease prevention and patient education are intrinsically part of these processes.

Treatment of Tobacco Use and Dependence

In the United States, tobacco use and dependence is the leading preventable cause of death and chronic diseases.[31] Health care costs attributable to tobacco use are quite significant. Effective evidence-based treatments are available, but their implementation by health care providers is lagging.[32] RTs can play a vital role in the treatment of tobacco-related diseases and are now using E-medicine as an aid to help tobacco users.

E-Medicine, including phone-based applications, provides exciting new components of treatment for tobacco use and dependence. With the extensive reach of the Internet and the demonstrated efficacy of some applications, the potential impact on health outcomes is immense. More than 10 million Internet users have searched for online information about how to quit smoking.[33]

Internet-based treatment programs can recruit tobacco users via search engines, or they can be an adjunct to telephone *quitline* counseling. Figure 7-4 shows the smokefree.gov tobacco treatment website. When E-medicine applications are tailored to individual tobacco users, with frequent automated contacts via e-mail or text messages, rates of long-term abstinence from tobacco use are similar to those with traditional evidenced-based interventions.[33-36]

Consistent with the U.S. Public Health Service clinical practice guideline recommendation for a high-intensity, multicomponent approach, web-based applications have the capacity to provide both counseling that promotes tailored quit strategies and tobacco cessation medications that have been approved by the U.S. Food and Drug Administration.[37] These applications can provide sustained access to virtually limitless numbers of participants and are therefore very cost-effective. Table 7-2 lists some websites related to the treatment of tobacco use and dependence.

FIGURE 7-4 Example of a web-based tobacco cessation resource. (From http://smokefree.gov.)

Education of the Public and Health Care Consumer

Today's savvy health care consumers understand that access to good information is essential to health-related decision making. The Pew Internet and American Life Project found that more than 80% of Internet users report seeking health information online; for those with chronic conditions, the rate is 86%.[38] Those percentages will most likely increase over the coming years.

E-Medicine applications offer unique public access to health education materials through the use of a variety of interactive tools such as websites, videos and graphics, chat rooms, e-mail, games, social media, and so on, through any web-enabled device. RTs should not underestimate the impact of these applications on public health education and disease prevention.

The amount of data available on health-related and wellness-related issues increases exponentially each year. RTs play an important role in helping their pulmonary patients assess accurate information found on E-medicine applications. Box 7-2 lists the factors to consider when educating pulmonary patients on evaluating the worthiness of E-medicine sources.[39]

INFORMATICS AND CLINICAL DECISION SUPPORT

Health informatics, which refers to the use of information technology in health care, combines advances in computer science and technology to improve clinical care, manage the health of populations, and accelerate research.

Business Intelligence

Business intelligence refers to a set of tools that permit capture, storage, and transformation of data into useful and actionable information. In health care, business intelligence tools are used to capture and integrate clinical data with relevant financial and

Box 7-2 Factors to Consider When Reviewing E-Medicine Sources

- Web address:
  - .com—A website most likely to a for-profit company
  - .org—A website most likely from a nonprofit organization
  - .edu—A website published by an educational institution such as a university
  - .go—A web page that belongs to a governmental organization
- When assessing credibility, consider the following:
  - Who are the authors?
  - What are their credentials?
  - Is there a hidden agenda?
  - Who published the information?
  - Is the information peer reviewed?
- When assessing accuracy, consider the following:
  - Is the information current?
  - Is the information supported by facts?
  - Is the information based on scientific evidence?
  - Is the original source listed?
  - Do other sources back up the information?
- Red flags to consider:
  - Anonymous information.
  - There appears to be a conflict of interest.
  - The information presented is one-sided or biased.
  - The information is outdated.
  - There is a claim of a miracle or secret cure.
  - No evidence is cited.
  - The grammar is poor and words are misspelled.

operational data. **Key performance indicators** (KPIs) are indicators of quality and efficiency that are selected based on reporting or operational requirements. Commercially available business intelligence systems allow KPIs to correlate with dimensions that typically include person, time, place, and so forth. For example, a hospital may be interested in ventilator-associated pneumonia (VAP) events. In this case, KPIs may include daily ventilator census and incidence of VAP, which are then correlated with dimensions such as practitioners involved in the care of the patient before the event, hospital unit, date of VAP, and so on. This allows an institution to not only report on the aggregate rate of VAP but also recognize patterns relating to specific units and caregivers. Business intelligence also can be quite useful in research, especially in accessing data for retrospective clinical studies, as discussed in Chapter 8.

Clinical Decision Support

Clinical decision support (CDS) has been defined as "Health information technology functionality that builds upon the foundation of an EHR to provide persons involved in care processes with general and person-specific information, intelligently filtered and organized, at appropriate times, to enhance health and health care."[40,41] Examples of CDS include computerized alerts and reminders, such as notification to a therapist that the selected tidal volume exceeds the recommended range for a patient, based on ideal weight and calculated using a previously recorded height measurement. CPOE systems, discussed elsewhere in this chapter, frequently incorporate decision support alerts for drug-drug interactions and drug-allergy reactions. More advanced implementations may include examples of drug-disease interactions, such as when the selected drug dose is high for a patient whose latest creatinine value indicates renal impairment. More complex clinical guidelines, such as for weaning from mechanical ventilation, may be embedded within the EHR system. Condition-specific order sets, such as "care paths" for patients admitted with COPD, can guide the caregivers to ensure provision of evidence-based care.

Documentation templates are frequently used for decision support where rules are embedded into the logic behind the templates. As an example, a template for charting may direct the therapist to chart breath sounds and then subsequently direct them to record the type of sounds and location in the chest. Similar directions also may be used to prompt the RT for volume and flow settings for volume control modes of ventilation versus pressure and inspiratory time for pressure control modes.

Summaries of patient data and patient lists created based on specific criteria are other examples of decision support. For example, a work list may summarize patients who have been on noninvasive ventilation longer than a specified time and are therefore appropriate candidates for evaluation for skin breakdown. There is also increasing use of contextual reference information within the EHR, using links to internal or external resources for additional information. Examples of this include reference links to internally hosted protocol documents from order sets and links to external web-based content providers such as UpToDate.

Evidence Supporting Clinical Decision Support

Several studies have evaluated the usefulness of CDS in patient care. CDS has demonstrated value in identifying high-risk patients using blood gas and laboratory results,[42-44] as a diagnostic aid and in early identification of patients for intervention.[45,46] Knowledge-based systems have been shown to improve outcomes such as length-of-stay after myocardial infarction[47] and weaning from mechanical ventilation.[48]

Mobile Applications

Increasingly, mobile applications are being used to not only provide information to users but also capture health care data. Applications such as AirStrip allow remote users to visualize streaming vitals sign data and graphics. At the consumer level, mobile applications are driving consumer engagement via telehealth, consumer education, and health applications that use mobile devices as a data collection tool.

Administrative Decision Support

Administrative decision support using electronic data takes two main forms, which could be considered as external and internal benchmarking. External benchmarking is most prominently represented by the American Association for Respiratory Care (AARC) Benchmarking System, which facilitates identification and adoption of best practices among similar respiratory care

departments. Internal benchmarking is exemplified by the hospital business review process. This form of benchmarking involves the creation and tracking of relevant quality and productivity metrics to inform internal process improvement activities.

American Association for Respiratory Care Benchmarking System

In the 1950s, the Xerox corporation invented a process called **benchmarking** as a way to identify and adopt best practices that have developed among similar organizations.[49] In 1989 Robert Camp wrote one of the first textbooks on benchmarking,[50] outlining four basic steps (1) know your operation, (2) know the industry leaders or competitors, (3) incorporate the best, and (4) gain superiority.

Early in 2006, the leadership of the AARC, recognizing the need to establish a valid benchmarking resource for respiratory care, created an official benchmarking website designed for respiratory care department managers (http://www.respiratorybenchmarking.org). Anyone can visit the site and take advantage of educational resources (from the Site Navigation drop-down menu). Department managers who are members (i.e., have a paid subscription to the AARC benchmarking system) may enter their department's profile, including information on structure and function as well as personal contact information, although an anonymous option is provided.[51] Next, managers enter productivity data on a monthly basis. This activity builds the communal database from which benchmarking reports are generated by all members.

Best practices are identified using reports. A manager creates a report based on a "compare group" comprising several other departments that are similar in structure and function. This compare group is identified by performing searches on the database using various criteria from the profile and studying the profiles of the departments matching those criteria. The report has two sections. The first section gives numeric values for various productivity metrics[52] (definitions are available on the AARC benchmarking website) that indicate the department's percentile ranking. The manager is given the option of entering a desired percentile ranking, and the report will then calculate the opportunity (both in terms of dollars and number of staff positions) associated with improving the percentile ranking. The second section of the report is a list of all the departments in the compare group ranked according to percentile[53] on each of the productivity metrics. This section of the report allows the department manager to identify the top performers. The next step for the manager is to study the profiles and monthly productivity data of the top performers to find clues about how they are achieving best practices. The manager is also encouraged to contact the top performers personally to ask questions.

The AARC Benchmarking System has grown and evolved since its inception and continues to provide essential information to forward-thinking managers. It is a valuable tool for maintaining a completive advantage in the ever more demanding economic environment of U.S. health care.

Research

Research is based on data (facts) that can be transformed into information (facts that answer questions). Thus any of the sources of data described earlier are potential research tools. Online databases provide both the framework and content for designing research studies (e.g., PubMed). Private databases (e.g., productivity and hospital business review resources) support internal process improvement initiatives.[54,55] These issues are discussed in more detail in Chapter 8.

TELEMEDICINE AND TELEMONITORING

Telemedicine refers to the use of electronic and telecommunication technologies to support health care at a geographically different location from the patient, increasing access to specialty and patient care. Telemedicine can allow for the evaluation, diagnosis, treatment, monitoring, triage, consultation, and follow-up of patients without travel.[56,57] According to the Centers for Medicare and Medicaid Services (CMS), telemedicine seeks to improve a patient's health by permitting two-way, real-time interactive communication between the patient and the physician or practitioner at the distant site. This electronic communication means the use of interactive computerized telecommunications equipment that generally includes audio and video equipment. Telemedicine is viewed as a cost-effective alternative to the more traditional in-person way of providing medical care, such as face-to-face consultations or examinations between the clinician and patient.[58] A form of telemedicine is **telemonitoring,** which involves the use of telecommunications and information technology to provide access to health assessment, diagnosis, intervention, consultation, supervision, and information across distance.

Although best-practices in this area are still emerging, telemedicine and telemonitoring are gaining ground in respiratory care and in the overall management of all type of patients, including those with pulmonary disease. In some cases, it has facilitated the timely diagnosis and treatment of patients with limited access to health care facilities. In particular, patients in remote geographic locations or those with limited mobility such as ventilator-dependent individuals with severe neuromuscular disease have benefited from telemedicine.[59] Computer interfaces for telemonitoring facilitate patient assessment through the two-way transmission of key clinical data such as vital signs, pulmonary function measures, and patient-ventilator data and even the patient's physical appearance captured by computer web cameras. Similar monitoring also can facilitate the early detection of and intervention for any deterioration in a patient's condition. Such inventions have been shown to be helpful in reducing doctor visits and hospital admissions, a benefit to the patient and to the economics of health care.[60]

In addition, telemedicine has proved useful in facilitating the patient's participation in computer-based disease management programs. In particular, selected telemedicine applications have been created that bundle patient education, disease

management, interactive communication, and other features. Such multipronged systems have been shown to be effective in helping reduce chronic disease exacerbations and enhance the daily functioning and quality of life of patients with asthma and COPD, as discussed earlier in this chapter.[61] Other telemedicine programs have shown promise in helping overcome logistical barriers such as transportation and scheduling that too often prevent individuals from participating in valuable disease management programs. In particular, telemedicine has helped facilitate the participation of COPD patients in remote access pulmonary rehabilitation programs in which they otherwise would not have been able to participate. Furthermore, their participation in such computer-aided rehabilitation programs has permitted these patients to achieve similar benefits associated with traditional rehabilitation programs (see Chapter 55), such as demonstrable enhancement in their tolerance for activities of daily living.[62]

Like many aspects of E-medicine, telemedicine seems to be in its infancy. As health care resource limitations and cost-containment pressures continue, as well as improvements in the applications and the efficiencies they offer, it appears inevitable that use of this and related technologies will expand and become commonplace in health care and more specifically in respiratory care.

SOURCES OF HEALTH INFORMATION

Considering that almost half of adults in the United States have limited health literacy, E-medicine applications have the potential to improve our patients' level of health literacy if used appropriately.[63] Low health literacy compromises patient safety, limits the overall quality of health care, and accounts for increased health care costs. When patients have poor knowledge about their disease and the management of it, positive outcomes become more difficult to achieve.[64]

Health Information Sources for Respiratory Therapists and Other Clinicians

Effective **information retrieval** is essential to evidence-based respiratory care. It enhances clinical expertise by providing information for the development of evidence-based, therapist-driven protocols, and it aids in clinical decision making for the clinician. Although assessment skills of RTs generally sharpen with experience, their knowledge of the most up-to-date therapies may diminish over time.[65] However, the best available medical evidence is dynamic rather than static and the amount of available information is staggering. RTs need to be knowledgeable about efficient ways to access, filter, and retrieve relevant information effectively. They also must be prepared to guide increasingly sophisticated patients, many of whom actively seek medical information on the Internet.

E-Medicine applications are a far-reaching, rich source of information. RTs can use search engines such as PubMed, MEDLINE, and Google Scholar to access, filter, and retrieve information effectively. RTs can "bookmark" helpful websites, manuscripts and other sources for clinical practice guidelines, evidence-based systematic reviews of clinical questions, accrediting agencies, or other relevant sources of important information (Table 7-3).

Health Information Sources for Consumers

As discussed earlier, patients increasingly seek knowledge about diseases and treatments on their own. However, many users neglect to scrutinize the quality or source of the information, which is largely unregulated. Selected resources for pulmonary patients are listed in Table 7-4 and include the AARC website for patients (http://www.yourlunghealth.org), the websites of the National Lung Health Education Program (http://www.nlhep.org) dedicated to COPD patients, and MedlinePlus.gov of the National Library of Medicine. MedlinePlus features online interactive tutorials, practical instructional handouts for patients, a medical encyclopedia, and videos of surgical procedures.

APPLICATIONS IN HEALTH CARE ADMINISTRATION

E-Medicine applications also play an integral role in helping respiratory care managers and leaders maximize the value they

add to their health care organizations. In addition to the benchmarking resources and business intelligence concepts described earlier in this chapter, there are other highly useful digital applications related to documentation, workload, and staffing; financial and quality management; human resources; regulatory compliance; and similar tools related to management and administration.

Documentation, Workload, Staffing, and Scheduling

Increasingly, the comprehensive software systems used by health care organizations, provide features that support department-specific functions, including those essential to respiratory care departments. These software packages enable respiratory care department managers and other authorized personnel to retrieve, sort, and use information-relevant managing strategic functions such as resource use, staffing, and financial management. In addition, such software systems can link these strategic functions with day-to-day operations, such as using hospital census (e.g., percentage occupancy) and acuity (e.g., average severity of illness) data, with how many RTs are needed during a given shift or other period to adequately handle such a patient load. These same data can be used by most such systems to calculate productivity of an individual RT or the department as a whole. Often such productivity results are expressed as a percentage of a certain benchmark or reference range. For example, if the productivity expectation for an RT to complete 24 aerosol treatments for an 8-hour shift (assuming no other workload), but because of several call-outs, the RT is assigned and completes 30 such treatments, then that therapist would have a productivity percentage of 30 (actual)/24 (assigned) or 125%. Figure 7-5 shows an example of a worksheet for workload calculation. These software packages also facilitate computerized documentation, including ventilator-patient monitoring or charting the delivery of all forms of respiratory therapy, through computers or remote devices interfaced with the EHR. These documentation systems not only provide a record of the care provided and patient's response, but are also interfaced with other facets of the comprehensive software platform, including those for billing and quality assurance.[66]

Financial Management

Computer hardware and software are universally used in the financial aspects of health care. The more predominant uses relate to financial accounting applications, including billing and accounts receivable, as well as managerial accounting functions, which encompass financial statement reporting, budgeting, and forecasting. A detailed description of each of these functions is beyond the scope of this text. Briefly, however, under the category of financial accounting, *accounts receivable* is a fancy term for billing for and monitoring of the reimbursement for services provided. Most of the billing to CMS and private health insurance providers and monitoring of such payments by hospitals is done through electronic software platforms. Often this process is facilitated by features within the health care organization's EHR system, which accesses a portal to the payment system of CMS, the health insurance providers, or a subcontractor acting on their behalf.[66]

The financial accounting systems facilitate billing and interface closely with the managerial platforms used for financial statement and budgeting. For example, once the software recognizes that a payment has been made by CMS, higher level financial statements such as the income statement can be immediately updated to show an increase in revenue received. These and other computerized functions permit almost immediate updating and real-time viewing of the financial condition of the health care organizations. Software applications have enhanced managerial accounting functions in other ways, by facilitating the budgeting process, which ensure the health care organizations and respiratory departments have adequate resources to provide their services and perform their functions. Likewise, computer software permits faster and often more accurate financial forecasting, as well as the ability to make predictions under various economic and environmental scenarios.[67]

Quality Assurance

Computer software applications are a vital tool in health care quality assurance. Chapter 3 of this text provides some detail

on the principles of and tools used for quality assurance in respiratory care and health care in general. However, it is important to note that many tools used in the **continuous quality improvement** (CQI) model, for both enhancing and monitoring quality, are computer-based. For example, a **root-cause analysis** is a process by which the underlying primary, secondary, and other notable causes of a medical error or other safety issues are identified, and then an action plan is created and implemented. Finally, an ongoing monitoring system is put in place to evaluate the plan's effectiveness. Software applications exist and are commonly used to perform such an analysis. More broadly, hospital quality assurance, risk management, and even respiratory care departments use software applications that track quality data such as unplanned extubations and noninvasive mask-induced facial sores, to examine trends and the potential impact of corrective action.[68]

Regulatory Compliance

In a similar way that accounts payable systems of health care organizations use portals to facilitate reimbursement of services rendered; shared applications exist for the reporting of key compliance and regulatory data. For example, compliance with the meaningful-use objectives HITECH ACT discussed earlier in this chapter is done in this manner. In addition, CMS has introduced the **value-based purchasing** system, whereby reimbursement by CMS to hospitals and health care providers is partially based on their ability to meet a predefined set of standards. Reporting by hospitals to CMS for this program and other similar ones, such as 30-Day Short-Term Readmission Rates, are monitored through similar computer-based reporting systems.[69]

Web Analytics

Web analytics is a generic term that encompasses the study of the impact of a website on its users. It employs software to measure trends such as how many people visited a website, how many of those visitors were first-time or repeat visitors, how they came to the site (i.e., if they followed a link to get to the site or came there directly), what keywords they searched within the site's search engine, how long they stayed on one or more web pages, what links they clicked on when they left the site, and other similar trends. Health care organizations have begun to use web analytics software for many purposes. In the realm of business management and administration, health care organizations are using web analytics to measure trends of current and potential customers, to help make predictions about future market conditions and as an aid in strategic business decisions. Many clinical applications for web analytics are gaining popularity, including to track usage of educational websites that are designed as patient resources—for example, those used to for patients with chronic disorders such as COPD, cystic fibrosis, and neuromuscular diseases.[70]

Human Resources

In addition to their use in staffing and scheduling described earlier in this chapter, computer databases have proved to be invaluable tools for human resource functions of heath care facilities and those more specific to respiratory care departments by enabling them to maintain employee records, track training and education, and keep abreast of licensure and credentialing renewals, among many other similar applications. In addition, web resources have proved invaluable in helping recruit talented staff. The AARC website has a "Job Bank" feature that enables employers to post openings and furnishes qualified candidates with instructions on how to apply. Many state societies for respiratory care offer similar resources, and there are many proprietary recruitment websites, including Monster.com, Indeed.com, and ZipRecruiter.com.

Beyond this, many health care organizations are using web resources to help evaluate job candidates. In addition to being able to search state agencies to confirm a candidates' licensure and the National Board for Respiratory Care (NBRC) websites to determine credentialing status, pre-employment criminal background checks can be easily done through services offered on the web for a fee-for-service basis. Furthermore, although it is controversial, employers are increasingly performing credit checks and reviewing the social media profiles and patterns in the screening process of candidates.[71]

Privacy and Confidentiality

The *Health Insurance Portability and Accountability Act* (HIPAA) of 1996 established standards and safeguards to protect the confidentiality of medical records, including those maintained on computers and other similar devices. Essentially all EHR software offered by reputable sources must be HIPAA compliant, and health care organizations are required to have their staff trained on performing their functions within the guidelines of this law. However, in some ways technologic advancements are threatening the protections offered by HIPAA. Increasingly, health information maintained and transmitted on portable devices such a laptop computers, tablets, and smartphones is circulating outside the HIPAA-protected zone. Such information is increasingly kept on, or downloaded to, storage devices such as "thumb drives" or in remote computerized servers known as "the cloud." Furthermore, clinical datasets and databases originally intended for one purpose, such as regulatory compliance reporting or for clinical purposes, are being acquired by other organizations for different purposes, such as research and marketing. The required protection of all protected health information within such datasets is not always properly done, which poses further threats to patient confidentiality. Patient information on social media is another area of concern. Although it will take some time for our governmental regulators to enact updated legislation to address the impact that such technology has had on HIPAA compliance and patient privacy and confidentially, the general sense is that such regulation will eventually be adopted. In the meantime, RTs need to be ever mindful to protect and respect the confidentiality of patient information. Whether communicating patient information verbally, in writing, or with the combined use of computerized hardware and software, RTs should apply the HIPPA principles in protecting such data and using it only for its

intended purpose (see Rule of Thumb). Failure to comply with HIPAA is a federal violation of the law with financial and legal consequences for those involved.[72]

RULE OF THUMB

Users can take steps to help prevent computer infiltration by malicious software by doing the following:

- Users should never share or use their password on public unsecured devices.
- Users should regularly update their computers with security patches from authorized sources. For example, patches for Windows operating systems are available on the Microsoft website (see http://www.update.microsoft.com).
- Users should install a virus scanning program and regularly update it.
- Most importantly, users should be careful when opening e-mail file attachments and refrain from downloading applications from unknown sources.

APPLICATIONS IN TRAINING AND EDUCATION

Computing plays a central role in the education of respiratory care students, credentialing of graduates of educational programs, and continuing education for RTs.

Clinical Simulations

Computerized **clinical simulations** are a powerful learning tool. Computer-based simulation is a long-standing educational method for hazardous occupations that have shown remarkably low rates of failure (e.g., airline pilots, members of the military, astronauts, and nuclear power plant operators). Health care education has progressed to include the use of computer-based, full-body manikins and high-fidelity clinical simulators. These devices feature software to program clinical scenarios and simulated vital signs and physical examination findings that either improve or deteriorate in response to the actions of the learners. The simulators can reproduce situations requiring complex airway management or advanced life support. In virtual surgical simulators, certain devices allow learners to exert force against simulated tissue that offers realistic resistance, and in virtual bronchoscopy simulators, vocal cord movements are exhibited that are synchronous with the phases of breathing and cough.

Learners are able to better immerse themselves in carefully planned case scenarios and performing in a manner similar to that of real clinical situations (Figure 7-6). They develop psychomotor, critical thinking, decision-making, and team-building skills. In contrast, traditional methods of didactic education in combination with clinical apprenticeships can result in increased knowledge, but limited, inconsistent experiential learning opportunities. Clinical simulators, allow for more in-depth evaluation of learners' competencies in a safe environment. They are an excellent tool to help respiratory care departments meet The Joint Commission (TJC) requirement of demonstrating the competencies of respiratory care staff in an ongoing manner.[73] Recommended steps in clinical simulation education are diagrammed in Figure 7-7.

Clinical simulators are particularly valuable for learning how to function in rare but high-risk clinical situations. Training via simulators has resulted in improved performance of health care providers in emergency airway management, advanced life support, bronchoscopy, and surgery. Computer-based simulators also have become a useful tool in promoting and optimizing the use of interprofessional teams within clinical settings.[74,75] Clinical simulators have the potential to reduce medical errors and improve patient safety. Simulations promote relatively comprehensive learning (Box 7-3) and allow for performance in clinical settings to become more refined and automatic.

FIGURE 7-6 Clinical simulation benefits students. (From Cummings CW, et al: Cummings otolaryngeal: head and neck surgery, ed 2, St Louis, 2005, Mosby.)

Box 7-3 Learner Objectives in Clinical Simulation

- Interpret data
- Recognize and prioritize problems
- Make decisions
- Observe consequences of decisions
- Develop leadership skills
- Develop interpersonal communication skills
- Develop team-building skills
- Use available resources
- Manage stress and crisis

Full-Scale Physiologic Clinical Simulators

There are several full-scale, physiologic, clinical simulators available, two of which are SimMan (Laerdal Medical, Wappingers Falls, NY) and the Human Patient Simulator (HPS) (CAE Healthcare, Quebec, Canada). These simulators generate physiologic functions, including pulse, blood pressure, cardiac rhythm, breathing, exhaled carbon dioxide, lung compliance, and bowel sounds. The airways are anatomically accurate to the level of the lung segments. Interdisciplinary teams can practice scenarios such as cardiac defibrillation, hemodynamic monitoring, apnea, right main stem intubations, tension pneumothoraces, anesthesia administration, occluded endotracheal tubes, high-pressure alarm limits during mechanical ventilation, and loss of medical gas.

Clinical Education Applications

Management of clinical education involves a significant amount of documentation, tracking, scheduling, evaluations, clinical competencies, reporting, and compliance with accreditation standards. E-Medicine software applications have been developed to help educators manage each of these aspects of the clinical education process.

These applications are secured, password-protected, web-based database management systems for documenting and reporting clinical educational activities for allied health professions, including respiratory care programs. The records help both students and faculty members track student progress in completing required competencies as they progress through their clinical rotation assignments (Figure 7-8). Functions may include the following:

- Streamlined data entry process minimizing data entry duplication that can occur between clinical sites, students, and the academic program
- A daily log for completed procedures and activities, which instructors validate
- Competency evaluations
- Automated surveys to accommodate questionnaires for students, graduates, and clinical affiliates as required by accrediting agencies
- Cloud-based data and backup storage

A variety of such as software applications are available to educational institutions. These include DataArc (http://www.dataarc.ws/), E*Value (http://evaluehealthcare.com), and Typhoon Group (http://www.typhongroup.com/), among others. Students and faculty can use any web-enabled device, including smart phones, to access these applications.

National Board for Respiratory Care Credentialing

The NBRC uses computerized credentialing examinations for both the written and clinical simulation examinations. Candidates must go to a designated testing center, sit at a monitored computer terminal, and take the examination during the designated timeframe. Once candidates are done with the examination, they receive their score immediately. In addition, to achieve the advanced credentialing level, or Registered Respiratory Therapist (RRT) designation, candidates must demonstrate their ability to gather and interpret clinical information and then make or recommend clinical actions based on a clinical scenario. In the computerized simulation examination (CSE), RRT candidates must complete a series of case-based simulations and demonstrate that they have adequately mastered the management of major respiratory diseases (Figure 7-9).

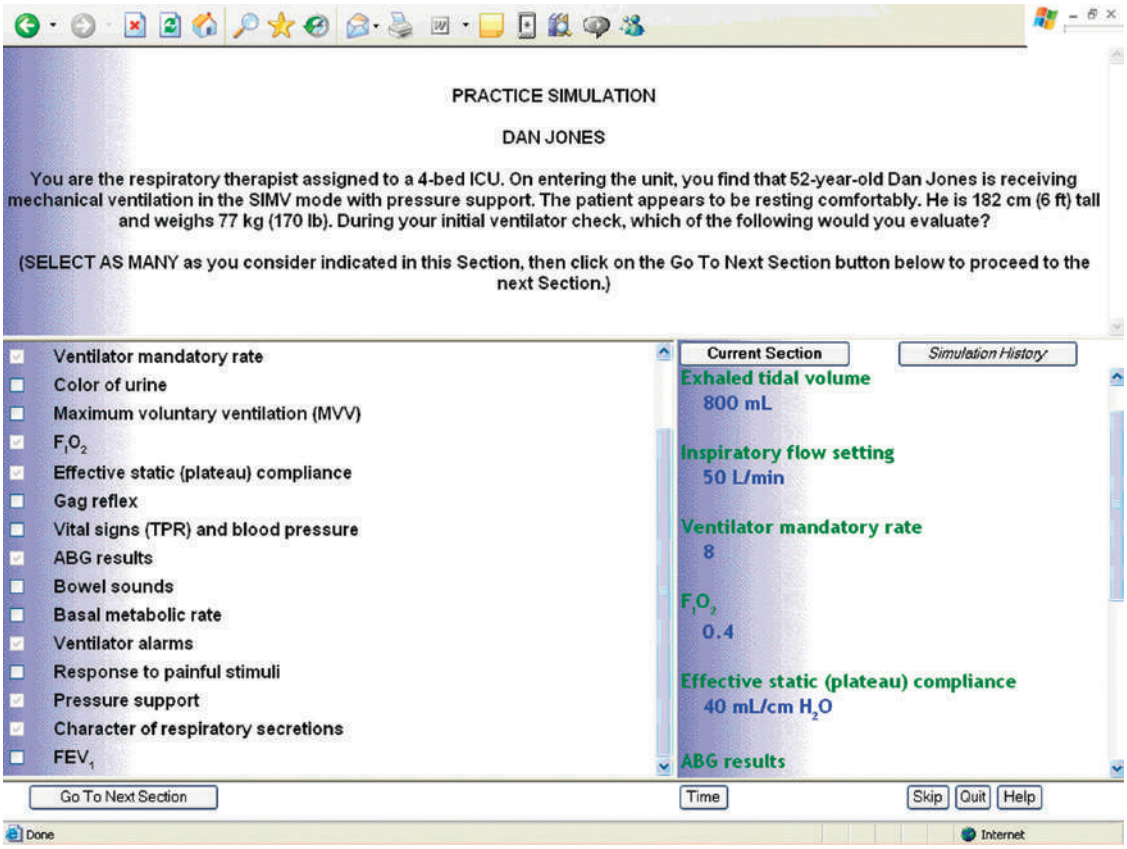

FIGURE 7-9 National Board for Respiratory Care. Practice simulation problem. (Courtesy NBRC, Olathe, KS.)

Continuing education is mandatory for national credentialing for the NBRC and often a requirement for state licensure. Credentials awarded by the NBRC are valid for a period of 5 years and are subject to renewal through the Continuing Competency Program (CCP) requirements. RTs are required to provide evidence to the NBRC that they are continuing to meet current standards of practice and have all the requirements for renewal. Web-based **continuing respiratory care education** (CRCE) courses, which have been preapproved or outright sponsored by the AARC, offer RTs an easily accessible, efficient, and cost-effective means of meeting continuing education requirements for CCP and state licensure purposes, as well as keeping current in their profession.

Learning Management Systems

To an increasing extent, respiratory care educators use online, web-based **learning management systems** platforms such as Moodle or Blackboard to augment traditional classroom courses known as web-enhanced courses or deliver entirely web-based courses (Figure 7-10). This technology improves access and management of course content for web-enhanced courses. Web-delivered courses make respiratory care education possible for students who might not otherwise be able to attend respiratory care programs such as those requiring flexible schedules or students in remote rural areas. Other adjunctive applications, such as Adobe Connect, permit live interaction between the student and faculty. Students can talk to their instructors and classmates via live audiovisual platforms. Participants also can have asynchronously access to archived classes and related course content and other material by the use of podcasts or recorded sessions.

American Association for Respiratory Care

The AARC provides many continuing education opportunities on the web (see http://www.aarc.org). Webinars and text-based courses are available in both live and asynchronous formats. RTs may earn CRCE credits by completing these courses (Figure 7-11). The AARC also provides web-based CRCE credits through the *Respiratory Care* journal. RTs can read the journal, use a copy of the test that appears in the journal to draft answers, and then complete the web-based test on the journal website (http://www.rcjournal.com/crce_ttj.cfm). The AARC maintains a transcript of members' CRCE credits, which RTs can access on the AARC website.

Additionally, to facilitate electronic networking among RTs, the AARC offers Specialty Sections and Roundtables. Each Specialty Section features an e-mail listserv for discussions, e-newsletters, e-bulletins, and a website.

FUTURE OF E-MEDICINE

If the recent degree of changes in E-Medicine is a predictor of future developments, this chapter in the next edition of this book will look very different from this one. In the future, computerized technologic applications described in this chapter, such as telemedicine and closed-loop decision-making on mechanical ventilators, will be more widespread, as well as refined and improved and most likely able to do more in much less time. In addition, new digital applications will emerge, including a vast assortment of diagnostic, treatment, educational, and disease management applications available to patients and clinicians alike. The current technology coupled with new developments hold great promise for helping optimize the large-scale effectiveness and efficiency our health care system, as well as providing notable benefits to health care organizations and clinicians, including the RTs operating within it.

SUMMARY CHECKLIST

- E-Medicine relates to the use of computerized or digital technology to enhance efficiency and effectiveness of health care in general and more specifically patient care.
- EMRs represent the computerized records produced every time a patient (or consumer) uses health services.
- The EHR is the sum of all EMRs produced by the different encounters of the consumer with various health care entities throughout a lifetime.
- Enterprise software packages are designed to provide integrated functionality for health care organizations to enhance both efficiency and effectiveness of patient care.
- E-Medicine applications can be used in acute or nonacute settings by RTs to provide support and care for the pulmonary patient.
- Health informatics combines advances in computer science and technology to improve clinical care, manage the health of populations, and accelerate research.
- Business intelligence refers to a set of tools that permit capture, storage, and transformation of data into useful and actionable information.
- CDS provides general and person-specific information, intelligently filtered and organized, at appropriate times, to enhance health and health care.
- Benchmarking includes four basic steps (1) know your operation, (2) know the industry leaders or competitors, (3) incorporate the best, and (4) gain superiority.
- Telemedicine and telemonitoring allow for the evaluation, diagnosis, treatment, monitoring, triage, consultation, and follow up of patients without travel.
- The Internet is a rich source of information for RTs and patients when the quality and source of information are appropriate.
- Information retrieval is essential to practice evidence-based respiratory care. It enhances clinical expertise by providing information for the development of evidence-based, therapist-driven protocols, and it aids in clinical decision making for the RT.
- Computers and digital information can be useful to clinicians in optimizing quality of care and to patients and their families participating in care plans.
- Common sense is the best prevention against infiltration by malicious software.
- Emerging computer applications are expected to support management of chronic disease and potentially reduce medical errors.
- The role of computer applications in clinical care, diagnostics, management, and education is essential and will continue to expand.

CHAPTER 8

Fundamentals of Respiratory Care Research

ROBERT L. CHATBURN

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Explain why research activities are important in health care.
- Describe several sources of information that are commonly used during a literature search.
- Give examples of how to develop a study idea and write a research protocol.
- Describe the three basic formats for publishing a research study.

CHAPTER OUTLINE

KEY TERMS

bibliographic database
synthesized database
portals
PubMed
hypothesis
research protocol

OVERVIEW OF RESPIRATORY CARE RESEARCH

The chances that any of us will become a famous researcher may be slim. For example, more than 100,000 people are practicing respiratory therapy in the United States. Of those, maybe half are members of the American Association for Respiratory Care (AARC). Of those people, fewer than 1 in 100 are involved in presenting their research at the annual AARC Congress. Yet, every one of the 100,000 people in the respiratory care field needs to know how to read and understand scientific articles in medical journals. The same holds true for all health care workers. Even if you never conduct a study, you must be familiar with the basic concepts of research to practice as a professional whose understanding grows from a scientific basis for respiratory care practice and from continuing education.

The main purpose of this chapter is to help you become an educated consumer of medical research. It will present a brief overview[1] of the specific steps in conducting research and presenting your results. But if you want to actually perform research, to be a respiratory care scientist, the best thing you can do is find a mentor—someone who has experience conducting scientific studies and publishing the results. A mentor can help you turn the ideas in this chapter into practical realities.

The Importance of Research in Health Care

Academic medicine has three basic missions: to heal, to teach, and to discover. Scientific research is the underlying theme that ties these activities together. These activities imply several classes of stakeholders: clinicians (who need the ability to assess the usefulness of new equipment and treatments), educators (who need the ability to find, summarize, and present evidence for clinical activities), administrators (who need to evaluate the quality of services and the validity of policies/procedures), and finally researchers (who need to be able to generate new ideas that inform the other stakeholders). *The one skill that is common to all these stakeholders is the ability to read and critically evaluate published scientific reports.* Without this skill, no meaningful evaluation of current practices can be made and no research can be planned.

HOW TO REVIEW THE LITERATURE

Students who have grown up in the digital age are quite familiar with finding information on the Internet. Practically everybody has a smart phone, and, in my experience, it is not uncommon for a therapist or medical resident to look up the answer to a clinical question in a matter of seconds during bedside rounds. Here is a true story: An experienced colleague and I were helping a young physician write a **research protocol**. One of his outcome variables was some measure of atelectasis. I asked him how he would quantitate that outcome. He suggested that maybe he could create some kind of score. I said that I had done that a number of years ago in a paper by me and a co-author named Deakins. Almost before I had completed the sentence, my colleague had entered our names into a Google Scholar[2] search and had the paper on the screen with the method for creating an atelectasis score. All this took less than 60 seconds. That is the power of knowledge in the information age!

Unfortunately, not all sources of information are equally reliable. Let's take a look at what is available.[3,4]

Bibliographic Databases

A database is a structured collection of facts. A list of names and phone numbers on a piece of paper is a database. A spreadsheet containing a business profit and loss statement is a database. And of course, a project created with a software database design program (e.g., Microsoft Access) is a database. A bibliographic, or library database, contains books, book chapters, reports, citations, abstracts, and either the full text of the articles indexed or links to the full text. Perhaps the most popular **bibliographic database** is **PubMed**, a service of the U.S. National Library of Medicine that includes over 18 million citations from MEDLINE and other life science journals for biomedical articles back to 1948.[5] PubMed (Figure 8-1) includes links to full text articles and other related resources in medicine, nursing, dentistry, veterinary medicine, health care systems, and preclinical sciences. It provides a *Clinical Queries* search filters page as well as a *Special Queries* page. The site also provides automatic e-mailing of search updates, the ability to save records, and filters for search results using "My NCBI." The My NCBI feature is particularly useful because it will periodically e-mail you results of automatic searches on subjects and authors of interest to you, saving you a lot of time in just keeping up to date, aside from any focused research. Another free bibliographic medical database you should know about is SearchMedica. According to the website,

> *SearchMedica . . . (delivers) only the most clinically reputable content intended for practicing medical clinicians. With guidance from our advisory board of specialty physicians and our staff editors, SearchMedica scans well-known, credible journals, systematic reviews, and evidence-based articles that are written and edited for clinicians practicing in primary care and all major specialties. Using similar expertise, SearchMedica also selects and scans patient-directed websites, online CME courses,*

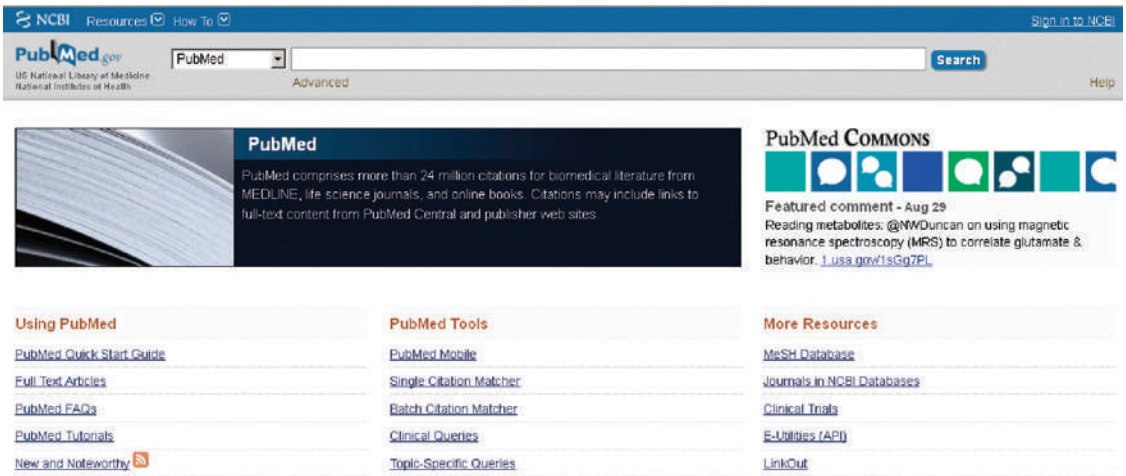

FIGURE 8-1 PubMed screenshot.

and government databases of clinical trials and practice guidelines.[6]

Synthesized Databases

Synthesized databases are prefiltered records for particular topics. They are usually subscription-based with relatively large fees. This type of database may provide the "best" evidence without extensive searches of standard bibliographic databases. The leading database in this category is the Cochrane Collaboration.[7] UpToDate is another subscription-based service.[8] It claims to be the largest clinical community in the world dedicated to synthesizing knowledge for clinicians and patients.

Portals

Portals are web pages that act as a starting point for using the Web or web-based services. One example of a subscription based service is ClinicalKey,[9] which provides links to books, journals, Clinics in Medicine, patient education resources, and images. Another example is Ovid,[10] which provides links to books, journals, evidence-based medicine databases (e.g., Cochrane Collaboration), and the Cumulative Index to Nursing and Allied Health Literature (CINAHL). Most medical libraries will have subscriptions to both of these services.

Electronic Journals and Books

We are rapidly reaching the point at which all medical journals are available online. Some are available *only* online. You should already be reading Respiratory Care journal.[11] Full text versions of Respiratory Care journal articles are available online back to January 2003. Open Forum abstracts (i.e., abstracts presented at the annual AARC Congress) are also available.

There are many sources of electronic versions of textbooks available on the Internet. From the PubMed homepage, select Books (instead of PubMed) from the drop down menu in the upper left-hand corner of the page. Enter a search term, and you will get a results page with links for books and figures from books. Subscription services include Oxford Reference Online,[12] STAT!Ref (great source for nursing and drugs),[13] and Safari Books Online (excellent source of technical reference books).[14] Again, your medical library will probably have subscriptions to these services. Another great book resource is Amazon.[15] Amazon sells new books, but many times you can find used editions for a small fraction of their original cost.

RULE OF THUMB

If you don't want to buy a book on Amazon.com, just use the website to get ideas before you go to the library. This is also a quick way to get the publisher information if you need to reference a book you do not have.

General Internet Resources

Google.com is perhaps the most popular of the general Internet search engines. Other options come and go, and, ironically, the best way to find new ones is to do a Google search on "search engines." But remember, these sites generally use proprietary search algorithms rather than controlled vocabularies like PubMed. As a result, you are likely to get unexpected results.

Suggestions for Conducting Searches

The first and most important suggestion I can offer is to talk to a professional librarian. These people can show you all the tricks of the trade—things you never imagined could be done. And in some cases, they will even do the search for you. Some libraries offer free courses on how to use all kinds of software tools for conducting searches.

Finally, buy and use bibliographic software such as EndNote[16] or RefWorks.[17] These programs let you import the results of your reference searches into your own database for future use. If you are an author, they will also help you manage the references in your manuscripts. Programs like these will save you a lot of time and effort. A great free alternative is Zotero.[18]

Before moving on, I want to call your attention to another challenge. Just finding a source of research information is not enough. You must know how to read it. A great resource on this topic is a comprehensive book called "Studying a Study and Testing a Test: Reading Evidence-based Health Research" by Richard Riegelman MD, MPH, PhD.

HOW TO BE A SCIENTIST

OK, so just being an educated consumer of research is not enough for you. You want to do your own research projects. Perhaps you need an abstract to advance on your career ladder. Maybe you are involved in a quality improvement project and need to know the basics of research methodology. Hopefully, you have decided to be the next leading scientist in the Respiratory Care field. Whatever your motivation, I remind you that your first task is to find a mentor. After that, find a good textbook. There have been only two textbooks on respiratory care research. One is fairly new,[19] and the other is out of print (but still very useful if you can find a used one on Amazon.com).[20] Of course, there are many other fine textbooks on health care research and I suggest you consider as many as you can find (again, search Amazon.com). Back in 2004, Respiratory Care journal dedicated a whole issue to research and publication. It contained 19 articles written by the leaders in Respiratory Care research. I highly recommend that you find it and read it (Respiratory Care, October 2004, Volume 49, Number 10).

In the next sections, we will look briefly at the major skills required to design, conduct, and report health care research.

How to Develop a Study Idea

No doubt, the biggest hurdle for someone new to research is how to generate an idea worth studying. You need passion. Those outside the research community often say that emotion and personal belief play no part in the scientific method and that only through detached objectivity can the truth be revealed. If this were in fact the case, there would be no human scientists. Without passion, there could be no **hypothesis**, without a

hypothesis there could be no experiment, and without experimentation there would be no science. Choosing and defining a research topic are the first steps in applying the scientific method to a clinical research problem. This process implies concern or doubt about some concept or observation, usually based on the observer's experience from clinical practice. Indeed, the scientific method itself can be viewed as nothing more than organized curiosity. Curiosity about the details of one's everyday activity provides the motivation for finding out how or why events are related. Curiosity and the creative energy it produces are vital ingredients of a productive research effort. The scientific method simply provides a standardized and efficient technique for describing relationships among events in a way that can be verified by other observers. You can think of the scientific method as a way of creating beliefs based on evidence.

RULE OF THUMB

Richard Feynman, who received the Nobel Prize in Physics in 1965, once said that *"Science is the belief in the ignorance of experts."*

Your interest may be stimulated in a number of ways. One of the most obvious ways is to read medical journals. Often one investigator's results will not completely answer the questions that another investigator seeks to answer. Perhaps the authors themselves suggest areas in which further work needs to be done (usually found in the Discussion section of a scientific paper). Occasionally, the results of an article contradict those of a previous study, creating the need for yet another look at the research problem. Review articles that cover the state of the art in some area of research are especially useful in helping you generate ideas along these lines. The basic concept to remember is that research breeds more research and that the truth in scientific research is defined when the results of earlier experiments and studies can be reproduced consistently by others.

RULE OF THUMB

One of the best study ideas for a beginning respiratory therapy researcher is to do a device evaluation (particularly a new device).[21] This kind of study is usually very inexpensive (vendors often donate or loan equipment and supplies) and does not require approval by the institutional review board (IRB) (as is required for studies of human subjects).

Trying to develop research topics from personal experience is often the most frustrating approach for the beginning researcher. The natural tendency is to choose a general problem that everyone seems to recognize but no one does anything about. The difficulty lies in trying to narrow the general idea to a specific problem statement.[22] There are at least two reasons for this. First, a general problem, by its nature, is often spoken about in vague, undefined terms. Second, in attempting to explicitly describe the problem, it may appear to be overwhelming. One may easily become frustrated to the point of not being able to write anything.

Box 8-1 Factors Affecting the Feasibility of a Research Project

1. Significance or potential benefits of study results
2. Measurability of research variables
3. Duration and timing of study
4. Availability of research subjects
5. Availability of equipment and funds
6. Knowledge and experience of investigators

One way to avoid this situation is to start small. Begin with a specific incident that stimulated either curiosity or irritation. *Simply state what you see happening and why it is important.* Write a narrative, first-person account of the incident. Now you can begin reviewing the literature, using key definitions related to your study idea to speed the search. Try to find similar problems in other disciplines to create original experimental approaches. For example, many problems concerning clinical measurement (e.g., airway pressure measurement) have been solved in the context of electrical or mechanical engineering. Keep in mind that not all ideas you have will be practical to study. When searching the literature, consider whether the experimental methods you will use are feasible for your situation (Box 8-1).

Once you have clarified your study purpose through your literature review, the next step is to develop a formal problem statement. This problem statement is the foundation of the actual study design. It dictates the concepts and methods used to gather data. It also determines the theoretical context in which the conclusion will be interpreted. From the problem statement comes either a brief statement of the study purpose(s) or a hypothesis statement. A hypothesis is a supposition or proposed explanation for an observation. For example, here is an actual problem statement from a published abstract:

> *Protective lung ventilation requires calculation of predicted body weight from gender and height. Thus, inaccuracy of height data in the electronic health record (EHR) is a risk factor for volutrauma. A study showed that bedside tape measurements or visual estimates of height in ventilated patients may be highly inaccurate but that height predicted by ulnar length might be an alternative. In our institution, height records are often based on patient self-reporting, with uncertain accuracy. The purposes of this study were: (1) to evaluate the difference between patient height of unknown origin recorded in the EHR and predicted height from ulnar length, and (2) to determine the effect of height difference in setting V_T during ventilation.*[23]

This is a descriptive study. There are no predetermined hypotheses. But such a study might generate hypotheses to test in future studies (e.g., error in height determination is associated with increased duration of mechanical ventilation).

Here is an example of another published abstract with explicit hypotheses:

> *The FiO_2 for constant flow (CF) oxygen therapy via nasal cannula depends on a combination of factors, including breathing frequency and the anatomic reservoir (AR). Patients with COPD have end expiratory flows which do not reach zero, potentially eliminating the AR and decreasing FiO_2. Pulsed flow (PF) devices that do not depend on the AR and FiO_2 should not be affected by loss of the AR. The purpose of this study was to test 2 hypotheses: (1) loss of AR reduces FiO_2 for CF, and (2) loss of AR does not affect FiO_2 for PF.*[24]

Creating clear statements of study purpose or hypotheses is a key element for success in research. The purpose or hypothesis makes clear what the experimental method should be. The Methods section of your study protocol is related to the purpose or hypothesis because it dictates what the outcome variables are and how to measure them, as well as how to analyze the data and what statistical tests to use.

How to Write a Study Protocol

Whether you are doing a small process improvement project, a device evaluation, or a major randomized controlled trial, you need a written study plan. Here are three reasons why: First, the process of writing it out will help you clarify the goals of the study and methods of investigation. The realization that problems in approach or analysis exist may not become clear until ideas are committed to paper. Second, you often must present a plan to obtain permission or approval to proceed with the study. Permission may need to be sought from a funding source, IRB, department manager, or student advisor before a study may begin. Third, the research plan, or research protocol, as it is often called, provides an operational guide for the entire research team. Successful coordination of study personnel is all but impossible without a detailed protocol. For these reasons, a properly formulated proposal is an essential first step in the research process. An example of a protocol outline, as might be required for review before gaining permission from an IRB for human studies, is shown in Box 8-2. The outline in Box 8-2 might seem like overkill, but you can simplify it to fit your needs and it will impose discipline in the planning stages of your project. Another reason to do this is that it serves as the outline for any publication you may consider once the study is completed.

How to Analyze the Data

You don't have to be a statistician to conduct research. However, you do need to understand some basic concepts, even if only to be able to communicate with a statistician consultant. Of course, you also have to understand at least some of the terminology just to be able to read a scientific paper. Space does not permit us to explore this topic to any useful extent, so I will leave you with some suggestions for self-study in a series of boxes. If you are not familiar with any of the terms or topics in the boxes, study those. Textbooks are a good resource, and the Internet is a rich source of online texts, tutorials, and even statistical calculators. Box 8-3 lists some basic concepts for making experimental measurements. Box 8-4 lists some basic concepts in statistics.

There are hundreds, perhaps thousands, of statistical procedures used to analyze data once they are collected. Fortunately, there are only a handful of procedures that are used most of the time in the medical literature. If you learn nothing else, you should be familiar with calculating the mean and standard deviation of a set of numbers. You should know what a *p*-value is, that a t-test is used to compare two mean values (i.e., to test the hypothesis that they are from the same population of data), and that analysis of variance (ANOVA) is used to compare more than two mean values. A chi-square (χ^2) or Fisher exact test is

Box 8-2 Elements of a Protocol for Submission to an Institutional Review Board

used to compare proportions. You do not need special statistical software; for many purposes, a Microsoft Excel spreadsheet functions quite well both for creating data collection forms and doing simple statistical procedures. Again, the Internet has many tutorials showing how to do these things. Finally, Figure 8-2 is an algorithm showing how to select the most appropriate statistical procedure for a given set of data.

RULE OF THUMB

Although you should be somewhat skeptical about what you read in Wikipedia (http://www.wikipedia.org), I have found it to be a rich and very detailed source of information about statistical concepts.

HOW TO GET A SCIENTIFIC PAPER PUBLISHED

Once you have completed a research project, you need to communicate the results. As a health care researcher, you will encounter three basic ways to formally present your findings: the abstract, the poster, and the paper. Abstracts and papers are published in electronic and/or printed form in medical journals. Posters are presented in person at medical conventions. All three venues share the same basic outline structure: Introduction, Methods, Results, and Discussion (or Conclusions [see the previous Rule of Thumb]). As with conducting the research itself, publishing your results requires much practice under the tutelage of an experienced mentor.

How to Write the Abstract

An abstract is a condensed version of a research paper that appears at the beginning of the publication. Many readers skim the abstract to see if they are interested enough to read the whole paper. Some readers do not have enough time to read anything more than abstracts. For these reasons, the abstract is an important element of a published paper. Furthermore, abstracts are sometimes published alone. For example, Respiratory Care journal devotes one issue each year (usually the November issue) to abstracts describing studies that were presented at the AARC Congress, the profession's annual scientific meeting.

Writing a good abstract is an art.[25] Most journals restrict the length of the abstract (e.g., 300 words or 2500 characters), so the challenge is to balance brevity with explicitness. My approach is to start with the text I wrote for the research protocol, including the Introduction, (study purpose, hypothesis) and Methods (outcome measures, procedures, data analysis). Then, because most journals restrict your abstract to having a single graphic (if any), I create one illustration (table or graph) that summarizes the data. Next, I simply describe that illustration in the Results section of the abstract. After that, I look again at the study purpose and/or hypothesis statements in the Introduction to the abstract. These are the key ideas that must be included in the Discussion/Conclusion section of the abstract. I explain how the results address the hypothesis and how I interpret the data. I may even provide a speculation or suggestion for further study.

My first draft of an abstract may be 800 words or more, which is way too long. Now the process of shortening or redaction begins. I read each word of every sentence and see which I can eliminate or replace with shorter ones or with abbreviations. If abbreviations are used, they should be placed in parentheses after the full word the first time they are used in the paper, to indicate the meaning of the abbreviation. *The idea is to decrease word count while increasing clarity*. It usually takes three or four passes through the entire abstract before the number of words is within the limit specified in the instructions to authors provided by the journal publisher. Needless to say, this process goes much more smoothly if you have an experienced mentor by your side. I find that if I have everything I need from the study, including the illustration, writing an abstract takes about 2 hours (but this is after 30 years of practice).

Once completed, the abstract is usually submitted online for peer review by the editors and reviewers of the medical journal. Figure 8-3 shows what such an abstract looks like after submitting online and conversion to a PDF format.

How to Make a Poster

If your abstract is accepted for publication, you may be invited to present a poster version at a medical convention, along with all the other studies from other authors that have been accepted.

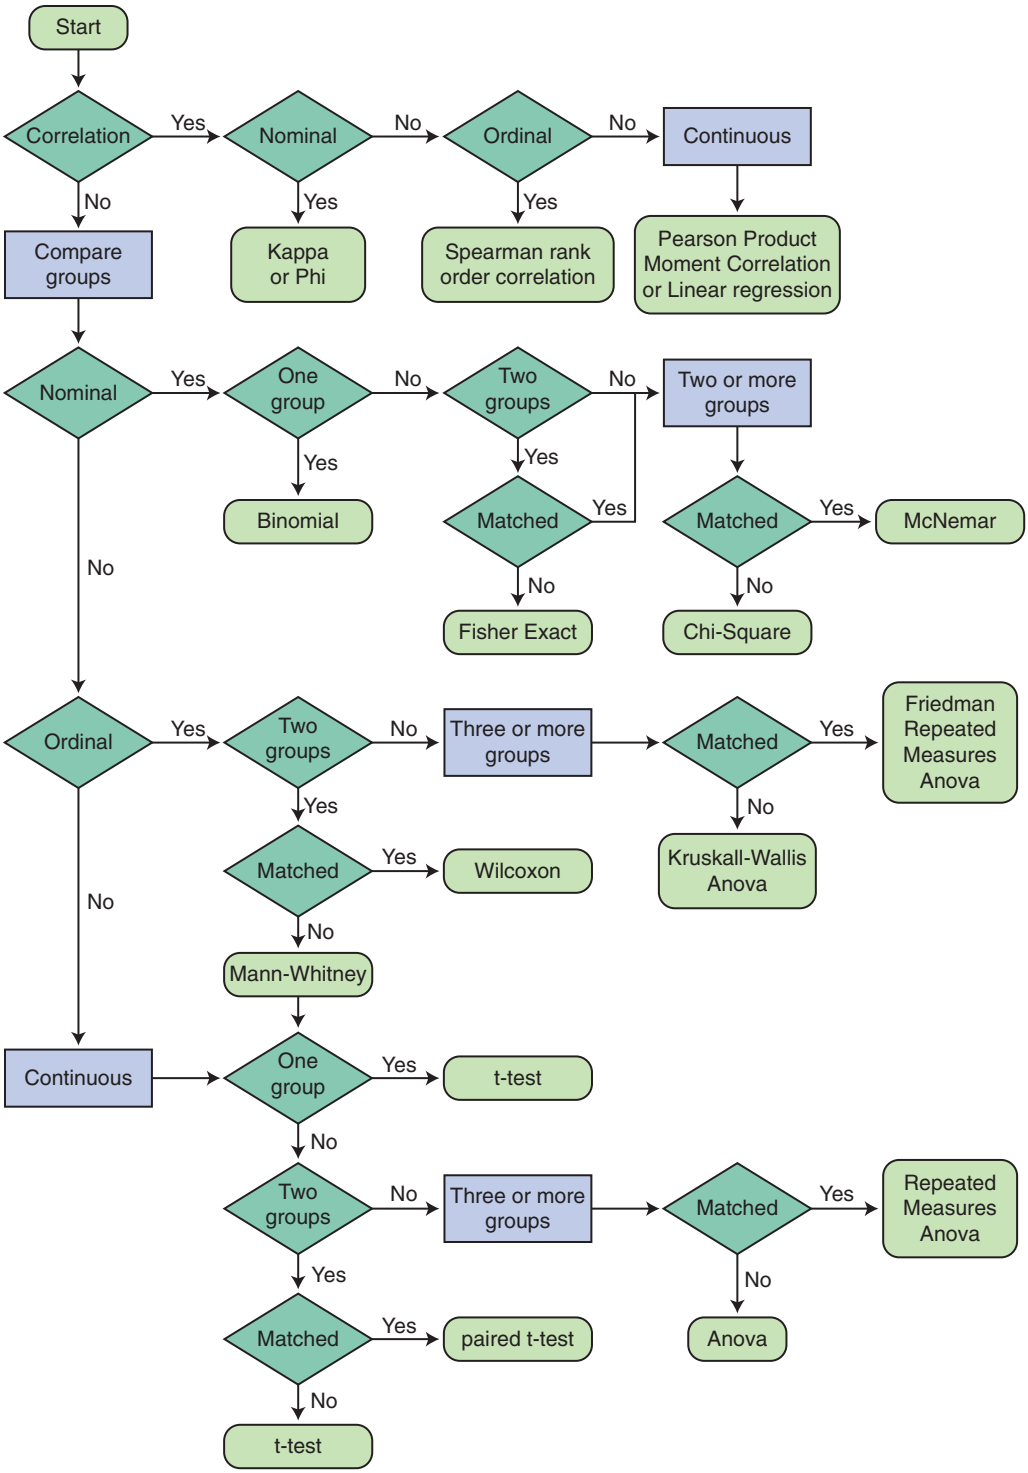

FIGURE 8-2 Statistics selector algorithm.

A poster allows a bit more freedom in terms of space.[26] You generally are allowed to create a paper or cardboard poster fitting a space of approximately 4 feet tall by 6 feet long. The way I do it is to create a template in Microsoft PowerPoint (Figure 8-4). On this template there are text boxes and graphics. Make sure the graphics are at least 300 dots per inch (dpi), usually TIFF files. If the graphics are not in the right format or have a resolution less than 200 dpi, they may look grainy when printed. Once the poster is created in PowerPoint (Figure 8-5), the file is taken to a printer (university or hospital art department or commercial establishment like Kinkos) and printed on a very large piece of poster paper (I use 42 by 74 inches). You can then roll it up and transport it in a special tube (cardboard—cheap; plastic—less cheap) made for the purpose (available at

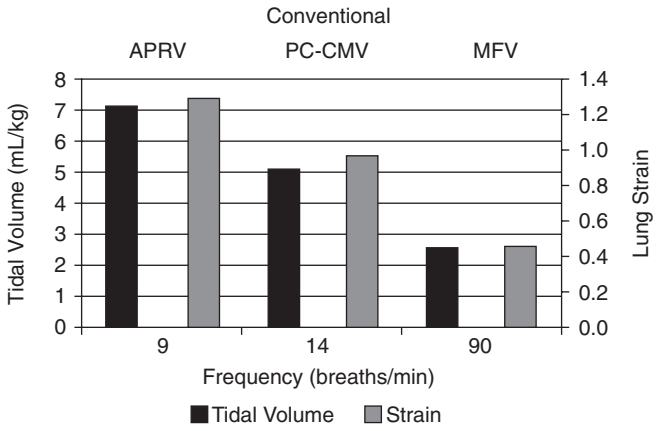

FIGURE 8-3 Abstract examination.

art supply stores). Such a tube is small enough to take as a carryon on a plane. Posters are usually presented in a group of maybe 10 to 15 in small rooms. The paper posters are hung on stands, and visitors walk around reading them and discussing them with the authors. In some cases, each author is given a few minutes at a podium to verbally summarize the study and answer questions.[27]

How to Write a Paper

If writing an abstract takes an experienced researcher 2 hours, then a full paper takes 20 to 100 hours. A paper has the same basic outline as an abstract or poster (Introduction, Methods, Results, Discussion or Conclusions) but goes into much greater detail. It also has an extra component, the References section.[28]

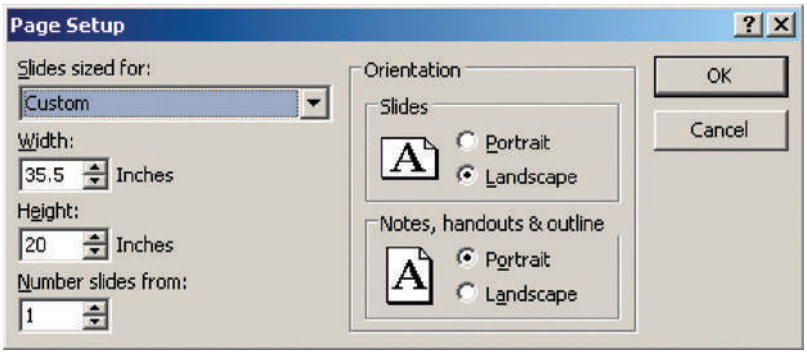

FIGURE 8-4 PowerPoint poster template.

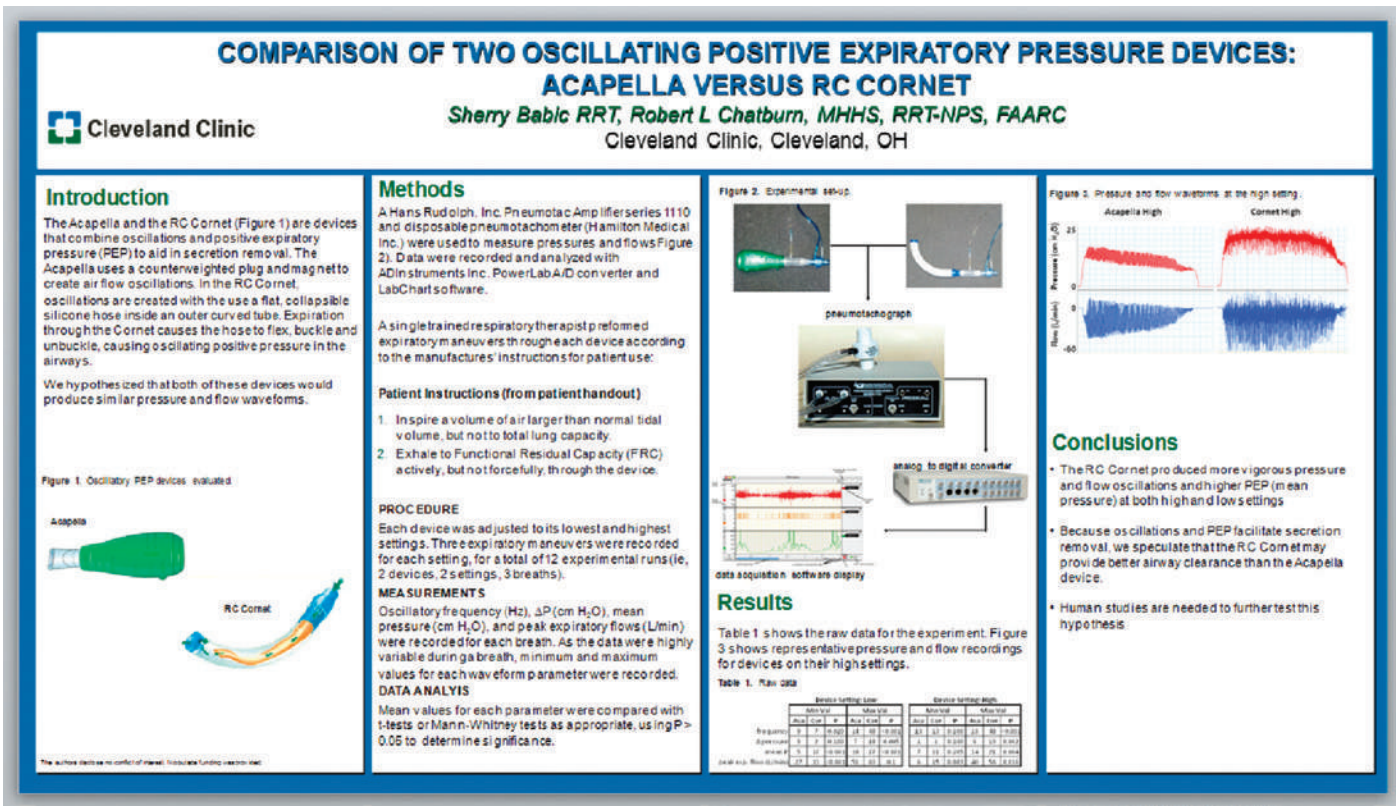

FIGURE 8-5 Example poster created in PowerPoint.

The Introduction of the paper can start with the full text of the Introduction from your research protocol. There is no word limit for the Introduction (within reason), but most journals have a maximal word count for the full text of the paper (usually in the range of 2000 to 3000 words, depending on the journal). The purpose of the Introduction is to provide a brief background explaining why the study was conducted and why it is of interest. A statement of the research problem or hypothesis should be included. The references cited in the Introduction (if any) should support the theoretical framework of the hypothesis, although an in-depth explanation should be saved for the Discussion section. The Introduction should also contain definitions of the general concepts discussed in the manuscript. Frequently used terms can be abbreviated after first being spelled out fully in the opening paragraphs.

RULE OF THUMB

Not including the hypothesis is a common mistake among beginners. Describing the hypothesis or research problem in the Introduction of the paper sets the stage for the Methods (which must describe how the hypothesis was tested), the Results (which must correspond to all the methods described), and the Discussion (which tells how the results addressed the hypothesis, discusses how this paper extends existing knowledge, and comments about limitations of the paper and further research opportunities to answer the questions posed in the paper).

The purpose of the Methods section is to explain to the reader exactly what was done to answer the research question and/or test the hypotheses described in the Introduction.[29] The key concept here is that the reader must be given enough detail to repeat the study, including all assumptions, calculations, and statistical procedures and descriptions of all equipment used. The Methods section may contain several subdivisions; description of experimental subject population, inclusion and exclusion criteria by which subjects are selected to participate in the research study, explicit experimental procedures, data analysis procedures, etc. An essential component of the Methods section is a complete description of any equipment used to gather the data. The calibration procedure for each measuring device should be described, along with any pertinent validation procedures. The procedure used to gather the data should be described. This description might include an outline of the experimental protocol that was approved by the hospital's IRB. If the study involves humans or animals, state that IRB approval was received before collecting data (as is required). A description of the experimental procedure should include the actual steps involved in gathering the data and the time elapsed during each phase of the experiment. Any problems or unforeseen events that occurred during the study should be mentioned. The information in this section should be detailed enough to guide other researchers who might wish to verify the results in their own studies. The Methods section also will help the reader evaluate the quality of the data gathered during the study. Finally, the Methods section should include a brief description of how the data were analyzed. Provide a short discussion of the statistical procedures used and why they were appropriate for the experimental design. Unless the procedures were unusual, do not give the statistical equations used. However, many statistical procedures are based on certain assumptions about how the data were gathered (e.g., normality of the data or independence of data points used in a linear regression). Thus enough information should be provided for the reader to evaluate the validity of any underlying statistical assumptions and, hence, the adequacy of the analysis. The specific statistical software that was used (if any) should also be cited in the Methods section.

The Results section of the paper presents the data gathered from the experiments. The order in which the information is given should correspond to the organization of the Methods section. In that section, the reader was introduced to the step-by-step procedure used to study a particular problem. An expectation has been created in the reader's mind for the result of each step of the procedure. Therefore the results should be presented in a logical progression from the beginning to the end of the experiment. This progression helps to assure the reader of the thoroughness of the experimental technique. The actual presentation of the data can take many forms. Use tables to summarize large amounts of raw data.[30] Each table should be constructed so that its meaning is clear without having to refer to the text. The idea is to summarize and guide the interpretation of large amounts of data and to reduce the time necessary to read the article. If the table appears to be too large or complex, make use of figures or graphs. Again, you do not need special statistical software; Microsoft Excel is an excellent tool for making tables and graphs. The information presented in the Results section is usually in the form of "bare facts," with little or no explanation of its significance. Interpretation of the data is presented in the Discussion section. Of course, this is a general rule and may be suspended at times if it is felt that elaboration of some point would help the reader's flow of understanding. The responsibility for interpreting the generalizability of the results ultimately rests with the reader. The significance of any statistical hypothesis tests is usually reported in terms of a *p*-value. Differences associated with *p*-values less than 0.05 are considered significant by convention in medical studies.

In the Discussion section, the author must show how the results answered the research question that was first described in the Introduction.[31] The results of statistical hypothesis tests must be translated into conclusions about the research hypotheses stated in the Introduction. The implications and practical meaning of the study results should be explained. Also, the Discussion should interpret the results in the face of earlier studies' conclusions. Specifically, how does the current study extend or add new knowledge? Does it contradict previous findings, and, if so, what is the proposed reason? In addition, the Discussion should describe the limitations of the study design, any problems encountered, and any recommendations for

future studies. The process of interpreting the results concerns not only the data generated by the study but also relates that data to other studies and theoretical frameworks. The Discussion is the appropriate place to include detailed reviews of other related research, including references, which would help to develop the reader's perspective and appreciation for the significance of the study.

Some journals require a separate Conclusion statement at the end of the paper. The conclusions made should be briefly explained, including reasons for rejecting alternative interpretations. In addition, there should be a statement regarding the population to which the results can be generalized. Because the implications of a given study are usually speculative, it is appropriate to use words that are somewhat tentative in nature. For example, "The results of this study suggest that . . . ." or "Because of the significant differences found, it may be possible to . . . ." Such language emphasizes the fact that your interpretation is itself a hypothesis that may be tested by further research.

How to Respond to Reviews

Once your paper is completed and submitted to a journal for review, it will be given to two or three "peer reviewers." These are your scientist peers who have expertise in the area of research described in your paper. They are invited by the editor of the journal to review the paper you submitted and will read and critique everything about your paper, from what words you use, to what measurements you made, to what statistical procedures you used. They will then recommend to the journal editor one of three outcomes: that your paper should not be considered for publication; that, with luck, your paper is rejected with an opportunity to revise and resubmit; or that the paper should be accepted as is. Rarely does a paper get accepted without any suggested revisions. The main reasons that papers get rejected are given in Box 8-5.[32]

Having a paper rejected is like being told your child is ugly and stupid. Most people react with negative emotions and give up. But if you can get past that phase, you have several options. First, examine whether the reviewers' comments are justified. Sometimes they have just misunderstood what you did. If the comments are justified, see what you can do to make the required changes. Generally, you will be given a list of reviewers' comments. In your response, you need to repeat each of the reviewer's comments and then give your explicit answers and what you did to achieve the requested change in the manuscript (I use a numbered list to keep track of everything in this so-called *point-by-point response* that must accompany any resubmission). Keep three things in mind: (1) The time spent in revision is generally only a small fraction of the time already invested—you should not give up if you receive a rejection with an opportunity to revise. (2) Most manuscripts require revision and you are not being singled out. (3) Authors have the right to overrule a reviewer's objection, but they must adequately support their points of view and convince the editor that they are right and that the reviewer's point is in error. When the revision is complete, resubmit the manuscript. Depending on the journal, it may take as many as three rounds of revisions before a manuscript is accepted and ready for publication.

Box 8-5 The 10 Most Frequent Reasons for Manuscript Rejections

1. Inappropriate statistics
2. Inappropriate interpretation of results
3. Instrumentation insufficient for the study purpose
4. Inadequate or biased sampling of experimental subjects
5. Unclear, poorly written, or overly complex text
6. Insufficient (or absent) problem statement
7. Inaccurate or inconsistent data
8. Incomplete, inaccurate, or outdated literature review
9. Insufficient data
10. Defective tables or figures

Modified from Pierson DJ: The top 10 reasons why manuscripts are not accepted for publication. Respir Care 49:1246, 2004.

SUMMARY

Hopefully, this chapter has introduced you to the importance and methods of scientific research and has helped you become an educated consumer of medical research. Not everybody is cut out to be a scientist. But, as professionals, everyone practicing respiratory care has the responsibility to intelligently evaluate what they are doing in light of scientific evidence. Unfortunately, most of the things we do in medicine are not supported by strong evidence, despite the wealth of information in printed medical journals and on the Internet (in the form of databases, portals, and electronic media). And even when evidence is available, it is often controversial. We rarely know anything for sure, and we only have varying degrees of confidence. On the one hand, this situation is frustrating. On the other hand, there is no doubt that we are progressing. Which would you prefer, your least favorite health maintenance organization today or the best medicine of 100 years ago? Our current situation provides infinite possibilities for anyone who has an interest in research and the willingness to help clarify the confusion just a bit. If you have enough interest (and hopefully a mentor) you can begin to create basic study ideas and conduct experiments. With perseverance, it is quite possible for you to get your abstract accepted in Respiratory Care journal and present your poster at the Annual AARC Congress. Even if your personal goals do not include becoming a scientist, you should publish at least one abstract in your career to understand what is involved with moving the profession forward as a clinician, educator, or administrator.

RULE OF THUMB

Even after doing research, we may still be confused, but we believe we are confused at a higher level about more important things.

SUMMARY CHECKLIST

- All health care professionals have the responsibility to intelligently evaluate what they are doing in light of scientific evidence.
- Information required to evaluate professional practice can be found in printed medical journals and on the Internet (in the form of databases, portals, and electronic media).
- Research ideas can be obtained from reading research and from simply observing daily practice. General ideas can be turned into statements of study purpose by describing what you see happening and why it is important.
- Research results can be disseminated in three main ways: abstracts, posters, and papers in peer-reviewed medical journals.

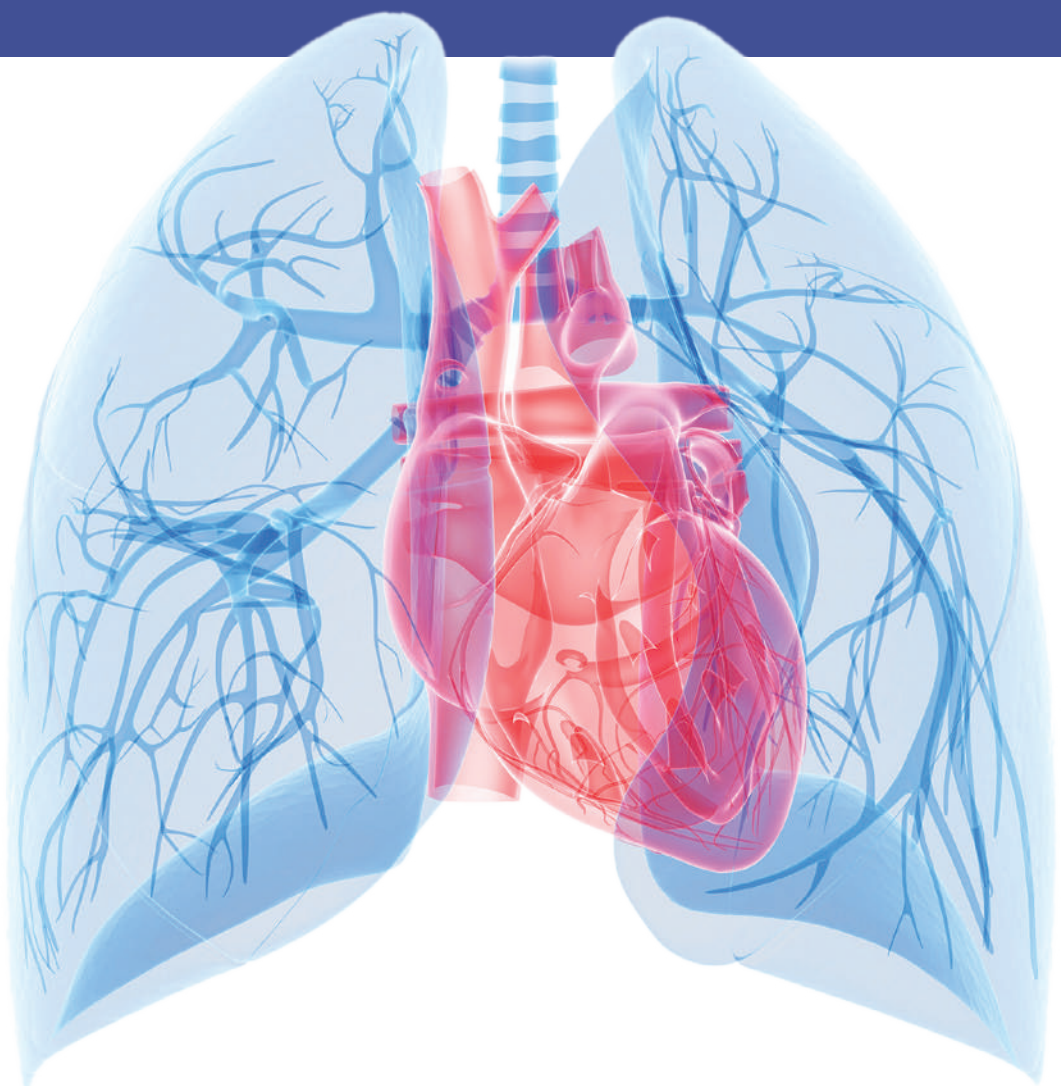
SECTION II

APPLIED ANATOMY AND PHYSIOLOGY



CHAPTER 9

The Respiratory System

CRYSTAL L. FISHMAN AND NARCISO E. RODRIGUEZ

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- State the major developmental events of the respiratory system.
- Describe how genes control lung development.
- Describe the key elements of normal fetal circulation.
- State what happens to the respiratory system at birth.
- Describe the developmental events in the respiratory system that continue after birth.
- Identify the main structures in the thorax and describe their functions.
- Identify and describe the primary and accessory muscles of breathing.
- Describe how the pulmonary and bronchial circulations are organized and their functions.
- Describe how somatic and autonomic nervous systems connect to and control the lungs and respiratory muscles.
- Identify the major structures of the upper respiratory tract and how they function.
- Describe how the lungs are organized into lobes and segments and the airways that supply them with ventilation.
- Describe how and why airways produce and move mucus.
- Describe how the structures in the respiratory bronchioles and alveoli are organized.
- Describe the blood-gas barrier.

CHAPTER OUTLINE

KEY TERMS

type I pneumocyte
type II pneumocyte
uvula
vallecula
visceral pleura
xiphoid process

The primary function of the respiratory system is the continuous absorption of oxygen and the excretion of carbon dioxide. This exchange between the gas of the atmosphere and blood is termed **external respiration.** This process supports **internal respiration,** which is the exchange of gases between blood and tissues. To carry out external respiration, the system brings gas into close proximity with the flowing blood in the pulmonary circulatory system. This close "match" of gas and blood across a large but extremely thin blood-gas barrier membrane enables efficient gas exchange to occur via simple diffusion.

The respiratory system includes the upper airways, chest wall, respiratory muscles, lower airways, pulmonary blood vessels, support nerves, and lymphatics. These organs support gas exchange and form early in the developing human. They undergo dramatic functional changes at the time of birth, beginning its primary role of breathing and external respiration at that moment.

From the moment of conception the human body undergoes tremendous growth and development—from embryo to fetus to infant and child, through puberty, and into young adulthood. A gradual loss of lung tissue and functional changes continue through the elderly years until the time of death. During the life span of a human, the respiratory system maintains external respiration by matching phenomenal amounts of air with a similar amount of blood flow. Approximately 250 million liters of each are moved and matched during an average 75-year life span. The respiratory system normally moves this amount of air and blood flow with a minimal amount of work. This system humidifies and warms inspired air while removing inhaled contaminants and filtering out chemicals and small blood clots deposited or formed in the blood. The respiratory system is regulated by the nervous system. It is capable of increasing function in response to elevated demands brought on by stressful conditions such as exercise and disease.

A functional understanding of the "normal" anatomy and physiology of the respiratory system is crucial to proper understanding of pulmonary disease and its treatment. The role of the respiratory care therapist in assessment and treatment of cardiopulmonary disorders requires an in-depth understanding of the structural and functional nature of the respiratory system.

DEVELOPMENT OF THE RESPIRATORY SYSTEM

The developing human undergoes a remarkable transformation from a single cell to an individual with a nearly complete set of organ systems. The developmental phases of a fertilized egg are divided into the *embryonic* and *fetal periods*. The embryonic period occurs during the first 8 weeks of pregnancy. Major organs will develop during this period. The fetal period occurs during the remaining 32 weeks of pregnancy. During this period, the organs continue to develop and refine their structure and function.

The respiratory system develops during these periods as a fluid-filled structure playing no role in gas exchange, yet must be developed sufficiently to assume this crucial activity at the time of birth. Its development is a continuous process that begins in the early stages of the embryonic period and extends for years after birth. The embryo is made up of three distinct germinal tissue layers that ultimately form all tissues and organs: *endoderm, mesoderm,* and *ectoderm*. From these layers the organs and systems will arise (Table 9-1).

The development of the respiratory system has been categorized into various stages.[1] Figure 9-1 shows the various stages of lung development, and Table 9-2 summarizes the major developmental events in each phase. Respiratory development begins in the embryonic period on or approximately day 22 after fertilization. A primitive laryngotracheal tube forms from a groove in the fourth pharyngeal pouch. From that groove a

tracheal bud forms by the end of the fourth week of life (Figure 9-2). During week 5 of development, the tracheal bud continues to develop and bifurcates into left and right primary bronchial buds.

Injury to the embryo or genetic dysregulation during this crucial phase of development can lead to many congenital anomalies, including tracheoesophageal fistulas, esophageal atresia, choanal atresia, pulmonary hypoplasia, and complex heart and vascular anomalies discussed later in this text.

At approximately 6 weeks of development, lung and airway growth has the appearance of a glandular structure—hence the name of the second phase of development, the *pseudoglandular stage* (Figure 9-3). For the next 10 weeks, the growth and branching of the tracheobronchial tree and pulmonary vasculature continue and culminate with formation of the terminal and respiratory bronchioles. The distinction between these two types of bronchioles is important. Terminal bronchioles are conducting airways only and do not participate in gas exchange with blood. Respiratory bronchioles have more superficial capillaries and are capable of gas exchange with blood, becoming more elaborate as development continues.

Branching and dividing of the tracheobronchial tree occurs in several ways as the result of differential gene expression. The epithelial lining of the airways begins to differentiate into columnar epithelia in the proximal airways and differentiates into cuboidal epithelia in the more distal bronchioles (Figure 9-4, *A*). Development of *cilia, mucous glands,* and *goblet cells* occur at this time and line most of the conducting airways.

Beginning with the trachea and moving distally, the amount of cartilage supporting the airway decreases as smooth muscle cells in the middle layer of the airway increase. Altered development of smooth muscle, cartilage, and vascular structures can lead to other congenital pulmonary disorders, such as tracheomalacia and anomalous pulmonary arteries, causing the vascular rings to pinch the airway.

The *canalicular stage* (see Figure 9-4, *B*) begins at week 16 and continues until week 26. The canalicular stage overlaps with the pseudoglandular stage because the superior regions are developing slightly faster than the inferior regions. During this phase, primary changes include the development of two to four more generations of respiratory bronchioles from each terminal bronchiole. In the last several weeks of this stage, the region beyond each terminal bronchiole forms the functional structure called the **acinus,** the basic gas-exchanging unit of the lung. At this time, the two principal epithelial cell types that cover the gas-exchange surface begin to appear, *type I* and *type II* pneumocytes. At the end of the canalicular period (24 to 26 weeks of gestation), the fetus, if born, is capable of sufficient gas exchange and viable if supported with supplemental O_2, ventilatory support, and surfactant administration.

During the *terminal saccular stage* (see Figure 9-4, *C*), more terminal bronchioles and their associated acini form and develop from 26 weeks to birth. The formation of the total number of terminal bronchioles is complete at the end of this phase. The cuboidal epithelia that line the blind tubules of the acinus continue to differentiate into rounded secretory cells (**type II pneumocytes**) and flatter squamous epithelial cells (**type I pneumocytes**). Capillaries continue to form near and bulge from the surface of the acinus. Although some type II pneumocytes form by 20 weeks of gestation, they are in such small numbers and of such primitive function that their impact on lung function is marginal. From this point until birth, there

TABLE 9-1

Structures Arising from the Three Germ Layers

Endoderm	Mesoderm	Ectoderm
Respiratory tract	Dermis and muscles	Epidermis, hair, and nails
Digestive tract, bladder and thyroid	Bone, connective and lymph tissue	Lens of eyes and skin glands
Liver and pancreas	Reproductive and cardiovascular system	Central and peripheral nervous system

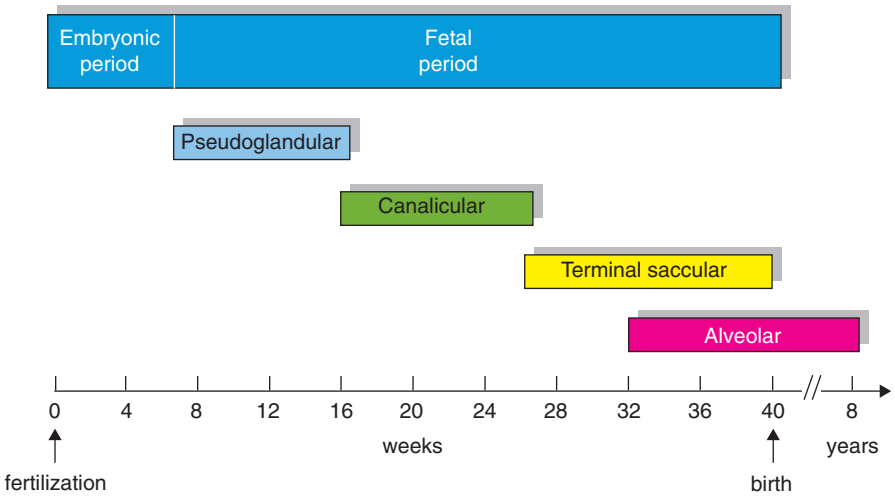

FIGURE 9-1 Major phases of respiratory development.

TABLE 9-2

Developmental Events of the Cardiopulmonary System

Gestational Age	Developmental Event
Embryonic Period	
20-22 days	Primordial pharyngeal arches form
21-23 days	Primordial respiratory cells form on fourth pharyngeal pouch, primordial heart starts forming
26th day	Laryngotracheal bud forms
4th wk	Primitive trachea develops
5th wk	Primary bronchial buds form, laryngeal structures develop
Fetal Period	
Pseudoglandular Stage	
6th wk	Segmental and subsegmental bronchioles form
7th wk	Diaphragm complete
8th wk	Heart complete, fetal circulatory pattern begins to develop
10th wk	Pulmonary lymphatic structures develop
12th wk	Major arteries formed
13th wk	Major airway epithelia and mucus-producing cells formed, smooth muscle cells developing
14th wk	Principal arteries formed
16th wk	Terminal bronchioles and associated pulmonary vessels form
Canalicular Stage	
16th-17th wk	Respiratory bronchioles and immature acini begin to form
20th-24th wk	Type I and II pneumocytes begin to appear and replicate
24th-26th wk	Pulmonary capillaries develop at surface of acinus, immature surfactant begins to appear in lung fluid
Terminal Saccular Stage	
26th wk–birth	Terminal saccules increase in number, pulmonary capillary density and proximity increase, type I and II pneumocytes continue to multiply, surfactant production increases, extrauterine life possible with support
Alveolar Stage	
32th-40th wk	Immature alveoli begin to form and increase in number; surfactant production matures
40th week	50 million immature alveoli formed
Period After Birth	
Birth	First breath and lung fluid cleared, adult circulatory pattern established
8-10 yr	470 million mature alveoli formed

is rapid proliferation of alveolar ducts and sacs formed from the respiratory bronchioles.

The type I pneumocytes of the saccule walls thin and elongate to cover the walls of this region. Type I cells become the primary gas-exchange cells in the lung with close approximation to developing pulmonary capillaries. Type II pneumocytes form and secrete the vital pulmonary surfactants that are necessary to alter surface tension and help keep the lungs inflated.

The development of mature alveoli, accompanied by capillary proliferation within the walls, marks the final phase of lung development and is known as the *alveolar period* (see Figure 9-4, *D*). This phase begins at about week 32 of gestation and continues for years after birth. During this phase the terminal saccules develop hexagonal pouchlike regions called *alveoli* within their walls, resulting in greater numbers of alveoli that enlarge to a mature state over time.

RULE OF THUMB

The development of mature alveoli marks the final stage of lung development, known as the *alveolar period*. This period begins at approximately 32 weeks of gestation and continues for years after birth. As a result, premature infants younger than 32 weeks are at greater risk for developing respiratory distress.

A full-term newborn infant has approximately 50 million alveoli, this number continues to increase for approximately 2 to 3 years after birth.[2,3] The alveoli are lined with type I and II pneumocytes covering the pulmonary capillaries forming just below the basement membrane.

Human **pulmonary surfactant,** which promotes lung inflation and protects the alveolar surface, begins to be produced around 24 to 25 weeks of development by type II pneumocytes. It is composed primarily of phospholipids, a small amount of protein (types SP-A, SP-B, and SP-C), and a trace of carbohydrates.[4] Early research in pulmonary surfactants centered on the phospholipid components, mainly phosphatidylcholine (lecithin [L] and sphingomyelin [S]) and phosphatidylglycerol (PG). The amount of these phospholipids (the *L/S ratio* and *PG concentration*) provides a predictive index of the lung maturity in a fetus before birth and the risks for the development of respiratory distress.[5] An L/S ratio of 2 or more indicates a relatively low risk for the development of respiratory distress syndrome, whereas an L/S ratio of less than 1.5 is associated with a high risk.

Surfactant synthesis is regulated by numerous hormones, genes, and factors, including glucocorticoids.[6] Glucocorticosteroid production increases at the end of gestation and stimulates receptors in type II pneumocytes, increasing surfactant production and improving the L/S ratio.

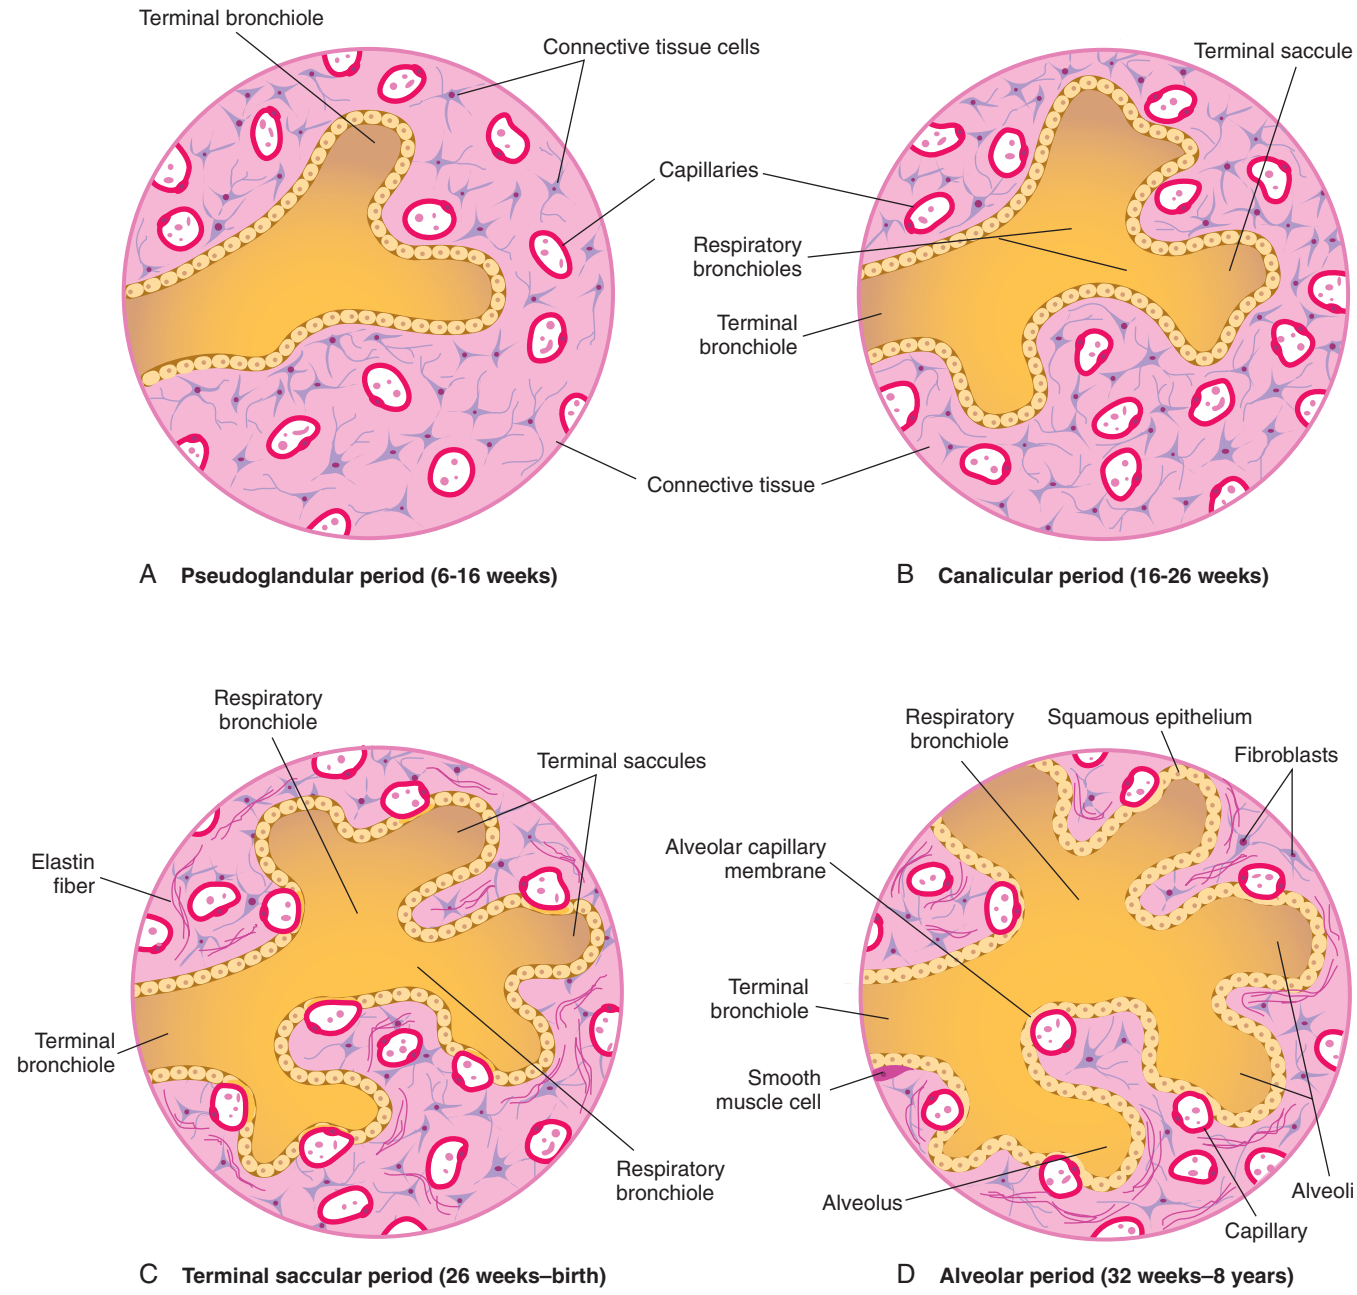

FIGURE 9-4 Histologic changes that illustrate various periods of airway development. **A and B,** There is considerable distance between the air within the airways and blood within the capillaries. **C and D,** The air-blood distance is considerably thinner and more supportive of effective air breathing. (From Moore KL, Persaud TVN: The respiratory system. In Moore KL, Persaud TVN, editors: The developing human: clinically oriented embryology, ed 8, Philadelphia, 2008, WB Saunders.)

A distinctive function of the developing lung is the formation of relatively large amounts of fetal lung fluid that passes into amniotic fluid. Fetal lung fluid is a unique combination of plasma ultrafiltrate from the fetal pulmonary microcirculation, components of pulmonary surfactant, and other fluids from pulmonary epithelial cells.[7] This fluid is constantly produced and replaced, keeping the fetal lung inflated at a slight positive pressure with respect to amniotic fluid pressure. This phenomenon is important in stimulating normal lung development.[8] At term, the fetal lung is filled with approximately 40 ml of fluid. Conditions that lead to inadequate fetal breathing and low amounts of amniotic fluid formation (oligohydramnios) are linked to incomplete inflation and poorly developed (hypoplastic) lungs.

A developing fetus begins to make respiratory efforts midgestation and continues these efforts until birth. During these efforts, the fetus moves little or no fluid in and out of the lungs. The rhythm and depth of fetal breathing are periodic and irregular, reflecting the development of the respiratory centers in the brain and respiratory muscles.

Throughout the developmental period, lung growth is similar in male and female fetuses. At birth, the lungs of male infants are, on average, larger and have a greater number of respiratory bronchioles than the lungs of female infants when adjusted for gestational age.[9] When evaluating breathing efforts and surfactant production at 26 to 36 weeks of gestation, female fetuses have better developed lung function and are slightly less susceptible to the development of respiratory distress syndrome.[10,11]

TRANSITION FROM UTERINE TO EXTRAUTERINE LIFE

At birth, the lungs undergo a rapid and remarkable transition. A liquid-filled organ that possesses very little circulation incapable of sufficient gas exchange becomes an air-filled organ that receives the entire cardiac output from the right heart. It then carries and delivers all gas necessary to sustain life.

Placental Structure and Function

Survival of the embryo/fetus requires an effective circulatory interface with the circulation of the mother, which is provided by the placenta.[12] Within 1 week of uterine implantation, vascular projections called *chorionic villi* arise from the chorion of the embryo and penetrate the uterine endometrium. As gestation proceeds, the villi increase in number and complexity, erode the endometrium, and create irregular pockets called *intervillous spaces* in the placenta, which fill with maternal blood. The maternal blood flowing through the intervillous spaces bathes the embryonic villi and creates an O_2-rich and nutrient-rich blood environment.

The maternal uterine tissues and blood vessels of the fetal chorionic villi make up the bulk of the placenta. Figure 9-5 shows a cross section of a well-developed placenta. Maternal blood flows into the intervillous space through the spiral arteries, whereas fetal blood is supplied to the villi from two umbilical arteries. Maternal and fetal blood come into close proximity but remain separated by an embryonic membrane that permits the exchange of O_2, CO_2, water, ions, various metabolic molecules, and hormones.

Various chemicals, hormones, bacteria, and viruses can also cross the intervillous space and cause a variety of fetal developmental problems. Oxygenated fetal blood leaves the chorionic villi capillaries through placental venules and returns to the

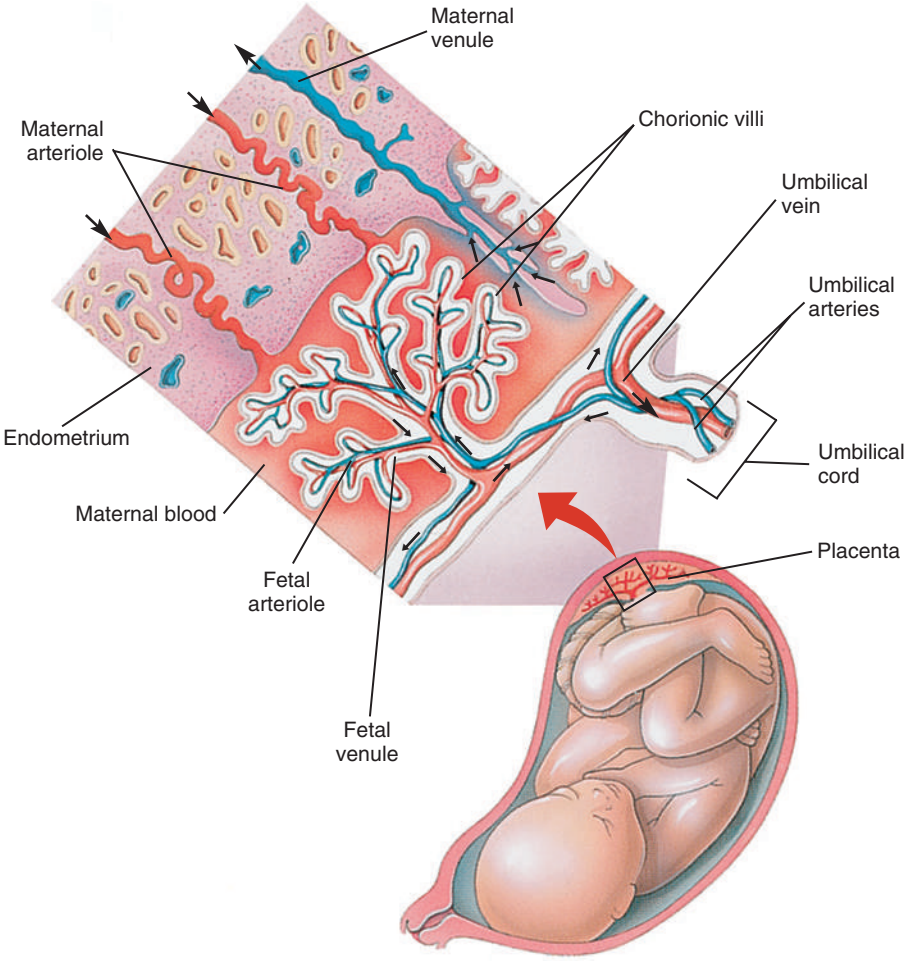

FIGURE 9-5 Cross-sectional view through the placenta showing the spiral arteries that supply maternal blood to the intervillous spaces. The fetal villi, immersed in maternal blood, are supplied with blood from the umbilical arteries and drain their blood back through the umbilical vein. (From Thibodeau GA, Patton KT: Anatomy and physiology, ed 7, St Louis, 2010, Mosby.)

TABLE 9-3

Approximate Normal Values of Blood Gases and Acid-Base in Fetal and Maternal Blood

Value	Maternal Intervillous Blood	Fetal Umbilical Artery Blood	Fetal Umbilical Venous Blood
pH	7.38	7.36	7.39
PCO_2 (mm Hg)	42	47	43
PO_2 (mm Hg)	50	19	30

fetus through a single umbilical vein. Abnormal implantation of the placenta, tearing of the placenta from the uterine wall, or decreased placental blood flow can stunt intrauterine growth. In severe cases this can cause fetal asphyxia, increasing the risk for brain damage and respiratory distress in the immediate postnatal period.

Many factors enhance the delivery of O_2 to fetal tissues. The partial pressure gradient for O_2 between maternal blood and fetal blood drives the diffusion of O_2 into fetal blood within the chorionic villi capillaries.[13,14] Maternal arterial blood has a partial pressure of O_2 (PaO_2) of approximately 100 mm Hg and mixes with the blood in the intervillous space, producing a mean PO_2 of approximately 50 mm Hg. Fetal blood that enters the villi has a PO_2 of approximately 19 mm Hg, and the pressure gradient between maternal and fetal blood PO_2 (50 – 19 = 31 mm Hg) causes O_2 to diffuse into fetal blood. Blood leaving the villi and entering the umbilical vein has a PO_2 of approximately 30 mm Hg. Table 9-3 summarizes the normal gas and acid-base values in normal fetal umbilical arteries and veins and maternal intervillous blood. Assessment of umbilical vein blood gas data (cord blood gas) shortly after birth is a method of determining the degree of fetal asphyxiation during the birth process.

The O_2 content and delivery by fetal blood are almost the same as adult blood despite the much lower PO_2. This is due to several factors, including relatively higher content of hemoglobin (18 g/dL) and hematocrit (54%) in fetal blood and the presence of fetal hemoglobin (HbF), which has an increased affinity for O_2 and a more pronounced Bohr effect (reduced oxyhemoglobin affinity with acidosis) to enhance O_2 release.[14] Figure 9-6 illustrates how the increased O_2 affinity is manifested by a leftward shift of the fetal oxyhemoglobin dissociation curve. The P_{50} (PO_2 that saturates 50% of the hemoglobin) is 6 to 8 mm Hg less than the P_{50} for adult hemoglobin (HbA), which indicates the degree of the shift toward higher affinity. At birth, approximately 70% of circulating hemoglobin is HbF. HbA gradually replaces HbF during the first 6 months of extrauterine life as HbA genes in bone marrow switch on and HbF genes in the liver (major site of fetal erythrocyte development) are switched off.

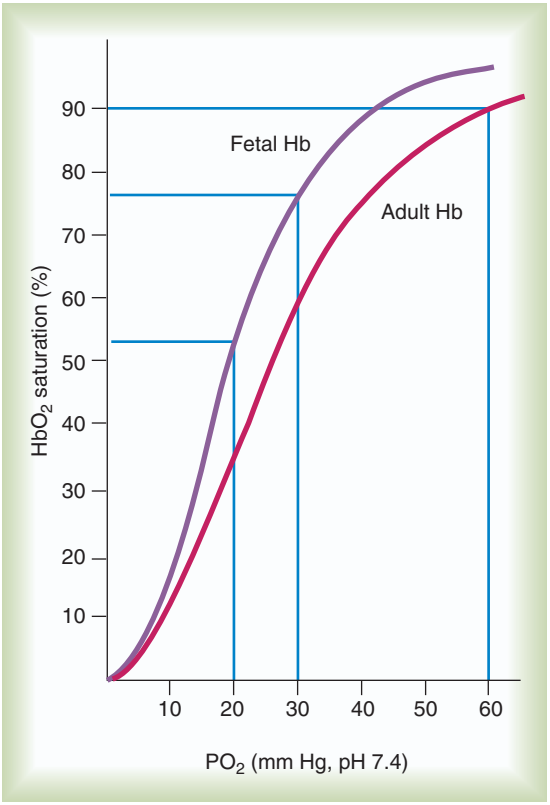

FIGURE 9-6 Fetal hemoglobin (Hb) has a leftward shift of the oxyhemoglobin (HbO_2) dissociation curve compared with adult Hb, indicating greater affinity for O_2. (Modified from Koff PB, Eitzman DV, Neu J: Neonatal and pediatric respiratory care, St Louis, 1988, Mosby.)

Fetal Circulation

Fetal circulation is different from the circulation of the neonate after birth.[15] Three important bypass pathways (shunts) function in the developing fetus to enhance the flow of blood to the developing organs: **ductus venosus**, **ductus arteriosus**, and **foramen ovale**. Oxygenated blood from the placenta is carried in the umbilical vein back to the fetal circulation via the hepatic circulatory system (Figure 9-7). Approximately one-third of this blood flows to the lower trunk and extremities. The other two-thirds flows through the *ductus venosus*, bypassing the liver's circulation, and flows to the inferior vena cava. This better oxygenated blood in the inferior vena cava mixes with the venous blood returning from the lower trunk and extremities entering the right atrium. Approximately 50% of this blood is shunted from the right atrium into the left atrium through an opening in the interatrial septum called the *foramen ovale*. Left atrial blood flows to the left ventricle and then to the ascending aorta, where it continues on to the brain, brachiocephalic trunk, and descending aorta. Venous blood from the superior vena cava is directed downward through the right atrium into the right ventricle and then into the main pulmonary artery.

The relatively low PO_2 and various prostaglandins in fetal blood cause the *ductus arteriosus* (a muscular vessel attached to the trunk of the pulmonary artery and the aorta) to dilate and the pulmonary arteries to constrict. This leads to an increase in pulmonary vascular resistance, resulting in pulmonary artery pressure higher than aortic blood pressure. As a result, 90% of

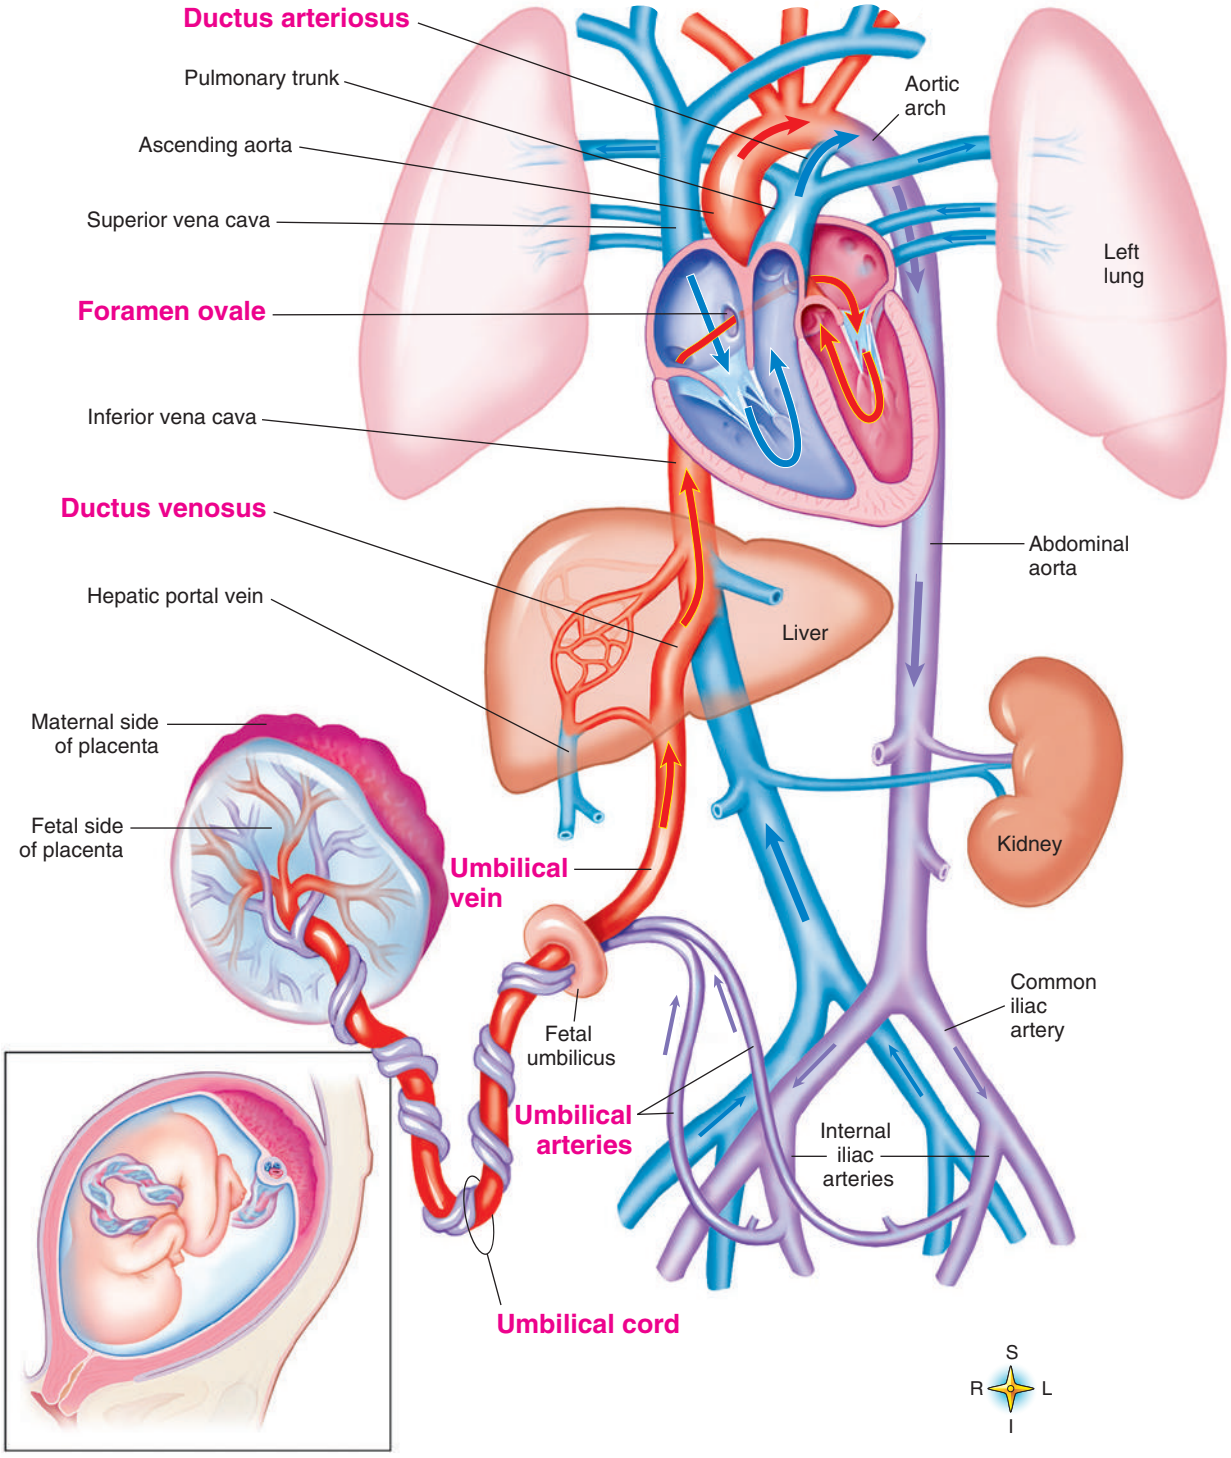

FIGURE 9-7 Fetal circulation before birth. Special features (shown in *red*) include the umbilical cord, two umbilical arteries, one umbilical vein, ductus venosus, foramen ovale, and ductus arteriosus. (From Thibodeau GA, Patton KT: Anatomy and physiology, ed 7, St Louis, 2010, Mosby.)

the blood flow entering the pulmonary artery takes the path of least resistance by shunting through the ductus arteriosus and flowing to the aorta. Only 10% flows into the lungs. Blood flowing through the ductus arteriosus mixes with blood flowing through the aorta, routing into the systemic circulation. Some of this blood flows to the gut, lower extremities, and placenta. Two umbilical arteries carry blood from the fetal aorta to the placenta, carrying out fetal-maternal gas and nutrient exchange.

Cardiopulmonary Events at Birth

Various mechanisms work together to reduce and clear the amount of lung fluid at birth in preparation for air inflation.[16]

Days before birth, the epithelia of the lung stop the production of lung fluid, which is actively absorbed back into fetal circulation. During normal vaginal delivery, approximately one-third of the lung fluid is cleared through compression of the thorax in the birth canal. The pulmonary capillaries and lymphatics clear the remaining fluid.

A newborn must develop very high transpulmonary pressure gradients during the first few breaths to open and replace the remaining lung fluid with air and establish a stable lung volume for gas exchange (Figure 9-8). These large pressure gradients overcome the opposing forces of fluid viscosity in the airways and surface tension in the alveoli. The stimulus for these initial respiratory efforts is sent via peripheral and central chemoreceptors and augmented further by skin thermoreceptors.

The first breath is triggered by new tactile and thermal stimuli. In addition, as placental gas transfer is suddenly interrupted, the newborn becomes hypoxemic, hypercapnic, and acidotic, triggering strong inspiratory efforts. The pressure-volume changes occurring during these first breaths are depicted in Figure 9-8. At first, no air enters the newborn lung until the transpulmonary pressure gradient exceeds 40 cm H_2O. As lung volume increases with each breath, decreasing amounts of pressure are needed to overcome the opposing forces. The volume trapped in the lung stabilizes quickly and is crucial to adequate gas exchange.

Figure 9-9 summarizes the major cardiopulmonary changes that occur during the transition from a fluid-filled lung to an air-filled lung. As the lung expands with air, and gas exchange starts within the lung, pulmonary blood PO_2 increases, PCO_2 decreases, and pH increases; this results in pulmonary vasodilation, lower pulmonary vascular resistance, and constriction of the ductus arteriosus, which facilitates greater blood flow through the pulmonary circulation. Ductus arteriosus closure is stimulated further by the loss of maternal prostaglandins. The combination of increasing alveolar air content and constriction

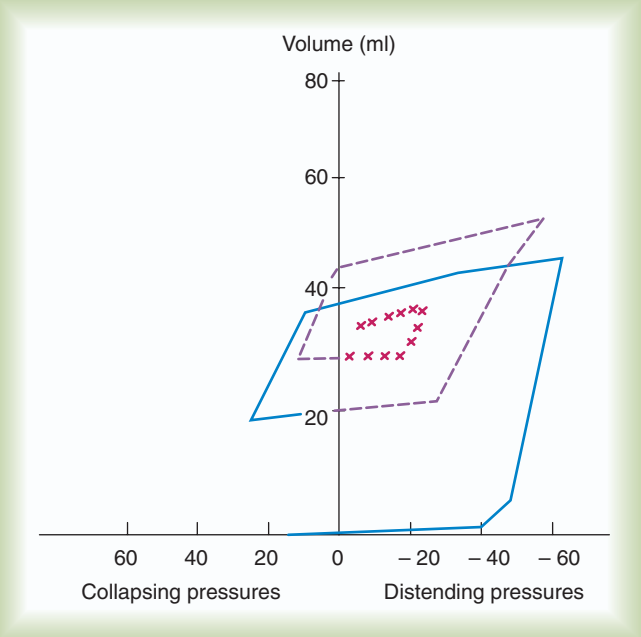

FIGURE 9-8 Pressure-volume changes in the human neonate during the first three breaths after birth: first breath (—), second breath (—), and third breath (xxx). (Modified from Taeusch WH, Ballard RA, Gleason, CA: Avery's diseases of the newborn, ed 8, Philadelphia, 2005, WB Saunders.)

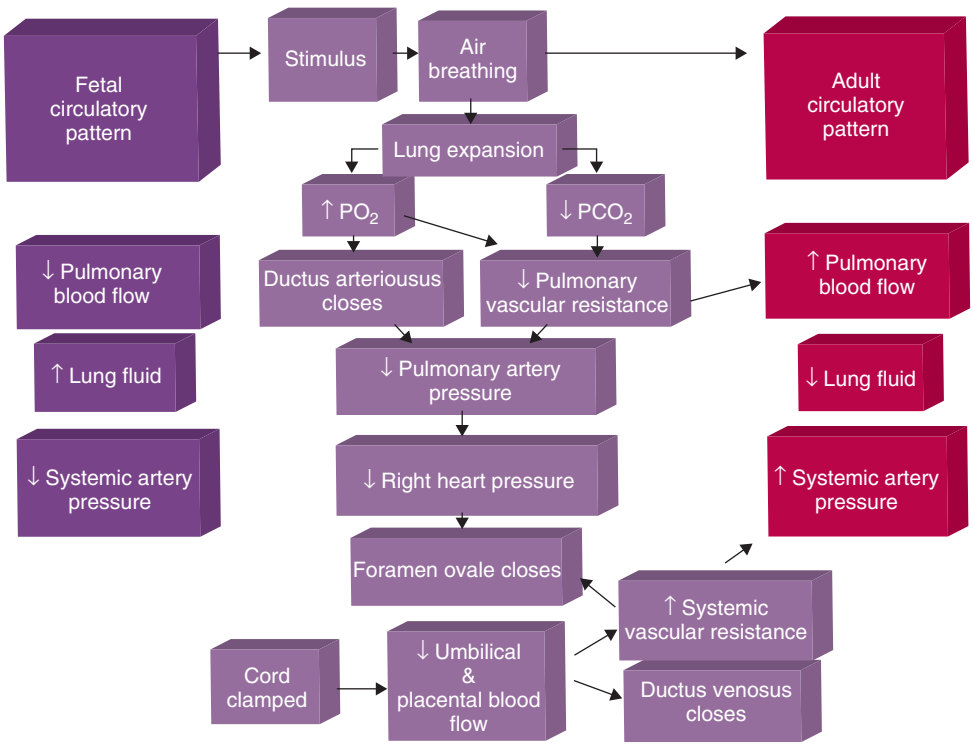

FIGURE 9-9 Major cardiopulmonary changes during the transition from the fetal to the adult circulatory pattern.

of the ductus arteriosus promotes progressive improvement in the matching of ventilation and blood flow, which increases the PO_2 and decreases the PCO_2 of blood leaving the lungs. After the clamping of the umbilical cord, cessation of umbilical and placental blood flow causes closure of the ductus venosus and a rapid increase in systemic vascular resistance. As systemic vascular resistance increases, left-sided heart pressures increase. Left atrial pressures also increase as a result of increased pulmonary blood flow that returns from the lungs. With left-sided heart pressures now higher than right-sided pressures, the foramen ovale closes.

When this last right-to-left shunt closes, the transition between fetal and extrauterine circulations is functionally complete. Full transition occurs later as the ductus arteriosus and foramen ovale close anatomically through the formation of fibrosis. Anatomic closure of the ductus normally occurs within 3 weeks of birth. Permanent closure of the tissue flap covering the foramen ovale may take several months.

All of these changes normally occur during the first few minutes after birth and allow the newborn to achieve normal gas exchange. Many abnormal conditions can interfere with these transition events, leading to persistence of the fetal circulation and cardiorespiratory failure.

POSTNATAL LUNG DEVELOPMENT

Upper Airway

The infant lung is a unique structure and not a mere miniaturization of the adult lung. The airways, distal lung tissue, and pulmonary capillary bed all continue to grow and develop after birth. Although the general pattern is well developed at birth, both the upper and the lower airways continue to change and are relatively unique in each person.

Figure 9-10 shows the relative differences of the upper airway in relation to body size in an infant and an adult. The greater relative weight of the head can cause acute flexion of the cervical spine in infants with poor muscle tone. Infant neck flexion causes acute airway obstruction. Although the head is larger, an infant's nasal passages are proportionately smaller than those of an adult. In addition, the infant's jaw is much rounder and the tongue is much larger relative to the size of the oral cavity.[17] These anatomic differences increase the likelihood of airway obstruction when an infant becomes unconscious and loses muscle tone.

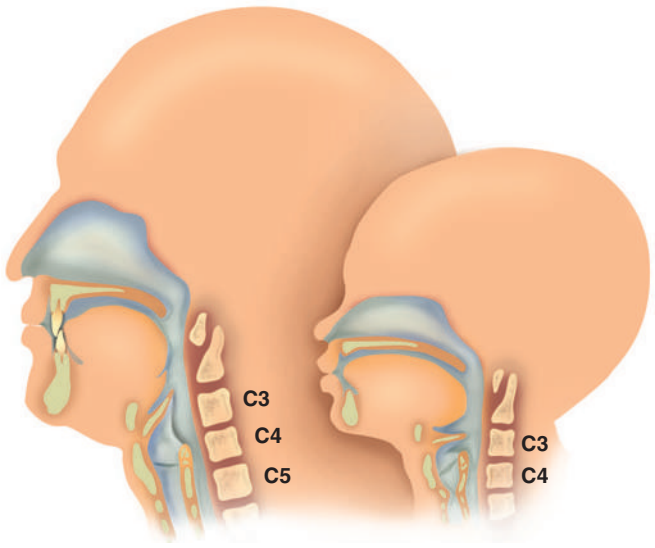

FIGURE 9-10 Adult and pediatric upper airways.

Most infants breathe preferentially through the nose. However, most term newborn infants shift to oral breathing in response to nasal occlusion and hypoxia.[18] As normal infants mature, they begin to use the oral breathing route more with increased capability of shifting to oral breathing when nasal obstruction is present.[19] At approximately 4 to 5 months of age, most infants are capable of full oral ventilation.

A newborn's larynx lies higher in the neck than the larynx of an adult, with the glottis located between C3 and C4, and is more funnel-shaped than that of an adult. In a child, the narrowest region of the upper airway is through the **cricoid cartilage,** rather than the **glottis,** as in adults. The **epiglottis** of an infant is longer and less flexible than the epiglottis of an adult and lies higher and in a more horizontal position. During swallowing, the infant's larynx provides a direct connection to the nasopharynx. This connection creates two nearly separate pathways, one for breathing and one for swallowing, allowing infants to breathe and suckle at the same time. Anatomic descent of the epiglottis begins at 2½ to 3 months of age. Mechanical and chemical irritant laryngeal reflexes develop at birth and can initiate protective laryngeal closure; these reflexes can trigger prolonged apnea in some and may be a cause of sudden infant death syndrome.[20] In addition, infections in this area, repeated attempts at intubation, or suctioning can easily cause swelling, leading to obstruction.

The large conducting airways of infants are shorter and narrower than the airways of adults. The normal newborn trachea is approximately 5 to 6 cm long and 4 mm in diameter, whereas in small preterm infants, it may be only 2 cm long and 2 to 3 mm in diameter. Because of the smaller airways, a newborn's anatomic dead space is proportionately smaller than the anatomic dead space of an adult, being approximately 1.5 ml/kg of body weight. Figure 9-11 compares the tracheal anatomy in an adult and newborn. The main stem bronchi branch off from the trachea in the infant at less acute angles than in the adult. Similar to that in adults, the right main stem bronchus of the infant is still more in line with the trachea, promoting right main stem intubation when airways or suction catheters are inserted too deeply. Mean airway diameter, from main bronchi to respiratory bronchioles, increases approximately two to three times from birth to adulthood.[21]

Smooth muscle is present in the airways of a neonate down to the level of the respiratory bronchioles and continues to increase until the infant is approximately 8 months old. Distinct C-shaped rings of cartilage are found in the trachea and main stem bronchi of the neonate. The amount of cartilage progressively decreases in the more distal bronchi and eventually disappears in airways smaller than 2 mm in diameter.

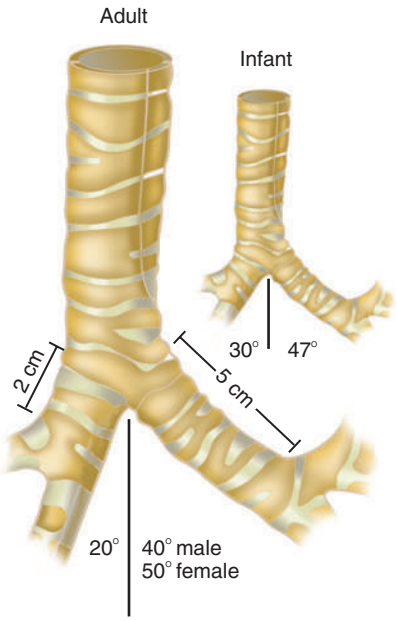

FIGURE 9-11 Adult and infant tracheas showing the different angles of main stem bifurcation.

Despite the presence of cartilage in the central airways of an infant, the trachea and larger bronchi of a neonate lack the rigidity of adult central airways. The compliant nature of these airways makes them prone to collapse and compression.

Lower Airway and Alveoli

The human lung continues to develop alveoli for years until it reaches a stable stage, at which the total number has increased to approximately 480 million alveoli.[22] All development is generally complete by 10 years of age, with most occurring in the first 1½ postnatal year.[23] By adulthood, the alveolar-capillary membrane has a gas exchange surface area of approximately 140 m^2.[24]

Compensatory lung growth can occur rapidly in the lung when part (or all) of the other lung is removed.[25-27] Stem cell activation in the lungs, in response to gene and mechanical stretch, appears to be responsible for alveolar development well into adulthood after loss of lung tissue.[28]

Development of Vascular, Lymphatic, and Nervous Systems

The basic architecture of the pulmonary circulation is complete at birth. The main pulmonary arterial trunk arises from the right ventricle and divides into left and right pulmonary arteries, which supply each lung. These arteries divide further to form direct or conventional arteries and supernumerary arteries. Both types of pulmonary arteries come together to supply blood to large clusters of alveoli that are supplied by a single bronchiole. Most of the growth in the vascular system that occurs after birth includes further smooth muscle growth within the walls of arteries and arterioles and greater density and refinement of the arterioles and capillaries in the distal airway region.[23,29]

The respiratory system is a unique organ in that it receives a double blood supply: one from the left ventricle and one from the right ventricle. The right heart supplies the bulk of the flow to the pulmonary circulation. The left heart supplies a smaller amount of flow (approximately 1% to 2% of cardiac output) to the bronchial arteries, which arise from the aorta and supply oxygenated blood to the tracheobronchial tree. The bronchial arteries supply O_2 to the airway tissue, blood vessels, nerves, lymphatics, and visceral pleura. In addition, O_2 is directly absorbed across the airway lumen. Although the pulmonary and bronchial circulations have entirely different origins and purposes, they mix and supply blood flow to the microcirculation of the alveoli; this provides some collateral circulation and allows the shunting of blood. The lung's double circulation benefits the entire lung in health and helps compensate for deficiencies or disease processes that can affect either circulation.

The lymphatic vessels located in the connective tissue tracts of the lung surround the bronchi, bronchioles, blood vessels, nerves, and pleural membrane. They play a central role in the control of fluid and protein balance within the lung and house various defensive cells. Fluid collected from the pleural space and interstitium is carried by the pleural capillaries and vessels through the lymphatic system back to the root of the lung (**hilum**), where numerous lymph nodes are located.

Before birth, neuronal centers in the brainstem (medulla oblongata and pons) form for the automatic control of breathing, and various afferent and efferent nerves form to sense and control different aspects of the respiratory system. The **phrenic nerves** and **intercostal nerves** are the primary components of the somatic (motor) nervous system that carry nervous signals from the brainstem to the respiratory muscles. They innervate the diaphragm (phrenic nerves) and intercostal muscles (intercostal nerves). These muscles are primarily responsible for enlarging the thorax during inspiration and allow exhalation by relaxing, letting the thorax and lungs recoil back to their preinspiratory position.

Visceral control of the smooth muscle of the respiratory system is carried out by branches of the sympathetic and parasympathetic nervous systems and mediators transported to the lungs via the pulmonary circulation. Nerve fibers from the brainstem and spinal cord enter the lungs and grow in the same connective tissue tracts that surround the airways and house the blood and lymphatic vessels long before birth. These nervous fibers innervate the smooth muscles of the bronchioles to cause bronchodilation (sympathetic fibers), the mucous glands to produce mucus (parasympathetic), and the blood vessels to cause vasoconstriction (sympathetic). Cranial nerve X (*vagus* nerve) carries motor and sensory signals of the parasympathetic system. Branches from each thoracic spinal nerve carry sympathetic motor and sensory signals to and from the lungs.

Chest Wall Development, Diaphragm, and Lung Volume

The thoracic wall in infants is more compliant and their muscles are less developed than the muscles of adults, providing little

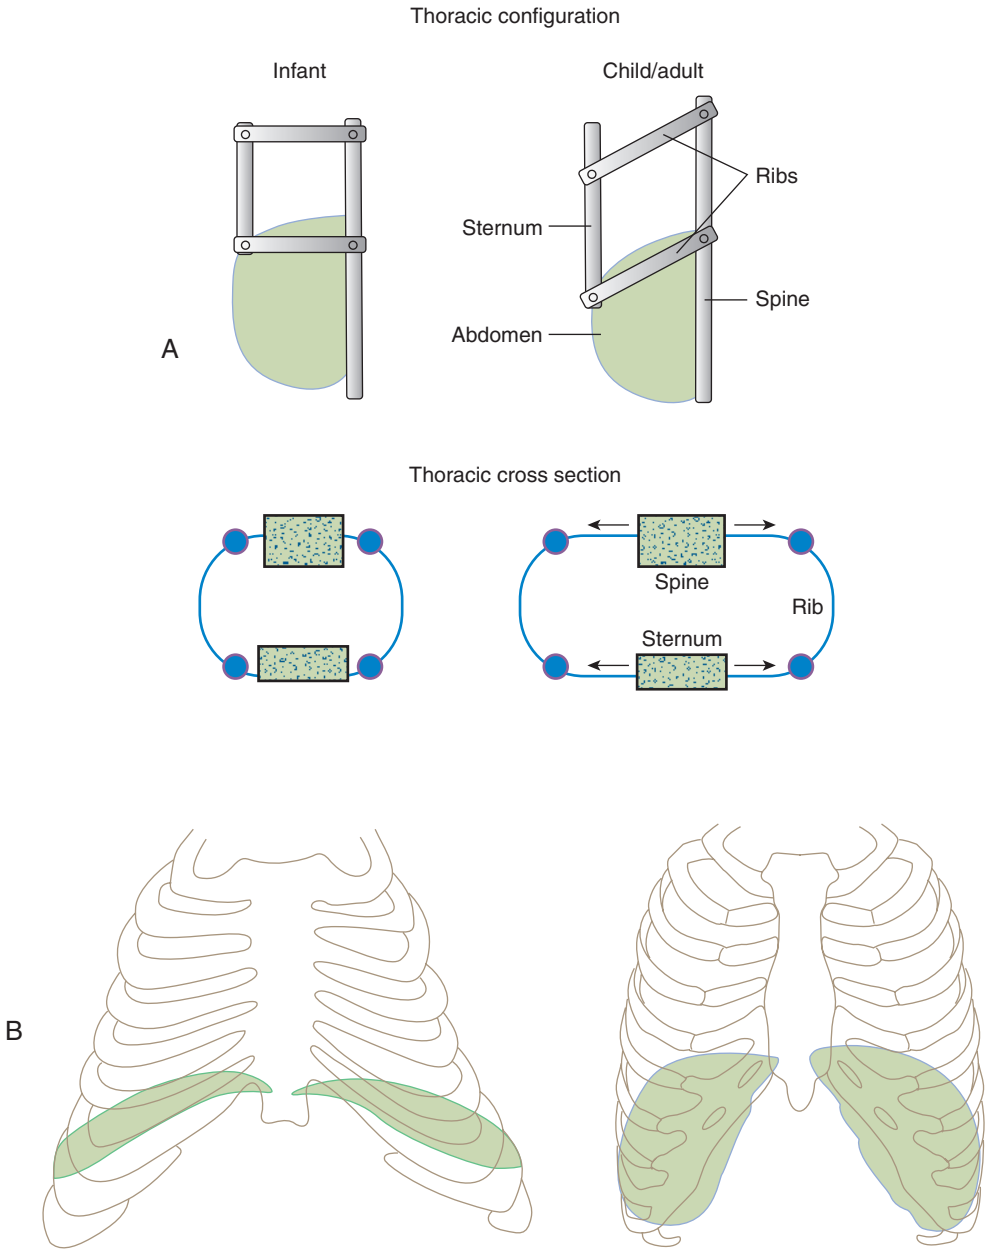

FIGURE 9-12 **A,** Changes in angularity of ribs and spine and cross-sectional shape of the thorax from an infant to an older child and adult. **B,** Anterior views of a newborn *(left)* and adult *(right)* rib cage and the relative position of the diaphragm *(shaded portions).* (Modified from Taussig LM, Landau LI, editors: Pediatric and respiratory medicine, ed 2, St Louis, 2008, Mosby.)

structural support. The infant thoracic cage is also more box-like, with the ribs being horizontally oriented or elevated (Figure 9-12). In addition, the diaphragm inserts into the thoracic cage in a horizontal plane decreasing the effective ability to enlarge the thorax.

As an infant inhales, the diaphragm moves down but the flexible chest wall moves very little in the anteroposterior dimension as the chest wall muscles attempt to pull it upward and outward. Compounding this situation is a proportionately larger abdominal visceral content that restricts the vertical motion of the diaphragm. The ribs take on a progressively downward slope as a child grows, and by 10 years of age the rib cage has the configuration seen in adults. Ossification of the ribs and sternum normally complete by 25 years of age, and this, combined with muscular development, results in a stiffer chest wall that moves more in the anteroposterior dimension with inspiratory effort.

The balance of these static forces results in reduced lung volume within this compliant thorax in an infant. Proportionately lower lung volumes can lead to early airway closure, widespread alveolar collapse (atelectasis), ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch, and resultant hypoxemia. The combination of a reduced lung volume and high O_2 consumption renders the infant more susceptible to profound hypoxemia in situations

disturbing ventilation, lung volume, or $\dot{V}/\dot{Q}$ matching. Infants possess a remarkable ability to elevate their lung volume dynamically. Infants in distress can actively increase lung volume by trapping gas, improving $\dot{V}/\dot{Q}$ matching and gas exchange. Infants actively accomplish gas trapping by using the diaphragm during exhalation. This slows expiration that adducts (closes) the vocal cords and narrows the glottis. The combination of these two maneuvers effectively regulates volume in the lung and dynamically elevates lung volume. The narrowing of the glottis or larynx during exhalation is referred to as "laryngeal braking" or "grunting." Infants in respiratory distress commonly grunt, a manifestation of laryngeal braking. A more compliant chest wall contributes to suprasternal, substernal, intercostal, and subcostal retractions in distressed infants and young children (see Mini Clini).

MINI CLINI

Significance of Thoracic Soft Tissue Retractions

Supraclavicular and intercostal retractions are inward movements of the soft tissues above the clavicle and between the ribs of the chest wall during inspiration. This inward movement causes the clavicle and ribs to stand out prominently during inspiratory efforts.

PROBLEM: Why do infants and adults in respiratory distress with severe airway obstruction or reduced compliant ("stiff") lungs exhibit thoracic soft tissue retractions?

ANSWER: The pressure within the intrapleural space is slightly negative (e.g., –5 cm H_2O) as a result of the tendency of the lung to recoil inward and the rib cage to recoil outward. This pressure becomes more negative (e.g., –8 cm H_2O) during inspiration. The respiratory muscles enlarge the chest as the diaphragm descends and the intrathoracic volume increases. During these conditions, a much greater inspiratory effort is required. This increased effort translates into a much greater decrease in intrathoracic and pleural pressures (e.g., –40 cm H_2O). This greater decrease in intrathoracic and pleural pressure "sucks" the soft tissues inward and causes soft tissue retractions. These retractions significantly increase work of breathing.

RESPIRATORY SYSTEM IN THE ADULT

Surface Features of the Thorax

Thoracic shape and dimension vary from individual to individual and are linked to age, gender, and race. At birth, the thorax has a smaller transverse (side to side) dimension, widening with the onset of walking. Thoracic size and volume continue to increase throughout childhood and especially during the adolescent growth spurt. When evaluating lung size and volume throughout puberty and into adulthood, boys and men are consistently found to have larger lungs than age-matched and height-matched girls and women.[30]

Imaginary lines are commonly used to establish reference points and identify landmarks on the thorax. These lines and points help identify the location of underlying structures and the location of abnormal findings. On the anterior chest, the *midsternal line* divides the thorax into equal halves. The left and right *midclavicular lines* are parallel to the *midsternal line*. These are drawn through the midpoints of the left and right clavicles (Figure 9-13). The *midaxillary line* divides the lateral chest into equal halves. The *anterior axillary* line is parallel to the midaxillary line. It is situated along the anterolateral chest. The posterior axillary line is also parallel to the midaxillary line. It is located on the posterolateral chest wall (Figure 9-14). Three imaginary vertical lines are located on the posterior thorax. The midspinal line divides the posterior chest into two equal halves. The left and right midscapular lines are parallel to the midspinal line. They pass through the inferior angles of the scapulae in a relaxed upright subject (Figure 9-15).

RULE OF THUMB

Anatomic Directions

Descriptions of various anatomic structures often use the following terms:

Anterior, anteriorly	Front of the body, toward the front
Posterior, posteriorly	Back of the body, toward the back
Anteroposterior	In a direction from the front to the back
Lateral, laterally	Side of the body, toward the side
Medial, medially	Midline of the body, toward the midline

Components of the Thoracic Wall

The thoracic cavity is formed by the tissues of the chest, upper back, and diaphragm.[31] It is a cone-shaped cavity that houses the lungs, heart, and the contents of the mediastinum (Figure 9-16). It protects the vital organs within and is capable of changing shape to enable air to be moved into and out of the lungs. The thoracic cavity is formed from epithelial, connective, and muscle tissues.

The various parts of the thoracic wall are shown in Figure 9-17. The outer covering of the thorax is formed by the integumentary system, which includes skin, hair, subcutaneous fat, and breast tissues. Skeletal muscle tissue forms the various muscles of the chest and back and lies over and between the ribs. The ribs lie in the inner portion of the thoracic wall. The inner layer of the thoracic wall is lined with a serous membrane called the **parietal pleura.** It is opposite to another serous membrane called the **visceral pleura,** which covers the lung. A thin, fluid-filled pleural space forms between the parietal and visceral pleural membranes.

The rigidity of the thorax is provided by the bone tissue of the rib cage. The bony parts of the rib cage include the sternum, ribs, thoracic vertebral bones, scapula, and clavicle (Figure 9-18). The **sternum** is a long, vertical flat bone found on the anterior side that is composed of three bones: the **manubrium,**

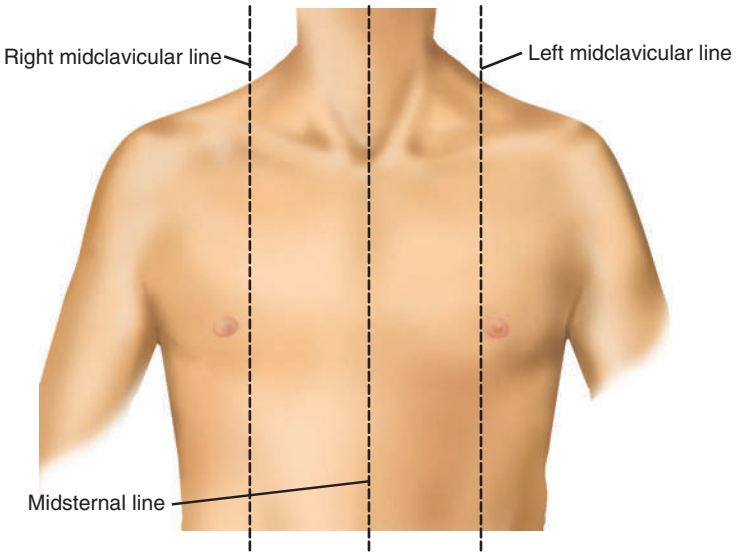

FIGURE 9-13 Anatomic reference lines on the anterior chest wall.

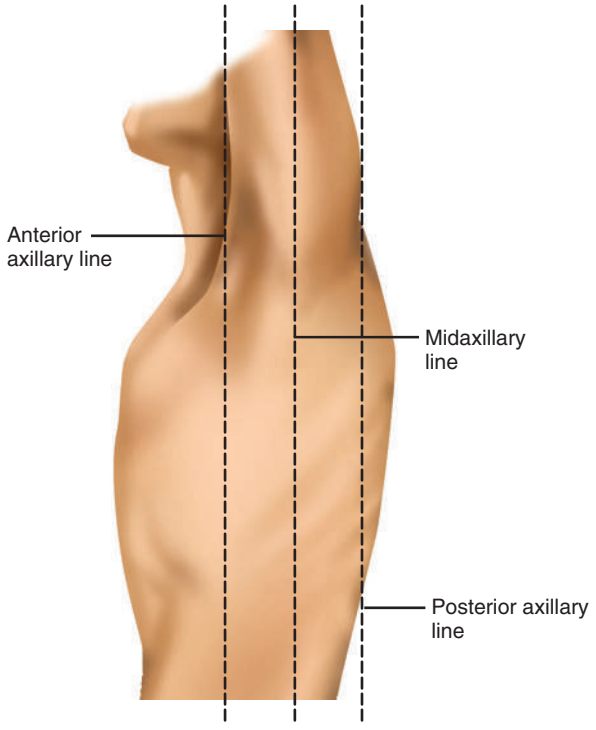

FIGURE 9-14 Anatomic reference lines on the lateral chest wall.

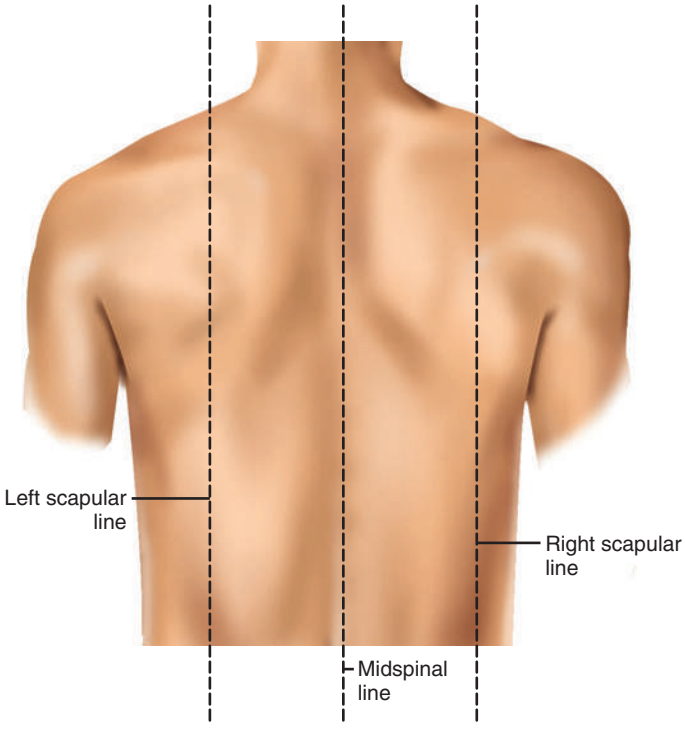

FIGURE 9-15 Anatomic reference lines on the posterior chest.

the body (or **gladiolus**), and the **xiphoid process.** The superior edge of the manubrium forms a shallow depression that is known as the **suprasternal notch** (or jugular notch). The fused connection between the manubrium and the body is known as the **sternal angle;** it is also known as the **angle of Louis.** The sternal angle is an external marker of the point where the trachea divides into the left and right main stem bronchi. A cartilaginous joint called the **costal cartilage** is on the lateral edges of the manubrium and sternal body and forms the attachment between the ribs and sternum. This joint allows the rib cage to bend and permits the thorax to increase and decrease in size.

RULE OF THUMB

Where the manubrium and body of the sternum meet, the anterior chest wall shows a slight depression that forms an oblique angle (when viewed from the side). This depression is referred to as the *angle of Louis*. Beneath this important landmark, the trachea divides into the right and left main stem bronchi.

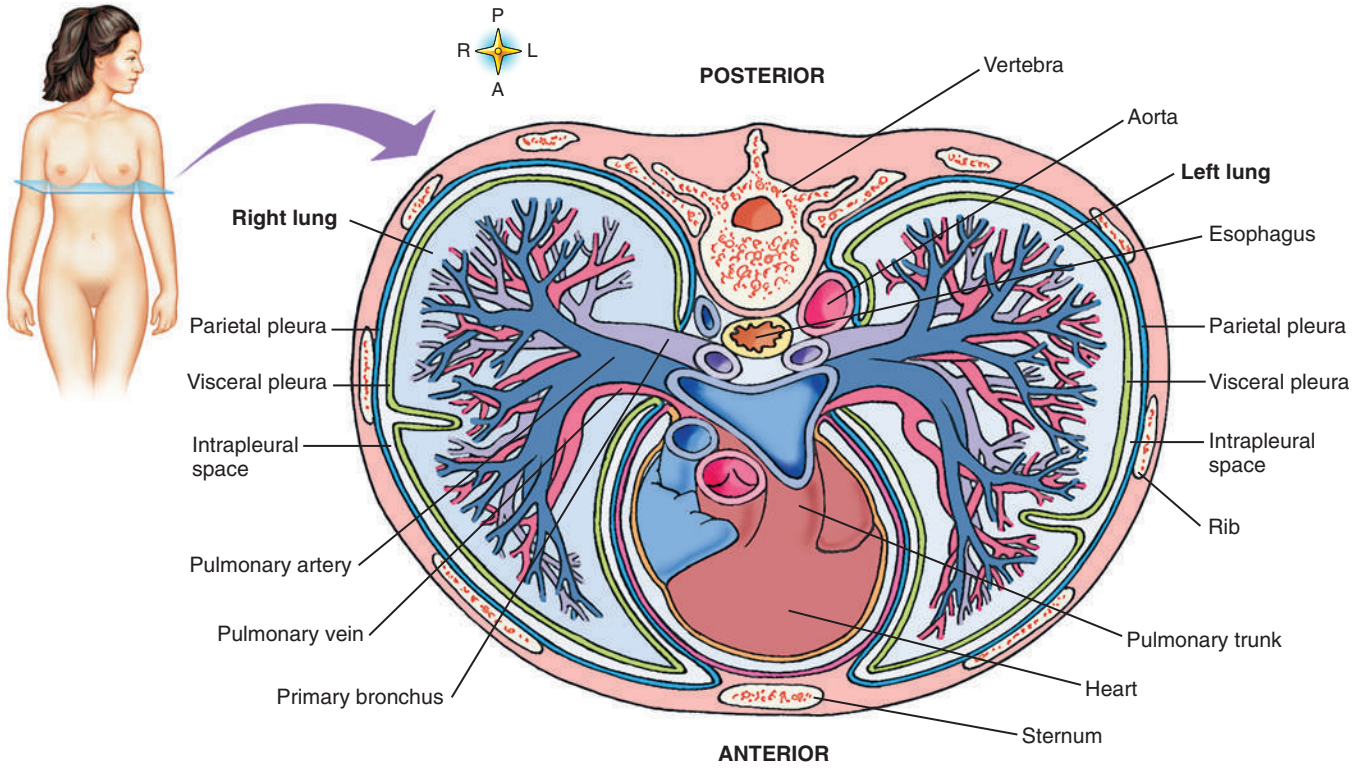

FIGURE 9-16 Transverse sectional view of the thorax showing its contents. (From Thibodeau GA, Patton KT: Anatomy and physiology, ed 7, St Louis, 2011, Mosby.)

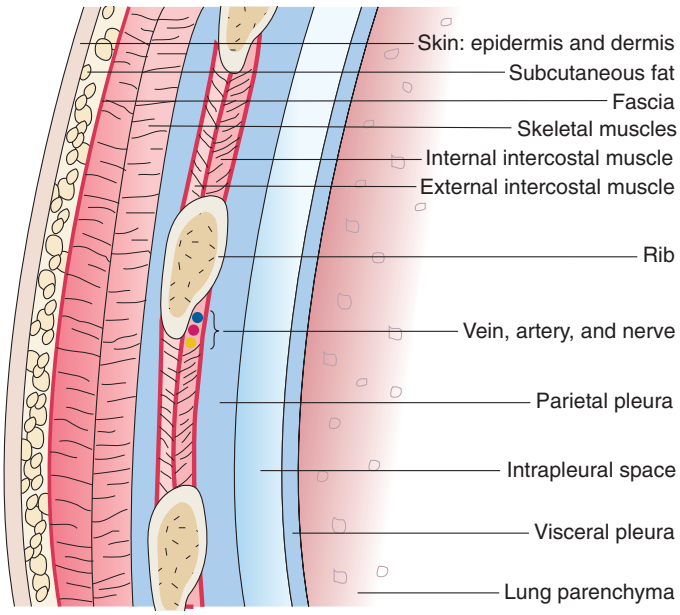

FIGURE 9-17 Sectional view of the thoracic wall. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

The rib cage is formed by 12 pairs of ribs.[31] Rib pairs 1 through 7 are known as the **true ribs** because they are attached directly to the sternum. The first ribs and the upper sternum form the opening into the thorax that is called the *thoracic inlet,* or *operculum.* Ribs 8 through 12 are called **false ribs** because they are neither directly nor indirectly attached to the sternum. The vertebrochondral rib pairs 8, 9, and 10 are indirectly attached to the sternum through a common cartilaginous strap. Rib pairs 11 and 12 are called **floating ribs** because they are not attached to the sternum. Each rib has a sternal end; a long, curved, and relatively flat body; and a head that articulates with the thoracic vertebrae (Figure 9-19). Intercostal muscles lie between the ribs and hold them together. Just below each rib, in the costal groove, is a thoracic artery, vein, and nerve, supplying blood flow and nerve communications to that region of the chest wall (see Figure 9-17).

RULE OF THUMB

Numerous procedures require entry into the pleural cavity, such as thoracentesis or chest tubes. Insertions made during these procedures are always done directly above a selected rib to avoid injuring important structures. The intercostal nerves, veins, and arteries all lie in a groove below each rib.

The upper and lateral regions of the thorax house the bones of the pectoral girdles. The pectoral girdle on each side is formed by the clavicle and scapula.[31] The scapula forms the socket for the shoulder joint and is stabilized or moved by skeletal muscles of the upper back. The clavicle supports and stabilizes the shoulder joint through a flexible attachment to the manubrium of the sternum.

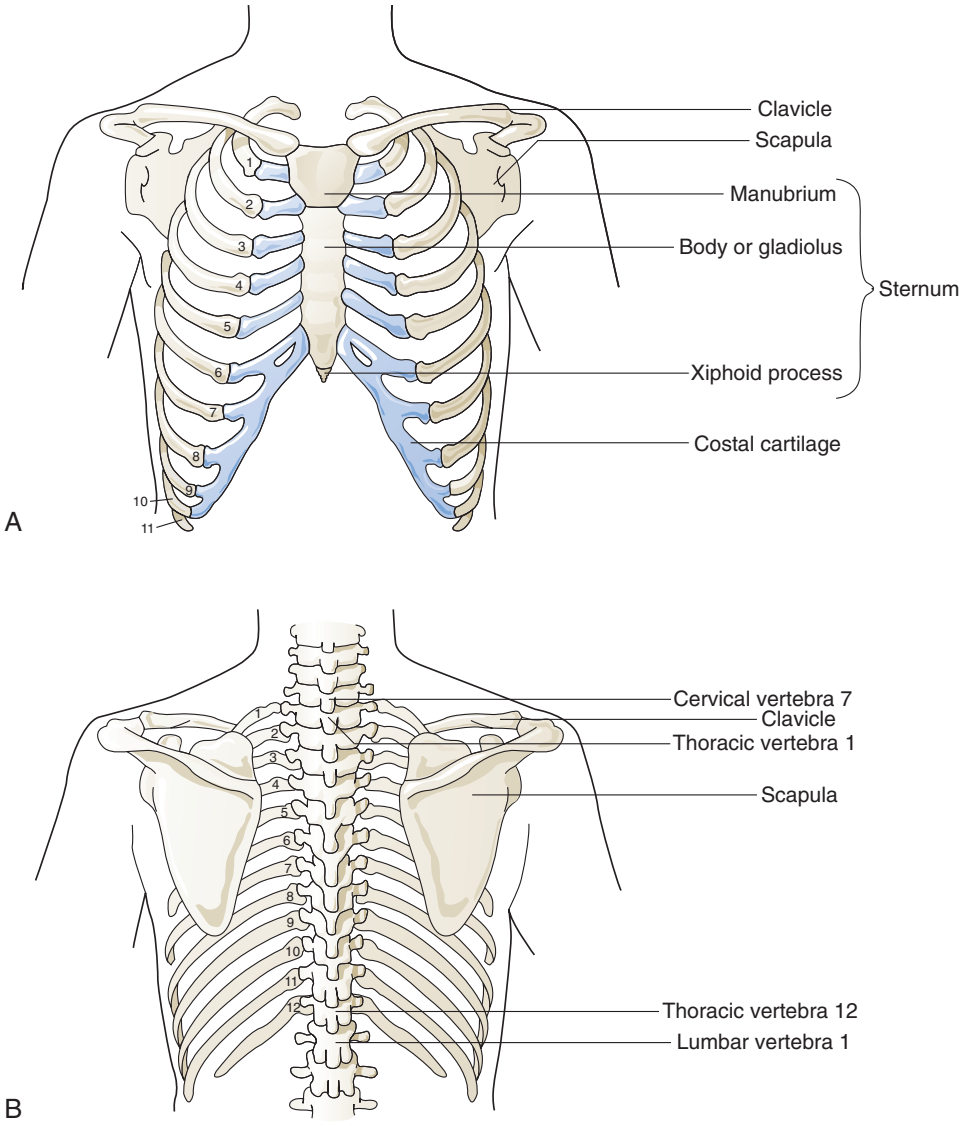

FIGURE 9-18 Anterior **(A)** and posterior **(B)** views of the bones of the thorax. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

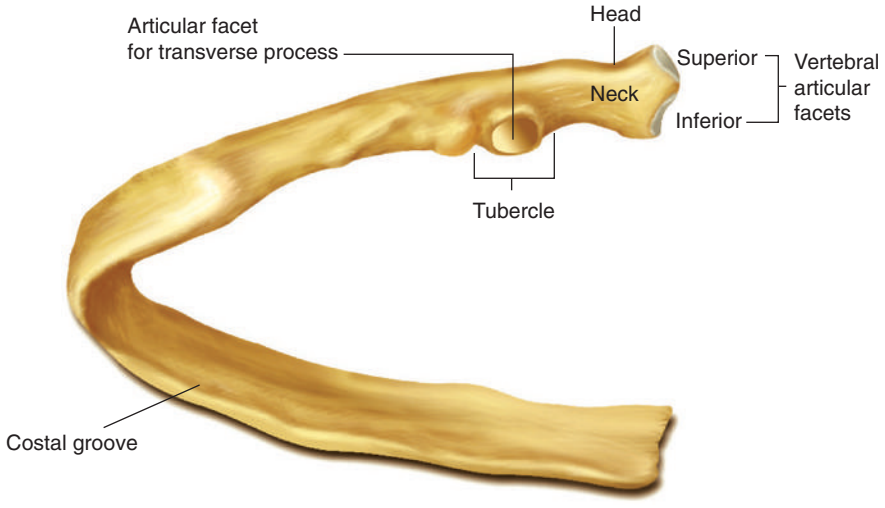

FIGURE 9-19 Typical middle rib as viewed from the posterior. The head end articulates with the vertebral bones, and the distal end is attached to the costal cartilage of the sternum.

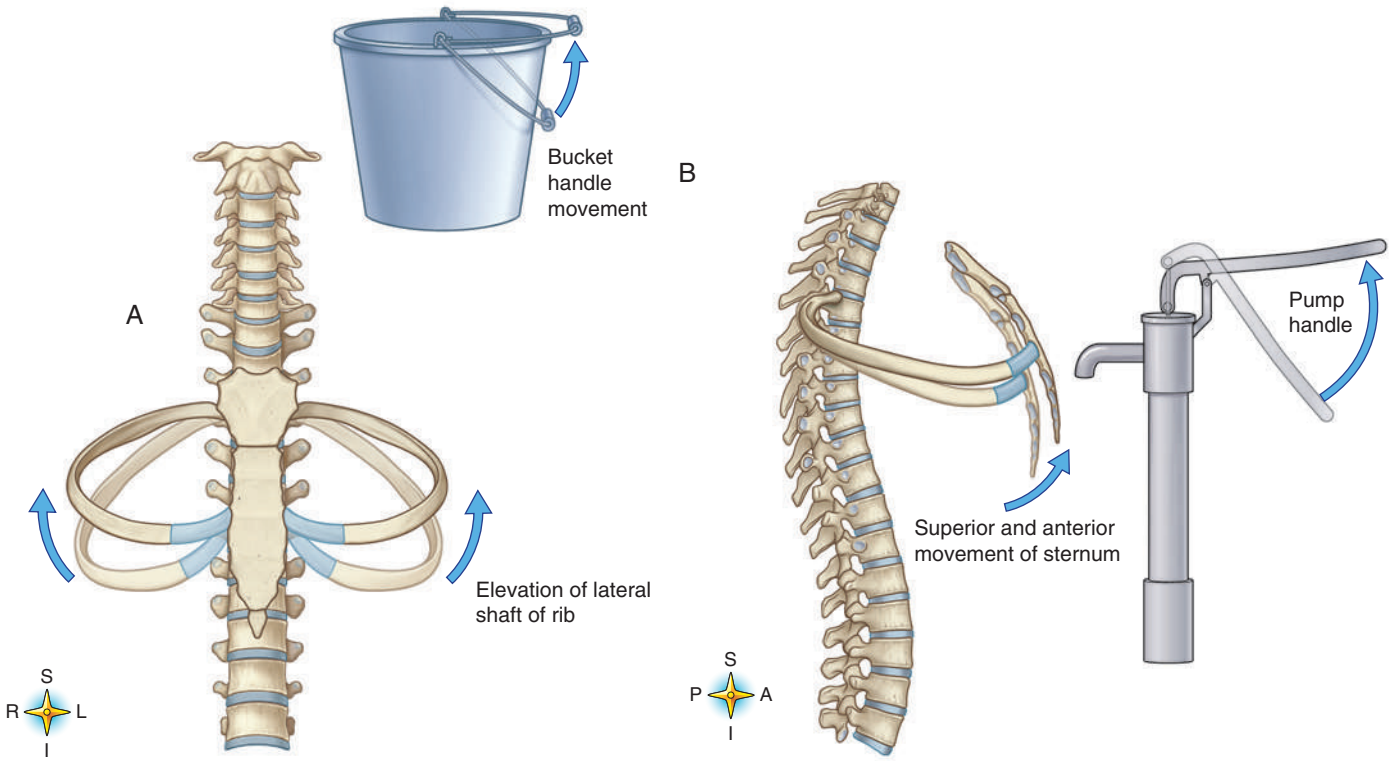

FIGURE 9-20 "Bucket handle" type and "pump handle" type of rib motions. (From Thibodeau GA, Patton KT: Anatomy and physiology, ed 7, St Louis, 2011, Mosby.)

Rib Movement

The various ribs move in different ways, and some may move more than others at different times. The first rib moves slightly, raising and lowering the sternum. Its slight motion increases the anteroposterior diameter of the chest. This action is not used during quiet breathing and becomes active only under conditions that require increased ventilation or deep breathing. Ribs 2 through 7 can move simultaneously about two axes (Figure 9-20). As each rib rotates about the axis of its neck its sternal end rises and falls. This movement increases the anteroposterior thoracic diameter in what is commonly referred to as a "pump handle" motion. At the same time, the rib moves about its long axis from its angle at the sternum. This motion causes the middle part of the rib to move up and down in what is commonly described as a "bucket handle." The compound action of ribs 2 through 7 changes both the anteroposterior and the transverse dimensions in an upward and outward motion. Ribs 8 through 10 rotate in a pattern similar to that of ribs 2 through 7. However, elevation of the anterior ends of these ribs produces a small backward movement of the lower sternum that slightly reduces the thoracic anteroposterior diameter. Outward rotation of the middle section of these ribs increases the transverse diameter of the thorax. Ribs 11 and 12 participate in changing the contour of the chest in a minor way as they are pulled upward and outward in a "caliper" motion.

Respiratory Muscles

Changes in thoracic cavity dimension during breathing are the product of tension developed by various skeletal muscles known as the *respiratory muscles.*[32] Their origins, insertions, somatic nervous supply, and actions are summarized in Tables 9-4 and 9-5. The **diaphragm** and **intercostal muscles** are the primary muscles of ventilation. They are active both while at rest and when the individual exhibits stress-induced increases in breathing. The accessory muscles of ventilation assist the diaphragm and intercostal muscles when ventilatory demand increases. The scalene, sternocleidomastoid, pectoral, and abdominal wall muscles are the predominant accessory muscles. Other abdominal and chest wall muscles may function as accessory muscles when needed.

The diaphragm is a thin, musculotendinous, dome-shaped structure that separates the thoracic and abdominal cavities (Figure 9-21).[33] It originates from the chest and abdominal wall and converges in a central tendon at the top of its dome. The diaphragm is a highly aerobic and fatigue-resistant muscle compared with other skeletal muscles and more capable of long-term rhythmic contraction.

In an upright position and with the diaphragm relaxed, the liver forces the dome of the right hemidiaphragm upward approximately 1 cm higher than the left hemidiaphragm at the end of a quiet exhalation. The highest portion of the right dome sits at the eighth or ninth thoracic vertebra posteriorly and at the fifth rib anteriorly. The left diaphragmatic dome sits at the ninth or tenth thoracic vertebra posteriorly and the sixth rib anteriorly. Movements of the hemidiaphragms are synchronous in healthy subjects. When lying down in a supine position, the weight of the abdominal contents forces the diaphragm farther up into the thoracic cavity. During quiet breathing, the

TABLE 9-4

Respiratory Muscles That Expand the Thorax During the Inspiratory Phase

Muscle	Origin	Insertion	Innervation	Action
Diaphragm	Xiphoid process, lower lateral ribs, lumbar vertebra	Central tendon of dome	Phrenic nerves (C3-5)	Diaphragm moves downward, abdominal wall forced outward
External intercostals	Upper ribs	Lower ribs	Intercostal nerves (T1-12)	Lift ribs upward
Scalene	Lower five cervical vertebrae	Ribs 1 and 2	Cervical nerves (C5-8)	Lifts ribs 1 and 2
Sternocleidomastoids	Manubrium and clavicle	Mastoid process of occipital bone	Accessory nerves (cranial nerve XI)	Lift sternum
Trapezius	Occipital bone, C7-T12 vertebrae	Scapula and clavicle	Accessory nerves (cranial nerve XI)	Stabilizes head
Pectoralis minor	Anterior region of ribs 3-5	Scapula	Pectoral nerves (C6-8)	Lifts upper ribs
Pectoralis	Clavicle and sternum	Humerus	Pectoral nerves (C5-C8)	Lifts sternum

TABLE 9-5

Respiratory Muscles That Compress the Thorax During the Expiratory Phase

Muscle	Origin	Insertion	Innervation	Action
Internal intercostals	Lower ribs	Upper ribs	Intercostal nerves (T1-12)	Pull ribs down
External oblique	Anterior lower eight ribs	Linea alba and iliac crest	Lower intercostal and iliohypogastric nerves (T7-12)	Pulls abdominal wall inward
Internal oblique	Lumbar vertebrae, iliac crest, and inguinal ligaments	Costal region of ribs and pubis	Lower intercostal and iliohypogastric nerves (T10-12 and L1)	Pulls abdominal wall inward
Transverse abdominis	Costal region of lower ribs, iliac crest, and inguinal crest	Linea alba	Lower intercostal and iliophypogastric (T7-L1)	Pulls abdominal wall inward
Rectus abdominis	Costal region and ribs 5-7	Pubis	Lower intercostal and iliophypogastric (T7-12)	Pulls abdominal wall inward
Serratus anterior	Costal region of upper eight ribs	Scapula	Long thoracic nerves (T5-7)	Compresses thorax when arm is stabilized
Serratus, posterior superior	Lower cervical and upper thoracic vertebrae	Posterior ribs 2-5	Intercostal nerves	Pulls ribs downward
Serratus, posterior inferior	Lower thoracic and upper lumbar vertebrae	Posterior ribs 9-12	Thoracic nerves	Pulls ribs downward
Latissimus dorsi	Lower thoracic, lumbar, sacral vertebrae, ilium, and lower ribs	Humerus	Thoracodorsal nerve (C6-8)	Compresses thorax when arm is stabilized

diaphragm is responsible for approximately 75% of the change in thoracic volume.[34] When the muscle fibers of the diaphragm are tensed during inspiration, the dome of the diaphragm is pulled down 1 to 2 cm; this results in enlargement of the thoracic cavity and compression of the abdominal contents. During maximal inspiration, the diaphragm can be pulled down approximately 10 cm. Exhalation results when diaphragmatic tension decreases and the diaphragm returns to its relaxed position.

Increased lung volume causes the diaphragm to flatten out. Contraction of a flattened diaphragm can result in tension on the lower ribs that causes them to be pulled inward, resulting in compression of the thoracic cavity. This condition can occur in individuals with severe gas trapping as a result of emphysema or asthma. To compensate, these individuals must recruit other muscles to enlarge the thorax. Less efficient breathing and excessive muscle work results. Nonpulmonary diseases also can affect diaphragm function. Abdominal wall muscle tensioning *(splinting)* owing to pain, abdominal distention with fluid *(ascites),* or other causes of rigidity of the abdominal wall can interfere with diaphragmatic descent during inspiration.

Functionally, the diaphragm is divided into a right and a left hemidiaphragm. Each hemidiaphragm is innervated by a phrenic nerve that arises from branches of spinal nerves C3, C4, and C5.[33] Spinal cord injuries at or above the level of the third cervical vertebrae result in diaphragmatic paralysis. In this situation, the individual has lost *all* nervous control of the respiratory muscles and is unable to spontaneously breathe. Unilateral phrenic nerve injury or disease to one side can spare the other nerve and permit unilateral ventilation.

Although the diaphragm is the primary ventilatory muscle, it is not essential for survival. Limited, short-term ventilation is possible using accessory muscles even if the diaphragm is paralyzed. If either or both of the hemidiaphragms are paralyzed, the affected hemidiaphragm remains in a resting position. During deep inspiration, the paralyzed diaphragm rises as other ventilatory muscles reduce the intrathoracic pressure. During quiet breathing, the paralyzed diaphragm may remain

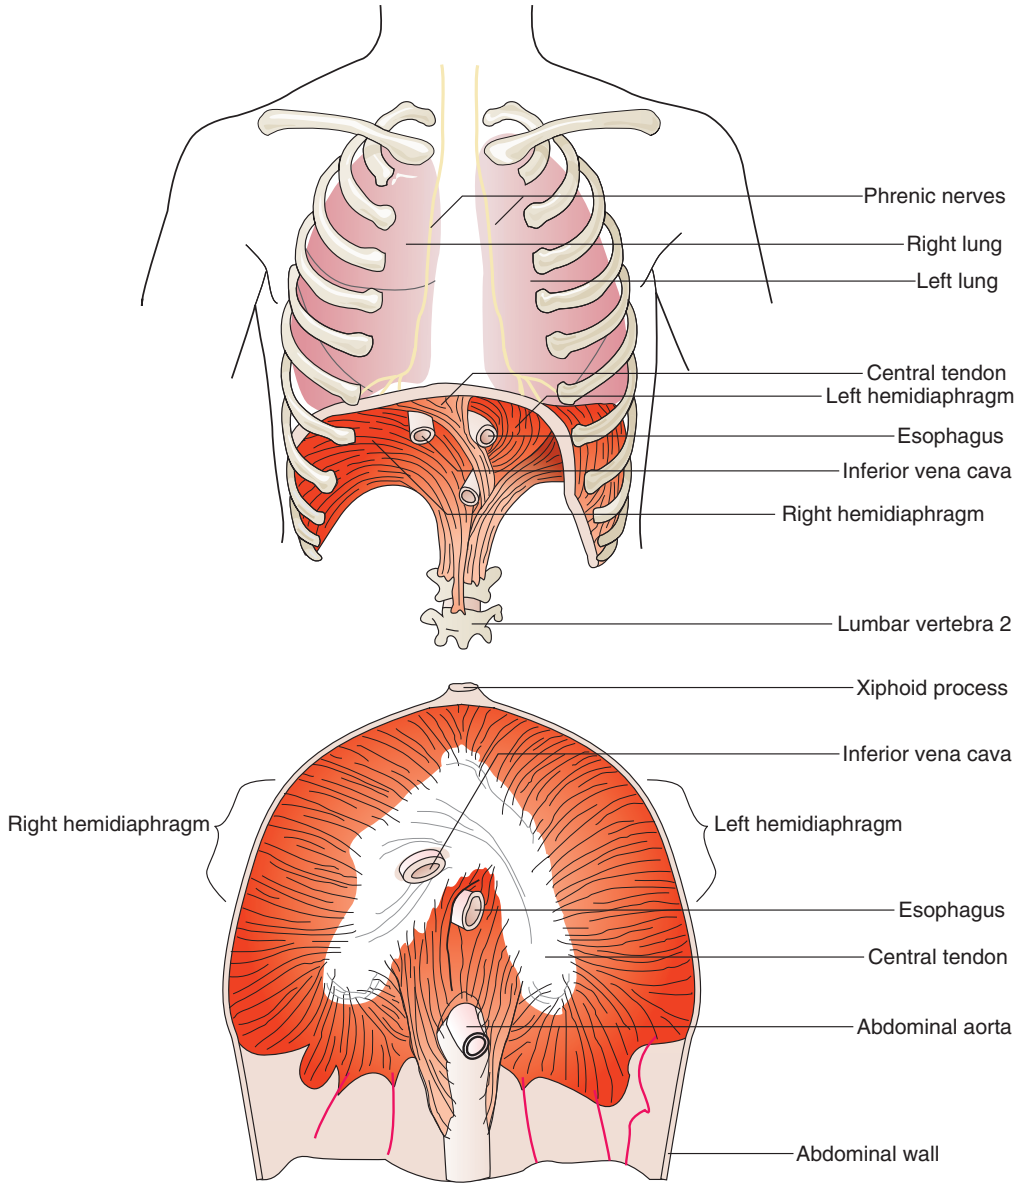

FIGURE 9-21 The diaphragm originates from the lumbar vertebrae, lower ribs, xiphoid process, and abdominal wall and converges in a central tendon. Note the locations of the phrenic nerves and openings for the inferior vena cava, esophagus, and abdominal aorta. MINI CLINI

Lung Hyperinflation in Emphysema

Emphysema is a disease characterized by the destruction of the alveolar region of the lungs. This destruction causes the emphysematous lung to have less elastic recoil than a normal lung.

PROBLEM: Why do patients with severe emphysema have enlarged or overinflated lungs? How does hyperinflation interfere with breathing? What can be done to alleviate the problem?

ANSWER: The pathologic findings of emphysema include the destruction of elastic fibers in the alveolar region, reduced lung recoil, and expansion of the remaining lung tissue. As the disease progresses, the tendency of the lungs to collapse (because of their inherent elasticity) becomes less than the normal outward expanding force of the rib cage (because of its higher elasticity). The stronger outward expanding force of the rib cage expands the lungs, increases their volume, and results in overinflated lungs at the end of a normal, resting exhalation.

Hyperinflation "flattens" the diaphragm for similar reasons, making it less effective during inspiration, increasing work of breathing. Loss of elastic tissues allows small airways to collapse, resulting in air trapping and exaggerating hyperinflation.

Therapy for emphysema is directed at reducing the effects of air trapping. Administration of bronchodilators and corticosteroids may improve airway opening, reducing trapped gas and the work of breathing. Maneuvers such as pursed-lip exhaled breathing also may assist in reducing gas trapping by splinting open the airways and facilitating exhalation. Surgical removal of overdistended lung tissue (bullae) is known as *lung volume reduction surgery* and also may be beneficial. Surgical removal of nonfunctional hyperexpanded tissue may allow the remaining lung tissue to be better ventilated and improve gas exchange at the alveolar level.

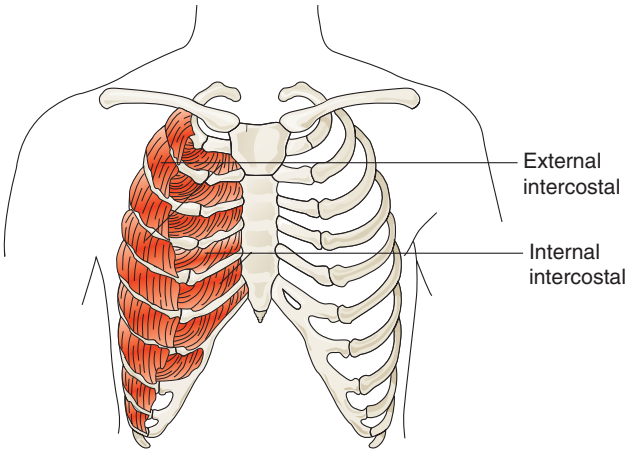

FIGURE 9-22 The external intercostal muscles lift the inferior ribs and enlarge the thoracic cavity. The internal intercostal muscles compress the thoracic cavity by pulling the ribs together. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

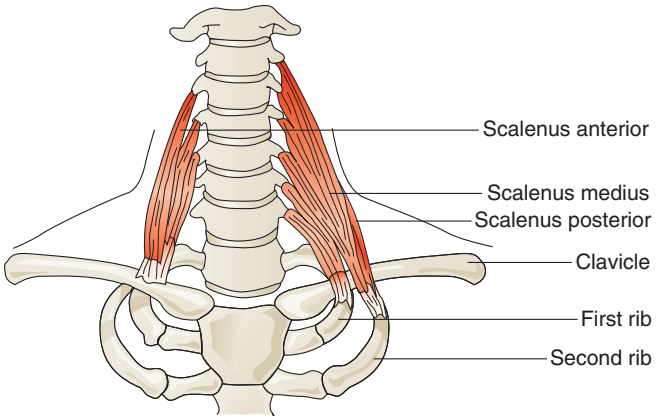

FIGURE 9-23 The scalene muscles originate from the lower cervical vertebrae and lift the clavicle and first two ribs. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

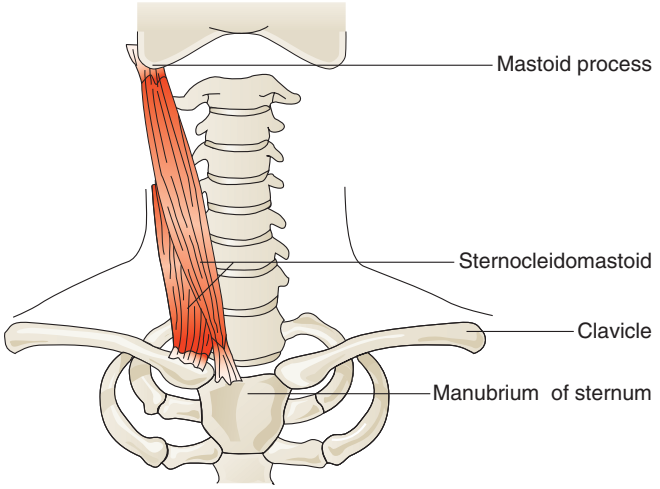

FIGURE 9-24 The sternocleidomastoid muscles originate from the manubrium and clavicle and insert on the mastoid process of the temporal bone. They lift the upper thorax when the trapezius stabilizes the head. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

immobile or may move in either direction. The pressures above and below a paralyzed diaphragm tend to make it rise during inspiration.

Because exhalation is *passive,* the diaphragm normally does not actively participate in exhalation. During exhalation it returns to its resting position during the passive recoil of the lungs and thorax. During forced exhalation, abdominal wall muscles compress the abdominal cavity and increase pressure in the abdominal cavity. The diaphragm is forced upward and the lungs compress, forcing gas from them. The diaphragm performs important functions other than ventilation; it aids in generating high intraabdominal pressures by remaining fixed while the abdominal muscles contract, facilitating vomiting, coughing, sneezing, defecation, and parturition.

During quiet breathing, the diaphragm does most of the work. Other muscles are slightly active during quiet breathing and become more active with forceful breathing. These other muscles are generally known as the **accessory muscles of breathing.**

The accessory muscles of inspiration include various muscles in the neck, chest, and upper back. The external intercostal muscles (Figure 9-22) originate on the upper ribs and attach to the lower ribs. The fibers of these muscles run at an oblique angle between the ribs. When they generate tension the ribs lift upward and cause the thoracic cavity to enlarge the thorax (Hamberger mechanism). Nerve signals are received from the intercostal nerves that arise from thoracic spinal nerves (T1 to 12). They are more active during the inspiratory phase of forceful breathing and are thought to play a role in stabilizing excessive rib motion during forceful breathing.[35]

Three pairs of **scalene muscles** (scalenus anterior, scalenus medius, and scalenus posterior) arise from the lower five or six cervical vertebrae and insert on the clavicle and first two ribs (Figure 9-23). They lift the upper chest when active. The scalene muscles are slightly active during resting inhalation and become more active with forceful inspiration, especially when ventilatory demands increase.[36] Such instances may occur in healthy subjects during exercise or in patients who have pulmonary disease. In healthy subjects, inspiratory efforts against a closed glottis or obstructed airway activate the scalene muscles. When alveolar pressure decreases to −10 cm H_2O, scalene muscles are active in all subjects. The scalene muscles are largely inactive during expiratory efforts but can become active to fixate the ribs as abdominal muscles contract during forceful exhalation such as coughing.

Sternocleidomastoid muscles (Figure 9-24) originate from the manubrium and clavicle and insert on the mastoid process of the temporal bone. Normally, this muscle flexes and rotates the head and is active during shoulder shrugging. When the head is held in an upright position by tensing the trapezius

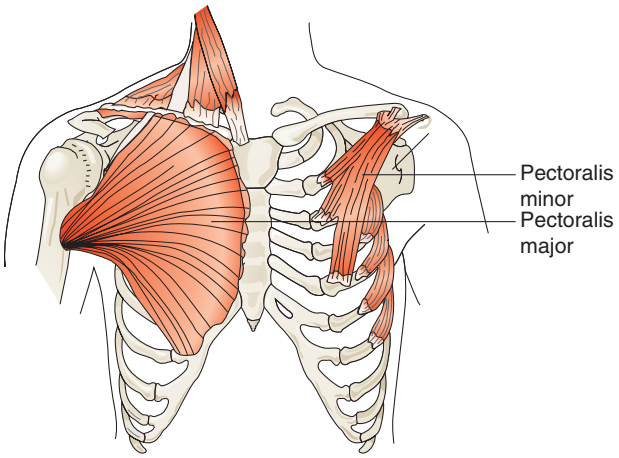

FIGURE 9-25 The pectoralis major and minor can lift and enlarge the thorax when the arms are braced by leaning forward on the elbows (tripod position). (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

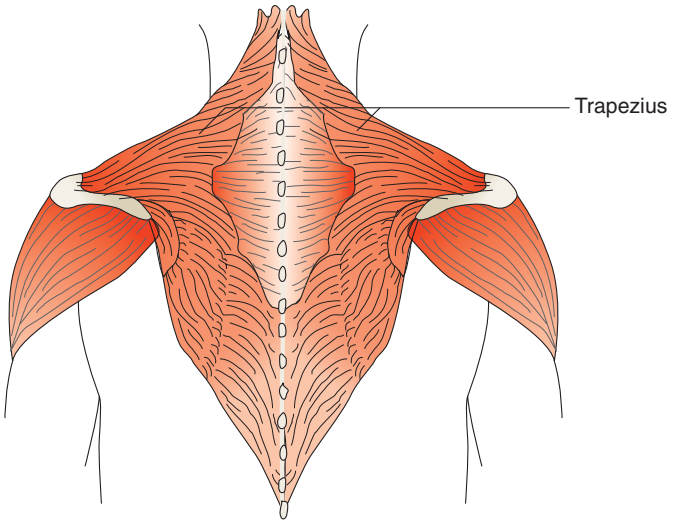

FIGURE 9-26 The trapezius assists forceful inspiration primarily by stabilizing the head, which allows the sternocleidomastoid to lift the anterior thorax. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

muscle of the upper back and neck, the sternocleidomastoid muscles can function to lift the upper chest. These muscles are active during forceful inspiration and become visible as thick bands on either side of the neck during the inspiratory phase in an individual who is in respiratory distress. This motion increases the anteroposterior diameter of the chest.[37]

RULE OF THUMB

Patients with advanced chronic obstructive pulmonary disease (COPD) often use accessory muscles to assist the flattened diaphragm, helping relieve their work of breathing. The muscle groups used include the shoulder and neck muscles. To use these muscles, the shoulder girdle must be stabilized. Patients with COPD often do this by supporting their arms on a stationary object in front of them, forming a "tripod" position. This immobilizes the shoulders and allows the accessory muscles to raise the anterior chest wall.

The major and minor pectoralis muscles are broad fan-shaped muscles of the upper anterior chest (Figure 9-25). The pectoralis major originates on the humerus and inserts onto the clavicle and sternum. The pectoralis minor originates from the anterior region of the ribs 3 through 5 and inserts onto the scapula. They normally function to adduct the arms in a hugging motion. They are also capable of generating some anterior thoracic lift when the arms are braced on a surface in front of a subject. Individuals who have chronic shortness of breath often use these muscles by sitting in the "tripod" position (see Rule of Thumb).

The trapezius muscles are flat, triangular muscles located on the upper back and neck (Figure 9-26). Their action is to rotate the scapulae, lift the shoulders, and flex the head up and back. During forceful inspiration, they become more active by helping brace the head and allowing the sternocleidomastoid muscles to lift the thorax.

The accessory muscles of exhalation become active during forceful breathing (see Table 9-5). Generally, these muscles compress the thoracic cavity and facilitate exhalation. The internal intercostal muscles (see Figure 9-22) lie between the ribs and just behind the external intercostal muscles. The muscle fibers of the internal intercostal muscles run downward and less obliquely than the external intercostal muscle fibers. This orientation causes these muscles to pull the ribs together, which results in compression of the thoracic cavity. They are stimulated by branches of the intercostal nerves and are most active during forceful exhalation. They also become active toward the end of deep inhalation and antagonize the lifting effect of the external intercostal muscles, which effectively stabilizes rib motion during forceful exhalation.[37]

When the abdominal wall muscles contract, they compress the abdominal cavity. This compression forces the diaphragm upward, compressing the thoracic cavity. The abdominal muscles include pairs of **external oblique**, **internal oblique**, transverse abdominis, and **rectus abdominis muscles** (Figure 9-27).[38] The external oblique muscles are the outermost layer of abdominal wall muscle and lie over the lateral aspects of the abdominal cavity. The internal oblique muscles lie just underneath the external oblique muscles. They originate on the lumbar vertebrae, iliac crest, and inguinal ligaments, inserting into the pubis and costal region of the lower ribs; this results in a fiber orientation that is at right angles to the external oblique muscles. The transverse abdominis muscles lie below the internal oblique muscles. Muscle fibers of the transverse abdominis run around the lateral wall of the abdomen. The rectus abdominis muscles are a pair of muscular bands that run vertically on the anterior surface of the abdomen. These muscular bands arise from the pubis, travel upward over the abdominal cavity, and insert into the costal region of ribs 5, 6, and 7 and the xiphoid process of the sternum.

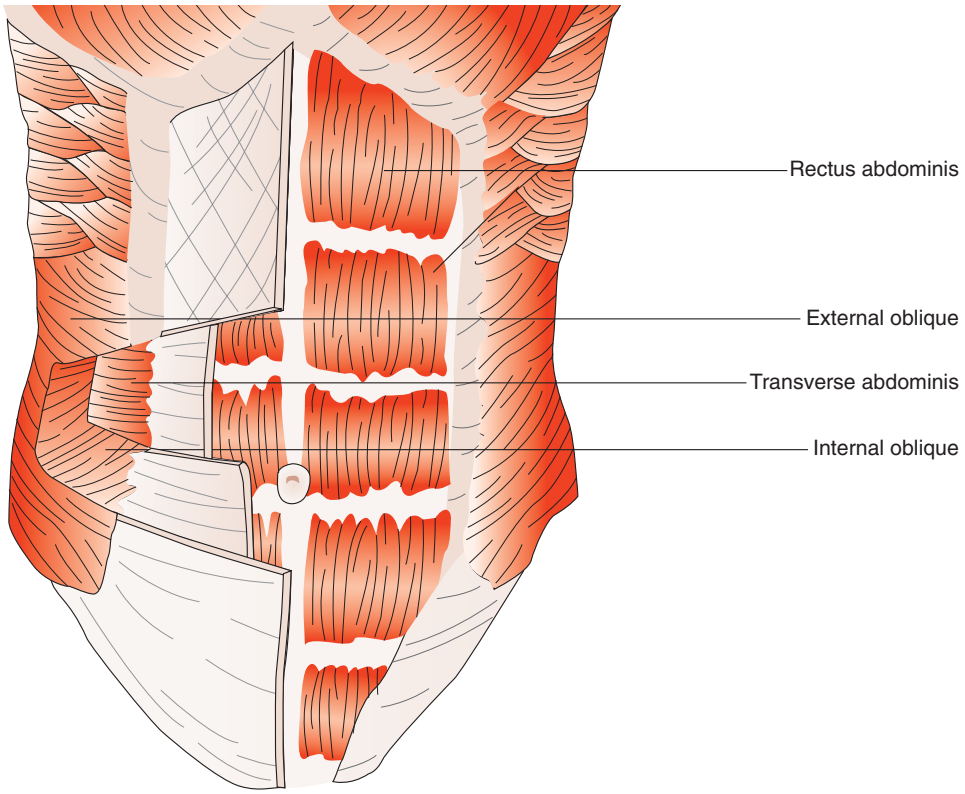

FIGURE 9-27 The abdominal wall muscles compress the thoracic cavity by compressing the abdominal wall and forcing the diaphragm upward. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

Forceful contraction of the abdominal wall muscle group results in increasing intraabdominal pressure, forcing the diaphragm upward and compressing the thorax.

Abdominal wall muscles are active during resting and forceful exhalation.[39] They become more active when the elastic recoil of the lung and thorax cannot provide the needed expiratory flow during forceful exhalation, such as coughing, sneezing, talking loudly, and playing wind-powered musical instruments.[40] The most active muscle of the group during resting and forceful exhalation in most body positions is the transverse abdominis. The least active muscles are the rectus abdominis. The abdominal muscles also can contribute to inspiration by contracting at end-exhalation. This contraction reduces end-expiratory lung volume so the chest wall can recoil outward, assisting the next inspiratory effort.[41] Elevating abdominal pressure increases both the length and the radius of curvature of the diaphragm. Both of these effects result in greater transdiaphragmatic pressure for a given contractile tension. In patients with chronic obstructive pulmonary disease (COPD), any increase in ventilatory demand significantly increases the use of the abdominal muscles. Loss of effective use of the abdominal wall muscles results in a marked inability to exhale forcefully and to cough effectively.

Pleural Membranes, Space, and Fluid

The thoracic cavity is subdivided into the mediastinum and the left and right pleural cavities. The centrally located mediastinum contains the trachea, esophagus, heart, great vessels, and other organs.[42] The left and right pleural cavities contain the lungs. The surfaces of the inner thoracic wall, mediastinum, and lungs are covered with serous membranes called the *pleural membranes* (see Figure 9-17). The parietal pleural membrane lines the chest wall and mediastinum, whereas the lungs are covered by the visceral pleura. Both membranes are constructed from a thin surface layer of mesothelial cells, and below the layer of mesothelial cells is a layer of connective tissue that houses blood vessels, lymphatic vessels, and nerve fibers.[43] Numerous microscopic openings, called *stomata,* are found in the surface of the pleura and are surrounded by mesothelial cells. The stomata open into the lymphatic drainage system of the pleural membrane. The parietal pleura contain sensory fibers that are responsible for the painful sensation that is associated with inflammation of the pleura—a condition called *pleurisy*.

The space between the membranes is called the *pleural space* and is filled with approximately 0.26 ml/kg, or about 18 ml in a 70-kg adult, of pleural fluid.[44] Pleural fluid is a clear fluid with a pH of 7.60 to 7.65 that has few cells, a small amount of protein (about 1 g/dl), and glucose and electrolytes in concentrations that approximate those of plasma. The small volume of pleural fluid is spread out over the entire surface of both lungs and functions as a lubricant to reduce friction as the lungs move within the thorax. It acts as an airtight seal that adheres together the two pleural membranes. Pleural fluid is secreted and reabsorbed by the two pleural membranes. A little more than half

of the pleural fluid is thought to be produced by the parietal pleura. Pleural fluid is formed from the systemic blood flow to each pleura. Blood pressure–driven filtration is supplied to the parietal pleura by blood flow from the intercostal arteries. The bronchial circulation of the lung supplies most of the blood flow to the visceral pleura.

It is estimated that the pleurae produce 150 to 250 ml of pleural fluid per day.[45] Most of the fluid is thought to be absorbed by the visceral pleura capillaries. The rest is cleared by drainage through the lymphatic stomata of parietal pleura by solute-coupled liquid absorption and through some transcytosis. Fluid and solutes or cells cleared by lymphatic drainage are carried by the pulmonary lymphatics to the hilar region. There they enter the major lymphatic vessels draining back to the subclavian veins and right heart.

The angle where the costal parietal pleura join the diaphragmatic parietal pleura is known as the **costophrenic angle.** It is located in the right and left lateral and inferior regions of the thoracic cavities. This angle is clearly visible and is an important landmark in the normal chest radiograph. Normally it is a sharp angle of approximately 30 to 45 degrees. Abnormal excess of fluids between the visceral and parietal pleura tend to pool here in an upright individual. This pooling of fluid causes the angle to appear blunted or flattened to 90 degrees when viewed in the chest radiograph.

Mediastinum

The **mediastinum** lies between the left and right pleural cavities that contain the lungs (see Figure 9-16). The mediastinum is bounded on either side by the pleural cavities, anteriorly by the sternum, posteriorly by the thoracic vertebrae, inferiorly by the diaphragm, and superiorly by the thoracic inlet. The mediastinum can be subdivided into three subcompartments. Between the sternum and pericardium is an anterior compartment containing the thymus gland and lymph nodes. The middle compartment contains the pericardium, heart, great vessels, phrenic and upper portions of the vagus nerves, trachea, portions of the right and left main stem bronchi, and lymph nodes. The posterior compartment contains the thoracic aorta, esophagus, and thoracic duct. Also found in the posterior mediastinum are the sympathetic nervous system ganglionic chains and lower portions of the vagus nerve and lymph nodes.

Lungs

The lungs are multilobed, cone-shaped, spongelike organs that lie within the pleural cavities (Figure 9-28). They are pink at birth and develop a gray coloration with age. Average adult lungs are hollow, low-density organs that occupy a volume of approximately 3.5 L and weigh approximately 900 g.[43] The organs within the mediastinum bulge into the left hemithorax, resulting in a narrower and slightly smaller left lung. The liver below the right lung elevates the right diaphragm and results in a slightly shorter right lung.

The lungs extend from the diaphragm to a point 1 to 2 cm above the medial third of the clavicles. The uppermost regions are called the **apexes.** At end-expiration, the anterior lower lung borders extend to approximately the sixth rib at the midclavicular line. Laterally, the lower lung border is at the eighth rib at the midaxillary line. The top of the lungs, viewed posteriorly, extend upward from the eighth or ninth thoracic vertebra to the first thoracic vertebra. The diaphragm rises and falls, with resting breathing between the ninth and twelfth thoracic vertebrae.

The anterior, lateral, and posterior lung surfaces lie and move against the thoracic inner wall. The medial surfaces of the lungs lie in close contact to the mediastinal surfaces. Figure 9-29 shows the medial surfaces of the lungs and the opening in this region known as the *hilum*. The main stem bronchi, blood vessels, lymphatics, and nerves that enter or exit the lung all pass through the hilum.

Each lung is divided into two or three **lobes** (see Figure 9-28) separated by one or more **fissures.** The right lung has upper, middle, and lower lobes. The left lung has only an upper and a lower lobe. Both lungs have an oblique fissure beginning on the anterior chest at approximately the sixth rib at the midclavicular line. These fissures extend laterally and upward until they cross the fifth rib on the lateral chest in the midaxillary line. The fissures continue to the posterior chest to approximately the third thoracic vertebra. The right lung also has a horizontal or "minor" fissure that separates the upper and middle lobes. This horizontal fissure extends from the fourth rib at the sternal border to the fifth rib at the midaxillary line.

MINI CLINI

Penetrating Chest Injury

Normally, the parietal and visceral pleurae are in physical contact with one another and are separated by only a thin liquid film or fluid. This liquid film allows these two pleural membranes to slide over one another with little friction. This film also provides a cohesive force that resists separation of the membranes. When the respiratory muscles move the rib cage outward in an inspiratory effort, the lung is literally pulled by the cohesive forces between the parietal and visceral pleurae. The elastic recoil forces of the lung resist this outward movement.

PROBLEM: A person sustains blunt force traumatic injury to the left chest. The fractured ribs are forced through the chest wall and parietal pleura, puncture the visceral pleura, and lacerate the lung. What happens to the lungs?

ANSWER: The lung on the affected side collapses as air and blood leak from the lacerated lung. As air and blood enter the pleural space (hemopneumothorax), the parietal and visceral pleurae separate. The chest wall expands outward, and the elastic recoil of the lung causes it to collapse. Both structures recoil in opposite directions as the pleural space between them separates, creating paradoxical movement. Treatment of a hemopneumothorax involves inserting a chest tube into the chest cavity and applying vacuum to remove the air and blood, reexpanding the lung.

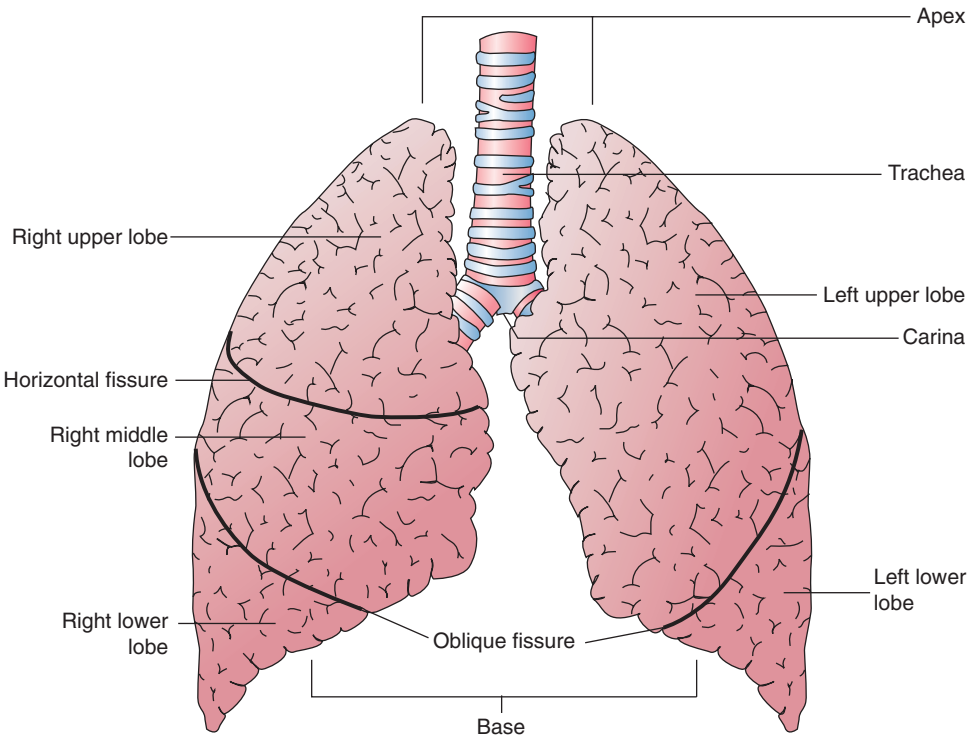

FIGURE 9-28 Anterior view of the lungs showing the lobes and fissures. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

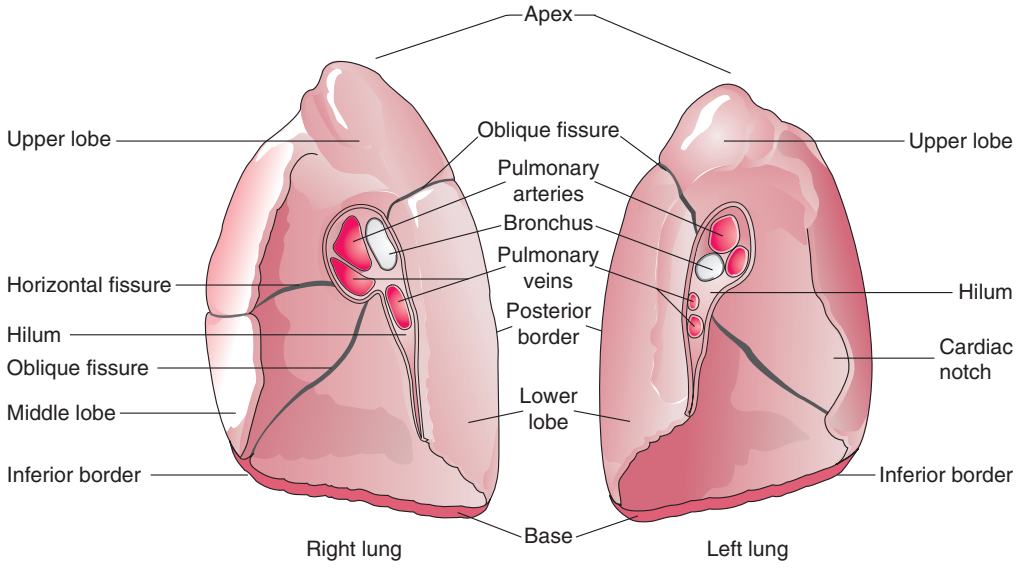

FIGURE 9-29 The medial surfaces of the lungs. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

The lungs are elastic organs that can expand when inflated with air and recoil back to their resting volume when exhalation occurs. Lung elasticity stems from surface tension forces in the alveoli, elastic properties of the tissues, and various connective tissue fibers. Three different fiber systems form a scaffold that supports the structure of the lungs as tension develops in them with inflation.[46] The axial system, primarily composed of collagen and reticulin fibers, originates in the hilum and extends outward in all of the airway walls almost all the way to the alveolar region. The septal fiber system composed of collagen, reticulin, and elastin, supports the alveolar walls and capillaries. The peripheral fiber system, primarily composed of collagen, originates in the outer viscera and extends into the lung tissue to divide the lung tissue effectively into interlobular regions.

Collectively, these connective tissue fibers provide support to the airway walls, lungs, and effective gas-exchange membrane as it is stretched during inflation. When a lung is removed from the chest cavity, the lung quickly collapses to a smaller size. The same occurs if air or fluid enters into the pleural space; it is possible that individual lobes can collapse as the result of airway obstruction and gradual diffusion of air from the lobe. This tendency of the lung to collapse is counteracted by the tendency of the thoracic wall to spring outward and hold the lung inflated. The "tension" developed by these two opposing tendencies results in the development of subatmospheric (negative) intrapleural pressure.

PULMONARY VASCULAR, LYMPHATIC, AND NERVOUS SYSTEMS

The vascular supply of the lungs is composed of the pulmonary and bronchial circulations. The pulmonary circulation carries mixed venous blood from the systemic circuit to the lungs to increase O_2 and reduce CO_2 content of blood. The bronchial circulation provides systemic arterial blood to the airways and pleura supporting their metabolic needs. A network of lymphatics is also involved in fluid transport from the lungs. The lymphatic system removes fluid from the lung tissue and pleural space and returns it to the systemic circulation. The nervous system of the lungs acts to sense and modify lung function, helping defend while improving function.

Pulmonary Circulation

Pulmonary circulation is supplied with blood from the right heart (Figure 9-30). O_2-reduced systemic venous blood flows to the right heart via the inferior and superior venae cavae. This blood is pumped to the lungs by the right ventricle through the pulmonic semilunar valve and into the trunk of the pulmonary artery. The trunk of the pulmonary artery passes upward and divides into right and left pulmonary arteries just below the point of tracheal bifurcation into left and right main stem bronchi (the **carina**). The pulmonary arteries accompany the right and left main stem bronchi through the hilar opening into the lungs and continue dividing along with the airways. These divide to form two types of arteries: conventional, which continue to follow the airway branching, and supernumerary, which branch at 90-degree angles from the conventional arteries and travel outside the common path. Both sets of arteries form arterioles, connecting to and supplying blood to the microcirculation of the respiratory zone of the lung.

The pulmonary arterial system continues to divide into increasing numbers all the way to the distal airspaces. They subdivide, forming dense "sheetlike" beds of alveolar capillaries located within the walls of the alveoli, just below approximately 90% of the alveolar surface (Figure 9-31). The wall of the pulmonary capillary is formed by endothelial cells. At rest, the pulmonary capillary bed contains 60 to 80 ml of blood and can expand to 200 ml through dilation and recruitment of collapsed capillaries during conditions of higher cardiac output (e.g., exercise).[47] Pulmonary blood is collected from the capillaries by the pulmonary venules, combining into larger veins. Similar to their arterial counterparts, the veins also form conventional and supernumerary types of veins that drain blood from the pulmonary capillary beds. The pulmonary veins possess less smooth muscle in their medial walls and have thinner walls than similar-sized pulmonary arteries. The veins follow the same connective tissue path that houses the bronchi and arteries, merging into larger and fewer vessels. Four major pulmonary veins (superior and inferior veins from each lung) exit through the hila and return arterialized blood to the left atrium of the heart for delivery to the systemic circulation (Figure 9-32).

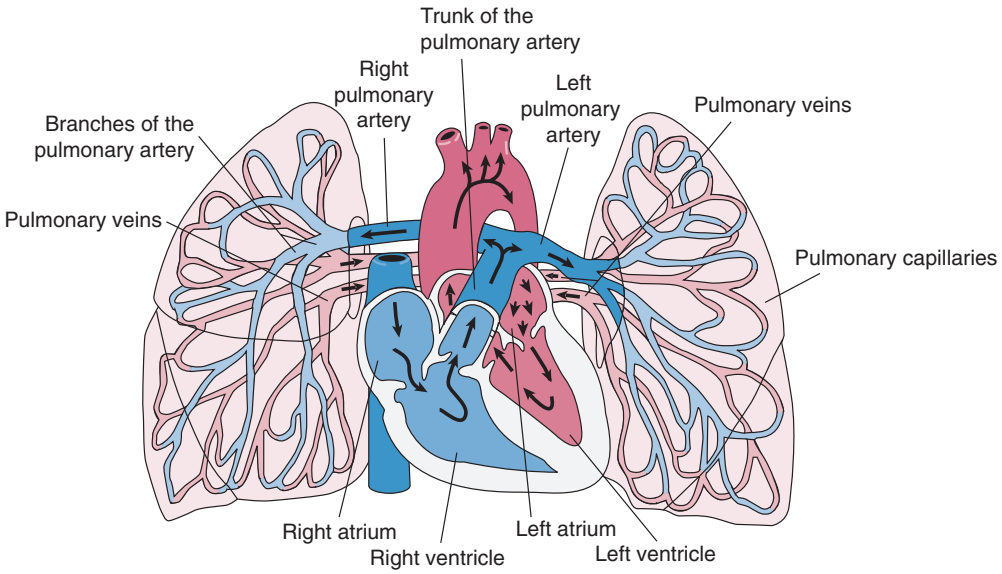

FIGURE 9-30 The pulmonary circulation. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

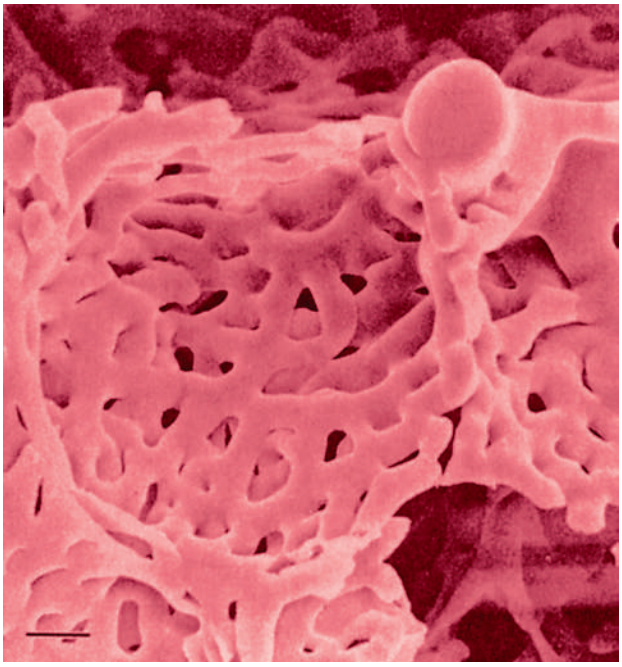

FIGURE 9-31 Scanning electron photomicrograph at high magnification of plastic cast of alveolar capillaries of the pulmonary circulation (black bar, 10 μm). (From Thibodeau GA, Patton KT: Anatomy and physiology, ed 7, St Louis, 2010, Mosby.)

RULE OF THUMB

The pulmonary artery and its branches are the only arteries in the body to carry deoxygenated blood. The pulmonary veins are the only veins that carry oxygenated blood back to the left side of the heart.

Respiratory Function of Pulmonary Circulation

The pulmonary circulation has several different functions.[48] Primary function of the pulmonary circulation is to deliver blood to the alveolar-capillary bed for the exchange of O_2 and CO_2 with alveolar gas, delivering it to the left heart. The second function is to serve as a barrier between the interstitial spaces and airspaces of the lung on one side and the blood within the capillaries on the other. Less than 0.3 μm thick, the endothelial capillary membrane is an active barrier that controls the exchange of fluid and solutes crossing it. In doing so, it plays a crucial role in the regulation of the fluid balance within the lungs. Injury to the pulmonary capillary often disrupts the fluid balance, resulting in excessive fluid leaks and the formation of pulmonary edema. The third function is nonrespiratory, involving the production, processing, and clearance of various chemicals and blood clots.

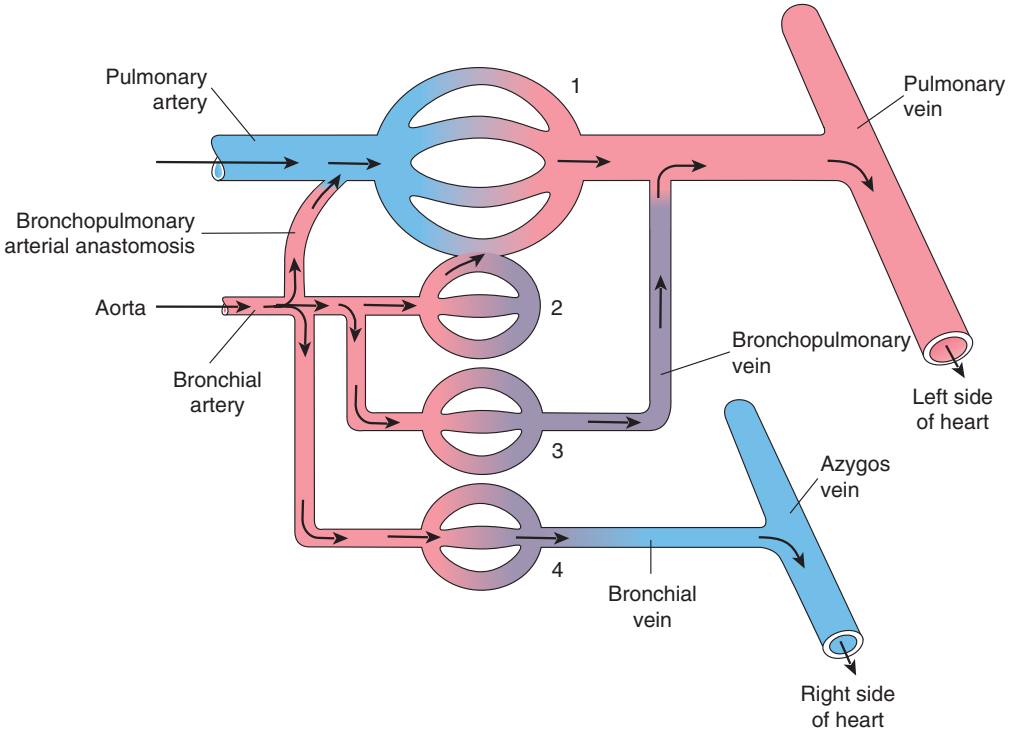

FIGURE 9-32 Schematic depiction of the interconnection of pulmonary and bronchial circulations. Bronchial blood flows to the pulmonary artery *(1),* through the capillary bed of the large airways and pleura and into pulmonary capillaries *(2),* through the bronchopulmonary veins and into the pulmonary veins *(3),* and through the bronchial vein and on to the azygos vein *(4).* The route through the bronchopulmonary vein allows less oxygenated blood to mix with the better oxygenated blood, which returns to the left side of the heart. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

TABLE 9-6

Resting Hemodynamic Values in Adult Systemic and Pulmonary Vascular Systems

Parameter	Systemic Circuit	Pulmonary Circuit
Blood flow (cardiac output, L/min)	5	5
Arterial blood pressure (mm Hg)	120/80	25/10
Vascular resistance (dynes/sec/cm^{-5})	1200	120

Table 9-6 compares hemodynamic parameters of the systemic and pulmonary circulatory systems.[49] Although the entire cardiac output passes through both pulmonary and systemic circuits, the pulmonary circulation offers much lower resistance and consequently has a much lower blood pressure. The low vascular pressures within the pulmonary circuit are essential in maintenance of fluid balance at the alveolar-capillary interface. The pulmonary capillaries are exposed to vascular pressures of approximately 7 to 10 mm Hg. Increased pressure in the pulmonary circulation can occur with mitral valve disease or congestive (left) heart failure, disrupting fluid balance and leading to excessive fluid leakage, fluid accumulation, and alveolar congestion, which can impair gas exchange and lead to hypoxia.

The low vascular pressures of the pulmonary circulation result in regional blood flow within the lungs that is highly influenced by gravity, airway pressure, and gas exchange.[48] In the upright lung, blood pressure in the pulmonary arteries increases approximately 1 cm H_2O for each 1 cm traversed downward from the apex to the base. A consequence of having a low blood pressure in the pulmonary circulation and being susceptible to gravity, blood flow is much higher in the lung bases in resting upright subjects. Gravity-related effects also occur in recumbent positions but are less pronounced. The distribution of pulmonary blood flow is also closely related to local airway gas pressure and pulmonary gas exchange. Areas experiencing higher airway pressure (e.g., during positive pressure ventilation) that equals or exceeds local arteriole and capillary pressure have reduced blood flow as a result of the opposing airway pressure (zone 1 airways). Regions where blood pressure is greater than the surrounding air pressure, such as in the bases of the upright lung during spontaneous breathing, have greater blood flow (zone 3 airways). Areas of regional lung hypoxia, because of reduced ventilation, congestion, or airway obstruction, can result in local pulmonary arterial vasoconstriction and cause blood flow to shift from these areas toward areas of higher O_2 content and pulmonary vasodilation.[47]

Nonrespiratory Function of the Pulmonary Circulation

The pulmonary circulation also serves as a blood reservoir for the left ventricle.[47,48] This reservoir maintains stable left ventricular volumes despite small changes in cardiac output. The pulmonary blood volume (approximately 600 ml) is sufficient to maintain normal left ventricle filling for several cardiac cycles. This reservoir is important if filling of the right heart is temporarily decreased or interrupted.

The pulmonary circulation also acts as a filter for the systemic circulation. The capillaries have an inner diameter of approximately 7 to 10 μm and theoretically trap particles (e.g., blood clots) down to this size before they enter the systemic circulation, where blockages could be life-threatening.

The lungs also play an active role in the clearance, activation, and release of various biochemical factors.[47,48] They are responsible for synthesis, activation, inactivation, and detoxification of many bioactive substances. Angiotensin I is converted to its active form (angiotensin II) as it circulates through the lung. Various proinflammatory cytokines are also released from the lung when it is injured or repetitively overinflated during mechanical ventilation.[50]

Bronchial Circulation

A separate arterial supply called the *bronchial circulation* supplies blood to the airways from the trachea to the bronchioles and to most of the visceral pleurae.[51] The metabolic needs of the lung are comparatively low, and much of the lung parenchyma is oxygenated by direct contact with inspired gas. The bronchial circulation is a branch of the systemic circuit and is supplied with blood from the aorta via minor thoracic branches. Blood flow through the bronchial circulation constitutes approximately 1% to 2% of the total cardiac output.

A single right bronchial artery supplying the right lung arises from the upper intercostal artery, the right subclavian artery, or an internal mammary artery. Two bronchial arteries supply the left lung and branch directly from the upper thoracic aorta. Bronchial arteries follow their respective bronchi. The bronchial arterial circulation terminates in a plexus of capillaries joining the alveolar-capillary bed. Bronchial venous blood drains through the *azygos, hemiazygos,* and *intercostal* veins to the right atrium. Some drains through the pulmonary capillaries to the pulmonary veins and to the left atrium. Figure 9-32 shows the interrelationship and comingling of the pulmonary and bronchial circulatory systems.

The bronchial and pulmonary circulations share an important compensatory relationship.[52] Decreased pulmonary arterial blood pressure tends to cause an increase in bronchial artery blood flow to the affected area. This compensation minimizes the danger of pulmonary infarction, as sometimes occurs when a blood clot (pulmonary embolus) enters the lung. Similarly, loss of bronchial circulation can be partially offset by increases in pulmonary arterial perfusion. The adult lung does not require the bronchial circulation to remain viable, as evidenced by the success of lung transplantation, which does not preserve the bronchial circulation. However, this circulation apparently plays a more important role in lung development, helps to preserve gas exchange during various congenital cardiac conditions, and appears to compensate in certain pulmonary diseases (e.g., pulmonary fibrosis) for the gradual obstruction of the pulmonary circulation.

Lymphatics

The lymphatic system of the lungs is an extensive system of lymphatic vessels, lymph nodes, the tonsils, and the thymus

gland.[53] The primary function of the lymphatic system is to clear fluid from the interstitial and pleural spaces to help maintain the fluid balance in the lungs. The lymphatic system also plays an important role in the specific defenses of the immune system. It removes bacteria, foreign material, and cell debris via the lymph fluid and through the action of various phagocytic cells (e.g., macrophages), providing defense against foreign material and cells that are able to penetrate deep into the lung. It also produces various lymphocytes and plasma cells to aid in defense. Both roles are essential for maintaining normal function of the respiratory system.

Most of the pulmonary lymphatic system consists of superficial and deep vessels.[54] The superficial (pleural) vessels that drain the lung surface and the deep (peribronchovascular) conduit-like vessels that travel through the connective tissue tracts. Both drain the blind lymphatic capillaries in the respective regions. The deeper lymph vessels are closely associated with the small airways but do not extend into the walls of the alveolar-capillary membranes. The lymphatic vessels are thin-walled vessels that contain little connective and muscle tissue in their walls.

Lymph fluid is collected by the loosely formed lymphatic capillaries and drains through the lymph vessels toward the hilum. The fluid is propelled through the lymphatic system by the collective actions of valves that direct flow toward the hilum. The combined milking actions of smooth muscle contractions in the deeper conduit-like vessels and the cycle of ventilation act as a pump and squeezes the lymphatic vessels.[55] Lymph fluid flow from the lungs can be increased after an injury to the pulmonary capillaries that results in increased leakage (e.g., acute respiratory distress syndrome) or from pulmonary capillary hypertension secondary to heart disease (e.g., left-sided heart failure).

The lymph vessels emerge from the hilum of each lung and drain lymph fluid through a series of lymph nodes clustered about each hilum and the mediastinum. From there, lymph fluid travels through various lymph nodes within the mediastinum (Figure 9-33). The lymph fluid rejoins the general circulation after passing through the right lymphatic or thoracic duct, draining into the jugular, subclavian, or innominate veins. The lymph fluid mixes with blood and returns back to the heart.

Lymphatic channels are not usually visible on chest radiographs. They may be detected if distended or thickened by disease. The "butterfly" pattern that radiates from the hilar region of both lungs during acute development of pulmonary edema is thought to be the result of interstitial and lymph vessel distention with fluid. In this situation, the lymphatic drainage system has been overwhelmed by a sudden and excessive surge of fluid from the circulation. The development of a pleural effusion is also evidence that the lymphatic system is unable to remove excess fluid in the lung.

Nervous Control of the Lungs

All of the major structures of the respiratory system are innervated by branches of the peripheral nervous system: the autonomic and somatic branches (Figure 9-34).[56] The somatic

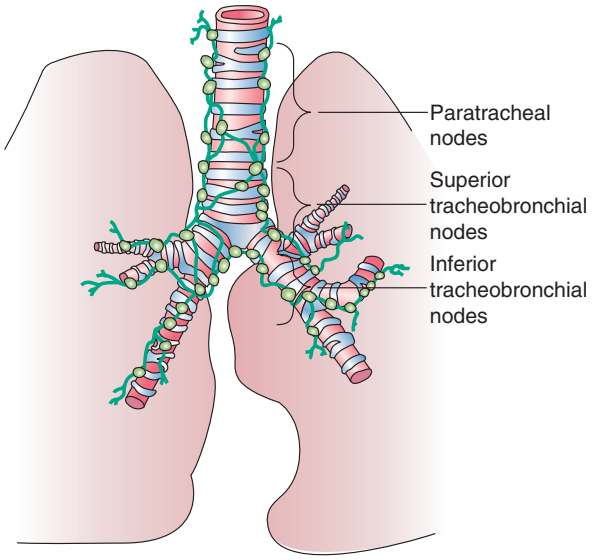

FIGURE 9-33 Mediastinal and paratracheal pulmonary lymph nodes. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

system provides voluntary and automatic motor control and sensory innervation to the chest wall and respiratory muscles. Most of the major motor nerves that carry nervous signaling to the respiratory muscles are summarized in Tables 9-4 and 9-5. The autonomic nervous system signaling to and from the lungs is carried through efferent and afferent pathways. These pathways carry unconscious autonomic nervous system motor signals to smooth muscles and glands and various sensory signals back to the brain.

Autonomic innervation of the lungs is carried from the brainstem through branches of the right and left vagus nerves (cranial nerve X) and from the spinal cord to four or five thoracic sympathetic ganglia that lie just laterally to the spinal cord.[57] Both contribute fibers to the anterior and posterior pulmonary plexus at the root of each lung. From these plexuses, sympathetic and parasympathetic fibers enter the lung through the hilum and innervate various structures.

Efferent Pathways

The parasympathetic nervous preganglionic fibers exit the brainstem via the two vagus nerves. On entry into the chest, the vagus nerve branches to the larynx. This branch is called the *recurrent laryngeal nerve.* Each vagus nerve also develops a branch called the *superior laryngeal nerve.* The external branch of this nerve supplies the cricothyroid muscle. The internal branch provides sensory fibers to the larynx. The recurrent laryngeal nerves provide the primary motor innervation to the larynx. Damage to laryngeal nerves can cause unilateral or bilateral vocal cord paralysis, depending on which branches are involved. Hoarseness, loss of voice, and an ineffective cough may result.

After forming ganglia and postganglionic nerve fibers, parasympathetic and sympathetic nerve fibers enter the lung through the hilum and run parallel to the airways as they branch (Figure 9-35). Parasympathetic fibers form their ganglia much closer to

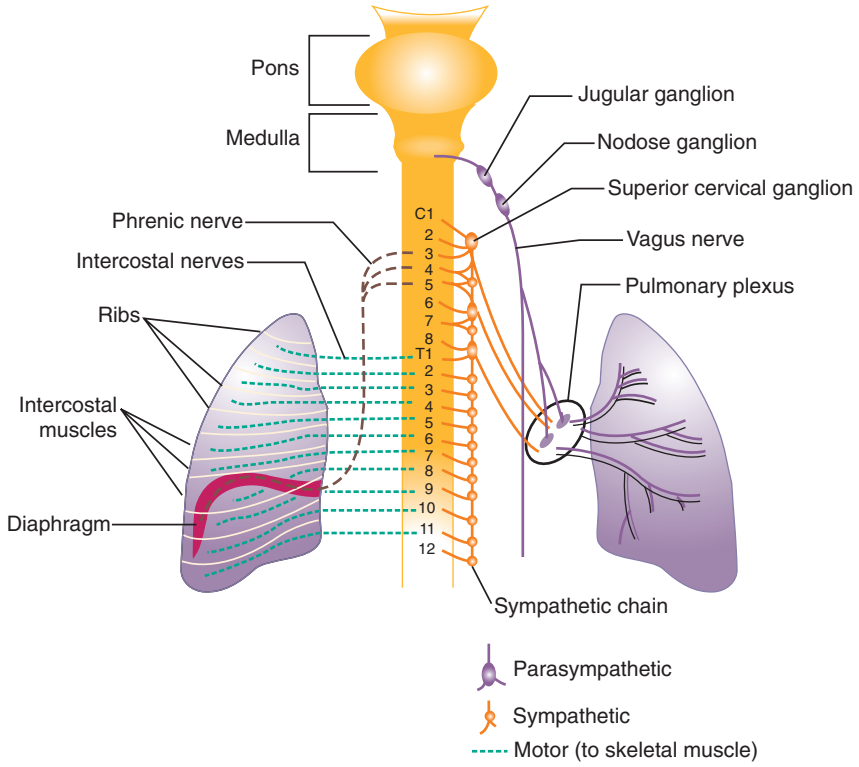

FIGURE 9-34 Schematic of the autonomic innervation (motor and sensory) of the lung and the somatic (motor) nerve supply to the intercostal muscles and diaphragm. (Modified from Murray JF: The normal lung, ed 2, Philadelphia, 1986, WB Saunders.)

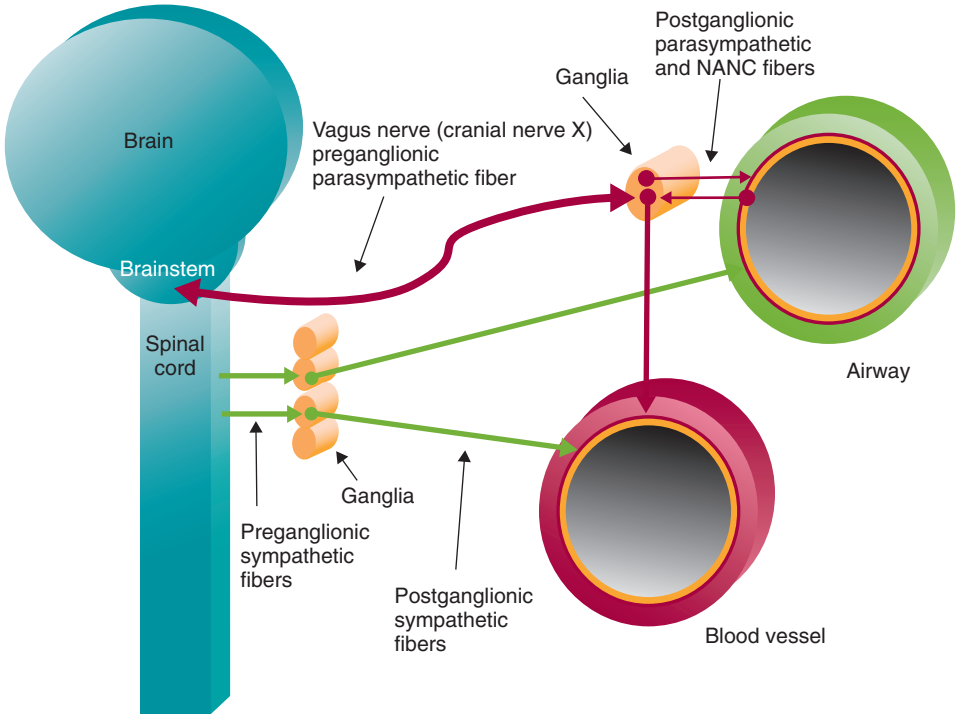

FIGURE 9-35 Schematic of sympathetic, parasympathetic, and nonadrenergic, noncholinergic *(NANC)* neural fiber connections to the airways and blood vessels of the lungs.

the target tissues (e.g., bronchioles, glands, and blood vessels) and have much shorter postganglionic nerve fibers. Most of the sympathetic fibers form their ganglia along the spinal cord and then form longer postganglionic fibers that penetrate the lungs and end on the airway smooth muscle and glands. Both sympathetic and parasympathetic postganglionic efferents innervate the smooth muscle and glands of the airways and the smooth muscles of the pulmonary arterioles. They influence the diameter of the airway by causing more or less tension in the smooth muscles that wrap around the airway and influence glandular secretion. The smooth muscles in the medial wall of the pulmonary arterioles cause constriction when tensed and dilation when relaxed. The combined effects of the parasympathetic and sympathetic nervous activity, which generally oppose each other's action, result in a balanced control of airway and vessel diameter and glandular secretion.

The parasympathetic postganglionic fibers generally secrete acetylcholine as their primary neurotransmitter when they receive signals from the brainstem. Acetylcholine binds to M_3 muscarinic cholinergic receptors, causing airway smooth muscle constriction, blood vessel dilation, and glandular secretion. The sympathetic postganglionic fibers are much less developed in comparison. The sympathetic postganglionic fibers in the lung primarily secrete norepinephrine. The adrenal glands release epinephrine into the circulation when they receive sympathetic signals from the spinal cord. Epinephrine and norepinephrine bind to alpha-adrenergic and beta-adrenergic receptors of blood vessels. This binding causes constriction in the alpha-adrenergic receptors and dilation and relaxation in the beta-adrenergic receptors of the bronchial airway and vessel smooth muscles.

The airways are provided with a third autonomic pathway that is neither parasympathetic nor sympathetic in action.[46] The nonadrenergic, noncholinergic (NANC) system nerve fibers travel within the vagus nerve to each lung. When active, the NANC nerve endings release a neurotransmitter that promotes the production of nitric oxide, causing the relaxation of airway smooth muscle and dilation. The NANC system is also thought to be capable of bronchoconstriction through the local reflex release of substance P and neurokinin A.

Afferent Pathways

Most afferent fibers follow pathways from the lungs to the central nervous system in the vagus nerve. The vagus afferent pathways are activated by a variety of different receptors within the lung that are sensitive to inflation, deflation, and chemical stimulation.[58]

Slow-adapting stretch receptors are concentrated in the small and medium-sized airways and are closely associated with the airway smooth muscle. Lung inflation and airway stretch stimulate the slow-adapting stretch receptors, and they continue to signal and do not adapt and drop their signaling rate—hence their name. In the mucosal layer of the airway, rapid-adapting receptors sense changes in tidal volume, respiratory rate, and lung compliance, responding to a wide variety of mechanical and chemical irritants. In addition, a variety of other chemical and congestion sensors, when active, seem to modify the sensation of breathing and modify the breathing pattern (e.g., cough reflex and response to alveolar congestion). Additional receptors are located outside the lungs; they include respiratory muscle proprioceptors that sense the stretch state of the muscles and peripheral chemoreceptors that sense the chemical condition of blood (e.g., O_2, CO_2, and hydrogen ion concentration) that are involved in the control of ventilation.

Pulmonary stretch slow-adapting and rapid-adapting receptors progressively discharge during lung inflation and are linked to inhibition of further inflation. This is a type of negative feedback known as the *inflation reflex*. It was originally described by Hering and Breuer and continues to bear their names. The inflation reflex is thought to be actively involved with controlling the depth of breathing and may affect the duration of the expiratory pause between breaths. The inflation reflex is probably very weak or absent during quiet breathing in healthy adults, but there appears to be evidence of its activity in newborns.[59]

Another reflex associated with slow-adapting and rapid-adapting receptor activity is the Head paradoxical reflex.[60] This reflex stimulates a deeper breath rather than inhibiting further inspiration. It may be the basis for occasional deep breaths or gasps. Deep breaths or sighs occur with normal breathing, presumably preventing alveolar collapse. The Head reflex also may be responsible for gasping in newborn infants as they progressively inflate their lungs.

Irritant or mechanical rapid-reacting receptors are found mainly in the posterior wall of the trachea and at bifurcations of the larger bronchi. These receptors respond to various mechanical, chemical, and physiologic stimuli and behave as irritant receptors. The stimuli include physical manipulation or irritation, inhalation of noxious gases, histamine-induced bronchoconstriction, asphyxia, and microembolization of the pulmonary arteries. Stimulation of the irritant rapid-adapting receptors can result in bronchoconstriction, hyperpnea, glottic closure, cough, and sneeze.[61] Stimulation of these receptors also can cause a reflex slowing of the heart rate (bradycardia). This response is referred to as the *vasovagal reflex*. It may occur during tracheobronchial suctioning, intubation of the airway, or bronchoscopy. These procedures can cause significant mechanical irritation of the airway.

Unmyelinated slow-conducting *C-fiber endings* (also known as *juxtacapillary* or *J receptors*), are present in the walls of the bronchial and terminal airway region and have been linked to a breathing reflex pattern associated with mechanical stretch, pulmonary congestion, and exposure to various chemicals.[62,63] When C-fibers become activated, signals are sent back to the brainstem via the vagus nerve, resulting in rapid, shallow breathing. C-fiber activation also has been shown to cause bradycardia, hypotension, bronchoconstriction, mucus production, and apnea in experimental animals.[64] Stimulation of these receptors may contribute to the sensation of dyspnea and, in severe cases, the vagovagal reflex, which can complicate pulmonary edema, pulmonary embolism, and pneumonia.

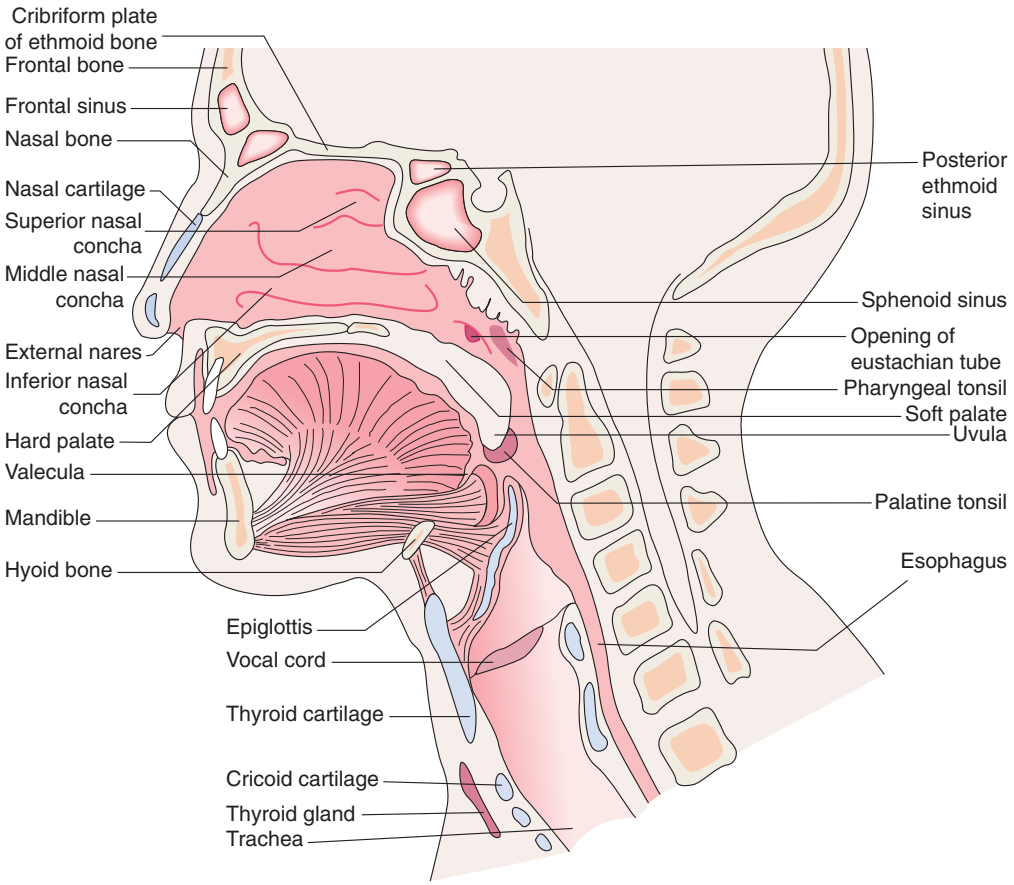

FIGURE 9-36 Midsagittal section through the upper airway. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

ANATOMY OF THE RESPIRATORY TRACT

Upper Respiratory Tract

The *upper respiratory tract* is defined as the airways that start at the nose and mouth and extend down to the trachea (Figure 9-36).[65,66] The upper airway is open to the outside environment through the external nares, or nostrils, of the nose and the mouth of the oral cavity. Most of the air moved through the respiratory tract during resting breathing enters through the nares and nasal cavity. Mouth breathing is used during exercise to reduce the resistance to gas flow at higher ventilation rates. The functions of the upper airway are summarized in Box 9-1.

Box 9-1 Functions of the Upper Airway

- Passageway for gas flow
- Filter
- Heater
- Humidification
- Sense of smell and taste
- Phonation
- Protection of the lower airways

Nasal Cavity and Sinuses

There are two flared openings called **alae** that form the **external nares.** The alae enclose a space on each side called the *vestibule.* The vestibules have hairs that act as a gross filter. Located posterior to the vestibules are the openings to the internal nose, or the **anterior nares.** The left and right nasal cavities are formed by cartilage and numerous skull bones. The roof is formed by the nasal, frontal, sphenoid, and ethmoid bones. The septum separating the two cavities is formed by cartilage and the ethmoid and vomer bones. The lateral walls are created by the maxilla, lacrimal, and palatine bones. The floor of the cavity, or **palate,** is primarily formed by the maxilla. Three shelflike bones protrude into the cavity from the lateral walls. These bony shelves are called the superior, middle, and inferior *conchae,* or **turbinates.**

The conchae function to increase the surface area and complexity of the nasal cavity, enabling the nasal cavity to work as a passageway, filter, humidifier, and heater of inhaled airway. The posterior openings of the nasal cavity are called the *internal nares* and are formed in part by the flexible soft palate.

The surface of the nasal cavity is covered with epithelia. The anterior portion is covered with stratified squamous cells and possesses hair follicles and hair. This is the same type of tissue that forms the epidermis of skin. The middle portion of the

cavity is covered with a mucous membrane composed of ciliated **pseudostratified epithelia** and goblet cells. The mucous membrane functions to secrete mucus, humidify inhaled air, and trap inhaled particles. Just below the mucous membrane is an extensive network of veins forming a venous plexus. These vessels supply water and heat to the gas within the nasal cavity. Inflammation of this mucous membrane is brought on by irritation or infection produced by vasodilation and increased vessel leakage. The consequence of nasal cavity inflammation is partial or complete blockage of the air passage. The vessels of the venous plexus can rupture as a result of breathing dry air or the passage of foreign bodies through the nose. Rupture of these vessels can cause considerable nasal bleeding (**epistaxis**). The posterior portion of the nasal cavity is covered with stratified squamous epithelium similar to the tissue covering of the nearby oral cavity.

Within the skull bones and around the nasal cavity are the *sinuses* (Figure 9-37). These hollow spaces are named for the bones in which they are found.[67] The sinuses are lined with a mucous membrane and drain into the nasal cavity through numerous ducts. They function to reduce the weight of the skull, strengthen the skull, and modify the voice during phonation.

The nasal cavity conducts air to and from the respiratory tract, conditions inhaled gas, acts as a sinus and eye fluid drain, and contains olfactory sensors for the sensation of smell. Conditioning inhaled gas helps defend the respiratory tract and involves filtering, heating, and humidifying air. Filtration of inhaled air is carried out by the hair in the anterior portion of the cavity and the sticky mucous membrane that covers the complex surface of the cavity. Filtration is enhanced by the flow pattern through the nasal cavity. Inspired gas is accelerated to a high velocity through the anterior nares. It changes direction sharply as it enters the internal nasal cavity. This pattern causes particles larger than 10 µm in diameter to have an impact on the nasal mucosa. Ciliary action or nose blowing clears these particles. Past the external nares, the cross-sectional area increases; this results in a decrease in gas velocity. Turbulence increases because of the narrow convolutions of the passages. Low velocity and turbulence combine to remove any remaining particles. Filtration is based on impaction, sedimentation, and diffusion of various-sized particles.

Surface fluids originate from the goblet cells and submucosal glands. This fluid lining has mild antibacterial properties. Ciliary activity in the nasal mucous membranes helps transport the mucus produced so it can be cleared. Foreign matter is typically cleared from the nasal cavity by sniffing and swallowing. During exhalation, the heated and moist expired air passes over the concha and is cooled. The excess moisture deposits on the concha as condensation to help retain and recycle water. These defense/conditioning mechanisms help ensure inspired air is free from particulate and bacterial contamination and is heated and humidified to 37° C and 100% relative humidity by the time it reaches the trachea. In addition, the mucous membrane contains chemoreceptors that send signals to the olfactory nerve for the sensation of smell in the superior portion of the cavity just above each of the superior conchae.

MINI CLINI

Exercise-Induced Asthma

The upper airway, along with the trachea and main stem bronchi, play crucial roles in conditioning the air being breathed. These airways not only conduct gas from the atmosphere to the lower airways but also warm, humidify, and filter it.

PROBLEM: Some individuals develop shortness of breath, wheezing, and coughing when they exercise outdoors. What could be causing their asthma attack? Is there an alternative form of exercise that could reduce the symptoms and allow them to receive an aerobic workout?

ANSWER: In many cases, exercise-induced asthma (EIA) or bronchospasm (EIB) appears to be triggered by reflexes from the large airways (upper airway, trachea, bronchi). These airways warm and humidify inspired gas. Water vapor is absorbed from the fluid lining of the airways and replenished from the cells lining the airways. As gas is expired, it cools, and some of the water vapor is reabsorbed. Only a small amount of water is lost from the body via this mechanism. Exercise (with its increased ventilatory demands) causes an increase in heat and water loss from the airways. The airways in some individuals are especially sensitive (hyperresponsive) to a wide variety of triggering agents. When these individuals exercise and increase their ventilation, the loss of heat or water from the large airways can trigger an asthmatic reaction (i.e., coughing, wheezing, and shortness of breath). This phenomenon is especially noticeable when susceptible individuals exercise in cold, dry conditions. Asthma is sometimes diagnosed by having patients hyperventilate breathing cold, dry gas and then measuring how much airflow decreases.

Swimming usually involves exercise in a warm, high-humidity environment. The preconditioned air breathed during swimming often reduces or eliminates EIB. Many asthmatic children can swim vigorously with few symptoms, even though other sports trigger their bronchospasm.

Oral Cavity

Air also can enter and exit from the respiratory tract through the oral cavity (Figure 9-38). The anterior roof of the oral cavity is called the *hard palate* and is formed by the maxillary bone. The posterior portion is known as the **soft palate.** Its soft tissue composition has the ability to move upward and seal off the nasal cavity. The end of the soft palate hangs down into the posterior portion of the oral cavity. This part of the soft palate is called the **uvula.** The walls of the oral cavity are formed by the cheeks, and the floor is dominated by the tongue.

The uvula and the surrounding walls control the flow of air, fluid, and food during eating, drinking, sneezing, coughing, and vomiting. The tongue is involved in mechanical digestion, taste, and phonation. The posterior surface of the tongue is supplied with many sensory nerve endings. These nerves produce a vagal gag reflex when stimulated, protecting the lungs from aspiration. This reflex must be considered when passing tubes or instruments through the mouth in conscious or semiconscious patients.

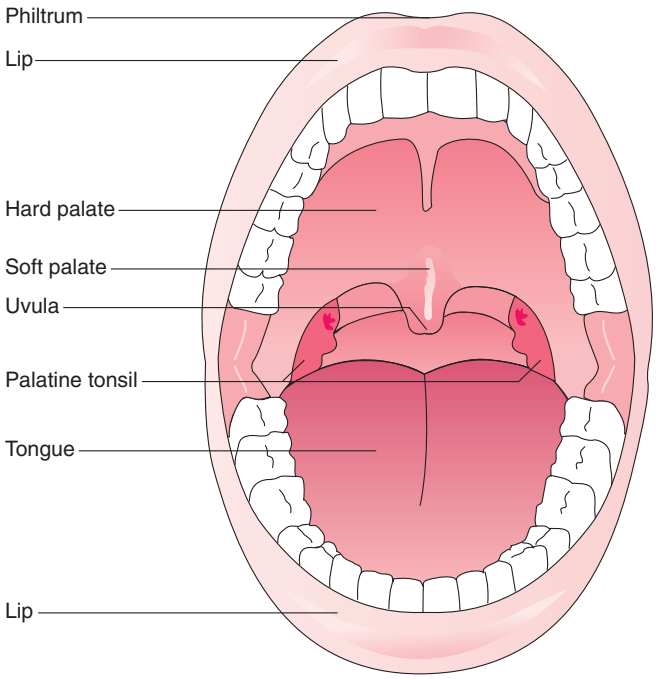

FIGURE 9-38 Frontal view into the open mouth showing the major structures within. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

The mucosal surfaces of the oral cavity also provide humidification and warming of inspired air. These surfaces are much less efficient than the nose. Saliva is produced by major and minor salivary glands. Saliva functions primarily as a wetting and digestive agent for food but provides some humidification of inspired gas. The oral cavity ends at a double web on each side, called the *palatine folds.* The palatine tonsils sit between these folds on each side (see Figure 9-38). The palatine tonsils are vascularized lymphoid tissues that play an immunologic role, especially in childhood.

Reflexes of the mouth, pharynx, and larynx help protect the lower respiratory tract during swallowing.[68] These protective functions can be severely compromised during anesthesia or unconsciousness. Loss or compromise of these important reflexes can result in aspiration of bacteria-colonized saliva or food causing pulmonary infection and asphyxiation in severe cases.

Pharynx

The posterior portion of the nasal and oral cavities opens into a region called the **pharynx.** The entire pharynx is lined with stratified squamous epithelium. The pharynx is subdivided into the **nasopharynx, oropharynx,** and **hypopharynx,** or **laryngopharynx.** The nasopharynx lies at the posterior end of the nasal cavity and extends to the tip of the uvula. Numerous foreign particles impact the surface of the nasopharynx. Located in this region are two pharyngeal tonsils (also called the *adenoids*) on either side of the lateral and posterior walls of the pharynx. They monitor and interact with the particles inhaled through the actions of the lymphoid cells located there. In the same

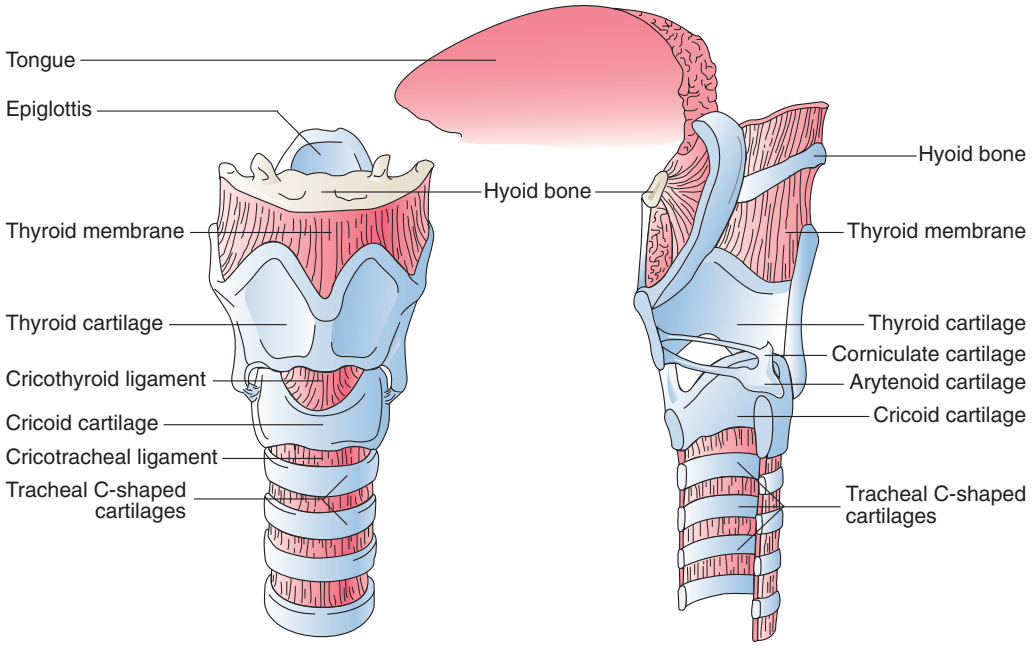

FIGURE 9-39 Anterior and lateral views of the larynx. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

region are two openings into the left and right **eustachian tubes** that link the upper airway with the middle ear (see Figure 9-36). The eustachian tubes drain fluid out of the middle ear and allow gas to move in or out, equalizing pressure on either side of the tympanic membrane.

The oropharynx is located in the posterior region of the oral cavity that spans the space between the uvula and the upper rim of the epiglottis. This region is also equipped with a pair of palatine tonsils that are located on the lateral walls of the oropharynx. These tonsils can become chronically swollen causing partial airway obstruction. If swelling is excessive and the individual has numerous repeat throat and ear infections, the tonsils can be removed by the surgical procedure known as a *tonsillectomy.*

The region below the oropharynx is known as the *hypopharynx.* It extends from the upper rim of the epiglottis to the opening between the vocal cords. The tissues of the nasopharynx and hypopharynx can move and undergo large changes of shape during speech and swallowing. Immediately below the hypopharynx the digestive and respiratory tracts separate.

During unconsciousness, the muscles of the tongue and hypopharynx can relax and allow the tongue and other soft tissues to collapse and occlude the opening of the hypopharynx. This condition can result in partial to complete blockage of the upper airway and limit air movement to and from the respiratory tract. This condition is a primary cause of obstructive sleep apnea (OSA), discussed later in this text.

Larynx

The **larynx** lies below the hypopharynx and is formed by a complex arrangement of nine cartilages and numerous muscles (Figure 9-39).[69] It protects the respiratory tract during eating and drinking and in phonation. The *thyroid cartilage* forms most of the upper portion of the larynx and is generally referred to as the *Adam's apple*. This cartilage is named for the thyroid gland that lies over its outer surface. Just below the thyroid cartilage is the *cricoid cartilage.* It is the only laryngeal structure that forms a complete ring of cartilage around the airway and is the narrowest region of the upper airway in infants. A membrane of connective tissue called the *cricothyroid ligament* spans the space between the thyroid and cricoid cartilage. This membrane is occasionally used as the location for placement of an emergency prosthetic artificial airway in patients who have a life-threatening blockage of the upper airway.

Sleep studies can document partial and complete airflow obstruction. Management of OSA includes weight loss (to reduce anatomic narrowing of the airway), nasal continuous positive airway pressure (CPAP) to hold open the airway, surgical correction (uvulopalatopharyngoplasty) to remove obstructing tissue, and oral appliances that modify the shape of the oropharynx.

The cartilaginous and leaf-shaped epiglottis lies within and is attached to the thyroid cartilage by a flexible joint. In adults, it is 2 to 4 cm long, 2 to 3 cm wide, and 2 to 5 mm deep. It is not easily visualized in adults, but it can be seen in small children and crying infants because of its higher position. During breathing, the thyroid cartilage slides down and remains apart from the epiglottis, allowing air to move in and out of the respiratory tract. The *epiglottis* helps prevent liquids and food entering the respiratory tract by forming a tight seal with the thyroid cartilage during swallowing. The act of swallowing is a complex series of muscular contractions. It results in early

MINI CLINI

Snoring and Sleep Apnea

The upper airway in adults and children primarily functions as an open pathway to convey gas to and from the respiratory zone for gas exchange. The position, size, and shape of the upper airway also contribute to "protect" the lower airways.

PROBLEM: Can abnormalities of upper airway anatomy lead to obstructive sleep apnea (OSA), sleep disturbances, chronic fatigue, and hypertension?

ANSWER: Snoring and breath holding during sleep are often associated with OSA. Snorers usually exhibit narrowing of the oropharyngeal, retropalatal, or hypopharyngeal airways. This narrowing is often observed in obese people; people with short, thick necks; people with large tongues and soft palates; and people with small, receding jaws (micrognathia). During sleep, the upper airway muscles relax and the tissues of the upper airway can partially or completely obstruct the airway. This obstruction can lead to apnea, the development of hypoxia, gasping, and sudden waking after 10 to 20 seconds. This cycle can be repeated multiple times to the point of disturbing the quality and quantity of sleep, inducing stress-related hypertension.

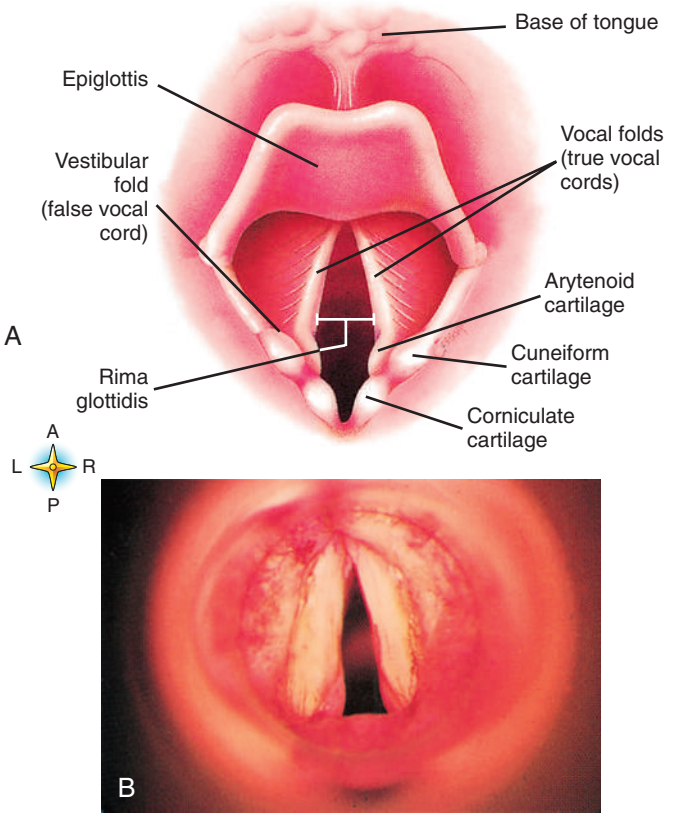

FIGURE 9-40 **A,** Superior view of true vocal cords, glottis (rima glottidis), epiglottis, and other structures within the larynx. **B,** Endoscopic photograph showing vocal cords in the open position. (From Thibodeau GA, Patton KT: Anatomy and physiology, ed 7, St Louis, 2011, Mosby.)

closure of the vocal cords, upward motion of the thyroid cartilage, and movement of the epiglottis down and back to form a tight seal as food is propelled to the back of the mouth and toward the esophagus.[69,70]

The inlet to the larynx lies below and behind the base of the tongue. Figure 9-40 shows the inlet as it appears when viewed with a laryngoscope. The base of the tongue is attached to the epiglottis by three folds. These folds form a space between the tongue and the epiglottis called the **vallecula,** which is a key landmark in oral intubation (see Figure 9-36).

Within the thyroid cartilage and just above the cricoid cartilage are the arytenoid cartilages. The vocal ligaments or true cords span the opening in the larynx by attachments to the thyroid and movable arytenoid cartilages that lie posteriorly. Just above and laterally are the vestibular folds, or false cords. The true vocal cords are composed of connective tissue and muscle and covered with a mucous membrane. They have poor lymphatic drainage and are susceptible to inflammation, which can result in airway obstruction. In the same region are the *corniculate* and *cuneiform cartilages* that function to support the soft tissue on either side of the vocal cords. The opening formed between the vocal cords is called the *glottis*. During swallowing, the vocal cords close to help protect the lower airways. Damage to the cricoarytenoid joint, which allows the *arytenoid cartilages* to rotate, can result in inability to open the vocal cords properly and cause difficulties in speaking and breathing. Laryngeal spasm and resultant partial or total temporary airway closure is brought about by laryngeal stimulation and reflex spasm of various laryngeal muscles that cause closure of the false and true vocal cords.

The muscles of the larynx are innervated by the *inferior laryngeal nerve,* also known as the *recurrent laryngeal nerve.* It is a motor nerve that branches from the vagus nerve. Impulses carried by this nerve are important in phonation and swallowing. Injuries to this nerve can cause partial or complete paralysis of the vocal cords and inability to swallow correctly. This nerve injury results in difficulty with speech and in severe cases can cause airway obstruction as a result of vocal cord closure.

Speech. The laryngeal component of speech is called *phonation*. It requires the adjustment of vocal cord tension and position relative to one another.[71] The action of the posterior cricoarytenoid muscles causes the arytenoid cartilages to rotate and opens the vocal cords. Closure of the vocal cords is accomplished by rotating the arytenoids in the opposite direction through the action of the lateral cricoarytenoid and oblique arytenoid muscles. On closure of the vocal cords, the expiratory muscles of breathing (e.g., abdominal wall muscle group) compress the thoracic cavity and can increase intrapulmonary pressures to 35 cm H_2O during forceful speech. To form sound, the cricothyroid muscles tilt the cricoid and arytenoid cartilages posteriorly with respect to the thyroid cartilage, elongating and tensing the vocal cords. Simultaneously, this action is opposed by the thyroarytenoid muscles, which pull the arytenoid cartilages anteriorly and relax vocal cord tension. Release

of pressurized airflow through the tensed vocal cords causes vocal cord vibration and the production of audible sound waves, which resonate in the upper airway and sinuses. By careful adjustment of thyroarytenoid muscle tension and mandible and tongue position, fine control over sound production or speaking is achieved. Swelling of the vocal cords or the adjacent tissues increases their mass and disturbs their ability to vibrate; this can result in hoarseness and the inability to speak.

Breath Hold, Effort Closure, and Cough. Tight closure of the larynx and the buildup of intrapulmonary pressure through muscular effort are called *effort closure*. Effort closure of the larynx is necessary to generate loud sounds and for effective coughing and sneezing. It is generated by closure of the false and true vocal cords of the larynx. The vocal cords are closed by the action of the cricothyroid, aryepiglottic, and arytenoid muscles. This action effectively "clamps" the airway closed and enables the intraairway pressures to climb to greater than 100 cm H_2O when the various expiratory muscles compress the thorax. Sudden opening of the larynx results in the immediate release of high-flow gas that is necessary for coughing and sneezing. Patients who have artificial airways have difficulty producing an effective cough because the artificial airway prevents closure of the larynx.

Patent Upper Airway

The relative positions of the oral cavity, pharynx, and larynx are crucial to the patency of the upper airway in unconscious patients. In upright subjects, the head and neck form a 90-degree angle with the axis of the pharynx and larynx (Figure 9-41, *B*). With loss of consciousness, the head flexes forward and decreases this angle (see Figure 9-41, *A*). This positional change can partially or completely obstruct the upper airway. Extension of the head and lower jaw into the "sniff" position alleviates this obstruction (see Figure 9-41, *C*). Extension of the head moves

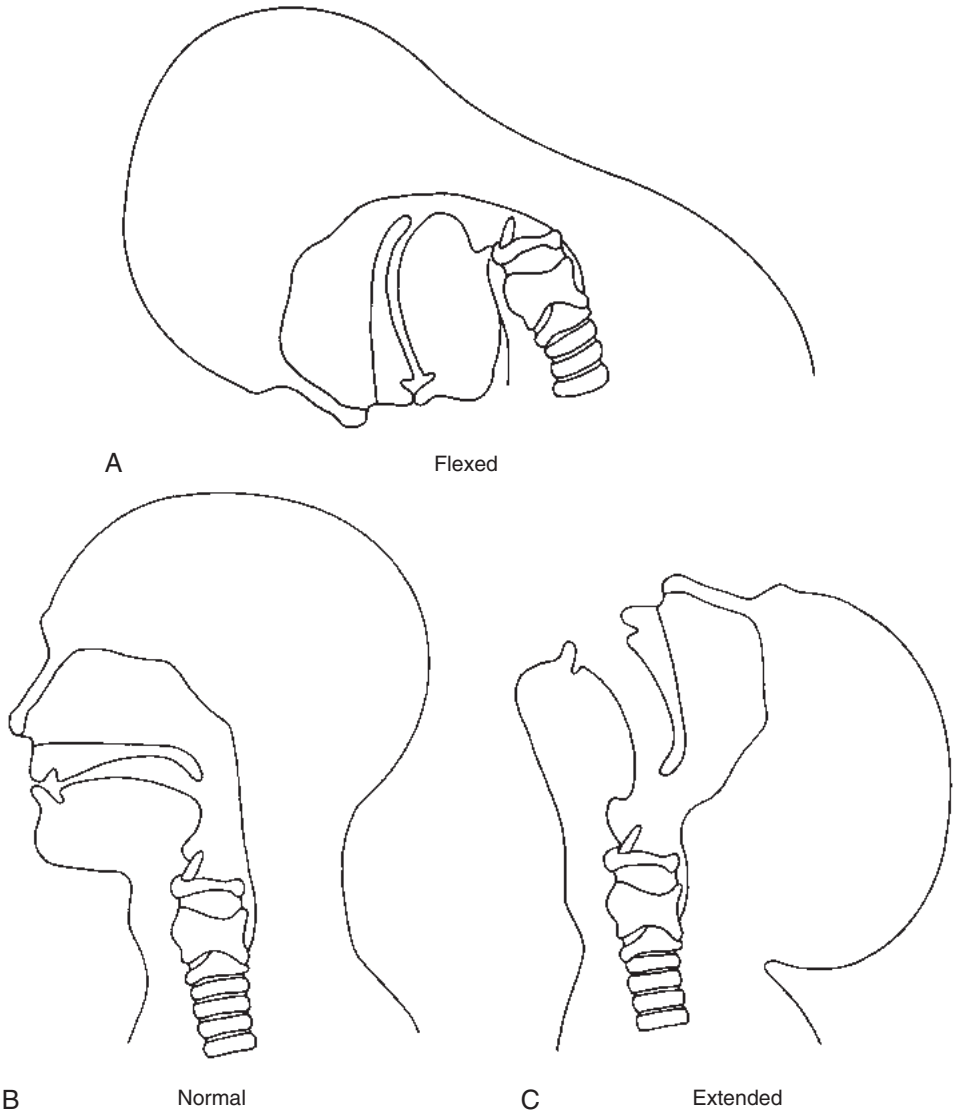

FIGURE 9-41 The position of the head affects patency of airway. **A,** With the head flexed, the airway may be kinked, making breathing or intubation difficult. **B,** Normal upright relationship of the head and neck to the chest. **C,** Extension of the head straightens the airway, making breathing, clearance of material, or intubation easier.

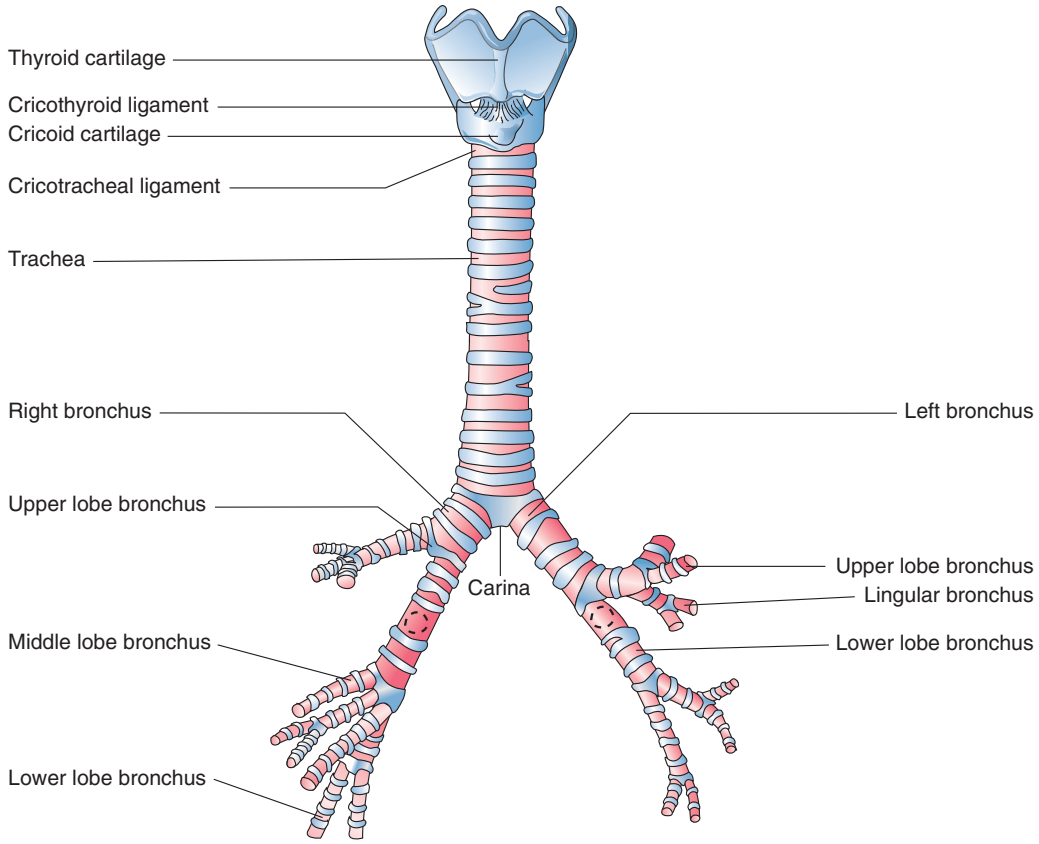

FIGURE 9-42 Major airways of the tracheobronchial tree. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

the tongue away from the rear of the pharynx. This technique is used to maintain the airway in unconscious patients and facilitates placement of artificial airways.

Lower Respiratory Tract

The airways of the tracheobronchial tree extend from the larynx down to the airways participating in gas exchange. Each branching of an airway produces subsequent generations of smaller airways. The first 15 generations are known as *conducting airways* because they convey gas from the upper airway to the structures that participate in gas exchange with blood. The microscopic airways beyond the conducting airways that carry out gas exchange with blood are classified as the *respiratory airways.*

Trachea and Bronchi

The **trachea** extends from its connection to the cricoid cartilage down through the neck and into the thorax to the articulation point between the manubrium and body of the sternum (angle of Louis). At this point, it divides into two main stem bronchi (Figure 9-42). The adult trachea is approximately 12 cm long and has an inner diameter of about 2 cm. Figure 9-43 shows the different layers of tissue that form the trachea. The outermost layer is a thin connective tissue sheath. Below the sheath are numerous C-shaped cartilaginous rings that provide support

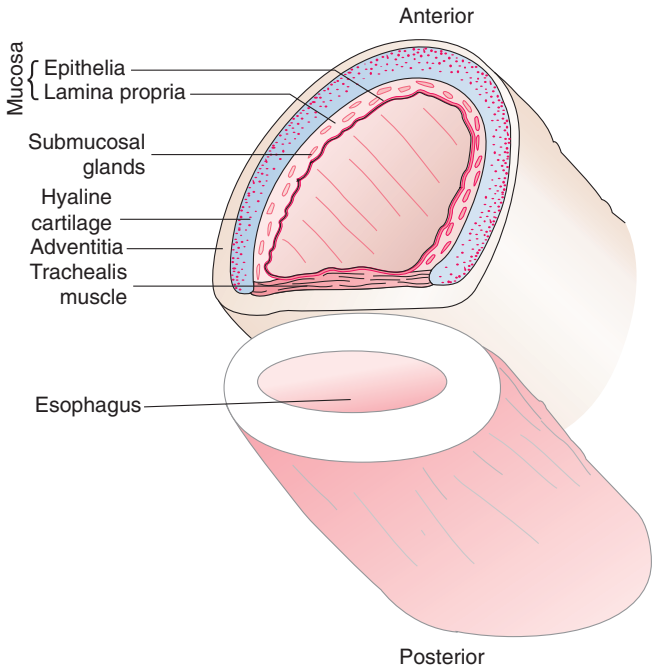

FIGURE 9-43 Cross-sectional view through the trachea and esophagus. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

and maintain the trachea as an open tube. The typical adult trachea has 16 to 20 of these rings. The inner surface of the trachea is covered with a mucous membrane. In the posterior wall of the trachea is a thin band of tissue, called the *trachealis muscle* that supports the open ends of the tracheal rings. The esophagus lies just behind the trachea.

The cartilaginous rings support the trachea so it does not collapse during exhalation. Some compression occurs when the pressure around the trachea becomes positive. During a strong cough, the trachea is capable of some compression and even collapse. The negative pressure generated around the trachea during inhalation causes it to expand and lengthen slightly.

The trachea is positioned midline in the upper mediastinum and branches into right and left main stem bronchi (see Figure 9-42). At the base of the trachea, the last cartilaginous ring that forms the bifurcation for the two bronchi is called the *carina*. The carina is an important landmark used to identify the level where the two main stem bronchi branch off from the trachea; this is normally at the base of the aortic arch. The right bronchus branches off from the trachea at an angle of approximately 20 to 30 degrees, and the left bronchus branches with an angle of about 45 to 55 degrees (Figure 9-44). The lower angle branching (closer to mid-line) of the right bronchus results in a greater frequency of foreign body passage into the right lung because of the more direct pathway.

MINI CLINI

Only Ventilating the Right Lung

The placement of an endotracheal tube through the upper airway and into the trachea is a common airway management technique to facilitate artificial airway placement.

PROBLEM: After placement of an endotracheal tube in a patient with a 70-kg predicted body weight (PBW), it is noted that breath sounds are heard in the right chest only and that the patient's oxygenation is deteriorating. Is the airway placement the cause of the problem? How can this problem be avoided?

ANSWER: An endotracheal tube (ET) of proper diameter should be placed in the trachea so the tip is 3 to 5 cm above the carina. If the ET is advanced too far, it often enters the right main stem bronchus because of the straighter path this bronchus offers. A right main stem intubation results in right lung ventilation only. The left lung continues to receive pulmonary blood flow but does not oxygenate adequately. To avoid this problem the ET generally should not be advanced more than 24 cm past the lips in a 70-kg PBW patient. At this point, auscultation is done with a stethoscope to confirm breath sounds in both lungs. A chest radiograph can be taken to confirm the ET position.

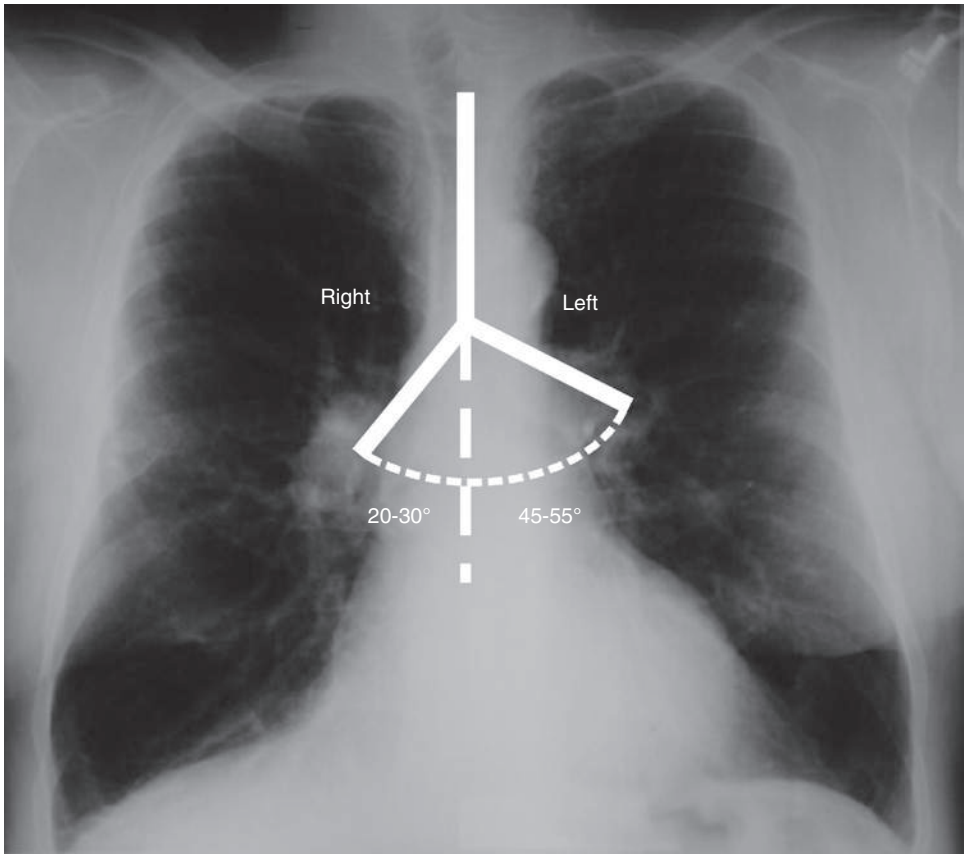

FIGURE 9-44 Course of trachea and right and left main stem bronchi, superimposed on a standard chest radiograph. The right main stem bronchus continues on a straighter course from midline than the left main stem bronchus.

TABLE 9-7

Bronchopulmonary Segments*

Segment	Number	Segment	Number
Right Upper Lobe		**Left Upper Lobe**	
Apical	1	Upper division	
Posterior	2	Apical-posterior	1 and 2†
Anterior	3	Anterior	3
Right Middle Lobe		**Lower Division (Lingula)**	
Lateral	4	Superior lingula	4
Medial	5	Inferior lingula	5
Right lower lobe		Left lower lobe	
Superior	6	Superior	6
Medial basal	7	Anterior basal	7 and 8
Anterior basal	8	Lateral basal	9
Lateral basal	9	Posterior basal	10
Posterior basal	10		

*The subdivisions of the lung and bronchial tree are fairly constant. Slight variations between right and left sides are noted by combined names and numbers.
†Some authors believe that the left lung should be numbered so that there are eight segments, where the apical-posterior is numbered 1 and the anteromedial is numbered 6.

Each bronchus carries gas to and from one lung. It enters the lung with the pulmonary vessels, lymph vessels, and nerves through the hilum. The bronchus branches repeatedly within each lung to supply gas to separate regions of each lung.

Lobar and Segmental Pulmonary Anatomy

The lungs have an apex and a base and are subdivided by fissures into lobes.[43] The lobes are subdivided further into bronchopulmonary **segments** (Table 9-7 and Figure 9-45). Each segment is supplied with gas from a single segmental bronchus. Controversy exists over the exact number of segments; some anatomists accept that each lung has 10 segments, whereas others maintain that the right has 10 and the left has 8. Knowledge of segmental anatomy is important in the physical examination of a patient to identify the location of a defect such as an infection site or a tumor mass in the lungs.

RULE OF THUMB

The 60-to-40 Rule

The right lung is slightly larger than the left lung because of the location of the heart. The right lung has a sizable middle lobe and the left lung has a smaller lingular segment in the left upper lobe. For purposes of estimating the contribution of the right and left lungs to ventilation and gas exchange, the 60-to-40 rule is sometimes used. The right lung is assumed to provide 60% of the ventilation/gas–exchange capacity, and the left lung is assumed to provide the remaining 40%. If a patient requires removal of the entire left lung (pneumonectomy), a 40% decrease in lung volume would be expected.

The airways continue to divide as they penetrate deeper into the lungs. The segmental bronchi bifurcate into approximately 40 subsegmental bronchi, and these divide into hundreds of smaller bronchi. Thousands of bronchioles branch from the smaller bronchi. Bronchioles do not possess cartilage in their walls. Tens of thousands of terminal bronchioles arise from the bronchioles. *Terminal bronchioles* are the smallest conducting airways and function to supply gas to the respiratory zone of the lung.

With further divisions, the number of airways increases tremendously. The cross-sectional area of the conducting system increases exponentially. At the level of the terminal bronchioles, the cross-sectional area is approximately 20 times greater than that at the trachea. Gas flow in these airways conforms to the laws of fluid physics. Increased cross-sectional area reduces the velocity of gas flow during inspiration. When inspired gas reaches the level of the terminal bronchiole, its average velocity has fallen to about the same rate as the speed of diffusing gas molecules.[72] Low-velocity gas movement at the level of the terminal bronchiole and beyond is physiologically important for two reasons. First, laminar flow develops minimizing resistance in the small airways and decreases the work associated with inspiration. Second, low gas velocity facilitates rapid mixing of alveolar gases. This mixing provides a stable partial pressure of O_2 and CO_2 in the alveolar environment that supports stable diffusion and gas exchange.[73]

Histology of the Airway Wall

All of the conducting airways from the trachea to the bronchioles have walls that are constructed of three layers (Figures 9-46 and 9-47): an inner layer that forms a mucous membrane called the *mucosa,* which is primarily composed of epithelia; a submucosa composed of connective tissue, bronchial glands, and smooth fibers that wrap around the airway; and an outer covering of connective tissue called the *adventitia.*[74] The cartilaginous rings and plates found in larger airways are located in the adventitia.

The mucosa is composed of many different types of specialized epithelial cells that sit on top of a basement membrane. The most common type of epithelia are the numerous pseudostratified, ciliated, columnar epithelia.[75] The pseudostratified epithelial cells are held together toward their surface or apical end through three types of junctions—apical tight junctions, zonal adherens junctions, and desmosome-type junctions—and they are anchored in place to the basement membrane.[76] The junctions, especially the tight junctions, play an important role in the maintenance of fluid and electrolyte (e.g., chloride ions) transport across the mucous membrane. These junctions prevent the movement of fluids and electrolytes between the apical surface and basal surfaces of the airway. Disturbances in this transport (e.g., Cl^- transport malfunction in cystic fibrosis transport receptor membrane channels) lead to mucus and mucus transport abnormalities.

Near the base of the pseudostratified cells are large numbers of basal cells. The basal cells contribute to the appearance of a "pseudostratified" cellular layer. Basal cells mature into pseudostratified cells and are thought to play an important role in repair of the mucous membrane after diseases and injury.

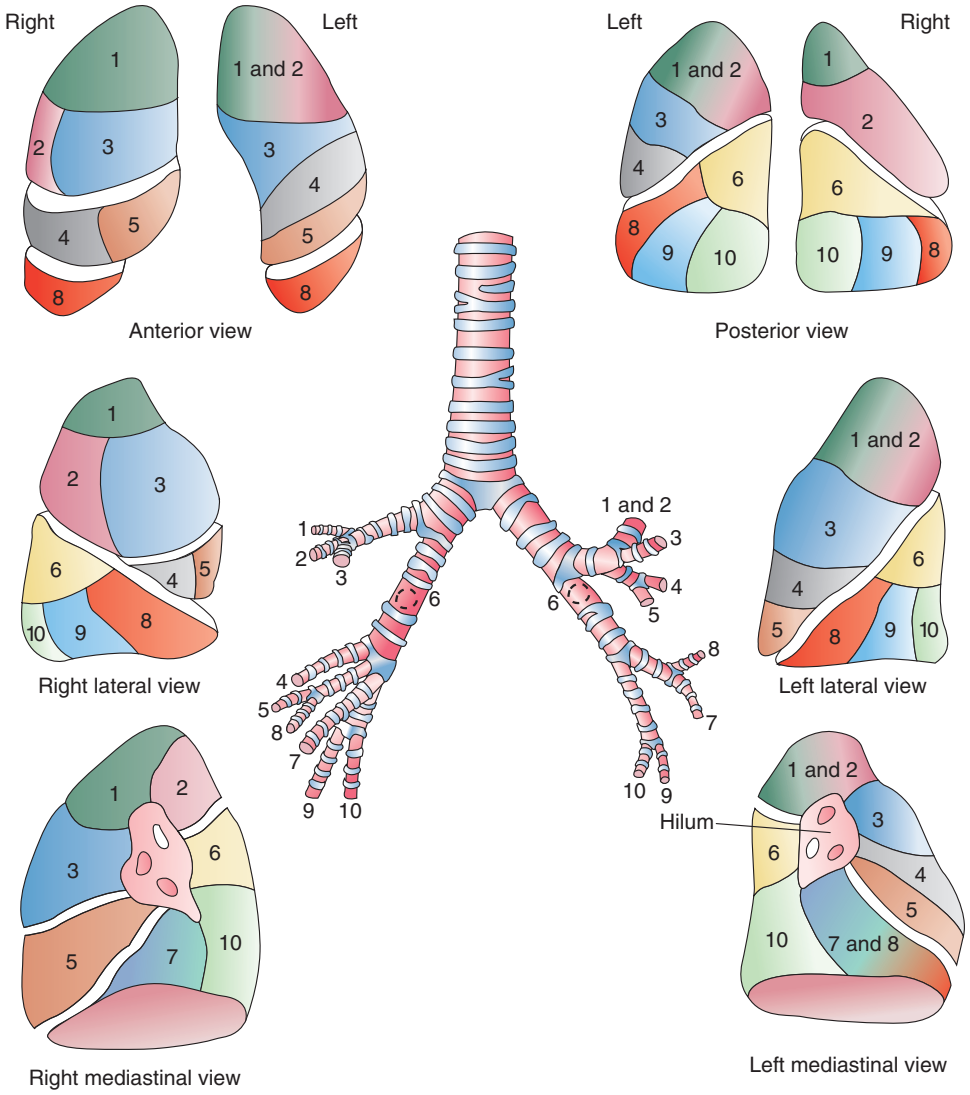

FIGURE 9-45 Bronchopulmonary segmental divisions of the lungs (see Table 9-7). (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

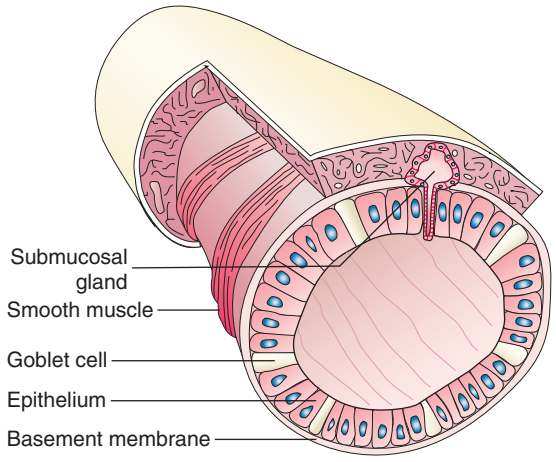

FIGURE 9-46 Cross-sectional view through a bronchiole. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

Dispersed between the pseudostratified epithelia are mucus-producing goblet cells and serous cells (in newborns) and the openings of submucosal bronchial glands. The bronchial glands are exocrine glands formed by secretory epithelial cells that sit on the basement membrane, extending down into the lamina propria and the submucosa. In this region are also neuroendocrine cells (also known as *Kulchitsky cells*), which often are organized into small clusters called *neuroepithelial bodies*.[77] Neuroendocrine cells are connected to the vagus nerve and are thought to function during lung development, are hypoxia and stress-strain sensors, and secrete various bioactive chemicals (e.g., serotonin, calcitonin, and gastrin-releasing peptide). Lymphocytes are found intermixed with these cells, and it is thought they may be migratory.

Below the epithelial and basement membrane of the mucosa is the *lamina propria*.[76] It is composed of loose fibroelastic connective tissue, lymphoid tissue, and a dense layer of elastic

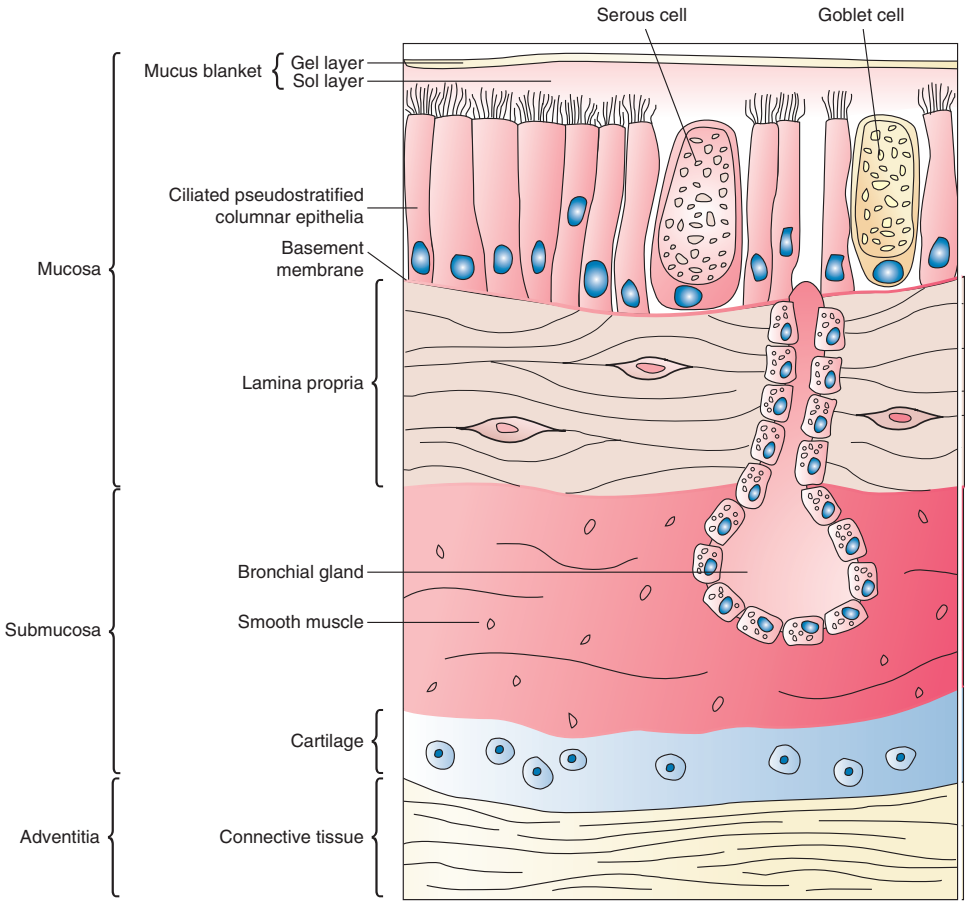

FIGURE 9-47 Microscopic view of mucous membrane. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

fibers. Below the lamina propria lies the submucosa. The submucosa of large airways contains bronchial glands, a capillary network, smooth muscle, some elastic tissue, and cartilage in larger airways. Bronchial glands vary in size up to 1 mm in length and connect to the bronchial surface via long, narrow ducts. The number of these glands increases significantly in diseases such as chronic bronchitis. Mast cells are also found in the submucosa and release numerous and potent vasoactive and bronchoactive substances such as histamine.[78] Histamine causes vasodilation and bronchoconstriction, acting directly on smooth muscle. The triggering of mast cell release of its various substances and the resultant inflammation and bronchospasm of the airway are characteristic of the pathologic changes of asthma.

The various secretory cells (primarily goblet cells) of the mucosa and bronchial glands of the submucosa contribute to the production of mucus.[79] Normally, the respiratory tract produces approximately 100 ml of mucus per day. Most of the mucus formed in the larger airways is produced by the bronchial glands. Goblet cells contribute more in the smaller airways. The amount and composition of mucus produced can increase and change with airway irritation and diseases such as chronic bronchitis and asthma.[80] Mucus is spread over the surface of the mucus membrane to a depth of approximately 7 µm and is propelled by the ciliated epithelia toward the pharynx. The outer layer of mucus is more gelatinous and is called the *gel layer*. The inner layer is much more fluid-like and is referred to as the *sol layer*. The mucus normally produced is a nearly clear fluid with greater viscosity than water. It is a mixture of 97% water and 3% solute.[79] The solute portion is produced primarily by goblet cells and bronchial glands; it is called *mucin* and is composed of protein and minerals. The glycoprotein, lipid, and water content of mucus provide its viscoelastic gel properties. *Viscoelastic* refers to the ability of mucus to deform and spread when force is applied.

Mucus functions to protect the underlying tissue. It helps prevent excessive amounts of water moving into and out of the epithelia.[79] It shields the epithelia from direct contact with potentially toxic materials and microorganisms. It acts like sticky flypaper to trap particles that make contact with it. This makes mucus an important part of the pulmonary defenses. The production of mucus is stimulated by local mechanical and chemical irritation, release of proinflammatory mediators (e.g., cytokines), and parasympathetic (vagal) stimulation.

The ciliated pseudostratified epithelia play a crucial role in the defense of the respiratory tract by propelling mucus toward the pharynx. Ciliated cells are found in the nasal cavity and all the airways from the larynx to the terminal bronchioles.

Each of the pseudostratified cells possesses approximately 200 **cilia** on its luminal surface.[76] Under the electron microscope, the surface of the mucus membrane looks like a "shag carpet" of cilia with approximately 1 to 2 billion cilia per square centimeter. Each cilium is an extension of the cell with an average length of about 6 µm and diameter of about 0.2 µm. A cross-sectional view through the cilium reveals it to be constructed of one inner and nine outer pairs of microtubules that are encased in the cell membrane. The outer pairs of microtubules are interlinked by a filamentous protein called *nexin.* From each of the outer pairs of microtubules, protein filaments called *dynein* extend toward the adjacent pair of microtubules. Each of the outer pairs also extends a protein spoke toward the central pair of microtubules. The presence of magnesium ions and adenosine triphosphate within the cilium causes the dynein arms and spokes to attach and slide along the outer and inner microtubules, similar to the action of actin and myosin. This action results in rapid bending of the cilium resembling a whipping motion (Figure 9-48).

The cilia "stroke" at a rate of approximately 15 times per second, producing a sequential motion of the cilia called a *metachronal wave.*[81] The metachronal "wavelength" is approximately 20 µm and propels surface material in a specific direction. In the nose, this motion propels material back to the pharynx. From the bronchioles up to the larynx, it moves material toward the pharynx. The stroking action of millions of cilia propels the surrounding mucus at a speed of approximately 2 cm/min. This action is commonly referred to as the **mucociliary escalator.** In healthy lungs, this mechanism allows inhaled particles to be removed within 24 hours. The control and coordination of ciliary motion are not totally understood and represent some of the many fascinating properties of pulmonary tissues.

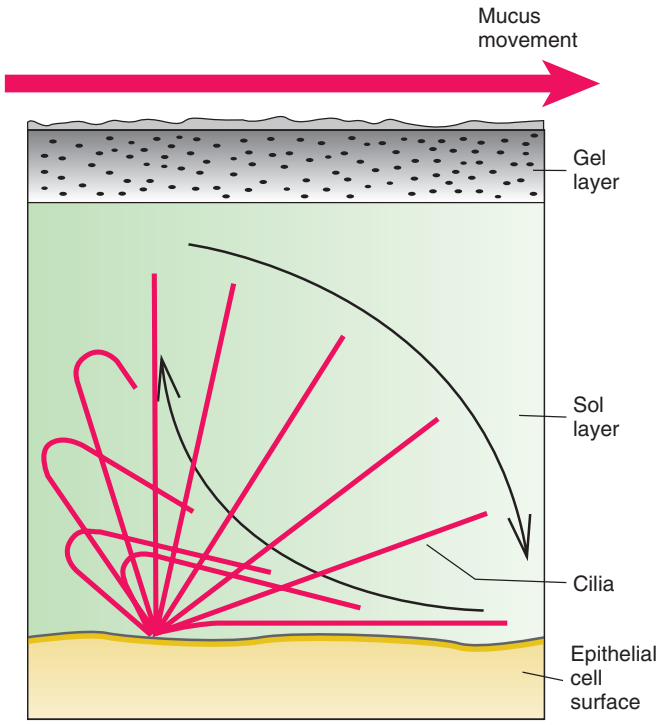

FIGURE 9-48 Whipping action of the cilium within the sol layer of mucus produces a metachronal wave motion. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

The production of mucus and the rate of ciliary beating are sensitive to various conditions and chemicals. Mucus production increases when the respiratory tract is irritated by particles and by various chemicals and during increased parasympathetic nervous stimulation.[80] Ciliary beating can be effectively slowed or stopped if the viscosity of the sol layer is increased by exposure to dry gas. Ciliary motion is also slowed or stopped after exposure to smoke, high concentrations of inhaled O_2, and drugs such as atropine.

The smooth muscle of the airways varies in location and structure. In the large airways (e.g., the trachea), smooth muscle is bundled in sheets. In smaller airways, smooth muscle forms a helical pattern that wraps the airway in bundles in decreasing quantities as the airways branch and become smaller. Muscle fibers crisscross and spiral around the airway walls. This placement reduces the diameter of the airway and shortens it when the muscle contracts. This pattern of smooth muscle continues but thins out on reaching the smallest bronchioles. The tone of the smooth muscle is increased and results in bronchospasm by the activity of the parasympathetic nervous system (release of acetylcholine) and proinflammatory mediator release from mast cells, inflammatory cells, and neuroendocrine cells.

The adventitia is a sheath of connective tissue that surrounds the airways. It is interspersed with bronchial arteries, veins, nerves, lymph vessels, and adipose tissue. Between the submucosa and adventitia of the large airways are incomplete rings or plates of hyaline cartilage, providing structural support for the larger airways. The small airways depend on transmural pressure gradients and the "traction" of surrounding elastic tissues to remain open. During a forced expiration, pressures across the walls of the small airways exceed the supporting forces of the elastic tissues. As a result, the small airways can collapse. The cartilage in the larger airways prevents their collapse during such maneuvers.

The cells of the respiratory mucosa change as they progress into the smaller airways (Figure 9-49). As the thickness of the airway walls decreases, bronchial glands become fewer in number. At the bronchiolar level, the number of ciliated cells decreases. Simple columnar and cuboidal epithelial cells begin to predominate and are interspersed with goblet cells. In this region, large numbers of *Clara cells,* nonciliated cuboidal cells with apical granules, are found. It is thought that these cells play a role in degrading various oxidants, contribute proteins for surfactant production, synthesize various lipids, and play a role in lung repair by being able to differentiate into other important epithelial cells in the mucosa after injury.[82]

Respiratory Zone Airways

The terminal bronchioles begin about 12 to 15 generations beyond the trachea (Figure 9-50).[83] There are about 16,000 terminal bronchioles with airway opening diameters of approximately 700 µm. This yields a combined cross-sectional area

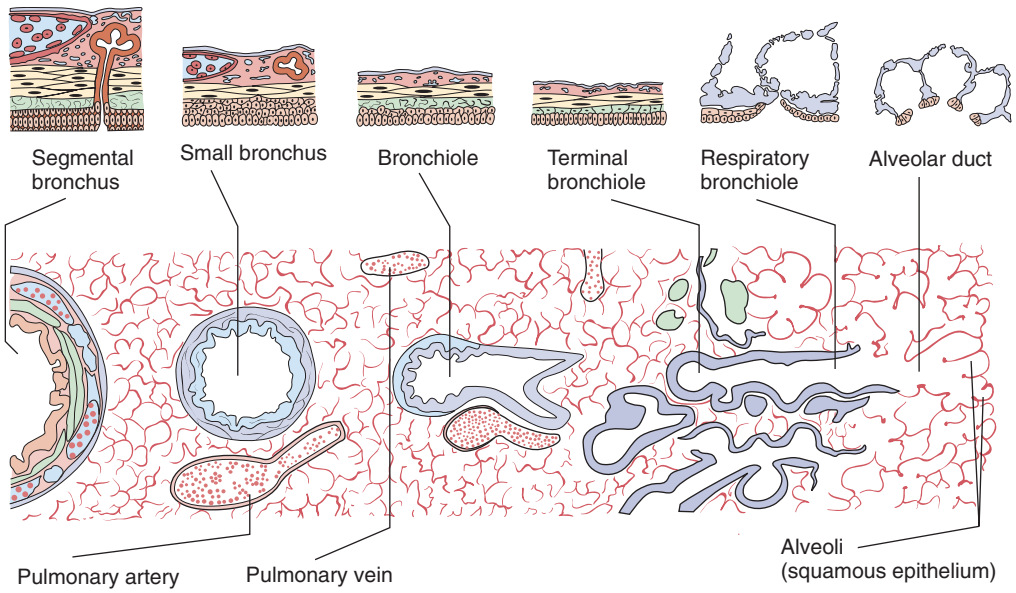

FIGURE 9-49 Histologic diagram of airways from the segmental bronchus to the alveolus. (Modified from Freeman WH, Bracegridle B: An atlas of histology, London, 1966, Heinemann Educational.)

opening that is almost 100 times that of the main stem bronchi. All of the airways down to and including the terminal bronchioles carry or conduct gas flow to and from the airways participating in gas exchange with blood. The airways from the nares to and including the terminal bronchioles constitute the *conducting zone airways,* which do not participate in gas exchange. These airways constitute the anatomic dead space of the respiratory system, which is rebreathed with each breath. In an adult human, the volume filling the airways of the anatomic dead space is approximately 2.2 ml/kg (1 ml/lb) of PBW, or about 150 ml in a typical adult.

Branching of the terminal bronchioles gives rise to unique airways called *respiratory bronchioles.* Respiratory bronchioles are approximately 0.4 mm in diameter and have walls formed largely from flattened squamous epithelia and a thin outer layer of connective tissue. They have some ciliated cells at the connection with the terminal bronchiole, generally lack mucus-producing cells, and have rings of smooth muscles where they branch to form alveolar ducts. Respiratory bronchioles have a dual function. Similar to conducting airways, they not only conduct gas flow but also have small outpouchings known as *alveoli* in their walls. The alveoli and their pulmonary capillary bed enable the respiratory bronchioles to carry out gas exchange. The respiratory bronchioles constitute a transitional zone type of airway.

A single terminal bronchiole supplies a cluster of respiratory bronchioles. Collectively, this unit is referred to as the *acinus,* or **primary lobule.** Each acinus comprises numerous respiratory bronchioles, alveolar ducts, and approximately 10,000 alveoli (Figure 9-51). The adult lung is thought to contain more than 30,000 acini. Each acinus is supplied with pulmonary blood flow from a pulmonary arteriole, and blood is drained away from several acini through a pulmonary venule. In addition, each acinus is equipped with a lymphatic drainage vessel and nervous fibers. These features make the primary lobule the functional unit of the lungs. Gas molecule movement in this region is largely via diffusion rather than convective flow, which occurs in larger airways.

Millions of alveolar ducts branch off the respiratory bronchioles (Figure 9-52). Alveolar ducts are tiny airways only 0.3 mm in diameter, and their walls are composed entirely of alveoli. Each alveolar duct ends in a cluster of alveoli, which is frequently referred to as an *alveolar sac.* Each alveolar sac opens into about 16 or 17 **alveoli,** and about one-half the total number of alveoli are found in this region.

Alveoli

More recent estimates suggest the number of alveoli in adult lungs range from 270 to 790 million, with an average of about 480 million.[22] The number of alveoli increases with an individual's height. Figure 9-53 shows alveoli in a normal rat lung at different states of inflation and how their shapes change. When inflated at and beyond the functional residual volume (see Figure 9-53, *A* to *C*), alveoli have a polyhedral shape resulting from numerous flat walls rather than a curved spherical structure. Alveoli found in the apical regions of the vertical lung have greater diameters than alveoli in the basal regions as a result of the gravitational effects. Alveoli in the basal regions are partially collapsed as a result of the weight of the organ.

The alveolar walls, or septa, are formed by various cell types that are arranged to provide a thin surface for gas exchange and strength.[84] The alveolar septa are covered with extremely flat squamous epithelia called *type I pneumocytes* (Figure 9-54). Although they represent only approximately 8% of all the cells found in the alveolar region, type I cells cover about 93% of the alveolar surface.[85] These cells form a "patchwork"-like surface

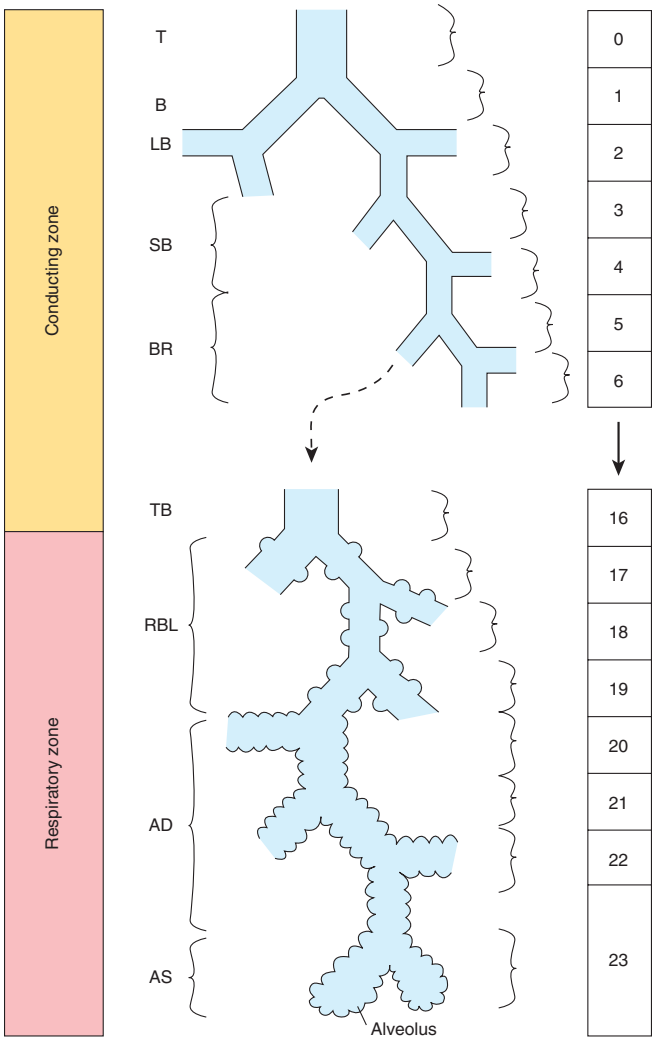

FIGURE 9-50 Airways of the conducting (generation *0* through *16*) and respiratory (generation *17* through *23*) zones: *T,* trachea; *B,* right and left bronchi; *LB,* lobar bronchi; *SB,* segmental and subsegmental bronchi; *BR,* bronchioles; *TB,* terminal bronchioles; *RBL,* respiratory bronchioles; *AD,* alveolar ducts; and *AS,* alveolar sacs. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

that covers the alveolar capillaries and forms the gas-exchange surface of the alveolus. At the edges where they meet one another, they form tight junctions. This helps to limit the movement of material into the alveolar airspace from the interstitial space just below. They are held in place and supported from below by a network of collagen and elastin fibers. They are susceptible to injury and apoptosis (programmed cell death) from inhaled particles (e.g., cigarette smoke), bacterial infection, and high concentrations of inhaled O_2.

Interspersed on the alveolar surface and concentrated in the corners of the alveolar septa are type II pneumocytes, which are cuboidal epithelia with apical microvilli (Figure 9-55). These cells are twice as numerous as the type I cells, but they occupy only 7% of the alveolar surface.[85] Type II cells do not function as gas-exchange membranes as the type I cells do. They (along with the Clara cells) manufacture surfactant, store it in vesicles called *lamellated bodies,* and secrete it onto the alveolar surface.[86] Surfactant is primarily composed of phospholipids (dipalmitoylphosphatidylcholine) and proteins (surfactant proteins A through D). As mentioned earlier in this chapter, surfactant reduces the surface tension of the alveolus, sheds water from the alveolar surface, helps prevent alveolar surface tension-driven collapse, improves lung compliance, reduces the work of breathing, and protects the alveolar surface. Normally, surfactant is removed from the alveolar space continuously by type II cells and macrophages. The type II cells recycle approximately 50% of it, whereas the macrophages primarily remove it through catabolism.[87]

Although the lungs do not have stem cells in the classic sense, the type II cells do have a "stem cell"–like action. They can proliferate and differentiate into type I cells to repopulate and repair the alveolar surface after injury.[88] They are also involved in alveolar defense through surfactant production and the release of some cytokines that trigger inflammation.

Macrophages are another common cell found in the alveolar region.[85] They can move from the pulmonary capillary circulation by squeezing through openings in the alveolar septa and then move out onto the alveolar surface. They are defensive cells that patrol the alveolar region and phagocytize foreign particles and cells (e.g., bacteria). They can present portions of the foreign particles and bacteria to lymphocytes as part of the immune response and contain various digestive enzymes (e.g., trypsin) that break down the material they engulf.

Within the interalveolar septum is an interstitial space that contains matrix material and the pulmonary capillaries. Also found in the interstitial space are bands of elastin fibers and a collagen fiber matrix.[46] These fibers support the alveolar cells and the shape of the alveolus. Small openings are located in the alveolar septa. Some of the openings allow gas to move from one alveolus to another. These are called the **pores of Kohn.** Other openings connect alveoli with secondary respiratory bronchioles. These passageways are called the *canals of Lambert.* All of these alveolar openings and passageways facilitate the collateral movement of gas and help maintain alveolar volume.[89]

Blood-Gas Barrier

Gas exchange between alveolar gas and pulmonary capillary blood occurs across the **alveolar-capillary membrane.** In a typical adult, this blood-gas barrier stretches over a surface area of approximately 140 m^2 and is less than 1 µm thick.[90] This makes the membrane more than 50 times larger than the area covered by skin and more than 2000 times thinner.

The blood-gas barrier is composed of many different layers through which O_2 and CO_2 diffuse (Figure 9-56). The outermost layer is a very thin film of fluid composed primarily of surfactant that forms into a tubular myelin matrix. Below the surfactant fluid layer is the thinly stretched type I cell. The delicate structure of type I cells makes them highly susceptible to injury from toxins carried to them by either airborne or bloodborne routes. The interstitial space and its contents lie below. Within this space are basement membranes, matrix material

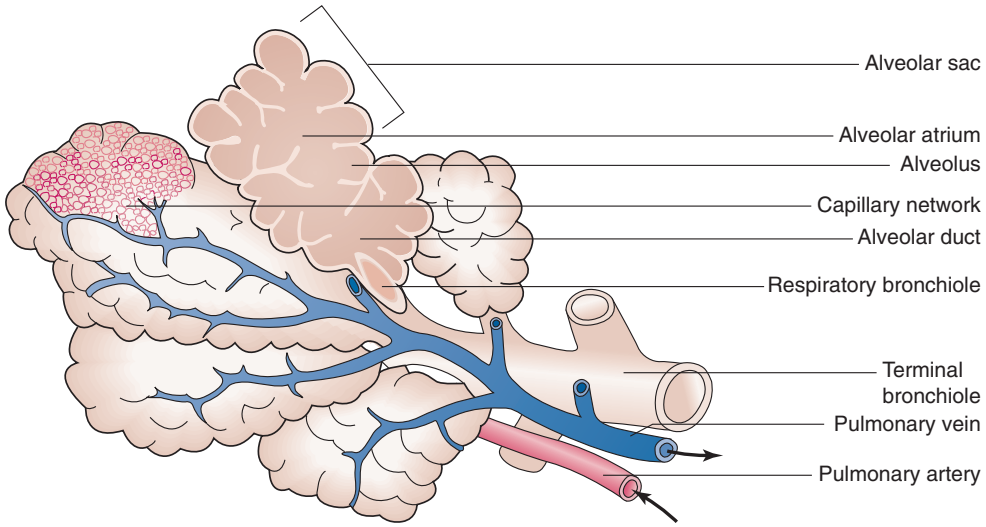

FIGURE 9-51 The acinus (primary lobule) of the lung is composed of a single terminal bronchiole, numerous respiratory bronchioles, alveolar ducts, sacs of alveoli, and about 10,000 alveoli. Pulmonary blood flow is delivered to the acinus by a pulmonary arteriole and drained from it by a pulmonary venule. (From Hicks GH: Cardiopulmonary anatomy and physiology, Philadelphia, 2000, WB Saunders.)

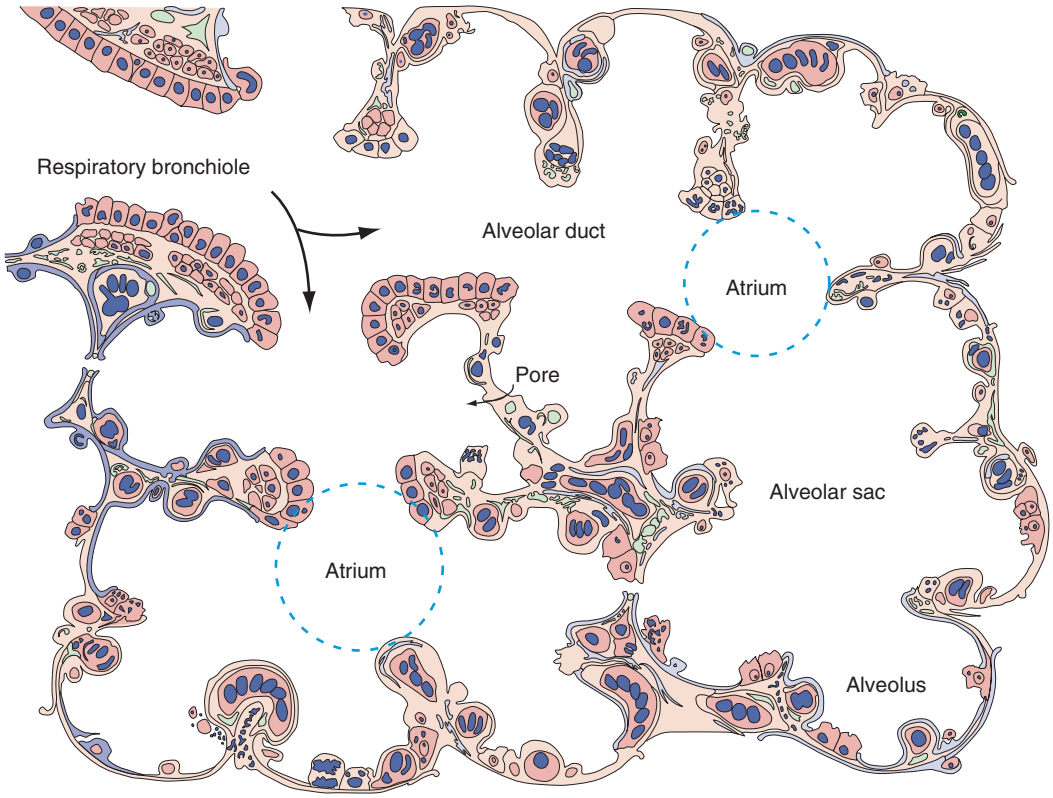

FIGURE 9-52 Microscopic view of respiratory zone airways. (Modified from Sorokin SP: The respiratory system. In Greep RO, Weiss L, editors: Histology, New York, 1973, McGraw-Hill.)

connective tissue fibers, and the alveolar capillary.[46] The capillary wall is formed from thin, flat squamous epithelia called *endothelial cells* that form a thin tube by connecting together at their edges with tight junctions. Within the capillary lie the plasma and, finally, the erythrocytes. Both O_2 and CO_2 cross through the membrane via partial pressure-driven diffusion.

The blood-gas barrier is not equal in thickness and chemical content from side to side (see Figure 9-56). On one side of the alveolar wall the type I cells and capillary endothelial cells lie close together, with a thin interstitial space. This part of the blood-gas barrier is, on average, 0.2 to 0.3 μm thick, and it is where the alveolar capillary bulges into the alveolar space.[90] On

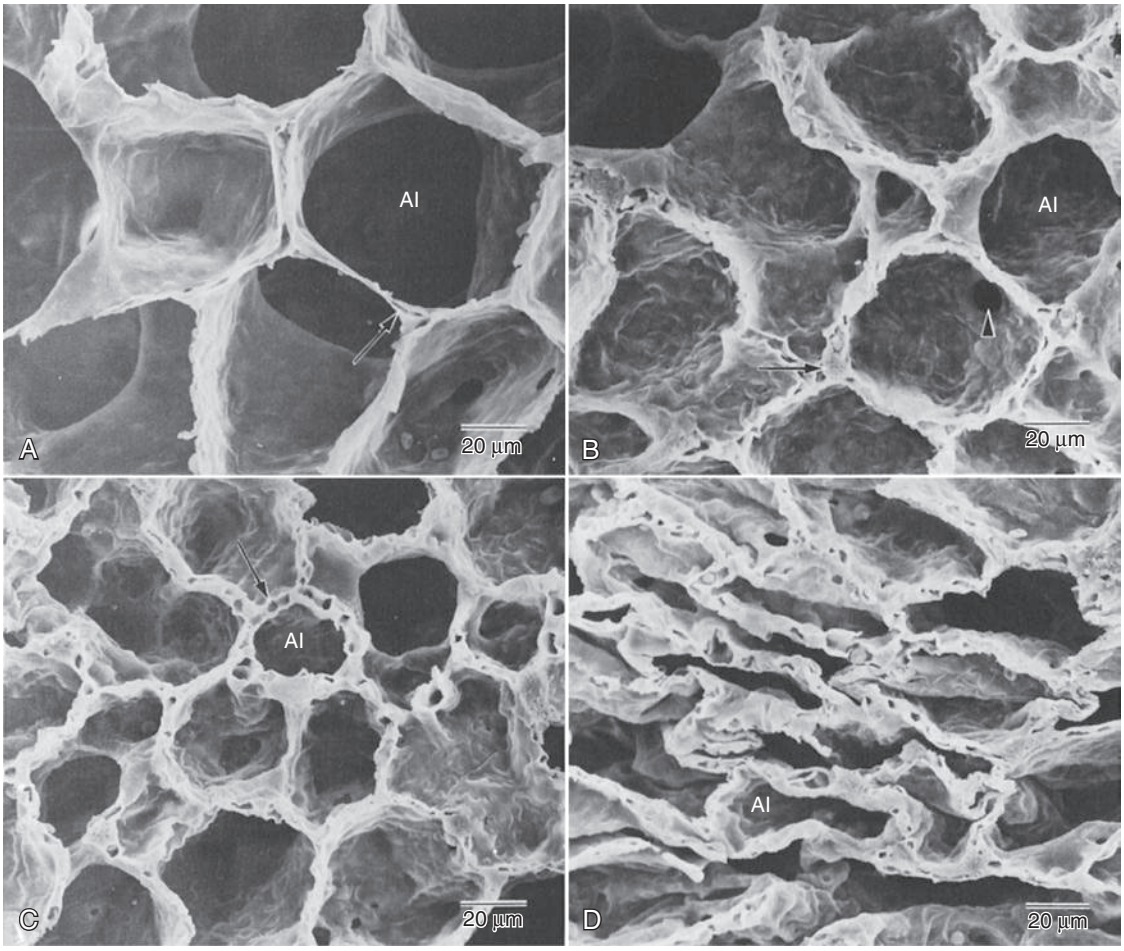

FIGURE 9-53 Scanning electron photomicrographs at the same magnification of perfusion-fixed normal rat lung at different degrees of inflation pressure. **A,** 30 cm H_2O (total lung capacity [TLC]). **B,** 8 cm H_2O (approximately 50% TLC). **C,** 4 cm H_2O (near resting inflation or functional residual capacity [FRC]). **D,** 0 cm H_2O (minimum volume). Pulmonary artery pressure was held constant at 25 cm H_2O, and left atrial pressure was held at 6 cm H_2O. Intrinsic shape of alveoli *(Al)* is maintained from FRC to TLC **(A-C).** Alveolar walls are flat with sharp corners where the adjacent walls meet. Note the flat shape of the alveolar capillaries *(arrow)* at TLC (**A,** lung zone 1 conditions, air pressure > blood pressure) compared with their round shape *(arrow)* at FRC (**C,** lung zone 3 conditions, blood pressure > air pressure). The alveolar walls are folded, and the alveolar shape is distorted at the minimum lung volume **(D).** The *arrow* in **B** identifies a type II pneumocyte at an alveolar corner. The *arrowhead* in **B** identifies a pore of Kohn through an alveolar wall. FIGURE 9-55 Transmission electron photomicrograph of human lungs at high magnification. **A,** Type II pneumocytes are cuboidal epithelial cells that contain characteristic lamellar bodies *(LB)* in their cytoplasm and have stubby microvilli *(Mv)* that extend from their apical surface into the alveolar airspace *(AS).* Other prominent organelles within the type II cells are mitochondria *(Mi),* a single nucleus *(Nu),* and a Golgi apparatus *(G),* which forms the lamellar bodies. Adjacent to the type II cell is a portion of a type I pneumocyte (I). The abluminal side of the epithelial cells of the alveolus rests on a continuous basal lamina *(arrowhead).* **B,** Apical region of a type II cell contains two lamellar bodies *(LB),* one of which has been fixed in the process of secreting its contents *(arrows).* The lamellar bodies are believed to be the source of surfactant. Type II cells are more often found in the corners of the alveolar walls. (From Mason RJ, Broaddus VC, Martin, T, et al, editors: Murray and Nadel's textbook of respiratory medicine, ed 4, Philadelphia, 2011, WB Saunders.)

the other side, where there is a thicker interstitial space with greater fiber, matrix, and nuclear material content, the barrier can be more than 3 to 10 times thicker. This difference between the two sides functionally results in "faster-weaker" and "slower-stronger" diffusion sides of the blood-gas barrier.

The interstitial space within the alveolar septum contains a network of fibers that form a kind of connective tissue skeleton holding the alveolar structures in place and together.[91] The fibers within the alveolar septum are part of the continuum of connective tissue fibers found in the pleural surface and in the airway walls that extends all the way to the root of the lung in the hilar region. Elastin and collagen fiber bands are formed by fibroblasts into a network within the interstitial space into which the capillaries are woven. Also around the fibers and capillaries is a nonliving matrix of fluid and solutes. The weaving path taken by the capillaries passes them from the thick to the thin sides of the blood-gas barrier as they extend through the septum. In the thin side, the basement membranes of the endothelial and type I cells fuse into a structure called the *lamina densa,* which is formed from collagen.[92] In the thick side, thick bands of collagen and elastin are found. The collagen and endothelial cells are attached to either side of the *lamina densa* by a

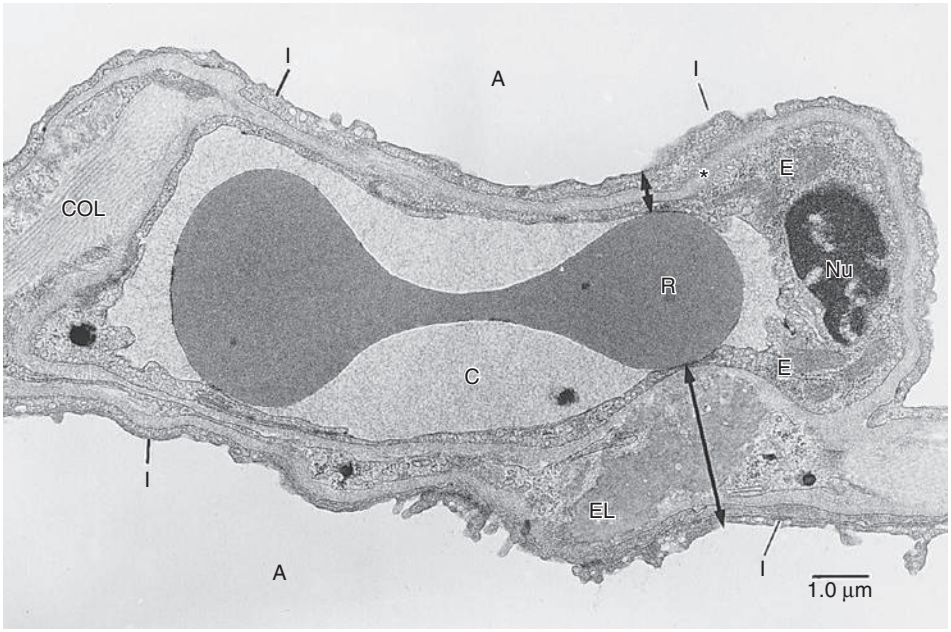

FIGURE 9-56 High-magnification transmission electron photomicrograph of a human lung showing a cross section of an alveolar wall through which O_2 and CO_2 diffuse. Air *(A)* in the alveolar space is seen on either side of the wall. The thin side of the alveolar-capillary membrane *(short double arrow)* consists of type I pneumocytes *(I),* interstitium *(*)* formed by the fused basement membranes of the type I cell and the endothelial cells *(E),* and its nucleus *(Nu)* that forms the pulmonary capillary wall. Within the capillary *(C)* is the erythrocyte *(R).* The thick side of the membrane *(long double arrows)* has an accumulation of elastin *(EL),* collagen *(COL),* and matrix material that jointly separates the type I cell from the capillary endothelial cell. Greater diffusion occurs across the thin side. (From Mason RJ, Broaddus VC, Martin T, et al, editors: Murray and Nadel's textbook of respiratory medicine, ed 4, Philadelphia, 2011, WB Saunders.)

series of protein fibers collectively known as *laminins.* Laminins effectively bind together the blood-gas barrier into a three-part laminate that results in a relatively strong and thin structure that can normally, with the additional support offered by the capillary network, withstand the everyday stress of alveolar and capillary stretch.[93]

However, conditions of pulmonary hypertension (e.g., capillary pressure >30 mm Hg during congestive heart failure and high-altitude pulmonary edema) and excessive tidal volume and airway pressure during positive pressure ventilation (e.g., tidal volume >6 to 8 ml/kg and airway pressures >30 cm H_2O) can result in stress failure of the blood-gas membrane. Stress failure results in endothelial or type I cell stretching and shearing injuries. Extreme examples are known to occur in racehorses that experience exercise-induced pulmonary hemorrhaging as a result of developing excessively high pulmonary vascular pressures (e.g., pulmonary capillary pressures 100 mm Hg).

RULE OF THUMB

The 30:30 Rule

Pulmonary hypertension (e.g., capillary pressure >30 mm Hg) and excessive tidal volume and airway pressure during positive pressure ventilation (e.g., tidal volume >6 to 8 ml/kg and airway pressures >30 cm H_2O) can result in stress failure of the blood-gas membrane.

SUMMARY CHECKLIST

- Many different genes regulate the development of the respiratory system from conception through adult life. Many pulmonary diseases are caused by genetic abnormalities.
- The development of the respiratory system follows a well-defined schedule; interruptions or insults in the course of development can result in respiratory disease at birth and in adulthood.
- Fetal circulation and respiration differ markedly from circulation and respiration in the postnatal period.
- The transition from intrauterine to extrauterine life involves a nonaerated, fluid-filled lung converting to an efficient air-filled organ of gas exchange.
- Closure of the foramen ovale and ductus arteriosus are important events in the transition to extrauterine life.
- The thorax houses and protects the lungs; it is also a movable shell that makes ventilation possible.
- The diaphragm is the primary muscle of ventilation; together with the accessory muscles and thoracic structures, it provides the ability to move large volumes of gas into and out of the lungs.
- The lungs receive blood flow from the pulmonary circulation for gas exchange and the bronchial circulation to support airway and pleural tissue metabolism.
- The pulmonary circulation is capable of acting as a reservoir, removing blood clots and numerous mediators, as well as activating important vasoactive agents.

- Motor and sensory neurons innervate the muscles of ventilation and various lung tissues. Autonomic neurons conduct motor and sensory signaling to control various tissues and sense various activities.
- The upper respiratory tract heats and humidifies inspired air. Its various structures also protect the lungs against foreign substances.
- The lower respiratory tract conducts respired gases from the upper airway to the respiratory zones of the lung. It contains many structures that help clear and defend the lung.
- The airways branch into lobes in both the right and the left lungs; these lobes consist of various segments.
- The respiratory bronchioles, alveolar ducts, and alveoli provide a large, yet extremely thin, membrane for the exchange of O_2 and CO_2 between air and blood. Disruption of the blood-gas barrier can occur from excessive capillary pressures, lung inflation, and exposure to various toxins (e.g., 100% O_2).

CHAPTER 10

The Cardiovascular System

NARCISO E. RODRIGUEZ

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the anatomy of the heart and vascular systems.
- State the key characteristics of cardiac tissue.
- Describe the local and central control mechanisms of the heart and vascular systems.
- Describe how the cardiovascular system functions under normal and abnormal conditions.
- Calculate cardiac output given stroke volume and heart rate.
- Calculate ejection fraction given stroke volume and end-diastolic volume.
- Identify the electrical and mechanical events in relation to the normal cardiac cycle.

CHAPTER OUTLINE

KEY TERMS

afterload
arteriovenous anastomosis
automaticity
baroreceptors
cardiac output
cardiac tamponade
chemoreceptors
congestive heart failure (CHF)
contractility
end-diastolic volume (EDV)
end-systolic volume (ESV)
Frank-Starling law
heart rate (HR)
negative feedback loop
negative inotropism
pericardium
positive inotropism
preload
regurgitation
stenosis
stroke volume (SV)
vasoconstriction
vasodilation

FUNCTIONAL ANATOMY

Heart

Anatomy of the Heart

The heart is a hollow, four-chambered muscular organ approximately the size of a fist. It is positioned obliquely in the middle compartment of the mediastinum of the chest, just behind the sternum (Figure 10-1). Approximately two-thirds of the heart lies to the left of the midline of the sternum between the 2nd through the 6th ribs. The apex of the heart is formed by the tip of the left ventricle and lies just above the diaphragm at the level of the 5th intercostal space to the left. The base of the heart is formed by the atria and projects to the right, lying just below the 2nd rib. Posteriorly, the heart rests on the bodies of the 5th to the 8th thoracic vertebrae. Because of its position between the sternum and the spine, compression of the heart can maintain blood flow during cardiopulmonary resuscitation.[1]

Externally, surface grooves called *sulci* mark the boundaries of the heart chambers. Compared with the ventricles, the atria are small, thin-walled chambers that contribute little to the total pumping activity of the heart.

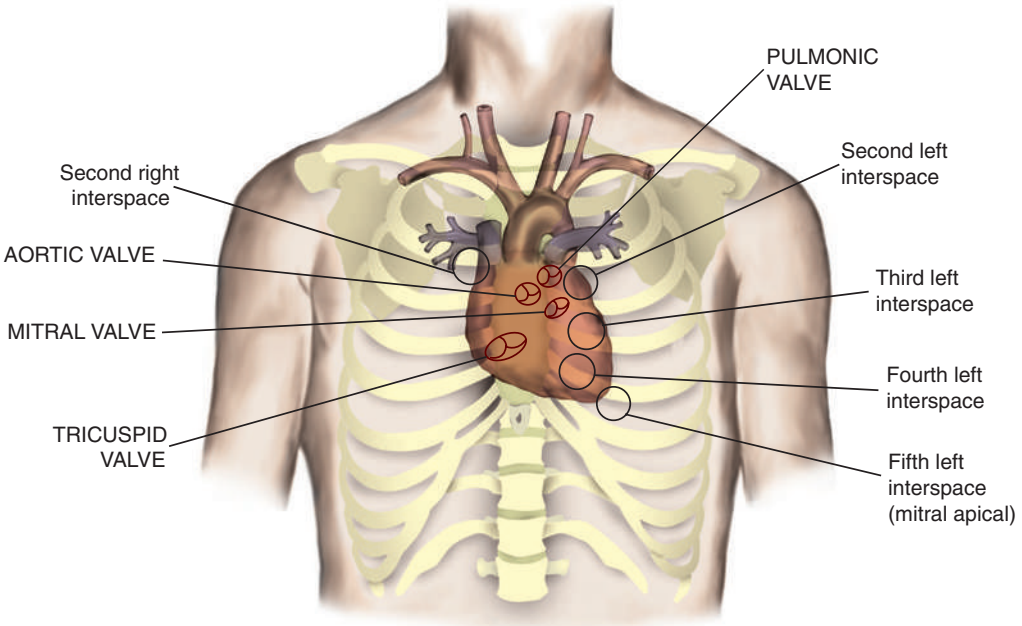

FIGURE 10-1 Anterior view of the thorax showing the position of the heart in relation to the ribs, sternum, diaphragm, and position of the heart valves. (From Seidel HM, et al: Mosby's guide to physical examination, ed 2, St Louis, 1991, Mosby.)

The heart is enclosed in a sac called the **pericardium**.[2] The structure of the pericardium can be summarized as follows:

1. *Fibrous pericardium:* Tough, loose-fitting, and inelastic sac surrounding the heart
2. *Serous pericardium:* Consisting of two layers:
   a. *Parietal layer:* Inner lining of the fibrous pericardium
   b. *Visceral layer or epicardium:* Covering the outer surface of the heart and great vessels

A thin layer of fluid called the *pericardial fluid* separates the two layers of the serous pericardium. This layer of fluid helps minimize friction within the pericardium. Inflammation of the pericardium results in a clinical condition called *pericarditis*. An abnormal amount of fluid can accumulate between the layers, resulting in a *pericardial effusion*. A large pericardial effusion may affect the pumping function of the heart, resulting in a **cardiac tamponade**. A cardiac tamponade compresses the heart muscle, leading to a serious decrease in blood flow to the body, which ultimately may lead to shock and death.[1,3]

The heart wall consists of three layers: (1) outer epicardium, (2) middle myocardium, and (3) inner endocardium. The myocardium composes the bulk of the heart muscle and consists of bands of involuntary striated muscle fibers. The contraction of these muscle fibers creates the pumplike action needed to move blood throughout the body.

Support for the four interior chambers and valves of the heart is provided by four atrioventricular (AV) rings, which form a fibrous "skeleton." Each ring is composed of dense connective tissue termed *annulus fibrosus cordis.* This connective tissue electrically isolates the atria from the ventricles. No impulses can be transmitted through the heart tissue from the atria to the ventricles.[1]

The two atrial chambers are thin-walled "cups" of myocardial tissue, separated by an interatrial septum. On the right side of the interatrial septum is an oval depression called the *fossa ovalis cordis,* the remnant of the fetal foramen ovale. In addition, each atrium has an appendage, or auricle, the function of which is unknown. In the presence of cardiac dysrhythmias (like atrial fibrillation), blood flow can pool on these appendages, leading to the formation of thrombi.

The two lower heart chambers, or ventricles, make up the bulk of the heart's muscle mass and do most of the pumping that circulates the blood (Figure 10-2). The mass of the left ventricle is normally approximately two-thirds larger than the mass of the right ventricle and has a spherical appearance when viewed across anteriorly.[4] The right ventricle is thin-walled, forming a pocket-like attachment to the left ventricle. Because of this relationship, contraction of the left ventricle pulls in the right ventricular wall, aiding its contraction. The effect, termed *left ventricular aid,* explains why some forms of right ventricular failure are less harmful than might be expected. The right and left ventricles are separated by a muscle wall termed the *interventricular septum* (see Figure 10-2).[4]

The valves of the heart are flaps of fibrous tissue firmly anchored to the *annulus fibrosus cordis* (Figure 10-3). Because they are located between the atria and ventricles, they are called *atrioventricular valves,* or AV valves. The valve in the right side is called the *tricuspid valve*. The valve on the left is the *bicuspid,* or *mitral, valve.* The AV valves close during systole (contraction of the ventricles), preventing backflow of blood into the atria. The free ends of the AV valves are anchored to papillary muscles of the endocardium by the *chordae tendineae cordis* (see Figure 10-2). During systole, papillary muscle contraction prevents the

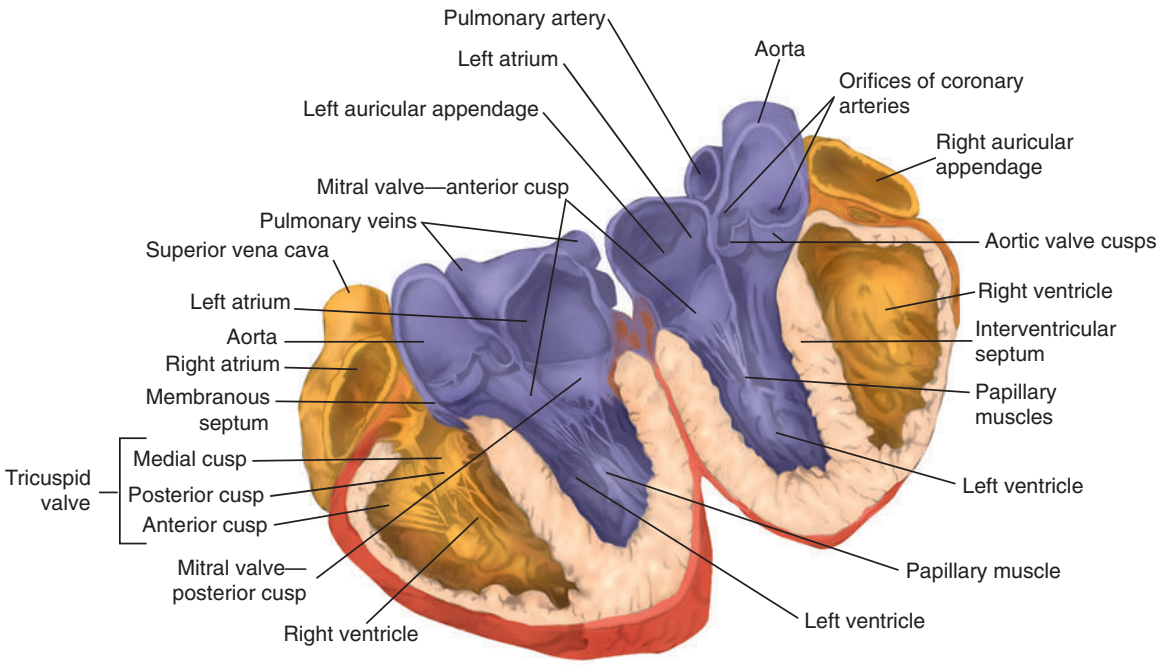

FIGURE 10-2 Drawing of the heart split perpendicular to the interventricular septum to illustrate anatomic relationships of the heart. (From Berne RM, Levy MN, editors: Physiology, ed 5, St Louis, 2004, Mosby.)

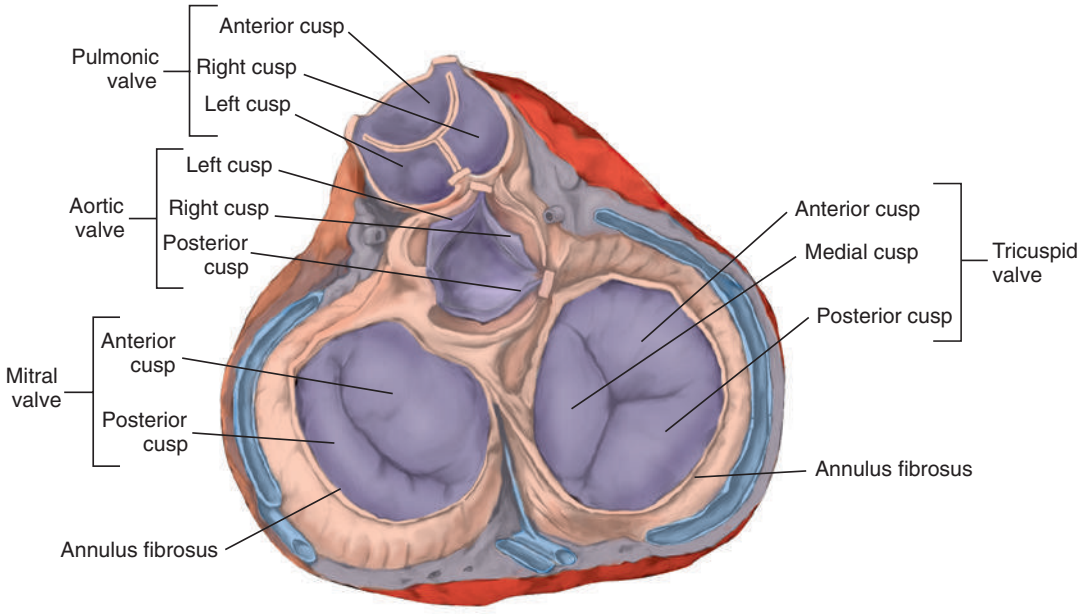

FIGURE 10-3 Four cardiac valves as viewed from the base of the heart. Note how the leaflets overlap in the closed valves.

AV valves from swinging upward into the atria. Damage to either the chordae tendineae cordis or the papillary muscles can impair function of the AV valves and cause leakage upward into the atria.[1]

Common valve problems include regurgitation and stenosis. **Regurgitation** is the backflow of blood through an incompetent or a damaged valve. **Stenosis** is a pathologic narrowing or constriction of a valve outlet, which causes increased pressure in the proximal chamber and vessels. Both conditions affect cardiac performance. In mitral stenosis, high pressures in the left atrium back up into the pulmonary circulation. This can cause pulmonary edema and a diastolic murmur (see Chapter 16).[3,5]

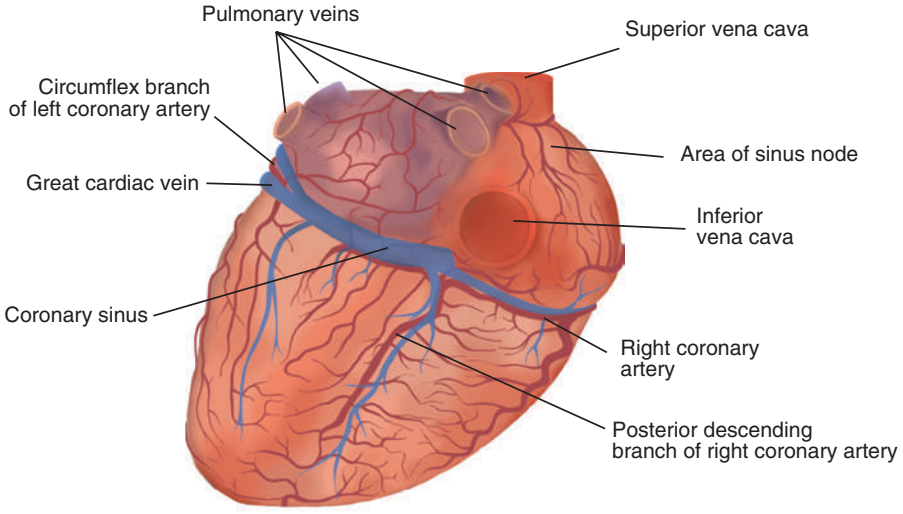
A set of semilunar valves separates the ventricles from their arterial outflow tracts, the pulmonary artery and the aorta (see Figure 10-3). Consisting of three half-moon–shaped cusps attached to the arterial wall, these valves prevent backflow of blood into the ventricles during diastole (or when the chambers

of the heart fill with blood). The pulmonary valve is at the outflow tract of the right ventricle. Similar to the AV valves, the semilunar valves can leak (regurgitation) or become partially obstructed (stenosis).[1]

Similar to the lungs, the heart has its own circulatory system, which is called the *coronary circulation.* However, in contrast to the lungs, the heart has a high metabolic rate, which requires more blood flow per gram of tissue weight than any other organ except the kidneys. To meet these needs, the coronary circulation provides an extensive network of branches to all myocardial tissue (Figure 10-4).

Two main coronary arteries, a left and a right, arise from the root of the aorta. Because of their position underneath the aortic semilunar valves (see Figure 10-4), the coronary arteries get the maximal pulse of pressure generated by contraction of the left ventricle. Blood flows through the coronary arteries only during diastole. A healthy heart muscle requires approximately $\frac{1}{20}$ of the blood supply of the body to function properly. Partial obstruction of a coronary artery may lead to tissue ischemia (decreased oxygen supply), a clinical condition called *angina pectoris*. Complete obstruction may cause tissue death or infarct, a condition called *myocardial infarction (MI).*[3]

After passing through the capillary beds of the myocardium, the venous blood is collected by the coronary veins that closely parallel the arteries (see Figure 10-4). These veins gather together into a large vessel called the *coronary sinus,* which passes left to right across the posterior surface of the heart. The coronary sinus empties into the right atrium between the opening of the inferior vena cava (IVC) and the tricuspid valve.[1] In addition, some coronary venous blood flows back into the heart through the *thebesian veins.*[1] The thebesian veins empty directly into all the heart chambers. Any blood coming from the



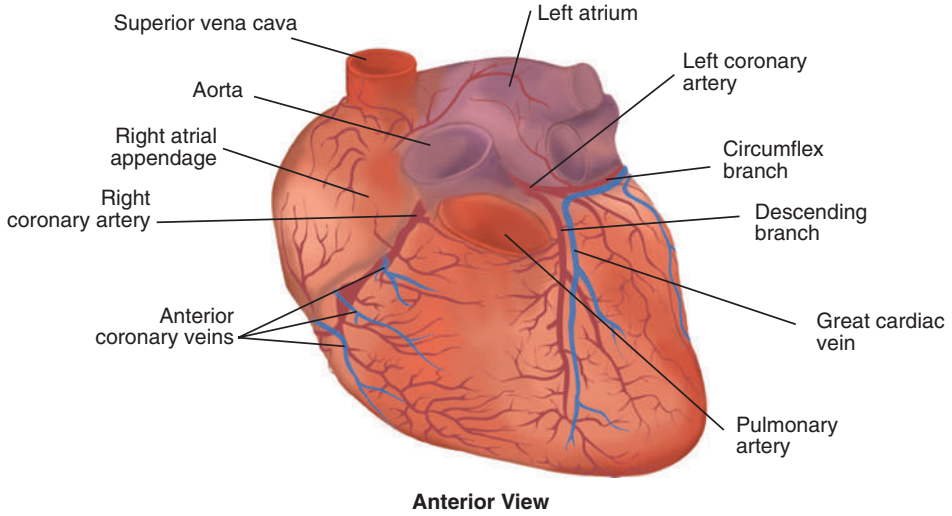


FIGURE 10-4 Coronary circulation as seen on anterior and posterior surfaces of the heart, illustrating the location and distribution of the principal coronary vessels.

MINI CLINI

Mitral Stenosis, Poor Oxygenation, and Increased Work of Breathing

The mitral valve lies between the left atrium and left ventricle. A stenotic mitral valve is one that is narrowed and offers high resistance to the blood flowing into the left ventricle from the left atrium. Pulmonary edema is a condition in which fluid collects in the alveoli and *interstitial spaces* in the lungs affecting oxygenation.

PROBLEM: Why does a patient with mitral stenosis have poor oxygenation of the blood and increased work of breathing?

DISCUSSION: Blood flows from the lungs into the left atrium, where it may encounter high resistance through a narrowed, stenotic mitral valve; this causes high pressure to build in the left atrium. Pressure in the pulmonary veins and eventually in the pulmonary capillaries also increases. This high pressure within the capillaries engorges them and forces fluid components of the blood plasma out of the vessels and into the interstitial spaces of the lungs and inside the alveoli, creating pulmonary edema. This collection of fluid interferes with O_2 diffusion from the lung into the blood. Engorged capillaries surrounding the alveoli create a stiff "web" around each alveolus, which makes expanding the lungs difficult. Some areas of the lung expand more easily than others, which causes inhaled air to be preferentially directed into these compliant regions, whereas "stiffer," more noncompliant regions are underventilated. The underventilated regions do not properly oxygenate the blood. Mitral stenosis, a cardiac problem, has significant pulmonary consequences.

MINI CLINI

Heart Rate and Coronary Perfusion

PROBLEM: Why might an extremely high heart rate decrease blood flow through the coronary arteries?

DISCUSSION: Blood flow through the coronary arteries occurs only during ventricular diastole when the aortic semilunar valves close. During systole, the myocardium contracts with such force that coronary artery pressures increase to values greater than aortic pressures. As the **heart rate (HR)** increases, both systolic and diastolic times must decrease. As diastolic time decreases, increasingly less time is available for coronary artery perfusion that occurs during diastole, until finally coronary blood flow is significantly reduced. This is critically important in an individual who already has reduced coronary circulation caused by arteriosclerotic heart disease. Not only is coronary artery perfusion compromised with severe tachycardia but also decreased ventricular filling time causes decreased **stroke volume (SV)** and decreased **cardiac output (CO)**.

thebesian veins that enters the left atrium or ventricle mixes with arterial blood coming from the lungs. Whenever venous blood mixes with arterial blood, the overall O_2 content decreases. Because the thebesian veins bypass or shunt around the pulmonary circulation this phenomenon is called an *anatomic shunt.* When combined with a similar bypass in the bronchial circulation (see Chapter 9), these normal anatomic shunts account for approximately 2% to 3% of the total CO.[1,5]

Properties of the Heart Muscle

The performance of the heart as a pump depends on its ability to (1) initiate and conduct electrical impulses and to (2) contract synchronously the heart's muscle fibers quickly and efficiently.[5] These actions are possible only because myocardial tissue possesses the following four key properties:

- Excitability
- Inherent rhythmicity or automaticity
- Conductivity
- Contractility

Excitability is the ability of cells to respond to electrical, chemical, or mechanical stimulation. The myocardial property of *excitability* is the same as that exhibited by other muscles and tissues. Electrolyte imbalances and certain drugs can increase myocardial excitability and produce abnormalities in electrical conduction that may lead to cardiac arrhythmias.

Inherent rhythmicity, or **automaticity**, is the unique ability of the cardiac muscle to initiate a spontaneous electrical impulse. Although such impulses can arise from anywhere in the cardiac tissue, this ability is highly developed in specialized areas called *heart pacemaker,* or *nodal tissues.* The sinoatrial (SA) node and the atrioventricular (AV) node are the heart primary pacemakers (see Chapter 18). An electrical impulse from any source other than a normal heart pacemaker is considered abnormal and represents one of the many causes of *cardiac arrhythmias.*

Conductivity is the ability of myocardial tissue to spread and conduct electrical impulses. This property is similar to that of smooth muscle in that it allows the myocardium to contract without direct neural innervation (as required by skeletal muscle). The rate at which electrical impulses spread throughout the myocardium is variable. These differences in conduction rates are needed to ensure synchronous contraction of the cardiac chambers. Abnormal conductivity can affect the timing of chamber contractions and decrease cardiac efficiency.

Contractility, in response to an electrical impulse, is the primary function of the myocardium. In contrast to the contractions of other muscle tissues, cardiac contractions cannot be sustained or tetanized because myocardial tissue exhibits a prolonged period of inexcitability after contraction. The period during which the myocardium cannot be stimulated is called the *refractory period,* and it lasts approximately 250 msec, nearly as long as the heart contraction or systole.

Microanatomy of the Heart Muscle

Understanding how cardiac muscle contracts requires knowledge of the microanatomy of the heart. Unlike skeletal muscle

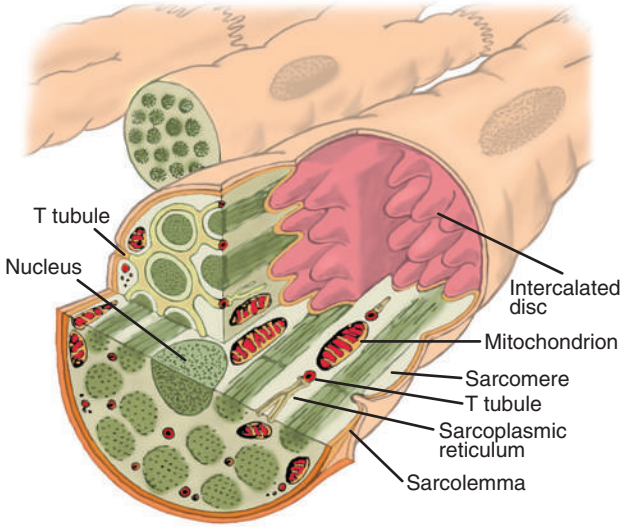

FIGURE 10-5 Major structural features of cardiac muscle fibers. Note the presence of intercalated discs connecting successive sarcomeres. (Modified from Moffett DF, Moffett SB, Schauf CL: Human physiology: foundations and frontiers, ed 2, St Louis, 1993, Mosby.)

fibers, cardiac cells are short, fat, branched, and interconnected. Individual cardiac fibers are enclosed in a membrane called the *sarcolemma,* which is surrounded by a rich capillary network (Figure 10-5).

Cardiac fibers are separated by irregular transverse thickenings of the sarcolemma called *intercalated discs.* These discs provide structural support and aid in electrical conduction between fibers. Each fiber consists of many smaller units called *myofibrils,* which contain repeated structures approximately 2 μm in size termed *sarcomeres.* Within the sarcomeres are contractile protein filaments responsible for shortening the myocardium during systole. These proteins are of two types: thick filaments composed mainly of myosin and thin filaments composed mostly of actin. Myocardial cells contract when actin and myosin combine to form reversible bridges between these thick and thin filaments.[2,5]

In principle, the tension developed during myocardial contraction is directly proportional to the number of cross-bridges between the actin and myosin filaments. This principle underlies Starling's law of the heart, also known as the **Frank-Starling law**. According to this law, the more a cardiac fiber is stretched (up to a point), the greater the tension it generates when contracted. This relationship is extremely important and is explored later in the discussion of the heart as a pump.[6]

Vascular System

The vascular system has two major subdivisions: the *systemic circulation* and the *pulmonary circulation*. The systemic circulation begins with the aorta on the left ventricle and ends in the right atrium. The pulmonary circulation begins with the pulmonary artery out of the right ventricle and ends in the left atrium. The blood flow to and from the heart is depicted in Figure 10-6.[1]

Venous, or deoxygenated blood from the head and upper extremities enters the right atrium from the superior vena cava (SVC), and blood from the lower body enters from the inferior vena cava (IVC). From the right atrium, blood flows into the right ventricle. The right ventricle pumps the blood into the pulmonary arteries, and on to the lungs.

Arterial, or oxygenated, blood returns to the left atrium through the pulmonary veins. The left atrium pumps blood into the left ventricle. The blood is then pumped to the body through the aorta. From the capillary network of the various body tissues, the deoxygenated venous blood returns to the right ventricle through the SVC and IVC.[1]

Systemic Circulation

The systemic circulation has three major components: (1) arterial system, (2) capillary system, and (3) venous system. These vessels regulate not only the amount of blood flow per minute (cardiac output) but also the distribution of blood to organs and tissues (perfusion). To achieve these functions, each component has a unique structure and plays a different role in the circulatory system as a whole.[2]

The *arterial system* consists of large, highly elastic, low-resistance arteries and small, muscular arterioles of varying resistance. With their elasticity, the large arteries help transmit and maintain the head of pressure generated by the heart. Together, the large arteries are called *conductance vessels*. Just as faucets control the flow of water into a sink, the smaller arterioles control blood flow into the capillaries. Arterioles provide this control by varying their flow resistance. Arterioles play a major role in the distribution and regulation of blood pressure and are referred to as *resistance vessels.*

The vast *capillary system,* or microcirculation, maintains a constant exchange of nutrients and waste products for the cells and tissues of the body. For this reason, the capillaries are commonly referred to as *exchange vessels*. Figure 10-7 shows the structure of a typical capillary network. Blood flows into the network by an arteriole and out through a venule. A direct communication between these vessels is called an **arteriovenous anastomosis**. When open, these anastomoses allows arterial blood to shunt around the capillary bed and flow directly into the venules. Downstream the arteriole divides into terminal arterioles, which branch further into thoroughfare channels and true capillaries.

Capillaries have smooth muscle rings at their proximal ends, called *precapillary sphincters.* Contraction of these sphincters decreases blood flow locally, whereas relaxation increases perfusion. In combination, these various channels, sphincters, and bypasses allow precise control over the direction and amount of blood flow to a given area of tissue.

The *venous system* consists of small, expandable venules and veins and larger, more elastic veins. Besides conducting blood back to the heart, these vessels act as a reservoir for the circulatory system. At any given time, the veins and venules hold approximately three-quarters of the body's total blood volume.

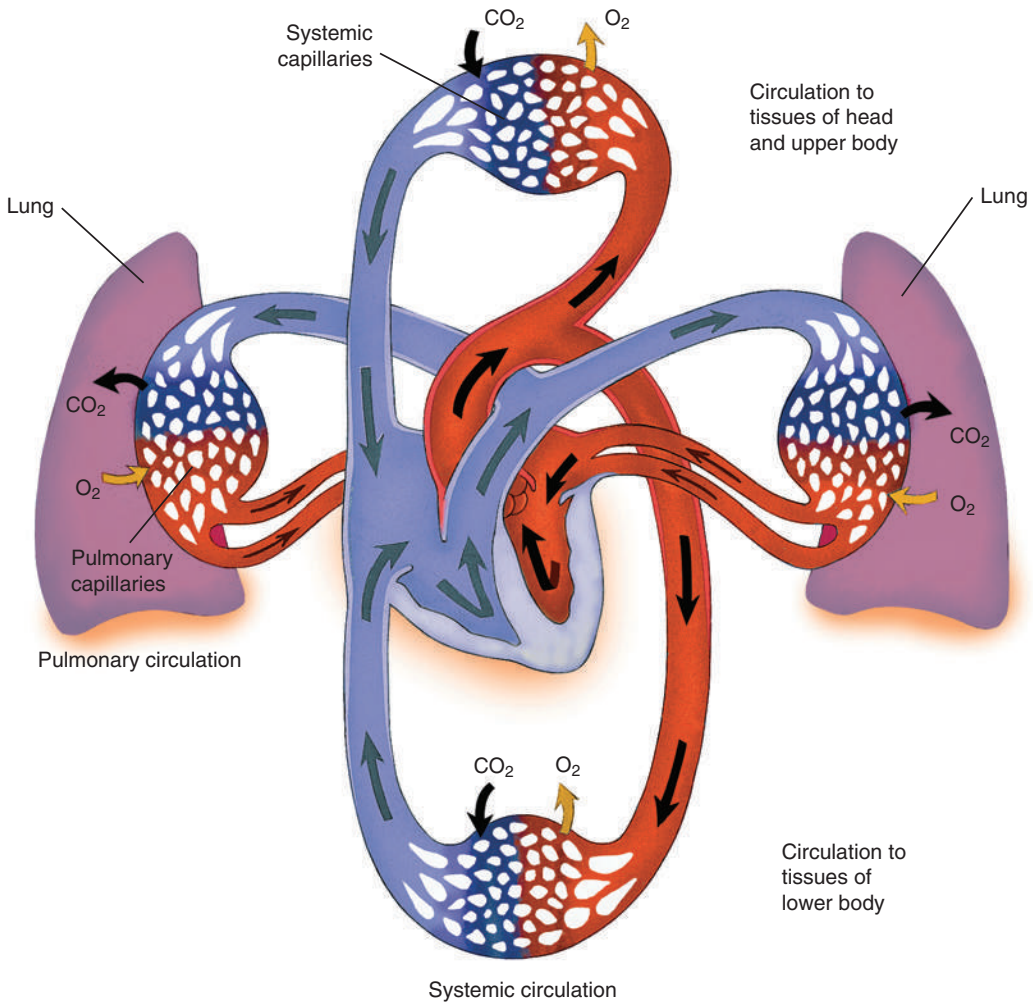

FIGURE 10-6 Generalized circulatory pathways between the heart, lung, and extremities.

The volume of blood held in this reservoir can be rapidly changed as needed simply by altering the tone of these vessels. By quickly changing its holding capacity, the venous system can match the volume of circulating blood to that needed to maintain adequate tissue perfusion. The components of the venous system, especially the small, expandable venules and veins, are termed *capacitance vessels.*

The venous system must overcome gravity to return blood to the heart. The following four mechanisms combine to aid venous return to the heart: (1) sympathetic venous tone; (2) skeletal muscle pumping, or "milking" (combined with venous one-way valves); (3) cardiac suction; and (4) thoracic pressure differences caused by respiratory efforts.[4]

The last mechanism is often called the *thoracic pump.* The thoracic pump is particularly important to respiratory therapists (RTs) because artificial ventilation with positive pressure reverses normal thoracic pressure gradients. Positive pressure ventilation (PPV) impedes, rather than assists, venous return. As long as blood volume, cardiac function, and vasomotor tone are adequate, PPV has a minimal effect on venous return. Patients who are hypovolemic or in cardiac failure are vulnerable to a reduction in CO when PPV is applied to the lungs.[6]

Although the heart is a single organ, it functions as two separate pumps. The right side of the heart generates a pressure of approximately 25 mm Hg to drive blood through the low-resistance, low-pressure pulmonary circulation. The left side of the heart generates pressures of approximately 120 mm Hg to propel blood through the higher pressure, high-resistance systemic circulation.

Vascular Resistance

Similar to the movement of any fluid through tubes, blood flow through the vascular system is opposed by frictional forces. The sum of all frictional forces opposing blood flow through the systemic circulation is called *systemic vascular resistance (SVR).* SVR must equal the difference in pressure between the beginning and the end of the circuit, divided by the flow. The beginning pressure for the systemic circulation is the mean aortic pressure; ending pressure equals right atrial pressure or *central venous pressure (CVP).* Flow for the system as a whole equals the CO. SVR can be calculated by the following formula:

$$\text{SVR} = \frac{\text{Mean aortic pressure} - \text{Right atrial pressure}}{\text{Cardiac output}}$$

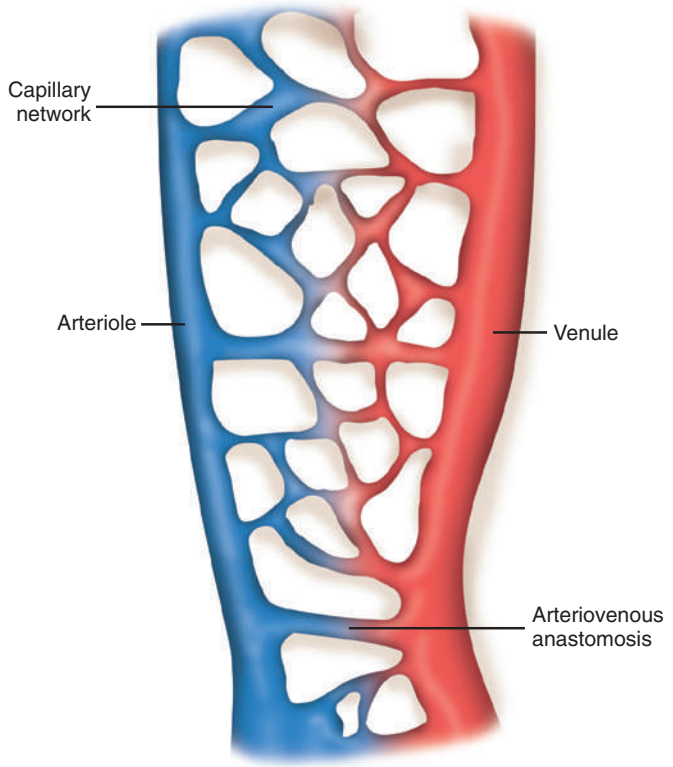

FIGURE 10-7 Components of a microcirculatory network. Blood flows from arteriolar to venular vessels through a network of capillaries. Opening of the arteriovenous anastomosis directs blood flow out of the capillary network. (Modified from Stevens A, Lowe J: Human histology, ed 2, St Louis, 1997, Mosby.)

Given a normal mean aortic pressure of 90 mm Hg, a mean right atrial pressure of approximately 4 mm Hg, and a normal CO of 5 L/min, normal SVR is computed as follows:

$$\text{SVR} = \frac{90\text{ mm Hg} - 4\text{ mm Hg}}{5\text{ L/min}}$$
$$= 17.2\text{ mm Hg/L/min}$$

The same concepts can be used to compute resistance in the pulmonary circulation. Beginning pressure for the pulmonary circulation is the mean pulmonary artery pressure; ending pressure equals left atrial pressure. Flow for the pulmonary circulation is the same as it is for the systemic system, which equals the CO. *Pulmonary vascular resistance (PVR)* can be calculated by using the following formula:

$$\text{PVR} = \frac{\text{Mean pulmonary artery pressure} - \text{Left atrial pressure}}{\text{Cardiac output}}$$

Given a normal mean pulmonary artery pressure of approximately 16 mm Hg and a normal mean left atrial pressure of 8 mm Hg, normal PVR is computed as follows:

$$\text{PVR} = \frac{16\text{ mm Hg} - 8\text{ mm Hg}}{5\text{ L/min}}$$
$$= 1.6\text{ mm Hg/L/min}$$

Resistance to blood flow in the pulmonary circulation is approximately one-tenth of the systemic circulation. The pulmonary circulation is characterized as a low-pressure, low-resistance system, and the systemic circulation as a high-pressure, high resistance system.

Determinants of Blood Pressure

A healthy cardiovascular system maintains sufficient pressure to propel blood throughout the body.[5] The first priority of the cardiovascular system is to keep perfusion pressures to tissues and organs normal, even under changing conditions. If the equation for computing SVR is rearranged by deleting the normally low atrial pressure, the average blood pressure in the circulation is directly related to both CO and flow resistance, as follows:

$$\text{Mean arterial pressure (MAP)} = (\text{CO} \times \text{SVR}) + \text{CVP}$$

Some MAP formulas disregard the CVP contribution because the CVP levels are generally negligible under normal circumstances (0 to 6 mm Hg). It is important to note that under many conditions, vascular resistance tends to vary inversely with the size of the blood vessels (i.e., the capacity of the vascular system).

All else being constant, MAP is directly related to the volume of blood in the vascular system and inversely related to its capacity:

$$\text{MAP} = \frac{\text{Volume}}{\text{Capacity}}$$

Based on this relationship, MAP is regulated by changing the volume of circulating blood, changing the capacity of the vascular system, or changing both. Volume changes can reflect absolute changes in total blood volume, such as changes resulting from hemorrhagic shock or blood transfusion. Alternatively, changes in "relative" volume can occur when vascular space increases or decreases. Vascular space decreases when **vasoconstriction** (constriction of the smooth muscles in the peripheral blood vessels) occurs; this causes blood pressure to increase even though blood volume is the same. Vascular space increases when **vasodilation** (relaxation of the smooth muscles in the arterioles) occurs; this causes blood pressure to decrease even though blood volume has not changed.

In a normal adult, MAP ranges from 80 to 100 mm Hg. When MAP decreases below 60 mm Hg, perfusion to the brain and the kidneys is severely compromised and organ failure may occur in minutes.[3]

To avoid organ and tissue damage and maintain adequate perfusion pressures under changing conditions, the cardiovascular system balances relative volume and resistance. When a person exercises, the circulating blood volume undergoes a relative increase, but blood pressure remains near normal; this is because the skeletal muscle vascular beds dilate, causing a large increase in system capacity. However, when blood loss occurs, as with hemorrhage, the system capacity is decreased by constriction of the peripheral vessels. Perfusion pressures are kept near normal until the volume loss is extreme.

Regulation of blood flow and pressure is much more complex than is suggested by these simplified equations. Cardiovascular

control is achieved by a complex array of integrated functions. Some of these functions are explained subsequently.

CONTROL OF THE CARDIOVASCULAR SYSTEM

The cardiovascular system is responsible for transporting metabolites to and from the tissues under various conditions and demands. It must act in a highly coordinated fashion. Coordination is achieved by integrating the functions of the heart and vascular system. The goal is to maintain adequate perfusion to all tissues according to their needs.[6]

The cardiovascular system regulates blood flow mainly by altering the capacity of the vasculature and the volume of blood it holds. The heart plays only a secondary role in regulating blood flow. In essence, the vascular system tells the heart how much blood it needs, rather than the heart dictating what volume of blood the vascular system will receive.

These integrated functions involve local and central neural control mechanisms. Local, or *intrinsic,* controls operate independently, without central nervous system control. Intrinsic control alters perfusion under normal conditions to meet metabolic needs. Central, or *extrinsic,* control involves both the central nervous system and circulating *humoral agents.* Extrinsic control mechanisms maintain a normal level of vascular tone. However, central control mechanisms take over when the competing needs of local vascular beds must be coordinated. Knowledge of vascular regulatory mechanisms and factors controlling CO is essential to understanding how the cardiovascular system responds under both normal and abnormal conditions.[2]

Regulation of Peripheral Vasculature

A normal level of vascular muscle tone is normally maintained throughout the vascular system at all times. Normal muscle tone must be present to allow for effective regulation. If blood vessels remained in a completely relaxed state, further dilation would be impossible and local increases in perfusion could not occur.

Local vascular tone is maintained by the smooth muscle of the precapillary sphincters of the microcirculation and can function independently of neural control at the local tissue level according to metabolic needs. Central control of vasomotor tone involves either direct central nervous system innervation or circulation hormones. Central control mainly affects the high-resistance arterioles and capacitance veins.

Local Control

Local regulation of tissue blood flow includes both myogenic and metabolic control mechanisms. *Myogenic control* involves the relationship between vascular smooth muscle tone and perfusion pressure. Myogenic control ensures relatively constant flows to the capillary beds despite changes in perfusion pressures.

Metabolic control involves the relationship between vascular smooth muscle tone and the level of local cellular metabolites. High amounts of carbon dioxide (CO_2) or lactic acid, low pH levels, low partial pressures of O_2 levels, histamines (released during inflammatory response), endothelium-derived relaxing factor, and some prostaglandins all cause relaxation of the smooth muscle and vasodilation, increasing flow to the affected area.

The influence of myogenic and metabolic control mechanisms varies in different organ systems, with the brain being the most sensitive to changes in the local metabolite levels, particularly CO_2 and pH.[1]

Central Control

Central control of blood flow is achieved primarily by the sympathetic division of the autonomic nervous system. Smooth muscle contraction and increased flow resistance are mostly caused by adrenergic stimulation and the release of norepinephrine. Smooth muscle relaxation and vessel dilation occur as a result of stimulation of either *cholinergic* or specialized *beta-adrenergic* receptors. Although the contractile response is distributed throughout the entire vascular system, dilation response appears to be limited to the precapillary vessels. In addition to the sympathetic control, blood flow through the large veins can also be affected by abdominal and intrathoracic pressure changes.

Regulation of Cardiac Output

The heart, similar to the vascular system, is regulated by both intrinsic and extrinsic factors. These mechanisms act together, along with vascular control, to ensure that the output of the heart matches the different needs of the tissues.

The total amount of blood pumped by the heart per minute is called the *cardiac output* (CO). CO is simply the product of the HR and the volume ejected by the left ventricle on each contraction, or stroke volume (SV):

$$CO = HR \times SV$$

A normal resting CO of approximately 5 L/min can be calculated by substituting a normal HR (70 contractions/min) and SV (75 ml, or 0.075 L, per contraction):

$$CO = 70 \text{ beats/min} \times 0.075 \text{ L/beat} = 5.25 \text{ L/min}$$

This is a hypothetical average because actual CO varies considerably in health and disease states and according to a person's sex, height, and weight.

Regardless of an individual's state of health or disease, a change in CO must involve a change in SV, a change in HR, or both. SV is affected primarily by intrinsic control of three factors: (1) preload, (2) afterload, and (3) contractility (all three factors are discussed subsequently). HR is affected primarily by extrinsic or central control mechanisms.[3,6]

Changes in Stroke Volume

The heart does not eject all of the blood it contains during systole. Instead, a small volume, called the **end-systolic volume (ESV)**, remains behind in the ventricles. During the resting phase, or diastole, the ventricles fill to a volume called the

end-diastolic volume (EDV). SV equals the difference between the EDV and the ESV, as follows:

$$SV = EDV - ESV$$

In a healthy man at rest, the EDV ranges from 110 to 120 ml. Given a normal SV of approximately 70 ml, a normal ejection fraction (EF), or proportion of the EDV ejected on each stroke, can be calculated as follows:

$$EF = \frac{SV}{EDV} \times 100$$
$$= \frac{70\ ml}{110\ ml} \times 100$$
$$= 64\%$$

On each contraction, a healthy heart ejects approximately two-thirds of its stored volume. Decreases in EF are normally associated with a weakened myocardium (heart failure), decreased contractility, or both. When the EF decreases below 30%, a person's exercise tolerance becomes severely limited.[6]

As shown in Figure 10-8, an increase in SV occurs when either the EDV increases or the ESV decreases. Conversely, a decrease in SV occurs when either the EDV decreases or the ESV increases. This relationship is key to understanding regulation of CO.

The heart's ability to change SV solely according to the EDV is an intrinsic regulatory mechanism. The force of the ventricle can generate results from the length of the myocardial fibers just before contraction. As the ventricle fills with blood, the myocardial fibers are stretched. As stretch increases, the tension (force) within the walls of the heart increases (analogous to stretching a rubber band). This relationship between cardiac muscle length and tension is called the *Frank-Starling law of the heart*.[7]

The concepts of tension or force and filling volume are often described in term of **preload** and **afterload**. As with many terms in medicine, the definitions of preload and afterload vary considerably in the literature.[8] This variability seems to be related to the term *load,* which in general means "a force against which something that causes motion (a pump or motor) acts." In the context of the cardiovascular system, the heart is analogous to a pump and force in this sense is related to stretch of the cardiac muscle according to the Frank-Starling Law.

Using this description of load, preload therefore represents the combined force of all the factors that contribute to ventricular wall stretch at the end of diastole. Preload may be calculated in a manner that recognizes the force that stretches the resting cardiac muscle to a given length before contraction. Many factors determine preload, including venous return, total blood volume and distribution, and atrial activity. These and the other factors that influence preload are summarized in Table 10-1.[8]

In a similar fashion, afterload can be described as the combined force of all of the factors the left ventricle encounters and must overcome when stimulated to contract and achieve the

TABLE 10-1

end of systole.[8] Several factors determine afterload; most notably peripheral vascular resistance and the physical characteristics of arterial blood. These and the other factors that determine afterload are summarized in Table 10-2.[8]

It should be noted that an increased preload or afterload caused by an abnormal increased downstream resistance over time can be "normalized" (up to a point) by increasing the wall thickness of the heart, which the body attempts to do by increasing muscle mass (hypertrophy), leading to cardiomyopathy and heart failure.[8]

RULE OF THUMB

Increases in preload result in increased SV in the healthy heart.

All else being constant, the greater the afterload on the ventricles, the harder it is for the ventricles to eject their volume. For a given EDV, an increase in afterload means the ESV increased. If the EDV remains constant while the ESV increases, the SV (EDV − ESV) decreases (see Figure 10-8). Normally, however, the healthy heart muscle responds to increased afterload by altering its contractility.

RULE OF THUMB

Increases in afterload can decrease SV, especially in the failing heart.

Contractility represents the amount of systolic force exerted by the heart muscle at any given preload. At a given preload (or EDV), an increase in contractility results in an increased EF, a decreased ESV, and an increased SV. Conversely, a decrease in contractility results in a decreased EF, an increased ESV, and a decreased SV.

Changes in contractility affect the slope of the ventricular function curve (Figures 10-9 and 10-10). A higher SV for a given preload (increased slope) indicates a state of increased contractility, often referred to as **positive inotropism**. The opposite is also true. A lower SV for a given preload indicates decreased contractility, referred to as **negative inotropism**. Drugs that increase contractility of the heart muscle are called

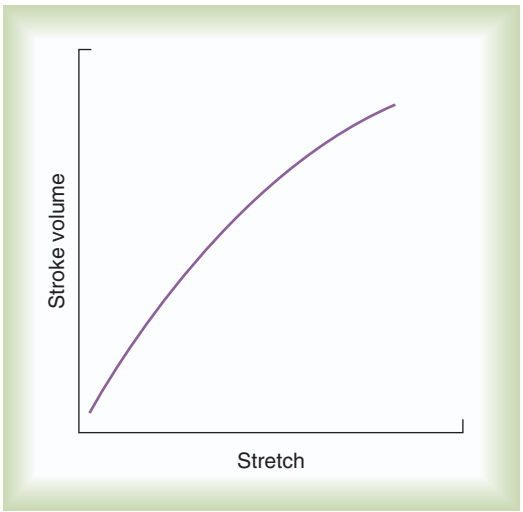

FIGURE 10-9 The Frank-Starling law: SV as a function of ventricular end-diastolic stretch. An increase in the stretch of the ventricles immediately before contraction (end-diastole) results in an increase in SV. Ventricular end-diastolic stretch is synonymous with the concept of preload.

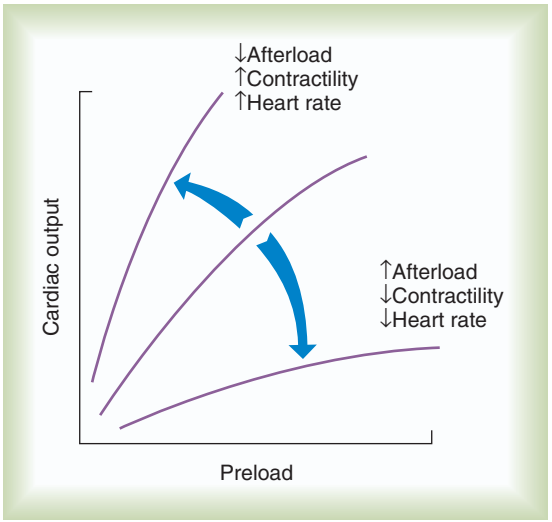

FIGURE 10-10 Effects of preload, afterload, contractility, and heart rate on cardiac output function curve. (Modified from Green JF: Fundamental cardiovascular and pulmonary physiology, ed 2, Philadelphia, 1987, Lea & Febiger.)

positive inotropes; drugs that decrease contractility are *negative inotropes.*[6]

In addition to local mechanisms, cardiac contractility is influenced by neural control, circulating hormonal factors, and certain medications. Typically, neural or drug-mediated *sympathetic* stimulation has a positive inotropic effect. Conversely, *parasympathetic* stimulation exerts a negative inotropic effect. *Profound hypoxia* and *acidosis* impair myocardial function and decrease cardiac contractility.

RULE OF THUMB

Hypoxia and acidosis decrease cardiac contractility and output.

Changes in Heart Rate

The last factor influencing CO is HR. In contrast to the factors controlling SV, the factors affecting HR are mainly of central origin (i.e., neural or hormonal). Factors that increase HR are called *positive chronotropic* factors. Likewise, factors that decrease HR are called *negative chronotropic* factors.

MINI CLINI

Effect of Increased Afterload on Cardiac Output in a Normal Heart

Afterload is the resistance the ventricle has to overcome, or the forces that oppose ejection of blood pressure generated as the heart works to eject its SV. As afterload increases, the SV ejected by the ventricle decreases, assuming that the contractility of the heart (force with which the heart contracts) remains constant.

PROBLEM: During exercise, a healthy person's blood pressure increases considerably, indicating that the afterload has increased. Yet the SV and CO in a healthy heart do not decrease. Why is this so?

DISCUSSION: When afterload increases, the initial ventricular contractions that experience the increased afterload produce smaller SVs; this causes more blood to remain in the ventricle at the end of systole (i.e., ESV is increased). During the subsequent diastole, blood rushes in from the atria to fill the ventricles, and because of the higher than normal ESV, the ventricle becomes more distended and stretched than before. Healthy heart muscle responds to increased stretch in a way described by the Frank-Starling law; that is, the heart now contracts with greater force than before, ejecting a greater SV. By increasing contractility in this fashion, SV and CO are not compromised by increased afterload in a healthy heart.

As expected, CO increases and decreases with similar changes in HR. However, this relationship is maintained only up to approximately 160 to 180 beats/min in a healthy heart. At higher HRs, there is not enough time for the ventricles to fill completely between each heartbeat, causing a decrease in EDV, SV, and CO. This phenomenon often occurs at significantly less than 160 beats/min in the failing heart.

RULE OF THUMB

Increase in HR increases CO in a healthy heart up to a rate of 160 to 180 beats/min.

The combined effects of preload, afterload, contractility, and HR on cardiac performance are graphically portrayed in Figure 10-10. The middle curve represents the normal state. The upper, steeper curve represents a hyperdynamic heart. In the hyperdynamic heart, a given preload results in a greater than normal CO. Factors contributing to this state include decreased afterload, increased contractility (decreased ESV), and increased HR. The bottom curve has a lower slope than normal, indicating a hypodynamic heart. Factors contributing to this state include increased afterload, decreased contractility (increased ESV), and decreased rate. When the pumping efficiency of the heart is so low that CO is inadequate to meet tissues needs, the heart is said to be in **congestive heart failure (CHF)**.[3,6]

Cardiovascular Control Mechanisms

Cardiovascular control is achieved by integrating local and central regulatory mechanisms that affect both the heart and the vasculature. The goal is to ensure that all tissues receive sufficient blood flow to meet their metabolic needs. However, when demands are increased or abnormal, such as during exercise or massive bleeding, central mechanisms take over primary control.

RULE OF THUMB

Blood flow to a specific vascular bed is primarily regulated by local mechanisms.

Central control of cardiovascular function occurs by interaction between the brainstem and selected peripheral receptors (Figure 10-11). The brainstem constantly receives feedback from these receptors about the pressure, volume, and chemical status of the blood. The brainstem also receives input from higher brain centers, such as the hypothalamus and cerebral cortex. These inputs are integrated with the inputs coming from the heart and blood vessels to maintain adequate blood flow and pressure in all but the most abnormal conditions.[2]

Cardiovascular Control Centers

Figure 10-11 is a simplified diagram of the cardiovascular regulatory centers. Areas in the medulla receive input from higher brain centers, peripheral pressure, and chemical receptors. Stimulation of the vasoconstrictor area within the medulla causes vasoconstriction and increased vascular resistance.

Closely associated with the vasoconstrictor center is a cardioaccelerator area. Stimulation of this center increases HR by increasing sympathetic discharge to the SA and AV nodes of the heart. A cardioinhibitory area plays the opposite role. Stimulation of this center decreases HR by increasing vagal (parasympathetic) stimulation to the heart.

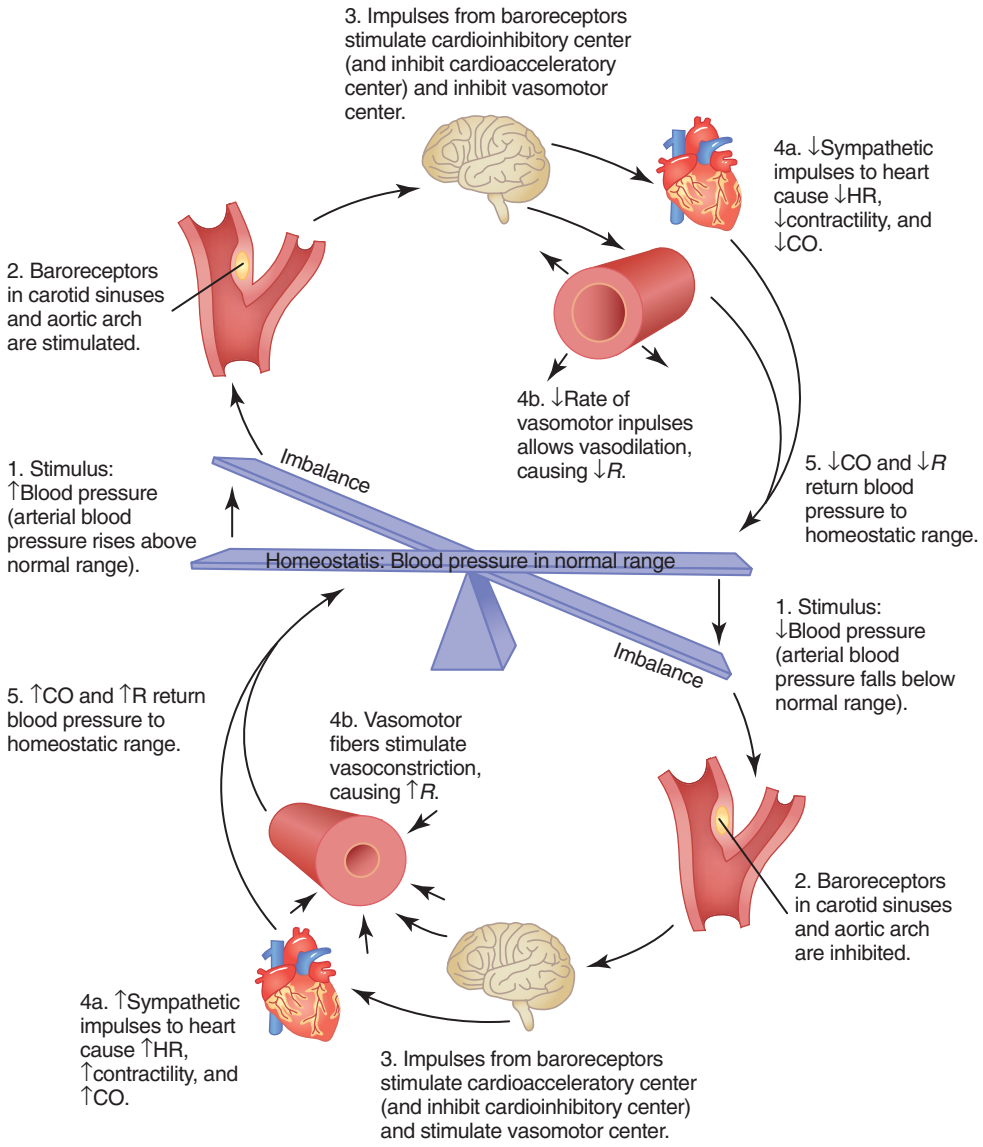

FIGURE 10-11 Simplified diagram of cardiovascular regulatory centers. *CO,* Cardiac output; *HR,* heart rate; *R,* respiration. (Modified from Marieb EN, Hoehn KN: Anatomy and physiology, ed 4, San Francisco, 2011, Pearson Benjamin Cummings.)

MINI CLINI

Heart Rate and the Administration of Bronchodilator Drugs

PROBLEM: You are giving a bronchodilator aerosolized drug to a patient, and you notice a significant increase in the patient's HR. Would you expect increased HR to be a common side effect of drugs that cause bronchodilation?

DISCUSSION: The discharge rate of the sinus node and the HR are increased by sympathetic nervous stimulation and decreased by parasympathetic nervous stimulation. The airways of the lung are dilated by sympathetic nervous stimulation and constricted by parasympathetic stimulation. Drugs that cause bronchodilation either mimic sympathetic stimulation (sympathomimetic) or block parasympathetic stimulation (parasympatholytic). Both of these drug actions also cause the HR to increase. Parasympatholytic drugs bring about effects similar to those of sympathetic stimulation; by inhibiting parasympathetic activity, they allow sympathetic impulses to predominate.

Higher brain centers also influence the cardiovascular system, both directly and through the medulla. Signals coming from the cerebral cortex in response to exercise, pain, or anxiety pass directly through the cholinergic fibers to the vascular smooth muscle, causing vasodilation. Signals from the hypothalamus, in particular its heat-regulating areas, indirectly affect HR and vasomotor tone through the cardiovascular centers.

The cardiovascular centers also are affected by local chemical changes in the surrounding blood and cerebrospinal fluid. Decreased levels of CO_2 tend to inhibit the medullary centers. General inhibition of these centers causes a decrease in vascular tone and a decrease in blood pressure. A local decrease in O_2 tension has the opposite effect. Mild hypoxia in this area increases sympathetic discharge rates; this tends to elevate both HR and blood pressure. Severe hypoxia has a depressant effect.

Peripheral Receptors

In addition to high-level and local input, the cardiovascular centers receive signals from peripheral receptors (see Figure 10-11). There are two types of peripheral cardiovascular receptors: **baroreceptors**, or stretch receptors, and **chemoreceptors**. Baroreceptors respond to pressure changes, whereas chemoreceptors respond to changes in blood chemistry.[3]

The cardiovascular system has two different sets of baroreceptors. The first set is located in the aortic arch and carotid sinuses. These receptors monitor arterial pressures generated by the left ventricle. The second set is located in the walls of the atria and the large thoracic and pulmonary veins. These low-pressure sensors respond mainly to changes in vascular volumes. Baroreceptor output is directly proportional to the stretch on the vessel wall. The greater the blood pressure, the greater is the stretch and the higher the rate of neural discharge to the medulla.

Together with the cardiovascular regulatory centers, these receptors form a **negative feedback loop**. In a negative feedback loop, stimulation of a receptor causes an opposite response by the effector. In the case of the arterial receptors, an increase in blood pressure increases aortic and carotid receptor stretch and their neuronal discharge rates. The increased discharge rates cause an opposite response by the medullary centers (i.e., depressor response decreasing blood pressure). Decreased blood pressure (decreased baroreceptor output) has the opposite effect, causing peripheral vessel constriction and increased HR and contractility. This mechanism usually restores blood pressure to normal (see Figure 10-11).[2,3]

Although the high-pressure arterial receptors constantly control blood pressure, the low-pressure sensors are responsible for long-term regulation of plasma volume. The low-pressure atrial and venous baroreceptors regulate plasma volume mainly by activating several chemical and hormonal mechanisms. Table 10-3 provides a detailed description of some of these mechanisms.

The major pathways for plasma volume control are outlined in Figure 10-12. Combined with a central nervous system–mediated increase in renal filtration, these humoral mechanisms decrease the overall plasma volume. A decrease in blood volume has the opposite effect (i.e., sodium and water retention and an increase in plasma volume).

Chemoreceptors are small, highly vascularized tissues located near the high-pressure sensors in the aortic arch and carotid sinus that are sensitive to changes in blood chemistry. They are strongly stimulated by decreased O_2 tensions, although low pH

TABLE 10-3

Hormonal Control Mechanisms Affecting Blood Pressure

Hormone	Place of Action	Effect
Angiotensin II	Arterioles	↑ SVR (vasoconstriction)
Antidiuretic hormone	Kidneys	↑ Blood volume (↑ water retention)
	Arterioles	↑ SVR (vasoconstriction)
Atrial natriuretic peptide	Arterioles	↓ SVR (vasodilation)
Aldosterone	Kidneys	↑ Blood volume (↑ water and salt retention)
Cortisol	Kidneys	↑ Blood volume (↑ water and salt retention)
Norepinephrine	Heart (beta-1 receptors)	↑ Cardiac output (HR and contractility)
	Arterioles (alpha receptors)	↑ SVR (vasoconstriction)

HR, Heart rate; *SVR,* systemic vascular resistance.

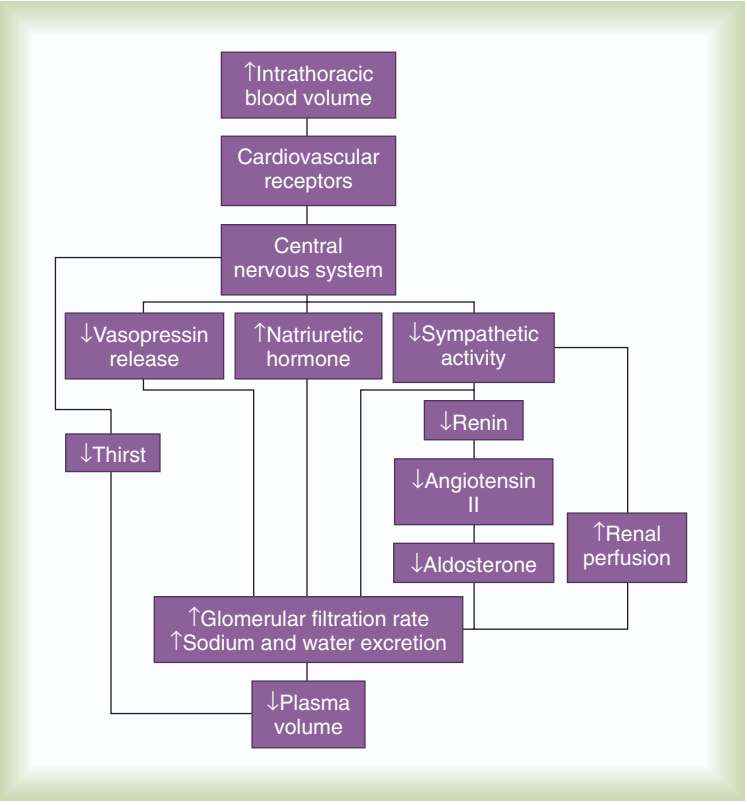

FIGURE 10-12 Major pathways for plasma volume control. See text for details. (Modified from Smith JJ, Kampine JP: Circulatory physiology: the essentials, ed 3, Baltimore, 1990, Williams & Wilkins.)

or high levels of CO_2 also can increase their discharge rate. Simply put, the major cardiovascular effects of chemoreceptor stimulation are vasoconstriction and increased HR.

Because these changes occur only when the cardiopulmonary system is overtaxed, the chemoreceptors probably have little influence under normal conditions. However, their influence on respiration is clinically important. For this reason, the peripheral chemoreceptors are discussed in greater detail in Chapter 9.

Response to Changes in Overall Volume

The coordinated response of the cardiovascular system is best shown under abnormal conditions. Among the most common clinical conditions in which all essential regulatory mechanisms come into play is the large blood loss that occurs with hemorrhage. Figure 10-13 illustrates changes in these key factors during progressive blood loss in an animal model.

With 10% blood loss, the immediate decline in the CVP causes a 50% decrease in the discharge rate of the low-pressure (atrial) baroreceptors. There is little change in the activity of the high-pressure (arterial) receptors. The initial response, mediated through the medullary centers, is an increase in sympathetic discharge to the sinus node; this causes a progressive increase in HR. At the same time, plasma levels of antidiuretic hormone (vasopressin) begin to increase, thus maintaining normal arterial blood pressure.

As the blood loss becomes more severe (20%), atrial receptor activity decreases further; this increases the intensity of sympathetic discharge from the cardiovascular centers. Plasma antidiuretic hormone and HR continue to increase, as does peripheral vasculature tone. An increase in vascular tone occurs through constriction of the capacitance vessels in the venous system, slowing the decrease in CVP.[3]

The arterial pressure does not start to decrease until blood loss approaches 30%. At this point, arterial receptor activity begins to decrease, resulting in a marked increase in systemic vascular tone. Despite the magnitude of blood loss, CVP levels off. As long as no further hemorrhage occurs, blood pressure and tissue perfusion can be maintained at adequate levels.

If blood loss continues, central control mechanisms begin to take over. Massive vasoconstriction occurs in the resistance vessels, shunting blood away from skeletal muscle to maintain blood flow to the brain and heart. Increasing levels of local metabolites in these areas, especially CO_2 and other acids, override central control and cause further vessel dilation and increased blood flow. As these metabolites build up and as the tissues become hypoxic, cardiac function becomes impaired and vasodilation occurs throughout the body. This vasodilation signals the onset of irreversible shock, after which death ensues.

EVENTS OF THE CARDIAC CYCLE

This chapter has focused on the mechanical properties of the heart; the electrical activities of the heart are discussed in Chapter 18. Although they are discussed separately, the mechanical and electrical events are interdependent. Given the role of RTs in dealing with cardiovascular problems, an in-depth knowledge of how these events relate is essential.[2]

The events of the cardiac cycle are depicted in Figure 10-14. The top of the figure shows a time axis scaled in tenths of a second. Next are the timing bars for ventricular systole and diastole and pressure events in the atria, ventricles, and aorta. These are followed by an electrocardiogram (ECG), heart sounds, and ventricular flow (see Chapter 18 for an explanation of the ECG waves).

Going from left to right, the P wave (atrial depolarization) begins the ECG. Earlier, the ventricles have been passively filling

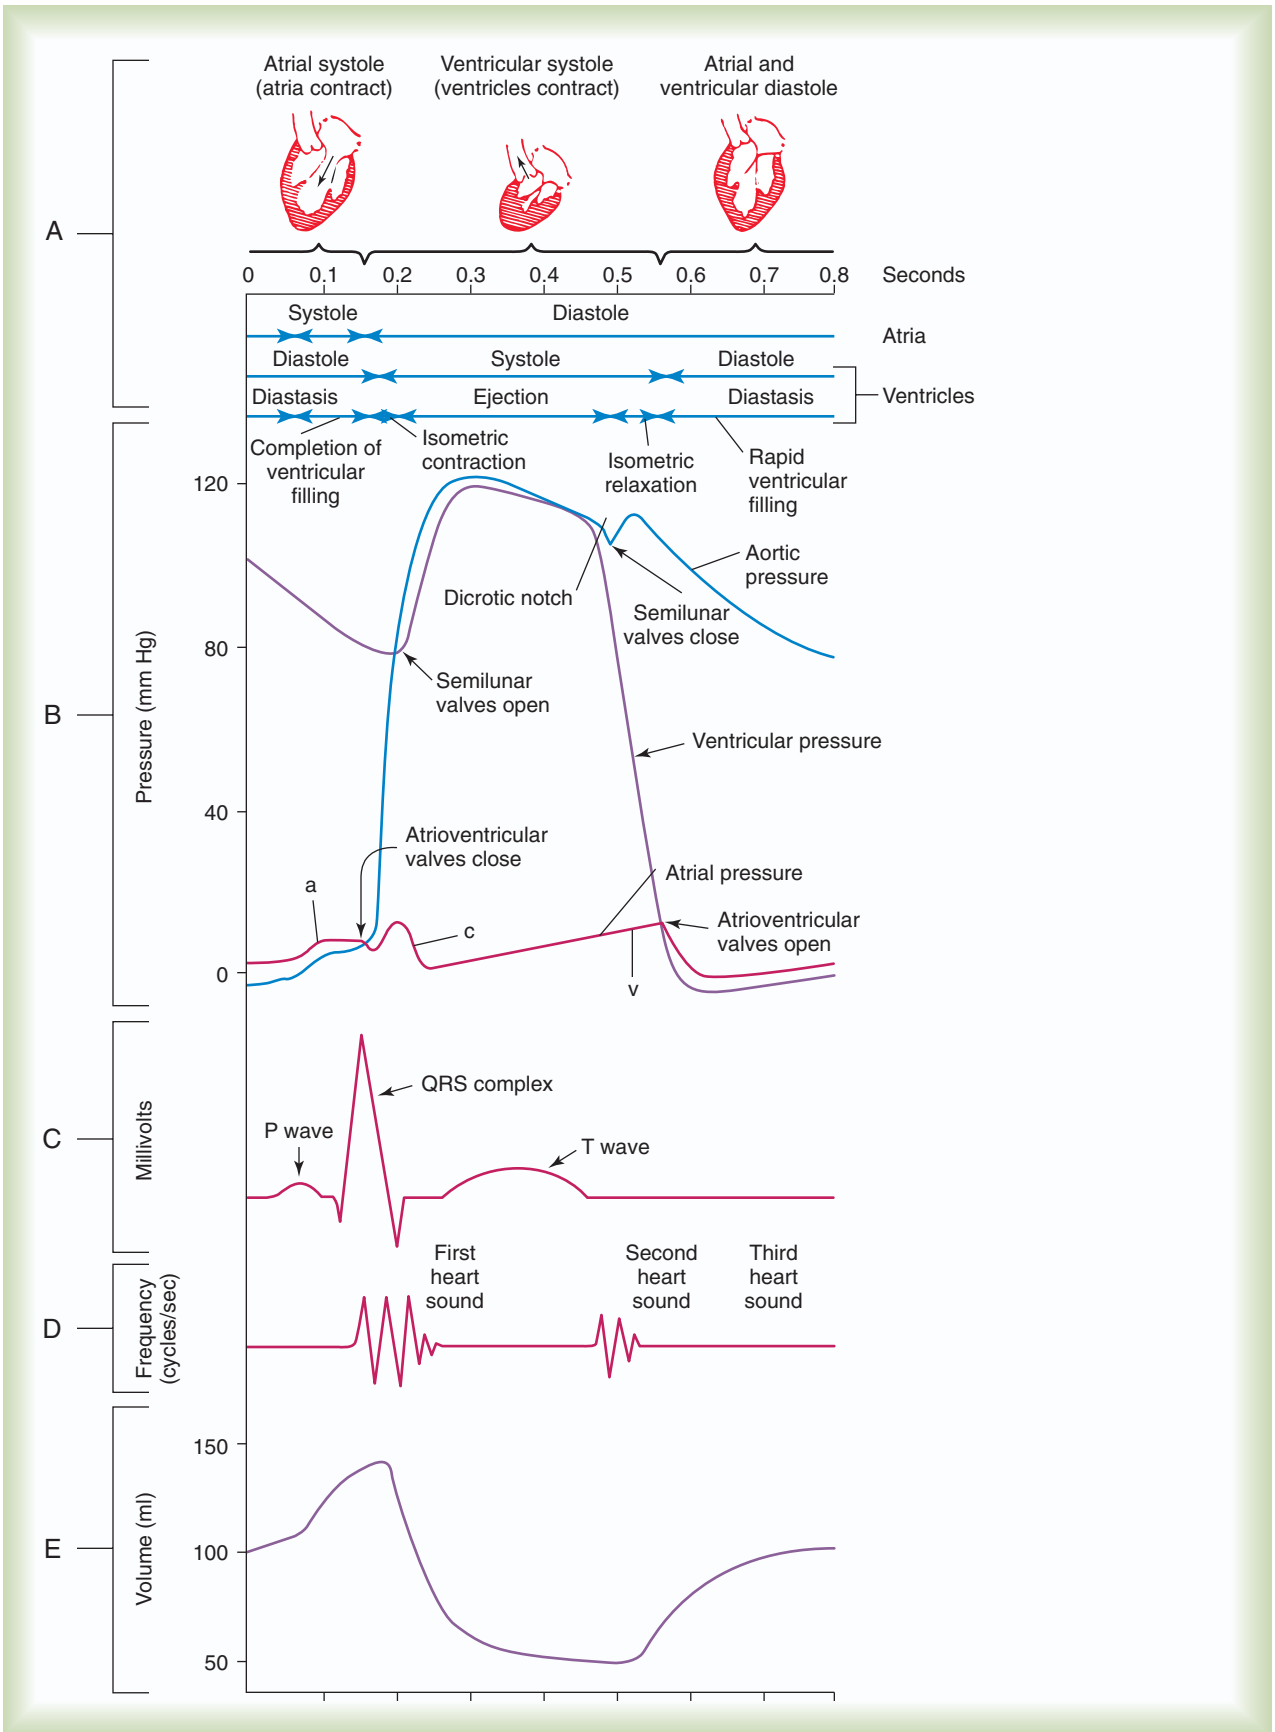

FIGURE 10-14 Cardiac cycle. **A,** Timing of cardiac events. **B,** Simultaneous pressures created in the aorta, left ventricle, and right atrium during the cardiac cycle. **C,** Electrical activity during the cardiac cycle. **D,** Heart sounds corresponding to the cardiac cycle. **E,** Ventricular blood volume during the cardiac cycle. (Modified from Moffett DF, Moffett SB, Schauf CL: Human physiology: foundations and frontiers, ed 2, St Louis, 1993, Mosby.)

with blood through the open AV valves. Within 0.1 second, the atria contract, causing a slight increase in both atrial and ventricular pressures *(a waves)*. This atrial contraction helps preload the ventricles, increasing their volume by 25%. This help from the atria to ventricular filling is called the *atrial kick*. Toward the end of diastole, the electrical impulses from the atria reach the AV node and bundle branches and ventricular depolarization (QRS complex) is initiated. Within a few hundredths of a second after depolarization, the ventricles begin to contract. As soon as ventricular pressures exceed pressures in the atria, the AV valves close. Closure of the mitral valve occurs first, followed immediately by closure of the tricuspid valve. This closure marks the end of ventricular diastole, producing the first heart sound on the phonocardiogram.[2]

Immediately after AV valve closure, the ventricles become closed chambers. During this short isovolemic phase of contraction, ventricular pressures increase rapidly. Upward bulging of the AV valves during this phase causes a slight upswing in atrial pressure graphs, called the *c wave*. Within 0.05 second, ventricular pressures increase to exceed the pressures in the aorta and pulmonary artery and opening the semilunar valves.

Toward the end of systole, as repolarization starts (indicated by the T wave), the ventricles begin to relax. Consequently, ventricular pressures decrease rapidly. When arterial pressures exceed pressures in the relaxing ventricles, the semilunar valves shut. Closure of the semilunar valves generates the second heart sound. Rather than immediately dropping off, aortic and pulmonary pressures increase again after the semilunar valves close. The *dicrotic notch* is caused by the elastic recoil of the arteries. This recoil provides the extra "push" that helps maintain the pressure created by the ventricles.

As the ventricles continue to relax, their pressures decrease to less than the pressures in the atria. This decline in pressure reopens the AV valves. As soon as the AV valves open, the blood collected in the atria rushes to fill the ventricles, causing a rapid decrease in atrial pressures (the *v wave*). Thereafter, ventricular filling slows as the heart prepares for a new cycle.

Knowledge of these events can help in understanding many of the diagnostic and monitoring procedures used for patients with cardiopulmonary disorders, including balloon-directed pulmonary artery catheterization and direct arterial pressure monitoring.

SUMMARY CHECKLIST

- The cardiovascular system consists of the heart and a vascular network that account for normal distribution and regulation of blood flow throughout the body to ensure tissue perfusion.
- Mechanical and electrical properties of cardiac tissue, combined with internal and external control mechanisms, provide the basis for coordinated cardiac function.
- The vascular system is regulated by local and central control mechanisms.
- CO is primarily determined by four factors: preload, afterload, contractility, and HR and is equivalent to the product of the SV × HR.
- Increased HR decreases CO by decreasing filling times (decreasing EDV) and decreasing contraction times, hence increasing ESV.
- Blood pressure is regulated by changing the volume of circulating blood, changing the capacity of the vascular system, or both.
- During increased demand, special compensatory mechanisms are called on to maintain stable blood flow.
- EF is the proportion of the EDV ejected on each stroke (SV/EDV).
- Failure of cardiovascular control mechanisms often requires clinical the intervention to help restore normal function.

CHAPTER 11

Ventilation

EDUARDO MIRELES-CABODEVILA, ROBERT L. CHATBURN

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the physiologic functions provided by ventilation.
- Describe the pressure gradients responsible for gas flow, diffusion, and lung inflation.
- Identify the forces that oppose gas movement into and out of the lungs.
- Describe how surface tension contributes to lung recoil.
- Describe how lung, chest wall, and total compliance are related.
- State the factors that affect resistance to breathing.
- Describe how various lung diseases affect the work of breathing.
- State why ventilation is not evenly distributed throughout the lung.
- Describe how the time constants affect alveolar filling and emptying.
- Identify the factors that affect alveolar ventilation.
- State how to calculate alveolar ventilation, dead space, and the V_D/V_T ratio.

CHAPTER OUTLINE

KEY TERMS

airway resistance
alveolar dead space
compliance
dynamic compression
dynamic hyperinflation (air trapping)
elastance
elasticity
equal pressure point (EPP)
hyperventilation
hypoventilation
hysteresis
minute ventilation
physiologic dead space
plethysmograph
pneumotachometer
pressure gradient
sub-atmospheric
surface tension
tidal volume (V_T)
time constant
transairway pressure gradient
transairway pressure (P_{TAW})
transalveolar pressure (P_{TA})
trans–chest wall pressure (P_{TCW})
transpulmonary pressure difference (P_{TP})
transpulmonary pressure gradient
transrespiratory pressure (P_{TR})
transthoracic pressure difference (P_{TT})

The main functions of the lungs are to supply the body with oxygen and to remove carbon dioxide. To perform these functions, the lungs must be adequately ventilated. **Ventilation** is the process of moving gas (usually air) in and out of the lungs. Ventilation is to be distinguished from respiration, which refers to the physiologic processes of O_2 use at the cellular level.

In health, ventilation is regulated to meet the body's needs under a wide range of conditions. In disease, this process can be markedly disrupted and often results in inadequate

ventilation and/or increased work of breathing. Respiratory care is directed toward restoring and supporting adequate and efficient ventilation. To provide effective respiratory care we need to have a solid understanding of the normal ventilation processes and of how diseases may affect it.

MECHANICS OF VENTILATION

Ventilation is a cycle. This cycle has two phases: inspiration and expiration. During each cycle, a volume of gas moves in and out of the respiratory tract. This volume, measured during either inspiration or expiration, is called the **tidal volume (V_T)**. The V_T refreshes the gas present in the lung, removing CO_2 and supplying O_2 to meet metabolic needs. The V_T must be able to meet changing metabolic demands, such as during exercise or sleep. To achieve ventilation the respiratory muscles (and/or a mechanical ventilator) have to generate changes in pressure (a pressure gradient, see later discussion) so that gas will flow on in or out of the lungs. To better understand the forces that the muscles (or/and the machine) have to overcome to generate ventilation, we use a formula. This formula is a simplified version of the equation of motion for the respiratory system:

$$\Delta\text{Pressure} = (\text{Elastance} \times \Delta\text{Volume}) + (\text{Resistance} \times \Delta\text{Flow})$$

where:

- ΔPressure = Force generated by the respiratory muscles or a mechanical ventilator, or both, during inspiration. This "pressure" is actually a pressure difference (see next section).
- Volume = Volume change (e.g., V_T)
- **Elastance** = Distensibility of the lungs and thorax (Δpressure/Δvolume); elastance is the reciprocal of compliance (Δvolume/Δpressure)
- Resistance = Airflow and tissue resistance (Δpressure/Δflow)
- Flow = Volume change per unit of time

In this equation, the terms *(elastance × volume)* and *(resistance × flow)* represent the loads (elastic and resistive) against which the respiratory muscles or ventilator must work to achieve gas movement. Thus you can now see that in patients with high elastance or/and high resistance the pressure needed to achieve ventilation will be high. In healthy lungs, this work is minimal and is performed during the inspiratory phase. Expiration is normally passive (i.e., no muscle force involved) and the result of the elastic recoil of the lung.

In discussing ventilation, it may be helpful to review some details about the equation of motion. First remember it is a mathematical model. This model lumps all the resistances of the many airways into a single flow-conducting tube and lumps *all* the elastances of the alveoli and airways into a single elastic compartment (see later discussions about elastance, compliance, and resistance). The graphic model is shown in Figure 11-1.[1] Surrounding the "lungs" is another elastic compartment representing the chest wall. This graphic depiction of the respiratory system allows us to define points in space where pressures may be measured (or inferred) as defined in Table 11-1.

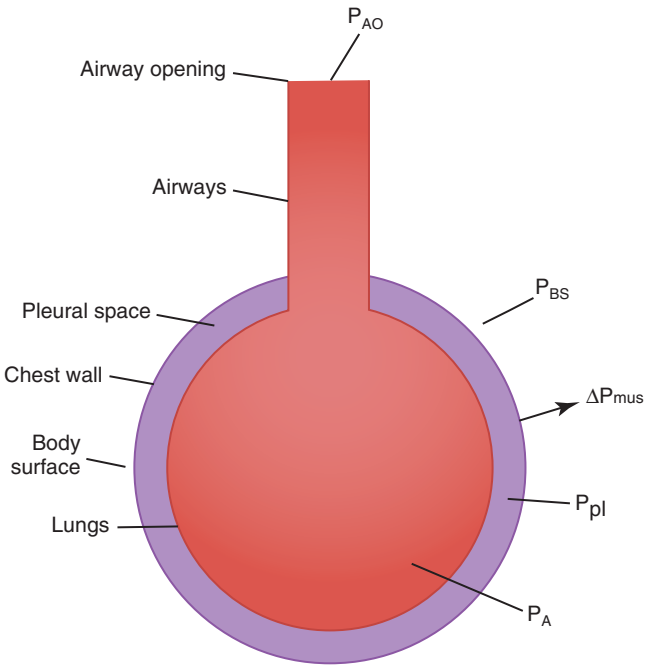

FIGURE 11-1 Schematic diagram of the respiratory system consisting of a flow-conducting tube (representing the airways) connected to a single elastic compartment (representing the lungs) surrounded by another elastic compartment (representing the chest wall). ΔP_{mus}, Muscle pressure difference; P_A, alveolar pressure; P_{AO}, pressure at the airway opening; P_{BS}, pressure on the body surface; P_{pl}, pressure in the intrapleural space. (From Primiano FP Jr, Chatburn RL: Zen and the art of nomenclature maintenance: a revised approach to respiratory symbols and terminology. Respir Care 51:1458, 2006.)

TABLE 11-1

Measurable Pressures Used in Describing Respiratory System Mechanics

Name	Symbol	Definition
Pressure at the airway opening	P_{AO}	Pressure measured at the opening of the respiratory system airway (e.g., mouth and nose, tracheostomy opening, and endotracheal tube opening)
Pleural pressure	P_{pl}	Pressure measured in the pleural space, changes that are often estimated by measuring pressure changes in the esophagus
Alveolar pressure	P_A	Pressure in the alveolar (gas space) region of the lungs
Body surface pressure	P_{BS}	Pressure measured at the body surface

Pressure Differences During Breathing

A pressure gradient is needed to achieve gas flow from one place to another. Using the equation of motion we can recognize the pressure gradients or differences in pressure between two points in space. in each of the components of the model. The components of the model (airways, lungs, and chest wall) are *defined*

as everything that exists between these points in space. Let's define each of these pressure gradients.

The *respiratory system* is everything that exists between the pressure measured at the airway opening (P_{AO}) and the pressure measured at the body surface (P_{BS}). The pressure difference is called the **transrespiratory pressure (P_{TR})**:

$$P_{TR} = P_{AO} - P_{BS}$$

The term P_{AO} comes before the term P_{BS} in the equation. This order is dictated by the direction of flow. For inspiration, P_{AO} is higher than P_{BS}, and P_{TR} is calculated by subtracting P_{BS} from P_{AO}. The same general principle applies to all the other pressure differences described subsequently. The components of transrespiratory pressure correspond to all the components of the graphic model (i.e., airways, lungs, and chest wall). We can further divide these components and their pressure gradients. Starting at the airways in this model, the airways are whatever exists between pressure measured at the airway opening (P_{AO}) and pressure measured in the alveoli of the lungs (P_A). The graphic model makes the lungs look like one giant alveolus, which means that alveolar pressure represents an average pressure over all alveoli in real lungs. The pressure difference is called the **transairway pressure (P_{TAW})**:

$$P_{TAW} = P_{AO} - P_A$$

Thus P_{TAW} represents all the airways (real and artificial).

The alveolar region is whatever exists between pressure measured in the alveolus and pressure measured in the pleural space (P_{pl}). The associated pressure difference is **transalveolar pressure (P_{TA})**:

$$P_{TA} = P_A - P_{pl}$$

The P_{TA} represents all the alveoli as if they were one single alveolus.

We also take into account the chest wall. The chest wall exists between pressure measured in the pleural space and the pressure on the body surface. The pressure difference is called **trans–chest wall pressure (P_{TCW})**:

$$P_{TCW} = P_{pl} - P_{BS}$$

Some of these components can be combined to encompass structures that are of clinical importance. One of the most used combinations joins the airways (P_{TAW}) and alveolar region (P_{TA}) to assess the pulmonary system, and this is called the **transpulmonary pressure difference (P_{TP})**:

$$P_{TP} = P_{AO} - P_{pl}$$

What may be confusing is that there are other definitions of transpulmonary pressure in the literature. Some authors define P_{TP} as $P_A - P_{pl}$. The confusion arises from the fact that $P_{TA} = P_A - P_{pl}$, *but only under static conditions*. Static conditions can be imposed during mechanical ventilation by using an inspiratory or expiratory hold maneuver. This situation should be considered a special case of P_{TP}; however, the general case is $P_{TP} = P_{AO} - P_{pl}$, which shows what pressures must be measured to derive the mechanical properties of the pulmonary system under either static or dynamic (breathing) conditions. If we want to evaluate the elastance and resistance of *the pulmonary system,* we substitute P_{TP} for P in the equation of motion. Alternatively, if we want to evaluate the *total respiratory system* elastance and resistance, we substitute P_{TR} for P.

TABLE 11-2

Pressure Differences Used in Describing Respiratory System Mechanics

Definition	Name	Symbol
$P_{AO} - P_{BS}$	Transrespiratory pressure difference	ΔP_{TR}
$P_{AO} - P_A$	Transairway pressure difference	ΔP_{TAW}
$P_{AO} - P_{pl}$	Transpulmonary pressure difference	ΔP_{TP}
$P_A - P_{pl}$	Transalveolar pressure difference	ΔP_{TA}
$P_A - P_{BS}$	Transthoracic pressure difference	ΔP_{TT}
$P_{pl} - P_{BS}$	Trans–chest wall pressure difference	ΔP_{TCW}
	Global muscle pressure difference	ΔP_{mus}

Sometimes it may be useful to define the pressure required to expand the lung and chest wall components; to do this we use the **transthoracic pressure difference (P_{TT})**, which is defined as:

$$P_{TT} = P_A - P_{BS}$$

We use the transrespiratory **pressure gradient** and the other gradients to understand the gas flow into and out of the alveoli during breathing. Table 11-2 summarizes these equations. For a spontaneously breathing person, P_A is **sub-atmospheric** in the beginning of inspiration compared with P_{AO}, causing air to flow into the alveoli. The opposite happens in the beginning of exhalation; P_A is higher than P_{AO}, causing air to flow out of the airway opening. During a normal breathing cycle, the glottis remains open. The P_{BS} and P_{AO} remain at zero (i.e., atmospheric) throughout the cycle; only changes in P_A and P_{pl} are of interest. It is often helpful to use these to describe the changes in pressures during a breathing cycle.

Before inspiration, pleural pressure is approximately −5 cm H_2O (i.e., 5 cm H_2O below atmospheric pressure), and alveolar pressure is 0 cm H_2O. The **transpulmonary pressure gradient** is also approximately 5 cm H_2O in the resting state, that is, $P_{TP} = P_{AO} - P_{pl} = 0 - (-5) = 5$. This positive end-expiratory P_{TP} maintains the lung at its resting volume, functional residual capacity (FRC). Airway opening and alveolar pressures are both zero, so the **transairway pressure gradient** also is zero. No gas moves into or out of the respiratory tract.

Inspiration begins when muscular effort expands the thorax. Thoracic expansion causes a *decrease* in pleural pressure. This decrease in pleural pressure causes a positive change to P_{TP} and P_{TA}, which induces flow into the lungs. The inspiratory flow is proportional to the positive change in transairway pressure difference; the higher the change in P_{TA}, the higher is the flow.

Pleural pressure continues to decrease until the end of inspiration. Alveolar filling slows when alveolar pressure approaches equilibrium with the atmosphere, and inspiratory flow decreases to zero (Figure 11-2). At this point, called *end-inspiration,* alveolar pressure has returned to zero, and the intrapleural

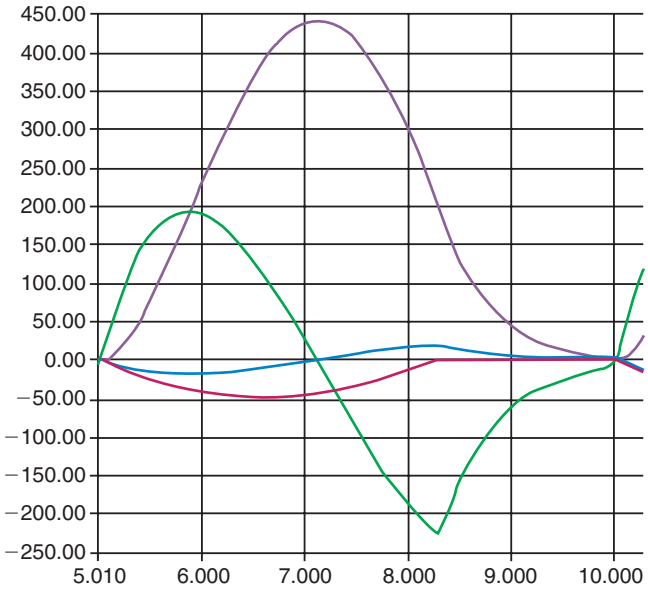

FIGURE 11-2 Waveforms for normal breathing. *Red,* Change in pleural pressure relative to end-expiratory value (cm H_2O, scaled times 10); *blue,* alveolar pressure (cm H_2O, scaled times 10); *green,* flow (L/min, scaled times 10); *purple,* volume (ml).

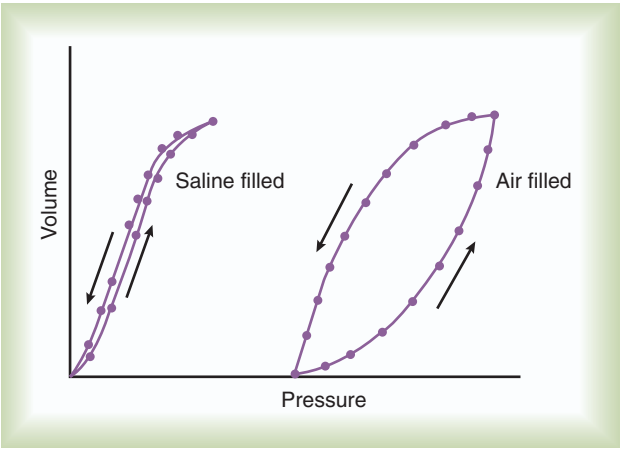

FIGURE 11-3 Static pressure-volume curves of saline-filled and air-filled excised lungs. In the saline-filled lung, the distending pressure is the same during inflation and deflation. The air-filled lung shows hysteresis (i.e., higher pressure for a given volume on inflation compared with deflation). The hysteresis results in part from the effects of surface tension forces caused by the air-liquid interface in the alveoli. (Modified from Slonim NB, Hamilton LH: Respiratory physiology, ed 5, St Louis, 1987, Mosby.)

pressure—and hence transpulmonary pressure gradient—reaches the maximal value (for a normal breath) of approximately 10 cm H_2O.

At end inspiration the muscle pressure relaxes and now alveolar pressure is higher than pressure at the airway opening, driving flow in the expiratory direction. The equation of motion shows this, setting the driving pressure, P_{mus}, to zero:

$$P_{mus} = 0 = (\text{Elastance} \times \text{Volume}) + (\text{Resistance} \times \text{Flow})$$

Rearranging the formula, we get:

$$(\text{Elastance} \times \text{Volume}) = -(\text{Resistance} \times \text{Flow})$$
$$= \text{Resistance} \times (-\text{Flow})$$

This equation says two important things: (1) Flow is negative, indicating expiration, and (2) the driving force (transthoracic pressure, equal to elastance × volume) for expiratory flow is the energy stored in the combined elastances of lungs and chest wall (the total elastance is the sum of the chest wall and lung elastances).

These events occur during normal V_T excursions. Similar pressure changes accompany deeper inspiration and expiration. The magnitude of the pressure changes is greater with deeper breathing. Pleural pressures are always negative (subatmospheric) during normal inspiration and exhalation. During forced inspiration with a big downward movement of the diaphragm, the pleural pressure can decrease to −50 cm H_2O, whereas during a forced expiration, pleural pressure may increase above atmospheric pressure to 50 to 100 cm H_2O.

Forces Opposing Inflation of the Lung

The lungs have a tendency to recoil inward, whereas the chest wall tends to move outward; these opposing forces keep the lung at its resting volume (i.e., FRC). To generate the previously described pressure gradients, the lungs must be distended. This distention requires several opposing forces to be overcome for inspiration to occur. As indicated in the equation of motion, the forces opposing lung inflation may be grouped into two categories: *elastic forces* and *frictional forces.* Elastic forces involve the tissues of the lungs, thorax, and abdomen, along with surface tension in the alveoli. Frictional forces include resistance caused by gas flow through the airways (natural and artificial) and tissue movement during breathing.

Surface Tension Forces

Part of the hysteresis (difference between inspiratory and expiratory pressure-volume curves) exhibited by the lung is a result of **surface tension** forces in the alveoli. If a lung is filled with fluid such as saline, the pressure-volume curves look much different than the pressure-volume curves of an air-filled lung (Figure 11-3). Less pressure is needed to inflate a fluid-filled lung to a given volume. This phenomenon indicates that a gas-fluid *interface* in the air-filled lung changes its inflation-deflation characteristics.

The recoil of the lung is a combination of tissue elasticity and the surface tension forces in the alveoli. During inflation, additional pressure is needed to overcome surface tension forces. During deflation, surface tension forces are reduced, resulting in altered pressure-volume characteristics (i.e., the leftward shift seen in Figure 11-3). In the intact lung (i.e., within the chest), the volume history also affects the degree of hysteresis that occurs. Factors such as the initial volume, the tidal excursion, and whether the lungs have been previously inflated or deflated help determine the volume history and the shape of the pressure-volume curves of the lung.

MINI CLINI

Surfactant Replacement Therapy and Lung Mechanics

PROBLEM: If an infant is born prematurely, the lungs may be unable to produce adequate amounts of pulmonary surfactant. How does this condition affect lung mechanics and what effect does surfactant replacement therapy have on lung compliance and the work of breathing?

DISCUSSION: The liquid molecules that line each alveolus attract one another. This attraction creates a force called *surface tension,* which tends to shrink the alveolus. A phospholipid called *pulmonary surfactant* reduces surface tension in the lung. Alveolar type II cells produce pulmonary surfactant. In contrast to typical surface-active agents, pulmonary surfactant changes surface tension according to its area.[2] The ability of pulmonary surfactant to reduce surface tension decreases as surface area (i.e., lung volume) increases. Conversely, when surface area decreases, the ability of pulmonary surfactant to reduce surface tension increases. This property of changing surface tension to match lung volume helps stabilize the alveoli. Any disorder that alters or destroys pulmonary surfactant can cause significant changes in the work of distending the lung.

The mechanism of action of pulmonary surfactant molecules is based on its weak intramolecular attractive forces. When surfactant molecules are mixed with other liquid molecules that have higher intramolecular attraction, the surfactant molecules are pushed to the surface of the liquid, where they form the air-liquid interface. Because of the weak intramolecular attraction between these surfactant molecules at the surface, the liquid lining of the alveoli exhibits much less surface tension than it would in the absence of pulmonary surfactant. In a premature infant with inadequate surfactant the intraalveolar surface tension is abnormally high; this produces a collapsing force that increases lung recoil and reduces lung compliance. Greater muscular effort is required to overcome increased recoil during inspiration, and the work of breathing is increased. The infant may eventually become fatigued and develop ventilatory failure. Instillation of artificial surfactant into the lungs reduces surface tension to its normal level. Lung compliance is increased, elastic recoil is reduced, and the muscular work required to inflate the lung is reduced.

Elastic Forces Opposing Lung Inflation

Elastin and *collagen* fibers are found in the lung parenchyma. These tissues give the lung the property of elasticity. **Elasticity** is the physical tendency of an object to return to an initial state after deformation. When stretched, an elastic body tends to return to its original shape. The tension developed when an elastic structure is stretched is proportional to the degree of deformation produced (Hooke's law). An example is a simple spring (Figure 11-4). When tension on a spring is increased, the spring lengthens. However, the ability of the spring to stretch is limited. When the point of maximal stretch is reached, further tension produces little or no increase in length. Additional tension may break the spring.

In the respiratory system, inflation stretches tissue. The elastic properties of the lungs and chest wall oppose inflation. To increase lung volume, pressure must be applied. This property may be shown by subjecting an excised lung to changes in transpulmonary pressure and measuring the associated changes in volume (Figure 11-5). To simulate the pressures during breathing, the lung is placed in an airtight jar. The force to inflate the lung is provided by a pump that varies the pressure around the lung inside the jar, simulating P_{pl}. This action mimics the pleural pressure changes associated with thoracic

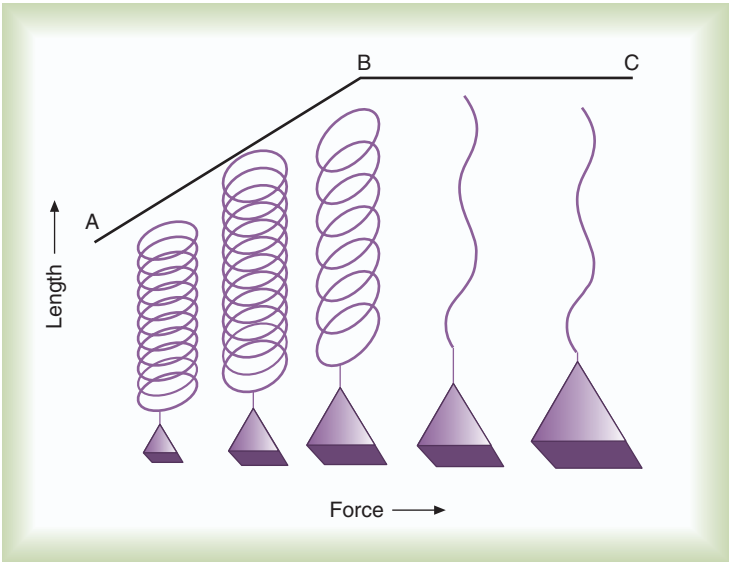

FIGURE 11-4 Graphic representation of the force-length relationship applied to a simple spring (increase in length with increase in force). With increasing force, or weight in this example, the spring lengthens from *A* to *B,* but at the point of maximal stretch, further force produces no additional increase in length (*B* to *C*).

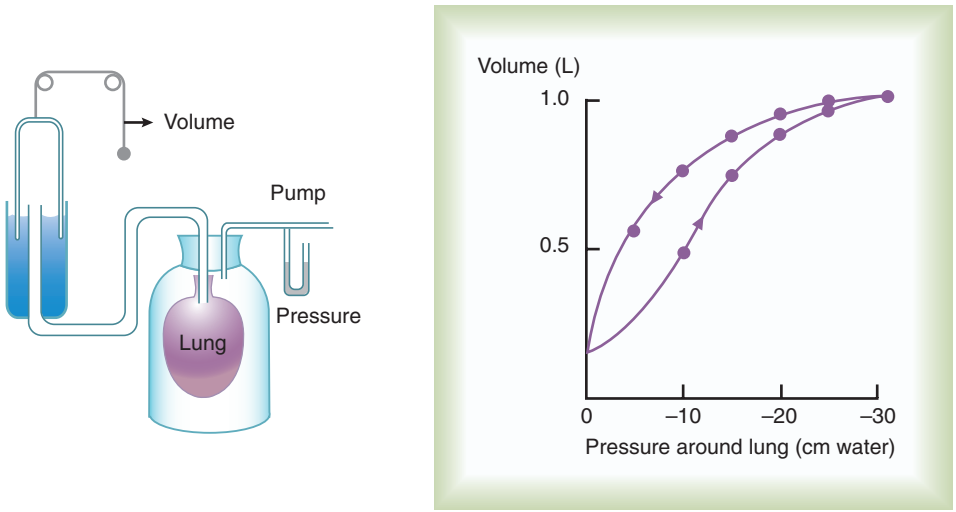

FIGURE 11-5 Measurement of the pressure-volume curve of an excised lung. The lung is placed in a sealed jar and connected to a spirometer (to measure volume). A pump generates sub-atmospheric pressure around the lung while its volume is measured. The curve plotting the relationship between pressure and volume is nonlinear and flattens at high expanding pressures (sub-atmospheric). The inflation and deflation curves are not the same. This difference is called *hysteresis.* (Modified from West JB: Respiratory physiology: the essentials, ed 7, Baltimore, 2005, Williams & Wilkins.)

expansion and contraction. The changes in transpulmonary pressure are made in discrete steps, allowing the lungs to come to rest in between so that all of the applied pressure opposes elastic forces and none of it opposes resistive forces (i.e., flow is zero when the measurements are made). The amount of stretch (inflation) is measured as volume by a spirometer. Changes in volume resulting from changes in transpulmonary pressure are plotted on a graph.

During inspiration in this model, increasingly greater negative pleural pressures are required to stretch the lung to a larger volume. As the lung is stretched to its maximum (total lung capacity [TLC]), the inflation curve becomes flat. This flattening indicates *increasing* opposition to expansion (i.e., for the same change in transpulmonary pressure, there is less change in volume).[3]

As with a spring when tension is removed, deflation occurs passively as pressure in the jar is allowed to return toward atmospheric pressure. Deflation of the lung does not follow the inflation curve exactly. During deflation, lung volume at any given pressure is slightly greater than it is during inflation. This difference between the inflation and deflation curves is called **hysteresis.**[3] Hysteresis indicates that factors other than simple elastic tissue forces are present. The major factor, particularly in sick lungs, is the opening of collapsed alveoli during inspiration that tend to stay open during expiration until very low lung volumes are reached.

Compliance

Compliance (C, the reciprocal of elastance, E) is caused by the tissue elastic forces and surface tension that oppose lung inflation. Compliance is defined as the constant of proportionality between volume (V) and pressure (P) in an elastic system and is usually expressed in units of ml/cm H_2O:

$$C = \frac{\Delta V}{\Delta P} = \frac{1}{E}$$

To calculate lung compliance, ΔP_{TP} is substituted for ΔP. To calculate respiratory system compliance, use ΔP_{TR}. To calculate chest wall compliance, use ΔP_{TCW}.

A graph of change in lung volume versus change in transpulmonary pressure (Figure 11-6, *A*) is called the *compliance curve of the lungs*. Figure 11-6, *B* compares a normal lung compliance curve with curves that might be observed in patients who have emphysema (obstructive lung disease) or pulmonary fibrosis (restrictive lung disease). The curve from a patient with emphysema is steeper and displaced to the left. The shape and position of this curve represent large changes in volume for small pressure changes (increased compliance). Increased compliance results primarily from loss of elastic fibers, which occurs in emphysema. The lungs become more distensible so that a normal transpulmonary pressure results in a larger lung volume. The term *hyperinflation* is used to describe an abnormally increased lung volume. A distinctly opposite pattern is seen in pulmonary fibrosis. Interstitial fibrosis is characterized by an increase in connective tissue. The compliance curve of a patient with pulmonary fibrosis is flatter than the normal curve, shifted down and to the right. As a result, there is a smaller volume change for any given pressure change (decreased compliance). Consequently, the lungs become stiffer, usually with a reduced volume.

Inflation and deflation of the lung occur with changes in the dimensions of the chest wall. The relationship between the lungs and the chest wall can be illustrated by plotting their relaxation pressure curves separately and combined (Figure 11-7). In the intact thorax, the lungs and chest wall recoil against each other. The point at which these opposing forces balance determines the resting volume of the lungs, or FRC.

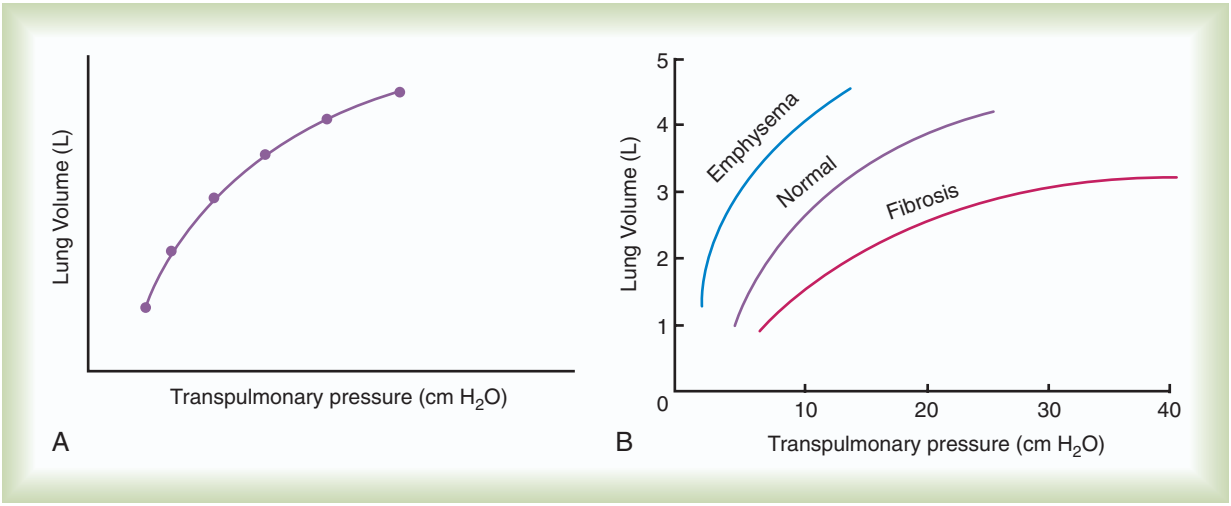

FIGURE 11-6 **A,** Compliance measurement (deflation curve). After swallowing an esophageal balloon, the person inhales a full breath and then exhales slowly. At specific lung volumes, he holds his breath with the glottis open, ensuring an alveolar pressure of zero. Lung volume is plotted against transpulmonary pressure (esophageal pressure is assumed to reflect pleural pressure) generating a compliance curve. **B,** Compliance curves. Normal lung compliance is approximately 0.2 L/cm H_2O (measured from the lower portion of the curve, near resting lung volume). Compliance is increased in emphysema because of the destruction of elastic tissue; conversely, it is decreased in pulmonary fibrosis because of increased elastic recoil. (Modified from Martin L: Pulmonary physiology in clinical practice: the essentials for patient care and evaluation, St Louis, 1987, Mosby.)

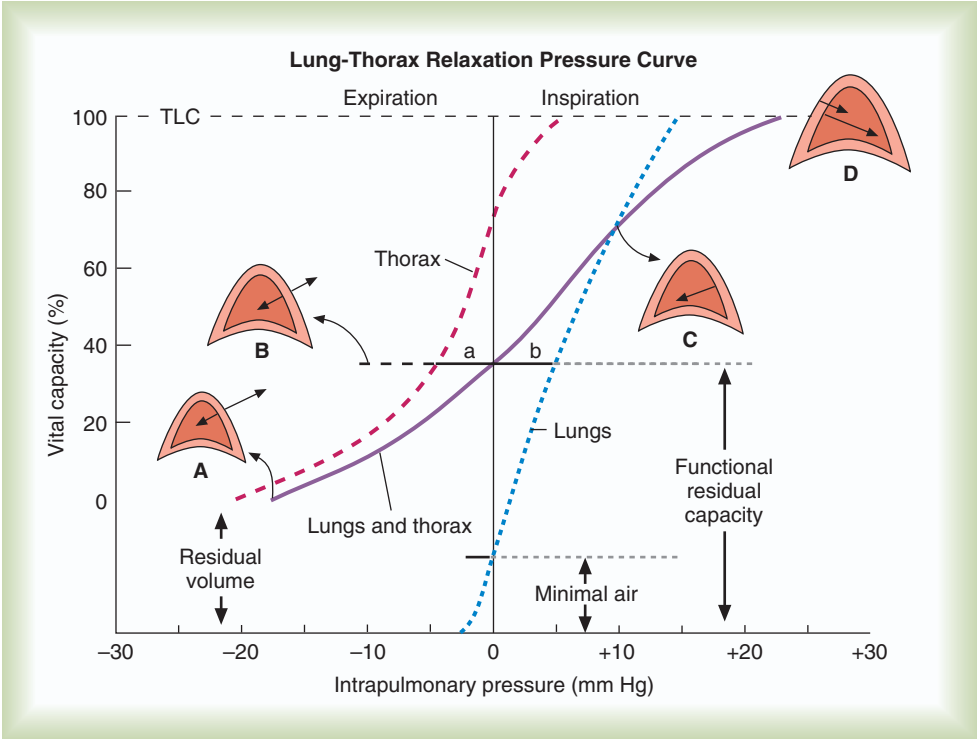

FIGURE 11-7 Relationship between the lungs and chest wall. Volumes of the lungs, thorax, and lungs and thorax combined are plotted as a percentage of vital capacity against intrapulmonary pressure (recoil pressure). The combined lung-thorax relaxation curve *(solid line)* is the sum of the individual lung and thorax curves. Equilibrium (zero pressure) occurs where the lung and thoracic recoil forces balance (a + b = 0). This point determines the functional residual capacity (lung *B*). Lung *A* represents low lung volume with greater recoil pressure exerted by the chest wall. Lung *C* shows a chest wall recoil of zero at approximately 70% of TLC. When lung volume is greater than 70% of TLC, greater pressures are required to distend both the lungs and the thorax (lung *D*). (Modified from Beachey W: Respiratory care anatomy and physiology, ed 2, St Louis, 2007, Mosby.)

This is also the point at which alveolar pressure equals atmospheric pressure. The normal FRC is approximately 40% of the TLC. The opposing forces between the chest wall and lungs are partially responsible for the sub-atmospheric pressure in the intrapleural space. Diseases that alter the compliance of either the chest wall or the lung often disrupt the balance point, usually with a change in lung volume.

Combined Compliances

The two lungs have their own (usually different) compliances. However, the muscles (or ventilator) see a combined compliance. Because the lungs have the same driving pressure but different flows, they are said to be connected in parallel. Parallel compliances combine by simple addition:

$$\text{Parallel compliances: } C_{total} = C_{right} + C_{left}$$

The total compliance of a parallel connection is more than any of the components.

The total lung compliance is connected in series with the chest wall compliance, meaning they have different driving pressures but the same flow. Series compliances combine as follows:

$$\text{Series compliances: } C_{total} = \frac{C_{chestwall} \times C_{lungs}}{C_{chestwall} + C_{lungs}}$$

The total compliance of a series connection is less than any of the components.

RULE OF THUMB

The lungs and chest wall each have their own compliance, or distensibility. In healthy adults, the compliance of the lungs and chest wall are each equal to approximately 0.2 L/cm H_2O. However, because the lungs are contained within the thorax, the two systems act as springs pulling against the driving force. This reduces the compliance of the system to approximately half that of the individual components, or 0.1 L/cm H_2O. This rule has many practical implications, particularly for mechanical ventilation of the lungs. Compliance of the chest wall, similar to lung compliance, is a measure of distensibility. Any disease process that alters the compliance of the lungs or chest wall can seriously disrupt the normal mechanics of ventilation. Obesity, kyphoscoliosis, ankylosing spondylitis, and many other abnormalities can reduce chest wall compliance and lung volumes.

Inhalation occurs when the balance between the lungs and chest wall shifts. Energy from the respiratory muscles (primarily the diaphragm) overcomes the contractile force of the lungs. At the beginning of the breath, the tendency of the chest wall to expand facilitates lung expansion. When lung volume nears 70% of the total lung capacity, the chest wall reaches its natural resting level. To inspire to a lung volume greater than approximately 70% of total lung capacity (TLC), the inspiratory muscles must overcome the recoil of both the lungs and the chest wall (see Figure 11-7).

For exhalation, potential energy "stored" in the stretched lung (and chest wall at high volumes) during the preceding inspiration causes passive deflation. To exhale below the resting level (FRC), muscular effort is required to overcome the tendency of the chest wall to expand. The expiration provides this energy.

Resistive Forces Opposing Lung Inflation

Frictional forces also oppose ventilation. Frictional opposition forces differ from the elastic properties of the lungs and thorax. Frictional opposition occurs only when the system is in motion. Frictional opposition to ventilation has the two components tissue viscous resistance and airway resistance.

Tissue Viscous Resistance. Tissue viscous resistance is the impedance of motion (opposition to flow) caused by displacement of tissues during ventilation. Displaced tissues include the lungs, rib cage, diaphragm, and abdominal organs. The frictional resistance is generated by the movement of each organ surface sliding against the other (e.g., the lung lobes sliding against each other and against the chest wall). Tissue resistance accounts for only approximately 20% of the total resistance to lung inflation. However, in conditions such as obesity, pleural fibrosis, and ascites, the tissue viscous resistance will increase the total impedance to ventilation.

Airway Resistance. Gas flow through the airways also causes frictional impedance, called *flow resistance*. Resistance to ventilation by the movement of gas through the airways is called **airway resistance.** Airway resistance accounts for approximately 80% of the frictional resistance to ventilation.

Resistance is defined as the constant of proportionality between pressure (P) and flow ($\dot{V}$) in a flow-conducting system and is usually expressed in units of cm H_2O/L/sec:

$$R = \frac{\Delta P}{\Delta \dot{V}}$$

To calculate airway resistance, R_{aw}, use ΔP_{TA} instead of ΔP. To calculate respiratory system resistance, use ΔP_{TR}.

Airway resistance in healthy adults ranges from approximately 0.5 to 2.5 cm H_2O/L/sec. To cause gas to flow into or out of the lungs at 1 L/sec, a healthy person needs to lower his or her alveolar pressure only 0.5 to 2.5 cm H_2O below atmospheric pressure.

R_{aw} in nonventilated patients is usually measured in a pulmonary function laboratory. Flow is measured with a **pneumotachometer.** Alveolar pressures are determined in a body **plethysmograph,** an airtight box in which the patient sits. By momentarily occluding the patient's airway and measuring the pressure at the mouth, alveolar pressure can be estimated (i.e., mouth pressure equals alveolar pressure under conditions of no flow). By relating flow and alveolar pressure to changes in plethysmograph pressure, airway resistance can be calculated.

Combined Resistances

The right and left main stem bronchi have their own (usually different) resistances. However, the muscles (or ventilator) see a combined resistance. Because these airways have the same

driving pressure but different flows, they are said to be connected in parallel. Parallel compliances combine like compliances in series, as follows:

$$\text{Parallel resistances: } R_{total} = \frac{R_{right} \times R_{left}}{R_{right} + R_{left}}$$

The total resistance of a parallel connection is less than that of any of the components.

The bronchial airway resistance is connected in series with upper airway (and artificial airway, if any), meaning that they have different driving pressures but the same flow. Series resistances combine like compliances in parallel:

$$\text{Series resistance: } R_{total} = R_{upper\ airway} + R_{bronchi}$$

The total resistance of a series connection is more than that any of the components.

MINI CLINI

Helium and Oxygen Therapy for Large Airway Obstruction

PROBLEM: Patients with significant obstruction in the upper airway, trachea, or main stem bronchi expend a large amount of energy overcoming the resistance to breathing. What type of gas therapy would be most advantageous in this situation?

DISCUSSION: Because most (approximately 80%) of the resistance to breathing occurs in the upper and large airways, disease processes that increase resistance in these airways cause tremendous increases in the work of breathing. Vocal cord edema, tumors in the trachea, and foreign bodies in main stem bronchi are examples of the types of clinical conditions that can markedly increase the work of breathing. Patients who must breathe against high levels of resistance are prone to respiratory muscle fatigue and failure. Gas flow in the upper and large airways is predominantly turbulent. Turbulent flow is highly influenced by gas density. Patients with large airway obstruction often can be treated with a mixture of helium and O_2 (heliox or HeO_2). HeO_2, usually an 80/20 or 70/30 mixture, can be administered to reduce the work of breathing until the obstructive process can be treated. HeO_2 mixture does little for patients with small airway obstruction, as occurs in emphysema or asthma. Flow in the small airways is mainly laminar and largely independent of the density of the gas breathed. However, heliox therapy can be used for patients with small airway obstruction to allow them to exercise longer and more strenuously with less dyspnea and dynamic hyperinflation.

Factors Affecting Resistance. The two main patterns that characterize the flow of gas through the respiratory tract are *laminar flow* and *turbulent flow* (see Chapter 6). A third pattern, *tracheobronchial flow,* is a combination of laminar and turbulent flow. Laminar flow requires less driving pressure than turbulent flow.

Poiseuille's equation (see Chapter 6) describes laminar flow through a smooth, unbranched tube of fixed dimensions (i.e., length and radius). This equation says that for gas flow to remain constant, the pressure is *inversely proportional* to the fourth power of the airway's radius. That is, by reducing the radius of a tube by half requires a 16-fold pressure increase to maintain a constant flow ($2^4 = 16$)! Clinically this means that to maintain ventilation in the presence of narrowing airways, large increases in driving pressure may be needed, resulting in marked increases in the work of breathing.

RULE OF THUMB

A change in the radius of an airway by a factor of 2 causes a 16-fold change in resistance. This rule applies to human airways and artificial airways (i.e., endotracheal and tracheostomy tubes). If the size of a patient's airway is reduced from 2 mm to 1 mm, airway resistance increases by a factor of 16. Similarly, if a 4.5-mm endotracheal tube is replaced with a 9-mm tube, the pressure required to cause a flow of 1 L/sec through the tube decreases 16-fold. This rule has many practical consequences. It is the basis for bronchodilator therapy and for using the largest practical size of artificial airway.

Distribution of Resistance. Approximately 80% of the resistance to gas flow occurs in the nose, mouth, and large airways, where flow is mainly turbulent. Only approximately 20% of the total resistance to flow is attributable to airways smaller than 2 mm in diameter, where flow is mainly laminar. This fact seems to contradict the fact that resistance is inversely related to the radius of the conducting tube.

Branching of the tracheobronchial tree increases the cross-sectional area with each airway generation (Figure 11-8). As gas moves from the mouth to the alveoli, the combined cross-sectional area of the airways increases exponentially. Turbulent flow predominates in the mouth, trachea, and primary bronchi (Table 11-3). Gas velocity is high in the bigger airways, favoring turbulent flow patterns. As we move deeper into the lung segments, the airways branch into smaller, but more, airways and more cross-sectional area. At the level of the terminal bronchioles, the cross-sectional area increases more than 30-fold. The arrangement of the branches at the same bronchial generation is in parallel (compared to in series), thus decreasing the total resistance. According to the laws of fluid dynamics, this increase in cross-sectional area causes a decrease in gas velocity. The velocity of gas flow and resistance in a branching system arranged in parallel is inversely related to the cross-sectional area of the airways. The decrease in gas velocity promotes a

TABLE 11-3

Distribution of Airway Resistance

Location	Total Resistance (%)
Nose, mouth, upper airway	50
Trachea and bronchi	30
Small airways (<2 mm)	20

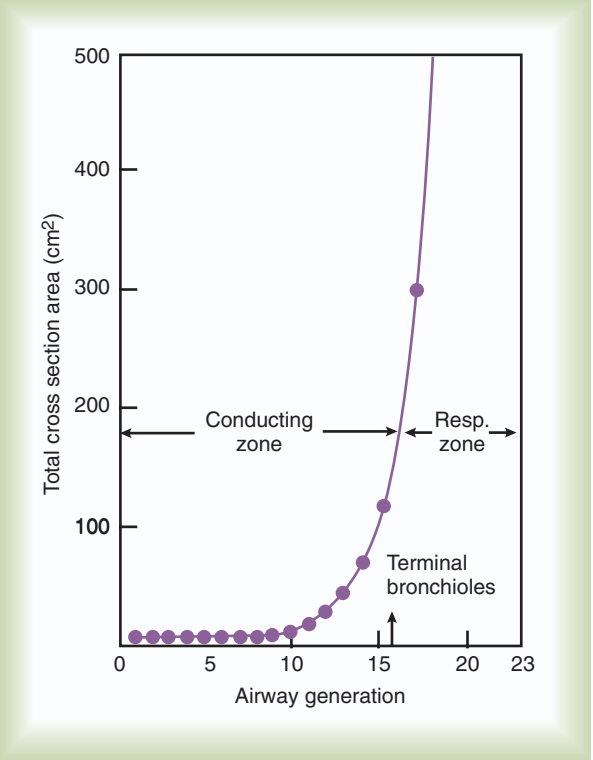

FIGURE 11-8 Cross-sectional area of the airways plotted against airway generation. The first 15 or 16 airway generations represent a conducting zone in which gas moves primarily by bulk flow, and no gas exchange takes place. These airways make up the anatomic dead space (see Chapter 9). The gas-exchange surface increases markedly at the level of the terminal bronchiole. (Modified from West J: Respiratory physiology: the essentials, ed 7, Baltimore, 2005, Williams & Wilkins.)

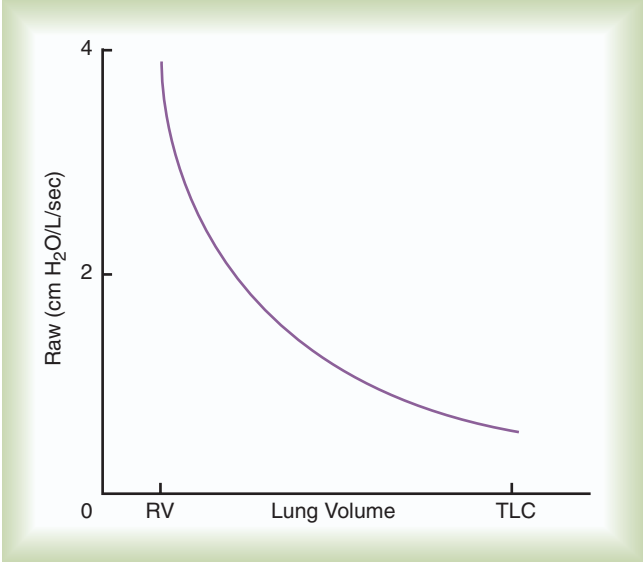

FIGURE 11-9 Change in airway resistance (R_{aw}) related to lung volume. Resistance to airflow is highly dependent on lung volume. At low lung volumes, near residual volume *(RV),* the airways are compressed and resistance increases markedly. At high lung volumes, near total lung capacity *(TLC),* the airways are distended and resistance decreases. See text for discussion.

laminar flow pattern, particularly in smaller (i.e., <2 mm) airways. The resistance to flow in these small airways is then very low. The driving pressure across these airways is less than 1% of the total driving pressure for the system.

We must remember that the diameter of the airways is not constant during the ventilatory cycle. During inspiration, the stretch of surrounding lung tissue and widening transpulmonary pressure gradient increase the diameter of the airways. The increase in airway diameter with increasing lung volume decreases airway resistance (Figure 11-9). As lung volume decreases toward residual volume, airway diameters also decrease and airway resistance dramatically increases; this explains why wheezing is most often heard during exhalation.

STATIC VERSUS DYNAMIC MECHANICS

Resistance and compliance can be evaluated under static or dynamic conditions.[4] The term *static* implies that flow throughout the respiratory system has ceased and all ventilatory muscle activity is absent ($P_{mus} = 0$). Static conditions can be imposed with an inspiratory pause when a patient is sedated and being mechanically ventilated. In contrast, the term *dynamic* (in this context) means that flow at the airway opening is zero. Mechanics are evaluated under dynamic conditions, for example, when a nonintubated patient breathes spontaneously. In this case, the pressure difference used to calculate lung resistance and elastance is P_{TP} and the driving pressure is P_{mus} instead of the ventilator.

In a single-compartment model (see Figure 11-1), estimation of resistance and compliance under static and dynamic conditions yields the same values. However, in a real respiratory system, composed of multiple compartments with different time constants (each compartment being a resistance in series with a compliance), mechanics estimated during static conditions yield different values than when evaluated during dynamic conditions. For a multiple-compartment system, when flow is zero at the airway opening, there may still be flow between compartments (pendelluft). As a result, dynamic mechanics become dependent on the respiratory frequency.[5,6] Typically, both compliance and resistance decrease as frequency increases.

MECHANICS OF EXHALATION

Airway caliber is determined by several factors, including anatomic (i.e., physical) support provided to the airways and pressure differences across their walls. Anatomic support comes from cartilage in the wall of the airway and from "traction" provided by surrounding tissues. The larger airways depend mainly on cartilaginous support. Because smaller airways lack cartilage, they depend on support provided by surrounding lung parenchyma.[7]

The airways are also supported by the pressure difference across their walls. This transpulmonary pressure gradient helps

stabilize the airways, particularly the small ones. During quiet breathing, pleural pressure is normally subatmospheric. Airway pressure varies minimally and is usually close to zero (atmospheric pressure). The **transmural pressure** gradient (the pressure difference between inside and outside the airway wall) during normal quiet breathing is negative, even during exhalation. It ranges from −5 to −10 cm H_2O. This negative transmural pressure gradient helps maintain the caliber of the small airways.

During a forced exhalation, contraction of expiratory muscles can increase pleural pressure above atmospheric pressure; this reverses the transmural pressure gradient, making it positive. If the positive transmural pressure gradient exceeds the supporting force provided by the lung parenchyma, the small airways may collapse.

Forceful contraction of the expiratory muscles causes pleural pressure to increase from its normal negative value to above atmospheric pressure (Figure 11-10). Alveolar pressure during forced exhalation equals the sum of pleural pressure and the elastic recoil pressure of the lung.[8]

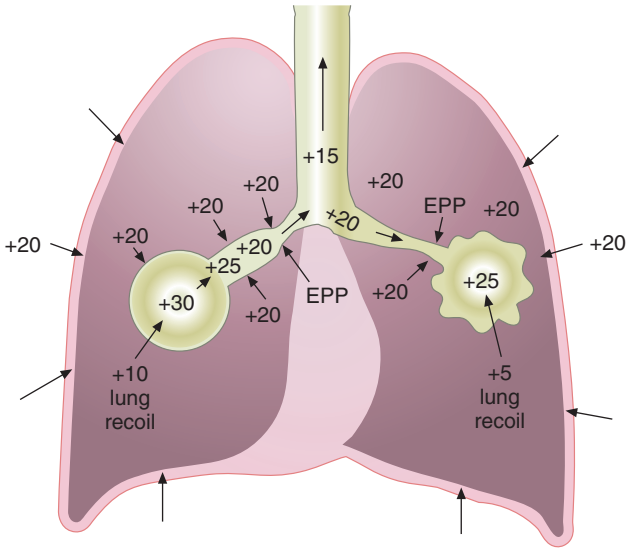

FIGURE 11-10 Generation of equal pressure point *(EPP)* in normal and diseased lungs during a forceful exhalation. In a normal lung *(left)*, pleural pressure (P_{pl}) increases to approximately +20 cm H_2O when a maximal expiratory effort is performed. Alveolar pressure is the sum of P_{pl} (+20 cm H_2O) and lung elastic recoil pressure (+10 cm H_2O), or +30 cm H_2O. Airway pressure falls along the airway from the alveolus to the mouth from +30 to 0 cm H_2O. At some point along the airway, pressure within the airway equals P_{pl}; this is the EPP. Further toward the mouth (downstream), airway pressure falls below P_{pl}, resulting in a narrowed airway and limitation of airflow. This narrowed airway normally occurs in healthy individuals only during forced exhalation. The EPP moves upstream from larger airways toward smaller airways as the lung empties. In lung diseases such as emphysema *(right)*, the same forces come into play. P_{pl} is still +20 cm H_2O, but lung elastic recoil pressure is only +5 cm H_2O. As a result, driving pressure is only +25 cm H_2O. This causes the EPP to occur in smaller airways (i.e., farther upstream) than normal; airways narrow or collapse at a higher lung volume than in healthy lungs. In patients with emphysema, airway collapse is complicated further by loss of support for the small airways. (Modified from Martin L: Pulmonary physiology in clinical practice: the essentials for patient care and evaluation, St Louis, 1987, Mosby.)

During exhalation, the pressure along the airway decreases as gas flows from the alveoli toward the mouth. Moving "downstream" (toward the mouth), transmural pressure decreases continually. At some point along the airway, the pressure inside the airway equals the pressure outside in the pleural space (i.e., transmural pressure equals zero). This point is referred to as the **equal pressure point (EPP).** Downstream from this point, pleural pressure exceeds the airway pressure. The resulting increase in transmural pressure gradient causes airway compression and can lead to collapse. Airway compression increases expiratory airway resistance and decreases flow. At the EPP, greater expiratory effort increases pleural pressure, restricting flow further.[9] Once the transmural pressure has increased sufficiently to cause this flow limitation (at the EPP), airflow becomes effort independent with airway caliber and elastic recoil pressure determining flow. **Dynamic compression** of the airways (narrowing of the airways owing to an increase in surrounding pressures) is responsible for the characteristic flow patterns observed in forced expiratory tests of pulmonary function.

In airways of healthy persons, airway collapse occurs only with forced exhalation and at low lung volumes. Tissue support opposes the collapsing force created by negative transmural pressure gradients. In pulmonary emphysema, the elastic tissue supporting the small airways is damaged.[9] Destruction of elastic tissue, such as occurs in emphysema, has multiple outcomes. It increases the compliance of the lung (i.e., elastic recoil decreases). The combination of decreased elastic recoil and loss of support for the small airways allows the airways to collapse during exhalation. Airway collapse causes air trapping and increase in the resting volume of the lung. Expiratory flow is reduced by airway collapse during exhalation (called *flow limitation*) and can occur during tidal breathing when emphysematous changes in the lung are severe.[10]

RULE OF THUMB

Patients who have emphysema can directly influence the EPP in their airways to reduce airway collapse and closure. Airway collapse may occur in patients who have emphysema because the normal support structure for small airways has been destroyed. By exhaling through "pursed lips," a patient with emphysema changes the pressure at the airway opening. The gentle back pressure created counters the tendency for small airways to collapse by moving the EPP toward larger airways.

WORK OF BREATHING

The respiratory muscles do the work for normal breathing. This work requires energy to overcome the elastic and frictional forces opposing inflation. Assessment of mechanical work involves measurement of the physical parameters of force and

distance as they relate to moving air into and out of the lung. Assessment of metabolic work involves measurement of the O_2 cost of breathing.

During normal quiet breathing, inhalation is active and exhalation is passive. The work of exhaling is recovered from potential energy "stored" in the expanded lung and thorax during inhalation. However, forced exhalation requires additional work by the expiratory muscles. The actual work of forced expiration depends on the mechanical properties of the lungs and thorax.

Mechanical Work

Work done on an object is the result of the force exerted on the object and the distance it is moved.

Work may be expressed in units of either dyne • centimeters (dyne • cm) or joules (J). For a constant applied force, the equation for work is:

$$\text{Work} = \text{Force} \times \text{Distance}$$

In physiology, work is expressed in terms of pressure difference across a structure (P) and the volume change of the structure (V). Because pressure is equal to force/area and volume is equal to area multiplied by distance, work can have the dimensions of P × V:

$$\begin{aligned}\text{Pressure} \times \text{Volume} &= \frac{\text{Force}}{\text{Area}} \times (\text{Area} \times \text{Distance}) \\ &= \text{Force} \times \text{Distance} \\ &= \text{Work}\end{aligned}$$

Graphically, the work is expressed as the area between the pressure-volume curve and the volume axis (Figure 11-11). Pressure, of course, is actually a pressure difference across a structure (i.e., inside pressure minus outside pressure), and the pressure difference *defines the structure* for which work is evaluated. For example, if we want to evaluate the work the muscles do to inflate the pulmonary system we use the transpulmonary pressure, P_{TP}. Similarly, if we want to evaluate the work done by a ventilator to inflate the respiratory system we use the transrespiratory system pressure (P_{TR}).

Also, because of the equivalence of work and energy, the energy stored in a rigid wall container holding compressed gas is simply the product of the volume of the container and the pressure inside the container (relative to the outside). The higher the pressure, the more energy stored in the container. When the pressure is released, useful work can be recovered. This is the principle used in air rifles.

Figure 11-11 shows a graph of transpulmonary pressure versus lung volume derived from measurements taken during dynamic conditions (e.g., during a normal inspiration). The line *AB* connects two points in time when flow is zero. The work done overcoming purely elastic forces opposing inflation is represented by the triangular area 1 in Figure 11-11. The work required to overcome flow resistive forces is represented by area 2. The total mechanical work for one breath is the sum of the work overcoming both the elastic and the resistive forces opposing inflation; this is represented as the sum of areas 1 and 2. In

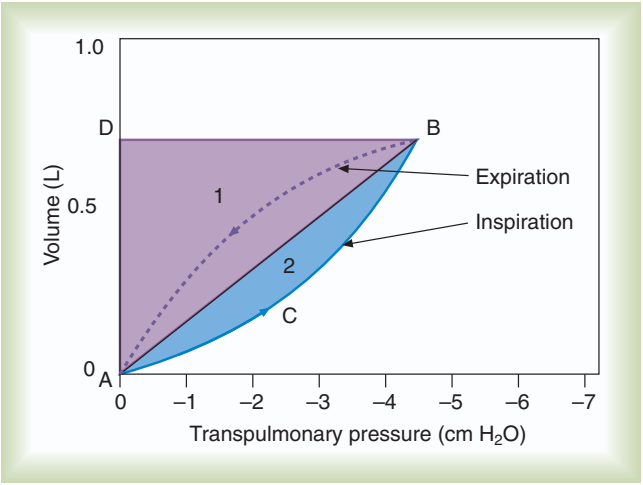

FIGURE 11-11 Factors involved in the work of breathing. Point *A* is the resting lung volume (functional residual capacity), and *B* is end-inspiration. The *straight solid line A-B* represents the pressure required to overcome simple elastic forces, and the *curved line A-C-B* represents the additional pressure required to overcome frictional resistance (airway and tissue). At *B,* where airflow momentarily ceases, frictional resistance is inactive. Area *1* represents the work (P × V) required to overcome elastic forces; area *2* represents the work required to overcome frictional forces. The work of breathing (inspiration) is the sum of these two areas. The *curved dashed line* within area *1* represents the pressure-volume curve of passive exhalation using energy stored during inspiration.

healthy adults, approximately two-thirds of the work of breathing can be attributed to elastic forces opposing ventilation. The remaining one-third is a result of frictional resistance to gas and tissue movement.

Traditionally, static pressure-volume curves have been created by injecting the lungs with discreet volume steps using a large calibrated syringe ("super syringe").[11] Alternatively, the line *AB* can be approximated under clinical conditions using a very slow inspiratory flow (with the patient heavily sedated) producing what is called a *quasistatic* pressure-volume curve.[12] Evaluation of this type of pressure-volume curve can be useful for setting optimal positive end-expiratory pressure (PEEP).[13] Ventilators made by Hamilton Medical (Reno, NV) offer the PV Tool, which generates a quasistatic pressure-volume curve using a slow pressure ramp rather than a slow inspiratory flow. This method allows evaluation of both compliance and lung recruitability.[14]

In the presence of pulmonary disease, work of breathing can increase dramatically (Figure 11-12). The areas of the volume-pressure curves for patients with obstruction or restriction are greater than in healthy persons.[15] The reasons for these increases in the mechanical work are quite different. In restrictive lung disease, the area of the volume-pressure curve is greater because the slope of the static component (compliance) is less than normal. The area of the volume-pressure curve in obstructive lung disease is increased because the portion associated with resistance is markedly widened. The leftward "bulge" of the loop

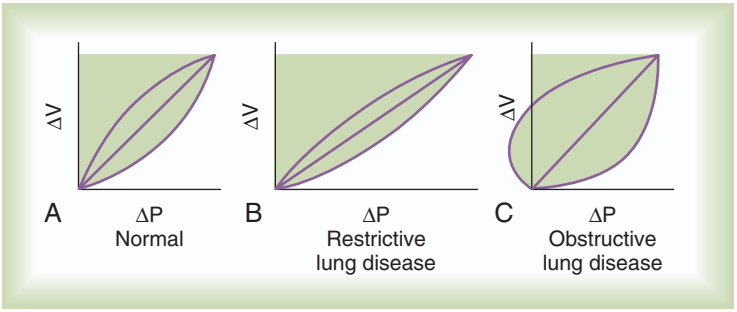

FIGURE 11-12 Comparison of the work of breathing *(shaded areas)* for a healthy person **(A),** a patient with restrictive ventilatory impairment (e.g., pulmonary fibrosis) **(B),** and a patient with airway obstruction (e.g., emphysema) **(C).**

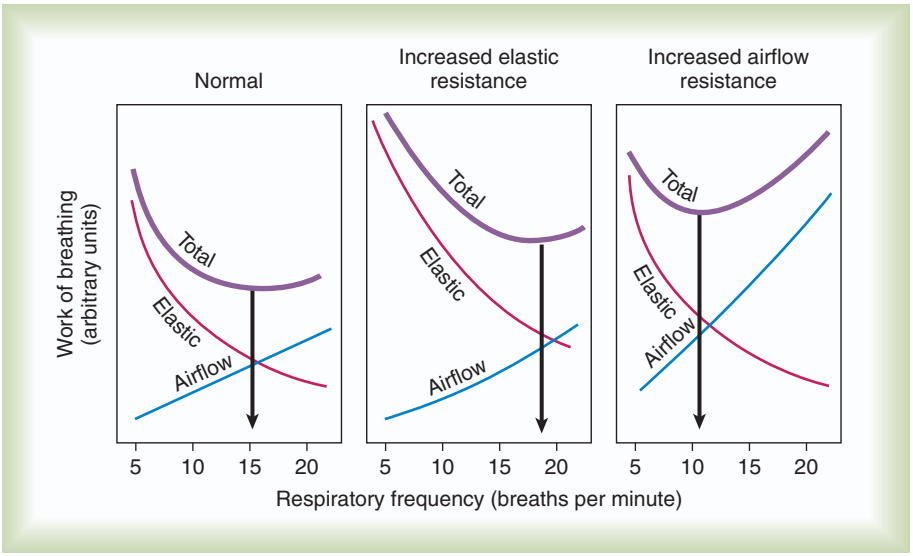

FIGURE 11-13 Work required to overcome airflow plus elastic resistance equals total work. In normal lungs, total work of breathing is minimal at approximately 15 breaths/min *(left).* To achieve the same minute volume with stiff lungs (increased elastic resistance), minimum work is performed at higher frequencies *(middle).* However, with increased airflow resistance (obstructive lung disease), minimum work requires lower rates of breathing *(right).* (Modified from Nunn JF: Applied respiratory physiology, ed 2, London, 1977, Butterworth.)

indicates positive pleural pressure that can occur during expiration, notably when lung compliance is increased (see Figure 11-12, *C*).

In healthy individuals, the mechanical work of breathing depends on the pattern of ventilation. Large V_T increases the elastic component of work. High breathing rates (and high flows) increase frictional work. When changing from quiet breathing to exercise ventilation, a healthy person adjusts V_T and breathing frequency to minimize the work of breathing.[5]

Similar adjustments occur in individuals who have lung disease (Figure 11-13). Patients with "stiff lungs" (i.e., increased elastic work of breathing), such as in pulmonary fibrosis, often assume a rapid, shallow breathing pattern. This pattern minimizes the mechanical work of distending the lungs but at the expense of more energy to increase breathing rate. Patients who have airway obstruction may assume a ventilatory pattern that reduces the frictional work of breathing. Breathing slowly and using pursed-lip breathing during exhalation minimize airway resistance.

Increased work of breathing is often complicated by *respiratory muscle weakness,* which may result from electrolyte imbalance, *acidemia,* shock, *sepsis,* or diseases affecting the muscles themselves.[16] When increased work of breathing occurs with respiratory muscle weakness, inspiratory muscles can fatigue. V_T decreases and respiratory rate increases as the muscles fatigue and fail.

Metabolic Work

To perform work, the respiratory muscles consume O_2. The rate of O_2 consumption ($\dot{V}_{O_2}$) by the respiratory muscles reflects their energy requirements. It also provides an indirect measure of the work of breathing.

The O_2 cost of breathing is assessed by measuring $\dot{V}_{O_2}$ at rest and at increased levels of ventilation. If no other factors increase O_2 consumption, the additional O_2 uptake is a result of respiratory muscle metabolism. The O_2 cost of breathing in healthy individuals averages 0.5 to 1 ml of O_2 per liter of increased ventilation. This range represents less than 5% of the O_2

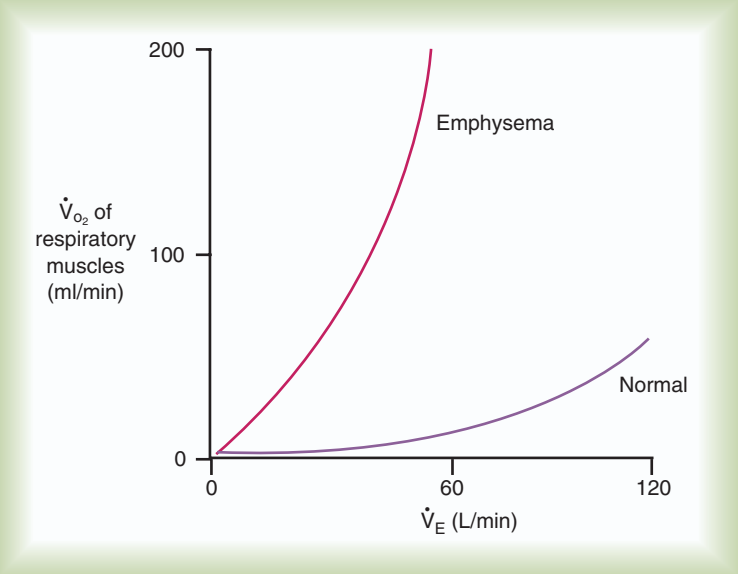

FIGURE 11-14 Relationship of oxygen cost of breathing to minute ventilation during maximum exercise for a healthy person and for a patient with emphysema. O_2 consumption ($\dot{V}O_2$) of the respiratory muscles is minimal at levels of ventilation up to approximately 100 L/min in normal persons. The metabolic demand is significantly higher in obstructive lung disease (e.g., emphysema), even at low and moderate levels of ventilation.

consumption of the body. At high levels of ventilation (i.e., >120 L/min), the O_2 cost of breathing increases tremendously and may exceed 30% of the O_2 consumption of the body.

The $\dot{V}_{O_2}$ of the respiratory muscles is closely related to the inspiratory pressures generated by the diaphragm. This transdiaphragmatic pressure can be measured by a technique similar to that used for measuring intrapleural pressure. A thin catheter with two small balloons is advanced into the esophagus. One balloon remains in the esophagus (above the diaphragm), and the balloon at the tip is placed in the stomach. The pressure difference between the balloons measures the pressure across the diaphragm. The greater the pressure required, the higher is the O_2 consumption of the respiratory muscles.

In the presence of pulmonary disease (either obstructive or restrictive), the O_2 cost of breathing may increase dramatically with increasing ventilation (Figure 11-14). In an obstructive disease such as emphysema, increased ventilation causes the O_2 consumption of the respiratory muscles to increase rapidly. This abnormally high O_2 cost of breathing is one factor that limits exercise in such patients. Increased O_2 consumption by the respiratory muscles may also contribute to the failure to wean patients from mechanical ventilation.[17] Intubation and mechanical ventilation in cases of shock may be indicated to decrease the excess O_2 consumption of the respiratory muscles and preserve the limited O_2 delivery (DO_2) for other vital body organs.

MINI CLINI

Oxygen Cost of Breathing During Weaning from Mechanical Ventilation

PROBLEM: During weaning from mechanical ventilation, O_2 cost of breathing may predict weaning failure. How can you simply detect O_2 cost of breathing at the bedside?

DISCUSSION: O_2 cost of breathing is the difference in O_2 consumption ($\dot{V}_{O_2}$) between unassisted breathing and passive assisted breathing during mechanical ventilation. Although O_2 consumption requires complicated equipment (indirect calorimetry or metabolic cart), simply looking at the mixed venous O_2 saturation (S_vO_2) before and after initiation of weaning may be a good surrogate for O_2 cost of breathing. If the S_vO_2 was 75% (normal) before initiation of weaning, and after 30 minutes of spontaneous breathing trial the value is 60% without other reason for increased O_2 consumption, it is fair to assume that the O_2 cost of breathing has increased significantly, and failure of weaning or extubation is possible. However, remember that a drop in S_vO_2 also may point toward cardiac dysfunction, clinical examination may help clarify this as the cause.

DISTRIBUTION OF VENTILATION

Neither ventilation nor perfusion is distributed evenly in healthy lungs, resulting in uneven ventilation-perfusion ($\dot{V}/\dot{Q}$) ratio (0.8). Regional and local factors account for this unevenness in the distribution of ventilation. Uneven ventilation helps explain why the lung is imperfect for gas exchange. In disease, the distribution of ventilation can worsen dramatically. The resulting deficiencies in gas exchange can be life-threatening. The maldistribution of ventilation in disease represents a primary cause of impaired O_2 and CO_2 exchange.

RULE OF THUMB

Gravity, to a large extent, determines where ventilation goes in the lungs. In an upright lung, the weight of the lung tissues causes alveoli at the bases to be smaller but more easily distended. Alveoli at the top of the lung are larger but distend less easily. Gravity also causes most blood flow through pulmonary capillaries to go to the bases. The pressure-volume characteristics of the upright lung direct most ventilation to these dependent portions, matching ventilation and blood flow to promote gas exchange. This phenomenon can be useful clinically when localized lesions (e.g., lobar pneumonia) cause $\dot{V}/\dot{Q}$ perfusion abnormalities.

MINI CLINI

Altering Patient Position to Improve Oxygenation

Altering patient position can improve oxygenation in some pulmonary diseases.[18]

PROBLEM: In patients with severe pulmonary disease causing hypoxemia, how can altering body position improve such hypoxemia?

DISCUSSION: In patients with unilateral lung disease (e.g., pneumonia), having the patient lie on his or her side with the good lung down may improve hypoxemia by altering the gravity-dependent ventilation distribution and the gravity-dependent perfusion distribution. Similarly in patients with severe bilateral pulmonary disease (e.g., acute respiratory distress syndrome [ARDS]), placing the patient in the prone position alters the ventilation and the perfusion, favoring the anterior areas of the lungs and improving the hypoxemia.

Regional Factors Affecting Distribution

Two factors interact with the effects of gravity to affect regional distribution of gas in the healthy lung: (1) relative differences in thoracic expansion and (2) regional transpulmonary pressure gradients. In upright individuals, these factors direct more ventilation to the bases and periphery of the lungs than to the apexes and central zones.

Differences in Thoracic Expansion

The conical configuration of the thorax and the action of the respiratory muscles cause proportionately greater expansion at the lung bases than at the apexes. Expansion of the lower chest is approximately 50% greater than expansion of the upper chest.[16] The action of the normal diaphragm preferentially inflates the lower lobes of the lung.

Transpulmonary Pressure Gradients

The transpulmonary pressure gradient is not uniform throughout the thorax. It varies substantially within the lung and from the top to the bottom of the lung. At a given level of alveolar inflation, the transpulmonary pressure gradient is directly related to the pleural pressure. Pleural pressure represents the pressure on the outer surface of the lung. Its effect lessens toward more centrally located alveoli. Changes in the transpulmonary pressure gradient are greatest in peripheral alveoli (i.e., near the surface of the lung). The changes are least in the alveoli of the central zones. Peripheral alveoli expand proportionately more than their more central counterparts.

Top-to-bottom differences in pleural pressure have an even greater effect on the distribution of ventilation, especially in the upright lung.[3] Pleural pressure increases by approximately 0.25 cm H_2O for each 1 cm, from the lung apex to its base for the average-sized adult lung. This increase in pressure results from the weight of the lung itself and the effect of gravity. In an adult-sized lung (approximately 30 cm from apex to base), pleural pressure at the apex is approximately −10 cm H_2O. At the base, pleural pressure is only approximately −2.5 cm H_2O. Because of these differences, the transpulmonary pressure gradient at the top of the upright lung is greater than it is at the bottom. As a result, alveoli at the apexes have a larger resting volume than do alveoli at the bases.

Because of their larger volume, alveoli at the apexes expand less during inspiration than alveoli at the bases. Apical alveoli rest on the upper portion of the lung's pressure-volume curve (Figure 11-15). This part of the curve is relatively flat. Each unit

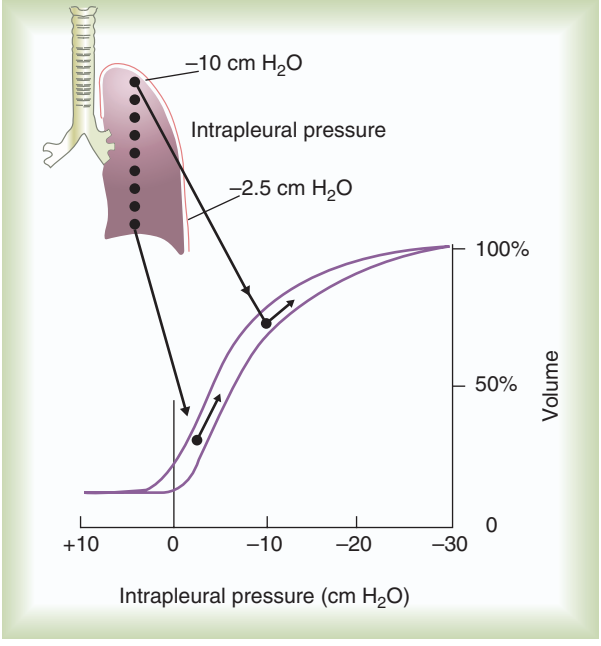

FIGURE 11-15 Causes of regional differences in ventilation from the apex to the base of an upright lung. Because of the weight of the lung and the influence of gravity, intrapleural pressure at the apex is more negative (sub-atmospheric) than at the base. Alveoli at the apex are maintained at a higher resting inflation volume than are further at the base. However, alveoli at the apex reside on the flatter upper portion of the pressure-volume curve. Alveoli at the base are positioned on the lower, steeper portion. For an equal change in intrapleural pressure, alveoli at the base expand more during inspiration than alveoli at the apex. This causes more ventilation to go to the bases in the upright lung. (Modified from West JB: Respiratory physiology: the essentials, ed 7, Baltimore, 2005, Williams & Wilkins.)

of pressure change causes only a small change in volume. Alveoli at the lung bases are positioned on the steeper middle portion of the pressure-volume curve. For each unit of pressure change, there is a larger change in volume (greater compliance). For a given transpulmonary pressure gradient, alveoli at the bases expand more than alveoli at the apexes. The bases of the upright lung receive approximately four times as much ventilation as the apexes.

These gravity-dependent differences also are observed in individuals lying down. The magnitude of the differences is less than in the upright lung because the top-to-bottom distance is less. Ventilation is still greatest in the dependent zones of the lung. In recumbent persons, the posterior regions are dependent. Lying on the side causes more ventilation to go to whichever lung is lower. This gravity dependence can be exploited to direct ventilation toward healthy lung segments or away from diseased segments by appropriate positioning of the patient.

Local Factors Affecting Distribution

Alveolar filling and emptying are affected by local factors. Individual respiratory units and their associated airways may differ from each other. These local factors contribute to uneven ventilation in healthy lungs. Their influence on gas distribution becomes particularly important in disease.

Each respiratory unit has an elastic element, the alveolus, and a resistive element, the airway. Change in alveolar volume and the time required for the change to occur depend on the compliance and resistance of each respiratory unit.[3] In terms of compliance, the more distensible the lung unit, the greater is the volume change at a given transpulmonary pressure. Lung units with high compliance have less elastic recoil than normal. These units fill and empty more slowly than normal units. Lung units with low compliance (high elastic recoil) increase their volume less. They fill and empty faster than normal. Alveolar surfactant helps to stabilize alveoli of different sizes and even out the filling and emptying times.

Airway resistance also affects emptying and filling. The size of the airway influences how much driving pressure reaches distal lung units. In healthy airways, the pressure decrease between the airway opening (i.e., the mouth) and the alveolus is minimal. Most of the driving pressure is available for alveolar inflation. If the airway is obstructed, high resistance to gas flow can occur in a local area. The pressure decrease across the obstruction may be substantial. Less driving pressure is available for alveolar inflation; there is less alveolar volume change.

Time Constants

Compliance and resistance determine local rates of alveolar filling and emptying. The time constant helps us understand these rates. The time constant is calculated as the product of resistance and compliance and is expressed in units of time (usually seconds). It is referred to as a "constant" because for any value of resistance and compliance, the time constant always equals the time necessary for the lungs to fill or empty by 63% in response to a sudden change in driving pressure. For unit of inspiratory or expiratory time equal to the time constant, lung volume changes by 63%. After two time constants, lung volume has changed 86%; after three time constants, it has changed 95%.

Time constants affect local distribution of ventilation within the lung. Areas having different time constants will have different volumes and pressures. Furthermore, the effects of unequal time constants within the lung are different for volume control ventilation (with constant inspiratory flow) compared with pressure-controlled ventilation (with constant inspiratory pressure).[19]

RULE OF THUMB

Understanding of the time constant is essential when setting mechanical ventilators (discussed later in this text). In pressure control modes, inspiratory time must be at least three time constants long to deliver 95% of the volume that is possible with the given pressure settings and lung mechanics. For any mode, expiratory time must be set to at least three time constants for the lungs to empty passively to 95% (i.e., 5% of inspired volume still remains). A lung unit has a long time constant if resistance or compliance is high. Units with long time constants take longer to fill and to empty than units with normal compliance and resistance. Lung units have a short time constant when resistance or compliance is low. Lung units with short time constants fill and empty more rapidly than lung units with normal compliance and resistance (see Figure 11-16).

Frequency Dependence of Compliance

Variations in time constants can affect ventilation throughout the lung. Abnormal ventilation is characteristic of obstruction in the small airways. This type of obstruction occurs in emphysema, asthma, and chronic bronchitis.[20] The time constants of many lung units are increased in obstructive lung disease. These long time constants are mainly caused by increased resistance to flow in the small airways. Loss of normal tissue elastic recoil, such as in emphysema, also contributes to slowed filling and emptying.

At increased breathing rates, units with long time constants fill less and empty more slowly than units with normal compliance and resistance. Increasingly more inspired gas goes to lung units with relatively normal time constants. When more inspired volume goes to a smaller number of lung units, higher transpulmonary pressures must be generated to maintain alveolar ventilation. Compliance of the lung seems to decrease as breathing frequency increases. This phenomenon is called *frequency dependence of compliance*.[5] If dynamic compliance decreases as the respiratory rate increases, some lung units must have abnormal time constants. Any stimulus to increase ventilation, such as exercise, may redistribute inspired gas. Mismatching of ventilation and perfusion can result in hypoxemia, severely limiting an individual's ability to perform daily activities.

Abnormal time constants in lung units and frequency dependence of compliance can have significant effects on patients

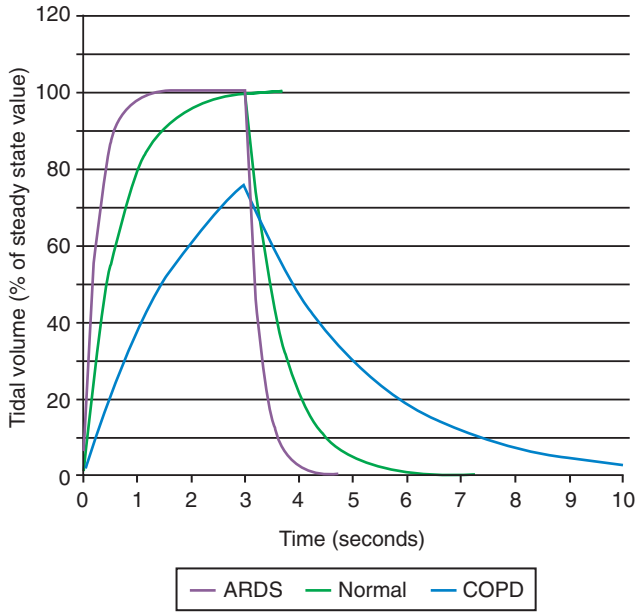

FIGURE 11-16 Graph illustrates the effect of the time constant on volume change in the lungs during passive ventilation with constant inspiratory pressure. The time constant for a ventilated patient with acute respiratory distress syndrome *(ARDS)* is short (in this example, 0.26 second) owing to normal resistance but low compliance. A person with normal lungs has a longer time constant (e.g., 0.65 second) owing to normal resistance and normal compliance. A patient with chronic obstructive pulmonary disease *(COPD)* has the longest time constant (e.g., 2.13 seconds) owing to high resistance and high compliance. The horizontal axis shows the expiratory time, and the vertical axis shows the percent of the V_T that remains at each moment. The curve representing the COPD time constant indicates significant gas trapping even after an expiratory time of 5 seconds.

requiring mechanical ventilation. When ventilation is controlled in terms of volume or inspiratory-expiratory times, **dynamic hyperinflation (air trapping)** can result. Lung volume can increase with mechanical ventilation in a manner similar to that occurring during exercise. Increased ventilation (i.e., breathing rates, flows, or both) exaggerates the differences between lung units with long or short time constants.

MINI CLINI

Breathlessness and Dynamic Hyperinflation in Obstructive Airway Disease

PROBLEM: Patients who have obstructive airway disease often complain of breathlessness (dyspnea). This breathlessness cannot be easily predicted from simple tests of lung function. Some patients with mild obstruction have debilitating dyspnea, whereas other patients with severe obstruction often have little sensation of breathlessness. Why does expiratory flow limitation cause dyspnea of varying degrees in patients who have obstructive lung disease?

DISCUSSION: Dynamic hyperinflation is an acute increase in the end-expiratory lung volume (EELV) as a result of insufficient expiratory time. This increase in EELV occurs because the rate of lung emptying, which is determined by the time constant, is prolonged while the expiratory time is shortened by the increase in ventilatory frequency. As a result, the inspiratory capacity decreases. Breathing at higher EELV increases the loading on the respiratory muscles and restricts the normal V_T expansion during exercise. There is a strong correlation between the sensation of dyspnea and the EELV. Patients with obstructive lung disease describe the sensation of dyspnea differently than normal exercising persons. Terms such as "difficulty inspiring" and "can't get the air in" are commonly used to identify the breathlessness associated with airflow limitation. These specific sensations suggest that patients with airway obstruction receive discordant sensory information from the receptors in the lungs and chest wall. The intensity of these sensations depends on the degree of dynamic hyperinflation that occurs. The use of bronchodilators and lung volume reduction surgery both relieve dyspnea by "deflating" the lungs and reducing hyperinflation. Both therapies improve dynamic airway function by improving lung emptying (more normal time constants). Patients are able to achieve the required ventilation at a lower operating lung volume with a lower O_2 cost of breathing.

EFFICIENCY AND EFFECTIVENESS OF VENTILATION

To be effective, ventilation must meet the body's needs for O_2 uptake and CO_2 removal. To be efficient, ventilation should consume little O_2 and should produce the minimum amount of CO_2.

Efficiency

Even in healthy lungs, ventilation is not entirely efficient. A substantial volume of inspired gas is wasted with each breath; this wasted ventilation is referred to as *dead space.* Gases must move in and out through the same airways leading to the gas-exchange units (alveoli). For each inspiration, the gas left in the conducting airways *(anatomic dead space)* does not participate in gas exchange and is, in effect, wasted. Alveoli that are ventilated but have no perfusion contribute what is called *alveolar dead space*. The sum of anatomic and alveolar dead space is called *physiologic dead space*. The relationship between V_T, dead space volume (V_D), and alveolar volume (V_A) is expressed as:

$$V_T = V_A + V_D$$

Because only alveolar volume participates in gas exchange, this equation shows that the larger the dead space, the less efficient the V_T would be in eliminating CO_2. That is, if efficiency is defined as output/input, CO_2 output would be less for a given input V_T as dead space increases.

Minute Ventilation

Ventilation is usually expressed in liters per minute of fresh gas entering the lungs. The total volume moving in or out of the lungs per minute is called *minute ventilation.* Minute

ventilation (exhaled) is denoted by $\dot{V}_E$, which is calculated as the product of frequency of breathing (f_B) times the expired tidal volume (V_T):

$$\dot{V}_E = f_B \times V_T$$

For a healthy adult breathing 12 breaths/min and having a V_T of 500 ml:

$$\dot{V}_E = \left(12\frac{\text{breaths}}{\text{min}}\right)\times\left(500\frac{\text{ml}}{\text{breath}}\right) = 6000\ \text{ml/min} = 6\ \text{L/min}$$

Minute ventilation is normally driven by the production of CO_2 and depends on the size of the person and his or her metabolic rate. Minute ventilation values range from 5 to 10 L/min in healthy adults at rest.

Alveolar Ventilation

The efficiency of ventilation depends on the volume of fresh gas reaching the alveoli (V_A):

$$V_A = V_T - V_D$$

Alveolar ventilation, $\dot{V}_A$, is the product of breathing frequency (f_B) and alveolar volume per breath (V_A):

$$\dot{V}_E = f_B \times V_A$$

In a healthy adult with a respiratory rate of 12, V_T of 500 ml, and dead space (V_D) of 150 ml, alveolar ventilation is calculated as follows:

$$\dot{V}_A = \left(12\frac{\text{breaths}}{\text{min}}\right)\times\left(500\frac{\text{ml}}{\text{breath}} - 150\frac{\text{ml}}{\text{breath}}\right)$$
$$= 4200\ \text{ml/min} = 4.2\ \text{L/min}$$

Compare this volume with that described for minute ventilation. $\dot{V}_A$ is always less than $\dot{V}_E$ because of the effect of dead space.

Anatomic Dead Space

The volume of the conducting airways (including the nasopharynx and oropharynx) is called the *anatomic dead space,* or $V_{D\ anat}$. $V_{D\ anat}$ averages approximately 1 ml/lb of ideal body weight (2.2 ml/kg). For a person who weighs 150 lb (68 kg), $V_{D\ anat}$ is approximately 150 ml. $V_{D\ anat}$ does not participate in gas exchange because it is rebreathed. During exhalation of a 500-ml tidal breath, the first 150 ml of gas exhaled comes from the $V_{D\ anat}$. The remaining 350 ml is alveolar gas. At the end of exhalation, the airways contain 150 ml of alveolar gas. During the next inhalation, this 150-ml volume is rebreathed. Only approximately 350 ml of fresh gas reaches the alveoli per breath.

Alveolar Dead Space

In addition to the ventilation wasted on the conducting airways, some alveoli may not participate in gas exchange. These alveoli are ventilated but not perfused with mixed venous blood. Without perfusion, gas exchange cannot occur. Any gas that ventilates alveoli with no blood flow (unperfused) is also wasted *(dead space effect)*. Some alveoli have ventilation out of proportion to their perfusion (high $\dot{V}/\dot{Q}$ ratios). These alveoli also contribute to the inefficiency of ventilation because ventilation in excess of what is needed to arterialize the blood in an alveolus is wasted.

The volume of gas ventilating unperfused alveoli is called **alveolar dead space,** or $V_{D\ alv}$. $V_{D\ alv}$ is usually related to defects in the pulmonary circulation. A common clinical example of such a defect is a pulmonary embolism. A pulmonary embolus blocks a portion of the pulmonary circulation; this obstructs perfusion to ventilated alveoli, creating alveolar dead space. Alveolar dead space occurs in addition to the anatomic dead space. In a normal upright person at rest, alveoli at the apexes of the lungs have minimal or no perfusion and contribute to the total volume of dead space ventilation.

Physiologic Dead Space

The sum of anatomic and alveolar dead space is called **physiologic dead space** ($V_{D\ phy}$):

$$V_{D\ phy} = V_{D\ anat} + V_{D\ alv}$$

The total volume of wasted ventilation, or physiologic dead space, equals the sum of the conducting airways and the alveoli that are ventilated but not perfused (Figure 11-17).

Physiologic dead space includes both the normal and the abnormal components of wasted ventilation. $V_{D\ phy}$ is the preferred clinical measure of ventilation efficiency. Measuring $V_{D\ phy}$ more accurately assesses alveolar ventilation:

$$\dot{V}_A = f_B(V_T - V_{D\ phys})$$

or

$$\dot{V}_A = \dot{V}T_E - \dot{V}_{D\ phys}$$

Physiologic dead space is measured clinically by using a modified form of the Bohr equation (see later).

The common estimation of $V_{D\ phy}$ based on body weight goes back to a study published in 1955.[21] More recent research has shown poor agreement between an individual patient's measured dead space and dead space estimated by this and other "rule of thumb" equations.[22] The dead space to tidal volume ratio (V_D/V_T) can be more accurately estimated for mechanically ventilated adult patients using more data available at the bedside[23]:

$$V_D/V_T = 0.32 + 0.0106\,(PaCO_2 - P_{ET}CO_2) + 0.003\,(RR) + 0.0015\,(age)$$

where $PaCO_2$ is arterial O_2 tension (mm Hg), $P_{ET}CO_2$ is end-tidal CO_2 tension (mm Hg), RR is respiratory rate (breaths/min), and age is in years.

Ratio of Dead Space to Tidal Volume

In clinical practice, $V_{D\ phy}$ is often expressed as a ratio to V_T. This ratio (V_D/V_T) provides an index of the wasted ventilation (anatomic plus alveolar dead space) per breath. Measurement of the V_D/V_T ratio requires measurement (or estimation) of the arterial CO_2 (P_aCO_2) and the *mixed expired* CO_2 ($P_E - CO_2$). P_aCO_2 is usually measured by obtaining an arterial blood gas specimen

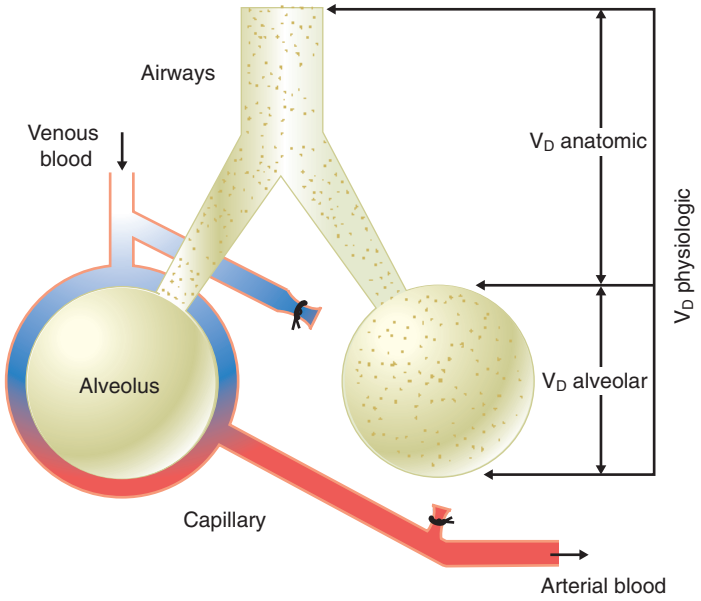

FIGURE 11-17 Three types of dead space. Anatomic dead space is composed of the conducting tubes leading to both alveoli. *Left,* Alveolus is normally perfused and ventilated. *Right,* Alveolus is ventilated but not perfused. The volume represents alveolar dead space. Physiologic dead space is the sum of the two components.

TABLE 11-4

Changes in Alveolar Ventilation Associated with Changes in Rate, Volume, and Physiologic Dead Space

Ventilatory Pattern	Rate of Breathing (breaths/min)	Tidal Volume (ml)	Minute Ventilation (ml)	Physiologic Dead Space (ml)	Alveolar Ventilation (ml)
Normal	12	500	6000	150	4200
High rate, low volume	24	250	6000	150	2400
Low rate, high volume	6	1000	6000	150	5100
Increased dead space	12	500	6000	300	2400
Compensation for increased dead space	12	650	7800	300	4200

but can be estimated from an end-tidal gas sample ($P_{ET}CO_2$). $P_E - CO_2$ may be collected in a sampling bag or balloon or estimated by means of capnography. The ratio is calculated using a modified form of the Bohr equation, which assumes that there is no CO_2 in inspired gas:

$$V_D/V_T \approx (P_aCO_2 - \overline{P}_ECO_2)/P_aCO_2$$

where $PaCO_2$ is arterial CO_2 tension and $\overline{P}_ECO_2$ is the average CO_2 tension in exhaled gas.

In a normal adult who has a P_aCO_2 of 40 mm Hg and an average expired (mixed expired) CO_2 of 28 mm Hg,

$$V_D/V_T = (40-28)/40 = 0.30$$

The equation indicates that the normal dead space ratio is approximately 30%. This equation assumes that all of the CO_2 in expired gas comes from ventilated alveoli. If all lung units contributed CO_2 equally to the expired gas and there was no anatomic dead space, P_ECO_2 would equal $PaCO_2$, and the V_D/V_T ratio would be zero. Because of anatomic and alveolar dead space, the P_ECO_2 is always less than P_aCO_2. In a healthy adult, physiologic dead space is approximately one-third of the V_T, with a normal range of 0.2 to 0.4. The V_D/V_T ratio normally decreases with exercise. Both V_T and V_D increase with increased ventilation during exertion, but the V_T normally increases to a greater degree; the ratio decreases (in healthy persons). V_D/V_T increases with diseases that cause significant dead space, such as pulmonary embolism.

Table 11-4 lists the effects of changes in the parameters that determine alveolar ventilation ($\dot{V}_A$). In healthy individuals, $\dot{V}_A$ changes with breathing rate and V_T because dead space is relatively fixed. High respiratory rate and low V_T result in a high proportion of wasted ventilation per minute (low $\dot{V}_A$). Generally, the most efficient breathing pattern is slow, deep breathing.

In pulmonary disease, increased $V_{D\,phy}$ causes a decrease in $\dot{V}_A$, unless compensation occurs. An increased breathing rate by itself worsens the problem. Effective compensation for increased $V_{D\,phy}$ requires an increased V_T. Elevating V_T increases the elastic work of breathing; however, this increases O_2 consumption by the respiratory muscles. In some patients, these increased

MINI CLINI

Minute Ventilation, Dead Space, and P_aCO_2

PROBLEM: A patient breathing at a rate of 12 breaths/min has a V_T of 600 ml and a measured physiologic dead space ($V_{D\,phy}$) of 200 ml. This ventilatory pattern produces a P_aCO_2 of 40 mm Hg with a pH of 7.39. Several hours later, the patient has a breathing rate of 24 breaths/min, but the minute ventilation ($\dot{V}_E$) has remained the same as before. Arterial blood gas analysis reveals a P_aCO_2 of 72 mm Hg with a pH of 7.20. Why has the P_aCO_2 increased even though the $\dot{V}_E$ remained constant?

DISCUSSION: The initial $\dot{V}_E$ and alveolar ventilation ($\dot{V}_A$) were as follows:

$$\dot{V}_E = 600 \times 12$$
$$= 7200 \text{ ml/min}$$
$$\dot{V}_A = (600 - 200) \times 12$$
$$= 4800 \text{ ml/min}$$

The $\dot{V}_A$ of 4800 ml/min was responsible for maintaining a P_aCO_2 of 40 mm Hg. When respiratory rate increased to 24 breaths/min and $\dot{V}_E$ remained at 7200 ml/min, V_T must have decreased:

$$\dot{V}_T = 7200 \div 24$$
$$= 300 \text{ ml}$$

However, if dead space remained at 200 ml, $\dot{V}_A$ subsequently decreased:

$$\dot{V}_A = (300 - 200) \times 24$$
$$= 2400 \text{ ml/min}$$

The reduction from 4800 ml/min to 2400 ml/min explains the increase in $PaCO_2$ from 40 to 72 mm Hg. $PaCO_2$ is inversely proportional to $\dot{V}_A$. Because $\dot{V}_A$ was reduced by half, P_aCO_2 should have doubled. This approximates the data actually observed. Normally, increased CO_2 tension in the blood resulting in acidemia causes an increase in $\dot{V}_A$. This patient, although tachypneic, is hypoventilating.

demands cannot be met. In such cases, $\dot{V}_A$ may be inadequate to meet body needs, and CO_2 is not removed as rapidly as it is produced. CO_2 retention causes respiratory acidosis, often requiring mechanical support of ventilation.

Effectiveness

Ventilation is effective when it removes CO_2 at a rate that maintains a normal pH. Under resting metabolic conditions, a healthy adult produces approximately 200 ml of CO_2 per minute. Alveolar ventilation must match CO_2 production per minute to ensure acid-base balance.

The equilibrium between CO_2 production ($\dot{V}CO_2$) and $\dot{V}_A$ determines the PCO_2 in the lungs and arterial blood. This balance also plays a key role in determining the pH of arterial blood. The partial pressure of CO_2 in the alveoli and blood is directly proportional to its production ($\dot{V}CO_2$) and inversely proportional to its rate of removal by alveolar ventilation:

$$P_ACO_2 = \frac{\dot{V}CO_2 \times (P_B - P_{H_2O})}{\dot{V}_A} \approx P_aCO_2$$

where P_ACO_2 is alveolar CO_2 tension, $\dot{V}CO_2$ is CO_2 production), $\dot{V}_A$ is alveolar ventilation, P_B is barometric pressure, P_{H_2O} is the water vapor tension in the alveoli, and P_aCO_2 is arterial CO_2 tension.

Alveolar and arterial partial pressures of CO_2 are normally in equilibrium at approximately 40 mm Hg. If $\dot{V}_A$ decreases, $\dot{V}CO_2$ exceeds the rate at which the lungs are removing it. The P_aCO_2 increases to greater than its normal value of 40 mm Hg, and the arterial pH level decreases. Ventilation that does not meet metabolic needs (resulting in respiratory acidosis) is termed **hypoventilation.** Hypoventilation is indicated by the presence of an elevated P_aCO_2 and a pH level below the normal range (7.35 to 7.45).

If alveolar ventilation increases, the lungs may remove CO_2 faster than it is being produced. In this case, P_aCO_2 decreases to less than its normal value of 40 mm Hg, and pH increases (i.e., respiratory alkalosis). Ventilation that exceeds metabolic needs is termed **hyperventilation.** Hyperventilation is indicated by a lower than normal P_aCO_2 and a pH above the normal range.

Hyperventilation is often confused with the increased ventilation that occurs in response to increased metabolism. The changes observed during low or moderate levels of exercise are an example. Ventilation increases in proportion to the increased $\dot{V}CO_2$ from exercise. The P_aCO_2 remains in the normal range of 35 to 45 mm Hg, and the pH level remains near 7.4. The increase in ventilation that occurs with increased metabolic rates is termed *hyperpnea.*

Effectiveness of ventilation is determined by the partial pressure of CO_2 and the resulting pH, specifically in arterial blood. Ventilation is effective when the $PaCO_2$ is maintained at a level that keeps the pH within normal limits.

SUMMARY CHECKLIST

- Ventilation occurs because of pressure differences across the lung during breathing. Gas flows into the lung when the diaphragm creates a sub-atmospheric pressure in the lung; gas flows out of the lung when the recoil properties of the lung create a slight positive pressure.
- The forces that oppose lung inflation may be grouped into two categories: elastic forces and frictional forces.
- Resting lung volume is determined by the opposing elastic forces of the lungs and chest wall.
- Frictional forces opposing ventilation include airway and tissue resistance.
- Airway resistance accounts for 80% of the frictional resistance to ventilation in a healthy adult lung.
- Exhalation is normally passive but may become active when airway resistance is abnormally high.
- The work of breathing is performed by the muscles of breathing.
- Obstructive lung disease increases the frictional work of breathing, whereas restrictive lung disease increases the elastic work of breathing.

- Respiratory muscle fatigue causes a decrease in the tidal volume and an increase in the respiratory rate.
- Even a healthy lung does not distribute ventilation evenly throughout the lungs; greater ventilation normally occurs in the bases.
- The total volume of gas moving in and out of the lungs each minute is called the *minute volume or minute ventilation.* It is determined by multiplying the V_T times the breathing frequency.
- Homeostasis is present when the alveolar ventilation matches CO_2 production.
- The portion of the V_T that does not come into contact with pulmonary blood flow is called *dead space ventilation.*
- Normally approximately 30% of the V_T is dead space. Most of this is called *anatomic dead space* because it is made up of the larger airways that serve to conduct gas to the alveolar sacs.
- Alveoli that are ventilated but have no blood perfusion are called *alveolar dead space.* Normally, alveolar dead space is minimal.
- The combination of anatomic and alveolar dead space is called *physiologic dead space.*

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe how oxygen and carbon dioxide move between the atmosphere and tissues.
- Identify what determines alveolar oxygen and carbon dioxide pressures.
- Calculate the alveolar partial pressure of oxygen at any given barometric pressure and fraction of inspired oxygen.
- State the effects that normal regional variations in ventilation and perfusion have on gas exchange.
- Describe how to compute total oxygen content for arterial blood.
- State the factors that cause the arteriovenous oxygen content difference to change.
- Identify the factors that affect oxygen loading and unloading from hemoglobin.
- Describe how carbon dioxide is carried in the blood.
- Describe how oxygen and carbon dioxide transport are interrelated.
- Describe the factors that impair oxygen delivery to the tissues and how to distinguish among them.
- State the factors that impair carbon dioxide removal.

CHAPTER OUTLINE

KEY TERMS

acute chest syndrome
alveolar dead space
alveolar shunts
Bohr effect
carboxyhemoglobin (HbCO)
dead space
dysoxia
fetal hemoglobin (HbF)
Fick equation
Fick's first law of diffusion
Haldane effect
Hamburger phenomenon
hypoxemia
hypoxia
methemoglobin
methemoglobinemia
oxyhemoglobin
P_{50}
right-to-left anatomic shunts
sickle cell hemoglobin
venous admixture
ventilation/perfusion ratio ($\dot{V}/\dot{Q}$)

Respiration is the process of getting oxygen into the body for tissue use and removing carbon dioxide into the atmosphere. This complex process involves both gas exchange (at the lungs and at the cellular level) and transport of the gases. O_2 must be moved into the lungs, where it diffuses into the pulmonary circulation and is transported in the blood to the tissues. CO_2 builds up in the tissues because of metabolism and diffuses into the capillary blood before being carried to the lung for exchange with alveolar gases. Normally, these processes are well integrated. However, in disease states, impaired gas exchange or transport can cause physiologic imbalances, which can alter function or threaten survival. At such times, respiratory care intervention may be the only way to maintain or restore a level of function consistent with life. This chapter provides the background knowledge that respiratory therapists (RTs) need to understand and treat patients with diseases that affect gas exchange.

DIFFUSION

Whole-Body Diffusion Gradients

Gas movement between the lungs and tissues occurs via simple diffusion (see Chapters 6 and 9). Figure 12-1 shows the normal diffusion gradients for O_2 and CO_2. For O_2, there is a stepwise downward "cascade" of partial pressures from the normal atmospheric inspired partial pressure of O_2 (PiO_2) of 159 mm Hg to a low point of 40 mm Hg or less in the capillaries. The intracellular PO_2 (approximately 5 mm Hg) provides the final gradient for O_2 diffusion into the cell.

The diffusion gradient for CO_2 is the opposite of the diffusion gradient for O_2. The partial pressure of CO_2 (PCO_2) is highest in the cells (approximately 60 mm Hg) and lowest in room air (1 mm Hg). This reverse cascade causes CO_2 movement from the tissues into the venous blood, which is transported to the lungs and—with the aid of ventilation—out to the atmosphere.[1]

Determinants of Alveolar Gas Tensions

Alveolar Carbon Dioxide

The alveolar partial pressure of CO_2 (P_ACO_2) varies directly with the body's production of CO_2 ($\dot{V}CO_2$) and inversely with alveolar ventilation ($\dot{V}_A$). The relationship is expressed by the following formula:

$$P_ACO_2 = \frac{\dot{V}_{CO_2}}{\dot{V}_A} \times K$$

where:

P_ACO_2 = Alveolar CO_2 tension (mm Hg)
$\dot{V}CO_2$ = CO_2 production (in ml/min standard temperature and pressure, dry [STPD])
$\dot{V}_A$ = Alveolar ventilation (L/min body temperature and pressure, saturated [BTPS])

Because $\dot{V}CO_2$ and $\dot{V}_A$ are measured under different conditions (STPD and BTPS, respectively), a correction factor of K is used. When conventional units are used for $\dot{V}CO_2$ (ml/min), and $\dot{V}_A$ (L/min), K = 0.863.

As an example, given $\dot{V}CO_2$ of 200 ml/min and alveolar ventilation of 4.315 L/min, application of this formula yields a P_ACO_2 of approximately 40 mm Hg:

$$P_ACO_2 = 0.863 \times 200 \div 4.315$$
$$= 40 \text{ (mm Hg)}$$

P_ACO_2 increases above this level if CO_2 production increases while alveolar ventilation remains constant or if alveolar ventilation decreases while $\dot{V}CO_2$ remains constant. An increase in **dead space**, the portion of inspired air that is exhaled without being exposed to perfused alveoli, also can lead to an increased P_ACO_2:

$$\dot{V}_A = f \times (V_D - V_D)$$

where:

$\dot{V}_A$ = Alveolar ventilation (L/min)
V_T = Tidal volume (L)

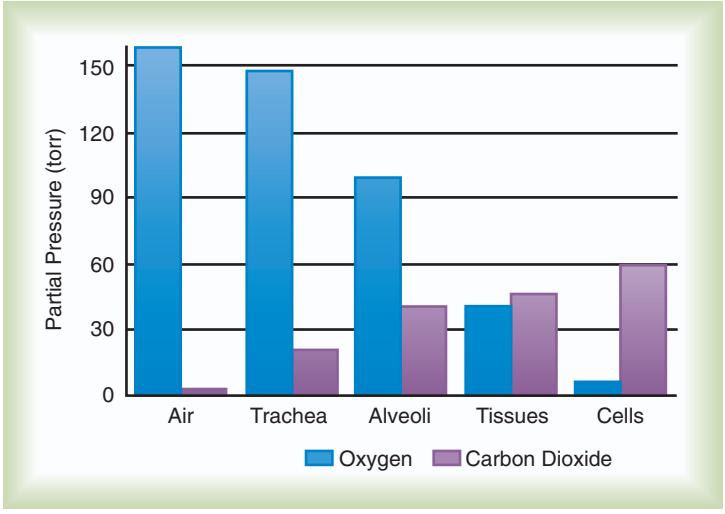

FIGURE 12-1 Normal diffusion gradients for O_2 and CO_2. There is a downward cascade for O_2 from air to cells, with a reverse gradient for CO_2.

V_D = Dead space volume (L)
f = Ventilatory frequency (breaths/min)

Likewise, P_ACO_2 decreases if CO_2 production decreases or alveolar ventilation increases. Normally, complex respiratory control mechanisms maintain P_ACO_2 within a range of 35 to 45 mm Hg under various conditions. If CO_2 production increases, as with exercise or fever, ventilation automatically increases to maintain P_ACO_2 within normal range.

Alveolar Oxygen Tensions

Many factors determine the alveolar partial pressure of O_2 (P_AO_2). The mathematical model relating these factors and applied here is called the *alveolar air equation*. One version of it is:

$$P_AO_2 = FiO_2 \times (P_B - P_{H_2O}) - (P_ACO_2 \div RQ)$$

where:

FiO_2 = Fraction of inspired O_2 (expressed in decimals)
P_B = Barometric pressure (mm Hg)
P_{H_2O} = Water vapor tension. At BTPS, a value of 47 mm Hg is usually used.
P_ACO_2 = Alveolar PCO_2 (mm Hg)
RQ = Respiratory quotent, usually estimated at 0.8.

In addition, $FiO_2 \times (P_B - P_{H_2O})$ represents the partial pressure of O_2 in the inspired air and is the most important determinant of P_AO_2. The expression ($P_ACO_2 \div RQ$) accounts for the alveolar CO_2. However, P_ACO_2 cannot simply be subtracted, as was done for water vapor. Instead, the equation must be corrected for the difference between O_2 and CO_2 movement into and out of the alveoli, which is done by dividing the P_ACO_2 by RQ. RQ is the ratio of CO_2 excretion to O_2 uptake, which normally averages 0.8 throughout the lung. In addition, because P_aCO_2 nearly equals P_ACO_2, P_aCO_2 can be substituted for P_ACO_2. For example, if FiO_2 is 0.21, P_B is 760 mm Hg, and $PaCO_2$ is 40 mm Hg, the normal alveolar partial pressure of O_2 can be estimated as follows:

$$P_AO_2 = 0.21 \times (760 - 47) - (40 \div 0.8)$$
$$= 99.73 \text{ (mm Hg)}$$

For patients at room air, sea level (FiO_2 = 0.21, P_B = 760), the equation can be simplified as:

$$P_AO_2 = 150 - P_aCO_2 \div 0.8$$

The accompanying Mini Clini provides an example of how to use the alveolar air equation.

Changes in Alveolar Gas Partial Tensions

In addition to CO_2, O_2, and water vapor, alveoli normally contain nitrogen. Nitrogen is inert and plays no role in gas exchange; however, it occupies space and exerts pressure. According to Dalton's law, the partial pressure of alveolar nitrogen (P_AN_2) must equal the pressure it would exert if it alone were present. To compute P_AN_2, subtract the pressures exerted by all the other alveolar gases, as follows:

$$P_AN_2 = P_B - (P_AO_2 + P_ACO_2 + P_{H_2O})$$

MINI CLINI

Alveolar-Arterial PO_2 Difference and P/F Ratio

Not all of the O_2 from the alveoli gets into the blood. Why this occurs is discussed later in this chapter. This Mini Clini considers how the efficiency of O_2 transfer from the alveoli to the blood can be computed.

Several bedside computations can be used to estimate the efficiency of pulmonary O_2 transfer. The most common computation is the difference between the alveolar and arterial PO_2, called the *A–a gradient* ($D_{A-a}O_2$). Normally, this difference is small—only 5 to 10 mm Hg. The reason for this slight difference in normal individuals is discussed later in this chapter. An increase in A–a gradient is often indicator of pulmonary parenchymal disease.

Another common bedside computation is the ratio of P_aO_2 to FiO_2, sometimes simplified to P/F (pronounced "PF") ratio. The P/F ratio has units of millimeters of mercury (because P_aO_2 has units of millimeters of mercury and FiO_2 is dimensionless). It is frequently used for ventilated patients as a measure of oxygenation abnormality and is one of the main criteria for diagnosing acute respiratory distress syndrome (ARDS). Mild ARDS is associated with a P/F ratio greater than 200 mm Hg and up to 300 mm Hg. Moderate ARDS is associated with a P/F ratio greater than 100 mm Hg and up to 200 mm Hg. Severe ARDS is associated with a P/F ratio of 100 mm Hg or less.

PROBLEM: Compute and interpret the $D_{A-a}O_2$ and P/F ratio for a 45-year-old woman breathing 70% O_2 at sea level, with the following blood gas values: P_aO_2, 50 mm Hg; P_aCO_2, 40 mm Hg.

SOLUTION: 1. Compute P_AO_2 using one form of the alveolar O_2 equation as follows:

$$P_AO_2 = FiO_2 \times (P_B - 47) - (P_ACO_2 \div 0.8)$$
$$P_AO_2 = 0.7 \times (760 - 47) - 40 \div 0.8$$
$$P_AO_2 = 449 \text{ mm Hg}$$

2. Compute $D_{A-a}O_2$ as follows:

$$D_{A-a}O_2 = P_AO_2 - PaO_2$$
$$D_{A-a}O_2 = 449 - 50$$
$$D_{A-a}O_2 = 399 \text{ mm Hg}$$

3. Compute P/F ratio as follows:

$$P_aO_2/FiO_2 = 50/0.7 = 71.4 \text{ mm Hg}$$

DISCUSSON: Both the $D_{A-a}O_2$ and the P/F ratio are abnormal. Compared with a normal value, the $D_{A-a}O_2$ of nearly 400 mm Hg is very high. This $D_{A-a}O_2$ indicates a large difference between the alveolar and arterial PO_2 values (i.e., inefficient O_2 transfer). Likewise, the P/F ratio of 71.4 indicates severe **hypoxemia.** Although the patient is receiving a high FiO_2 (0.70), she has a severe problem getting O_2 into her blood and needs immediate evaluation by a critical care physician.

$$P_AN_2 = 760\ mm\ Hg - (100\ mm\ Hg + 40\ mm\ Hg + 47\ mm\ Hg)$$
$$P_AN_2 = 760\ mm\ Hg - 187\ mm\ Hg$$
$$P_AN_2 = 573\ mm\ Hg$$

Because both water vapor tension and P_AN_2 remain constant, the only partial pressures that change in the alveolus are O_2 and CO_2. Based on the alveolar air equation, if FiO_2 remains constant, P_AO_2 must vary inversely with P_ACO_2.[2-4]

RULE OF THUMB

When the patient is breathing room air, the sum of P_AO_2 and P_ACO_2 is approximately140 mm Hg (100 mm Hg + 40 mm Hg). This equation assumes a constant value for RQ. Changes in ventilation that affect P_ACO_2 will also alter P_AO_2 to keep the total at 140 mm Hg. If P_ACO_2 of a patient breathing room air decreases from 40 mm Hg to 20 mm Hg (a decrease of 20 mm Hg), P_AO_2 should increase by approximately 20 mm Hg. It is important to note that although hyperventilation will allow halving the PC_AO_2 (from 40 to 20), it will result only in modest increase of P_AO_2 (from 100 to 120; Figure 12-2).

Mechanism of Diffusion

Diffusion is the process whereby gas molecules move from an area of high partial pressure to an area of low partial pressure. To diffuse into and out of the lung and tissues, O_2 and CO_2 must move through significant barriers.

Barriers to Diffusion

The barrier to gaseous diffusion in the lung is the alveolar-capillary membrane. For CO_2 or O_2 to move between the alveoli and the pulmonary capillary blood, the following three barriers must be penetrated: (1) alveolar epithelium, (2) interstitial space, and (3) capillary endothelium. In addition, to pass into and out of the red blood cells (RBCs), these gases also must traverse the erythrocyte membrane.[5,6]

Fick's First Law of Diffusion

The bulk movement of a gas through a biologic membrane ($\dot{V}_{gas}$) is described by **Fick's first law of diffusion:**

$$\dot{V}_{gas} = \frac{A \times D \times (P_1 - P_2)}{T}$$

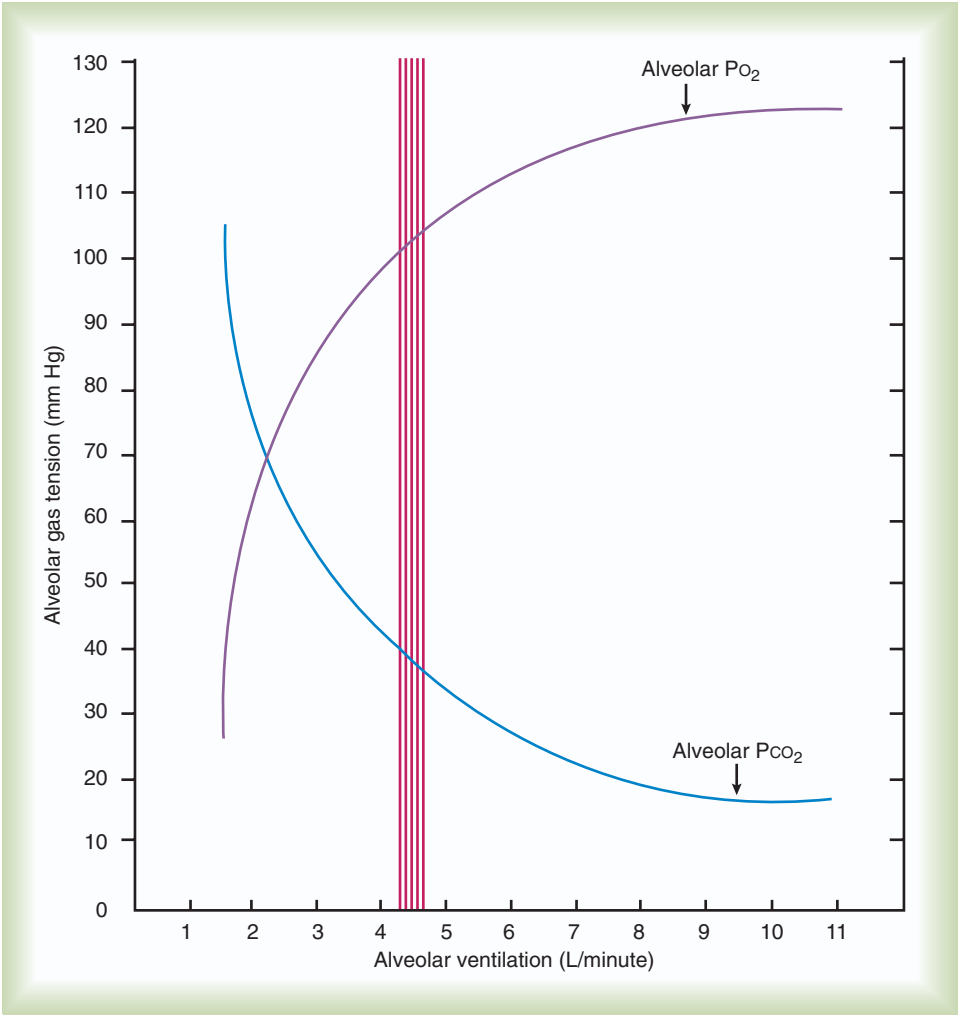

FIGURE 12-2 Effect of alveolar ventilation on alveolar gases. (Modified from Pilbeam SP: Mechanical ventilation, ed 4, St Louis, 2006, Mosby.)

In this formula, A is the cross-sectional area available for diffusion, D is the diffusion coefficient of the gas, T is the thickness of the membrane, and $(P_1 - P_2)$ is the partial pressure gradient across the membrane. According to Fick's law, the greater the surface area, diffusion constant, and pressure gradient, the more is the diffusion that occurs. Conversely, with greater the distance across the membrane (thickness), less diffusion occurs. Given that the area of and distance across the alveolar-capillary membrane are constant in healthy people, diffusion in the normal lung mainly depends on gas pressure gradients.

In clinical practice, it is impossible to measure the area and the thickness of the membrane, so the formula is often rewritten as:

$$\dot{V}_{gas} = D_L \times (P_1 - P_2)$$

where D_L (the diffusing capacity of the lungs) combines the area, thickness, and diffusion properties of the gas and the membrane and can be helpful in evaluating certain diseases. For various reasons, carbon monoxide is the gas is used to measure the diffusing capacity. Chapter 20 provides details on the technique for measuring D_L and its diagnostic use.

Pulmonary Diffusion Gradients

For gas exchange to occur between the alveoli and pulmonary capillaries, a difference in partial pressures $(P_1 - P_2)$ must exist. Figure 12-3 shows the size and direction of these gradients for O_2 and CO_2. In the normal lung, the alveolar PO_2 averages approximately 100 mm Hg, whereas the mean PCO_2 is approximately 40 mm Hg. Venous blood returning to the lungs has a lower PO_2 (40 mm Hg) than alveolar gas. The pressure gradient for O_2 diffusion into the blood is approximately 60 mm Hg (100 mm Hg – 40 mm Hg). As blood flows past the alveolus, it takes up O_2 and moves to the left atrium with a PO_2 close to 100 mm Hg in healthy people.

Because venous blood has higher PCO_2 than alveolar gas (46 vs. 40 mm Hg), the pressure gradient for CO_2 causes it to diffuse in the opposite direction, from the blood into the alveolus. This diffusion continues until capillary PCO_2 equilibrates with the alveolar level, at approximately 40 mm Hg. Although the pressure gradient for CO_2 is approximately one-tenth of the pressure gradient for O_2, CO_2 has little difficulty diffusing across the alveolar-capillary membrane. CO_2 diffuses approximately 20 times faster across the alveolar-capillary membrane than O_2 because of its much higher solubility in plasma.

Time Limits to Diffusion

For blood leaving the pulmonary capillary to be adequately oxygenated, it must spend sufficient time in contact with the alveolus to allow equilibration.[5,8] If the time available for diffusion is inadequate, blood leaving the lungs may not be fully oxygenated. As depicted in Figure 12-4, blood normally takes approximately one-third of the time it spends in the capillary to be fully oxygenated. If blood flow increases, such as during heavy exercise, capillary transit time can decrease to 0.25 second. This short period is still adequate to ensure that equilibration occurs as long as no other factors impair diffusion. However, in the presence of a diffusion limitation, it would take longer than 0.25 second for the blood to be fully oxygenated and rapid blood flow through the pulmonary circulation can result in

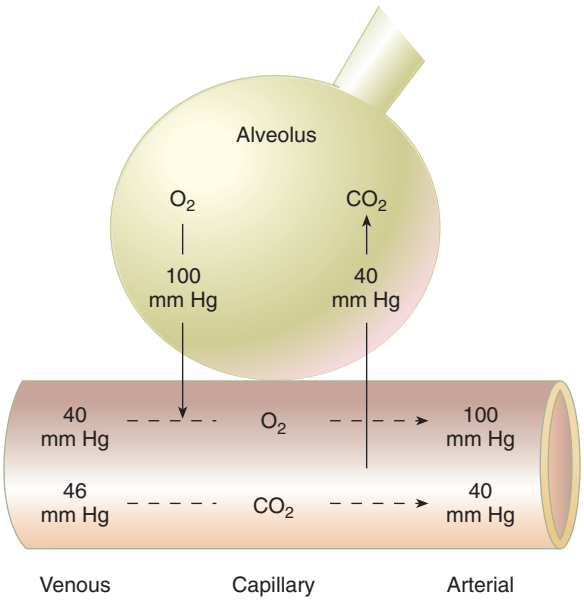

FIGURE 12-3 Ventilation maintains mean alveolar gas pressures for O_2 and CO_2 at approximately 100 mm Hg and 40 mm Hg. As blood enters the venous end of the capillary, it gives up CO_2 and loads O_2 until these two gases are in equilibrium with alveolar pressures. At this point, the blood is "arterialized."

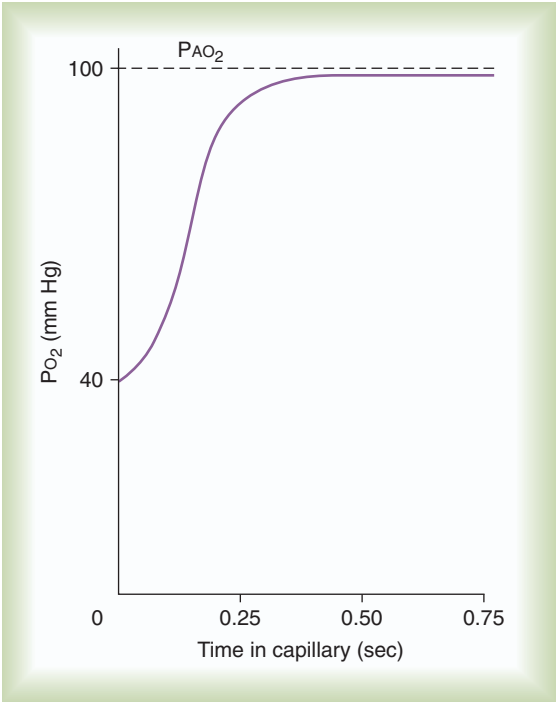

FIGURE 12-4 Alveolar-capillary PO_2 gradient. Normal transit time for RBC in the pulmonary capillary is approximately 0.75 second. Normally, blood PO_2 equilibrates with the alveolar PO_2 well before it reaches the end of the capillary.

inadequate oxygenation. For this reason, many patients with lung disease will have normal O_2 saturation at rest, but will quickly desaturate even on minimal exertion.

Systemic Diffusion Gradients

Partial pressure gradients in the tissues are the opposite of the partial pressure gradients in the lung. As cellular metabolism depletes its O_2, intracellular PO_2 decreases below PaO_2. O_2 diffuses from the tissue capillary blood ($PO_2 = 100$ mm Hg) to the cells ($PO_2 < 40$ mm Hg). Simultaneously, CO_2 diffuses from the cells ($PCO_2 > 46$ mm Hg) into the capillary blood ($PCO_2 = 40$ mm Hg). After equilibration, blood leaves the tissue capillaries with a PO_2 of approximately 40 mm Hg and PCO_2 of approximately 46 mm Hg.

Just as arterial blood reflects pulmonary gas exchange, venous blood reflects events occurring in the tissues. The use of venous blood to assess tissue oxygenation is discussed in Chapter 51.

VARIATIONS FROM IDEAL GAS EXCHANGE

As discussed previously in this chapter, there is a slight difference between alveolar and arterial PO_2 (normally 5 to 10 mm Hg). Two factors account for this difference: (1) right-to-left shunts in the pulmonary and cardiac circulation and (2) regional differences in pulmonary ventilation and blood flow.

Anatomic Shunts

A shunt is the portion of the cardiac output that returns to the left heart without being oxygenated by exposure to ventilated alveoli. Two **right-to-left anatomic shunts** exist in normal humans: (1) bronchial venous drainage and (2) thebesian venous drainage (see Chapters 9 and 10). A right-to-left shunt causes poorly oxygenated venous blood to move directly into the arterial circulation, reducing the O_2 content of arterial blood. Together, these normal shunts account for approximately three-fourths of the normal difference between P_AO_2 and P_aO_2. The remaining difference is a result of normal inequalities in pulmonary ventilation and perfusion.[5]

Inequalities in Ventilation and Perfusion

The normal respiratory exchange ratio of 0.8 assumes that ventilation and perfusion in the lung are in balance, with every liter of alveolar ventilation ($\dot{V}_A$) matched by approximately 1 L of pulmonary capillary blood flow ($\dot{Q}$). Any variation from this perfect balance alters gas tensions in the affected alveoli. The **ventilation/perfusion ratio** ($\dot{V}/\dot{Q}$) is one of the key concepts in pulmonary physiology because it plays a major role in gas exchange in health and disease.

Ventilation-Perfusion Ratio

Changes in $\dot{V}_A$ and $\dot{Q}_c$ are expressed as a ratio called the *ventilation-perfusion ratio* ($\dot{V}/\dot{Q}$). An ideal ratio of 1 indicates that ventilation and perfusion are in perfect balance. A high $\dot{V}_A/\dot{Q}$ indicates that ventilation is greater than normal, perfusion is less than normal, or both. Conversely, a low $\dot{V}_A/\dot{Q}$ indicates that ventilation is less than normal, perfusion is greater than normal, or both.

Effect of Alterations in Ventilation-Perfusion Ratio

Figure 12-5 shows graphs of the effect of $\dot{V}_A/\dot{Q}$ changes on the respiratory exchange ratio (R), plotting all possible values of P_AO_2 and P_ACO_2. When ventilation and perfusion are in perfect balance ($\dot{V}_A/\dot{Q} = 1$), R equals 0.8. At this point, P_AO_2 and P_ACO_2 values equal the ideal values of 100 mm Hg and 40 mm Hg.

As the $\dot{V}_A/\dot{Q}$ increases above 1 (see Figure 12-5, following the *curve* to the right), less blood reaches O_2-rich, CO_2-poor inspired gas. The result is a higher P_AO_2 and lower P_ACO_2. At

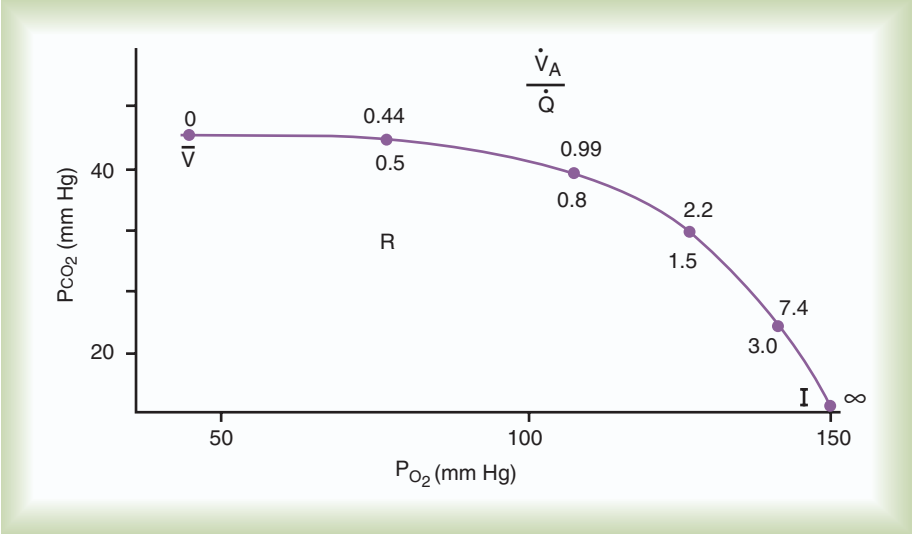

FIGURE 12-5 Relationship between alveolar PO_2 and PCO_2 with changes in $\dot{V}_A/\dot{Q}$ and respiratory exchange ratio. (From Cherniak RM, Cherniak L: Respiration in health and disease, ed 3, Philadelphia, 1983, Saunders.)

the extreme right of the graph, perfusion is zero ($\dot{V}_A/\dot{Q} = \infty$). Areas with ventilation but no blood flow essentially represent dead space. The makeup of gases in these areas is similar to that of inspired air (PO_2 = 150 mm Hg; PCO_2 = 0 mm Hg).

Dead space, mentioned earlier, has two components: **Alveolar dead space** is the portion of the tidal volume that enters into alveoli that are without any perfusion or without adequate perfusion. Conditions that can lead to alveolar dead space include pulmonary emboli, partial obstruction of the pulmonary vasculature, destroyed pulmonary vasculature (as can occur in chronic obstructive pulmonary disease [COPD]), and reduced cardiac output. Anatomic dead space is the portion of the tidal volume that never reaches the alveoli for gas exchange (upper airways, trachea, bronchi and so on until the respiratory bronchiole). The sum of alveolar and anatomic dead space is often referred to as physiologic dead space (V_D). The dead space to tidal volume ratio (V_D/V_T) affects alveolar ventilation:

$$\dot{V}_A = \dot{V}_E\left(1 - \frac{V_D}{V_T}\right)$$

where

$\dot{V}_A$ = alveolar ventilation (L/min)
$\dot{V}_E$ = minute ventilation (L/min)
V_D = dead space volume (ml)
V_T = tidal volume (ml)

The clinical significance of increased dead space, or V_D/V_T ratio, is that it decreases alveolar ventilation and hence increases P_aCO_2. This can happen by the addition of extra tubing to the ventilator (exogenous V_D), lung disease (increased alveolar V_D), or shallow breathing (decreased V_T that leads to increased V_D/V_T ratio). In the face of increased dead space, minute ventilation must increase to achieve normal $\dot{V}_A$ and P_aCO_2. This additional ventilation comes at a cost with an increase in the work of breathing, which consumes additional O_2 and further adds to the burden of external ventilation. Similarly, patients with rapid shallow breathing will often have ineffective ventilation with increased P_aCO_2 despite elevated minute ventilation.

As the $\dot{V}_A/\dot{Q}$ decreases below 1.0 (Figure 12-5, following the *curve to the left*), more O_2-poor, CO_2-rich blood reaches alveolar air. The result is a lower P_AO_2 and higher P_ACO_2. At the extreme left of the graph, there is perfusion but no ventilation ($\dot{V}_A/\dot{Q}$ = 0). With no ventilation to remove CO_2 and restore fresh O_2, the makeup of gases in these areas is similar to that of mixed venous blood (P_VO_2 = 40 mm Hg; P_VO_2 = 46 mm Hg).

Venous blood entering areas with $\dot{V}_A/\dot{Q}$ values of zero cannot pick up O_2 or unload CO_2 and leave the lungs unchanged. As this venous blood returns to the left side of the heart, it mixes with well-oxygenated arterial blood, diluting its O_2 contents in a manner similar to that described for a right-to-left anatomic shunt. To distinguish such areas from true anatomic shunts, exchange units with $\dot{V}_A/\dot{Q}$ values of zero are called **alveolar shunts.** Anatomic and alveolar shunts together cause venous blood to mix with the arterial blood, a phenomenon called **venous admixture.** Alveolar shunts can be caused by COPD, restrictive disorders, or any condition resulting in hypoventilation.

In addition to blood that perfuses anatomic and alveolar shunts, a portion of venous blood travels from the right heart to the left heart without being involved in adequate gas exchange with ventilated portions of the lung. Together, they are called *physiologic shunt.* The shunt equation quantifies the portion of blood included in the $\dot{V}_A/\dot{Q}$ mismatch, in which $\dot{V}_A/\dot{Q}$ is less than 1. It is usually expressed as a percentage of the total cardiac output:

$$\frac{Q_s}{Q_t} = \frac{C_cO_2 - C_aO_2}{C_cO_2 - C_vO_2}$$

where:

Q_s = Shunt flow; blood entering systemic blood without being oxygenated in the lungs
Q_t = Total cardiac output
C_cO_2 = O_2 content at the end of the ventilated and perfused pulmonary capillaries
C_aO_2 = Arterial O_2 content
C_vO_2 = Mixed venous O_2 content

Although arterial O_2 content can be directly measured from a systemic artery and mixed venous O_2 content can be directly measured from the pulmonary artery, the end capillary content must be derived from an additional calculation requiring use of the alveolar air equation and the Hb concentration. A more practical *estimation* of the shunt fraction is as follows: each increase of $D_{A\text{-}a}O_2$ by 100 mm Hg corresponds to 5% increase in shunt fraction.

Causes of Regional Differences in Ventilation-Perfusion Ratio

Regional variations in $\dot{V}_A/\dot{Q}$ for a normal lung are mainly caused by gravity and are most evident in the upright posture. Because the pulmonary circulation is a low-pressure system, blood flow in the upright lung varies considerably from top to bottom (see Chapter 9). Farther down the lung, perfusion increases linearly in proportion to the hydrostatic pressure so that the lung bases receive nearly 20 times as much blood flow as the apexes.

Regional differences in ventilation throughout the lung also occur, but they are less drastic than the differences in perfusion. Similar to perfusion, ventilation also is increased in the lung bases, with approximately four times as much ventilation going to the bases than to the apexes of the upright lung. These regional differences in ventilation are caused by the effect of gravity on pleural pressures (see Chapter 11).

Table 12-1 summarizes the relationships between ventilation and perfusion by lung region.[8] At the lung apexes, ventilation exceeds blood flow, resulting in a high $\dot{V}_A/\dot{Q}$ (approximately 3.3), high PO_2 (132 mm Hg), and low PCO_2 (32 mm Hg). Farther down the lung, blood flow increases more than ventilation owing to gravity. Toward the middle, the two are approximately equal ($\dot{V}_A/\dot{Q}$ = 1.0). At the bottom of the lung, blood flow is greater than ventilation, resulting in a low $\dot{V}_A/\dot{Q}$ (approximately 0.66), low PO_2 (89 mm Hg), and slightly higher PCO_2 (42 mm Hg).

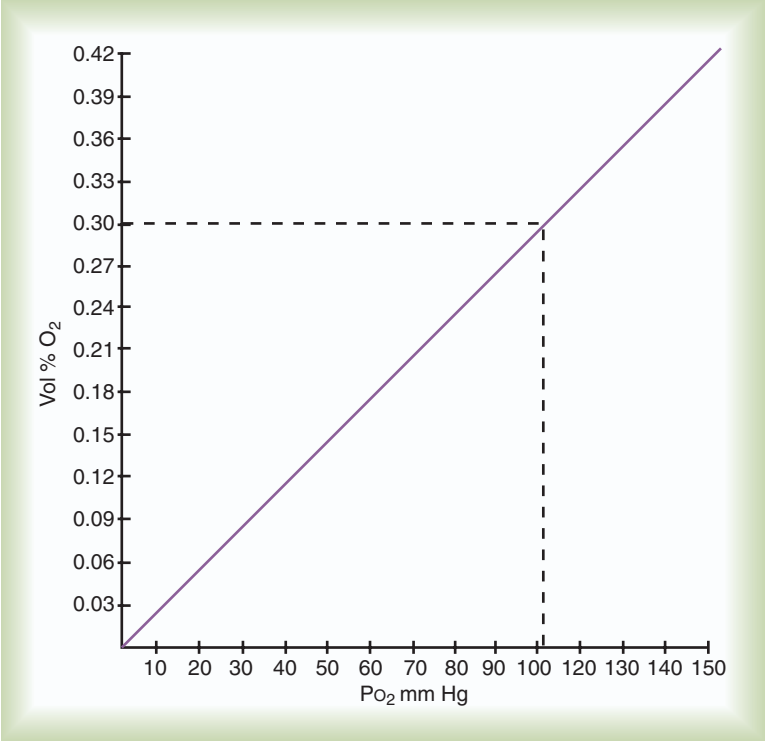

FIGURE 12-6 Relationship between PO_2 and dissolved O_2 contents of plasma at 37°C. The *dashed line* emphasizes the fact that arterial blood, with average PO_2 of 100 mm Hg, has 0.3 ml of O_2 dissolved in each deciliter (100 ml).

TABLE 12-1

Summary of Variations in Gas Exchange in the Upright Lung by Region

Lung Region	$\dot{V}_A/\dot{Q}$ Ratio	Mean P_AO_2 (mm Hg)	Mean P_ACO_2 (mm Hg)	Blood Flow
Apexes	3.3	132	32	Low
Middle	1.0	100	40	Moderate
Bases	0.66	89	42	High

As shown in Table 12-1, because of gravity, most blood flows to the lung bases, where PO_2 is less than normal and PCO_2 is greater than normal. After leaving the lung, this large volume of blood combines with the smaller volume coming from the middle and apical regions. The result is a mixture of blood with less O_2 and more CO_2 than would come from an ideal gas-exchange unit.

OXYGEN TRANSPORT

Blood carries O_2 in two forms. A small amount of O_2 exists in a simple physical solution, dissolved in the plasma and erythrocyte intracellular fluid. However, most O_2 is carried in a reversible chemical combination with hemoglobin (Hb) inside the RBC. As gaseous O_2 diffuses into the blood, it immediately dissolves in the plasma and erythrocyte fluid. By applying Henry's law (see Chapter 6), the amount of dissolved O_2 in the blood (at 37°C) can be computed with the following simple formula:

$$\text{Dissolved } O_2 \text{ (ml/dl)} = PO_2 \text{ (mm Hg)} \times 0.003$$

This equation is plotted in Figure 12-6, which shows that the relationship between partial pressure and dissolved O_2 is direct and linear. In normal arterial blood with PaO_2 of approximately 100 mm Hg, there is approximately 0.3 ml/dl of dissolved O_2. However, if an individual with normal arterial blood breathes pure O_2, PaO_2 increases to approximately 670 mm Hg. In this case, the dissolved O_2 would increase to approximately 2.0 ml/dl. The blood of someone breathing pure O_2 in a hyperbaric chamber at 3 atmospheres (2280 mm Hg) would carry nearly 6.5 ml/dl dissolved O_2 in the plasma. Despite such extreme conditions ($FiO_2 = 1$, barometric pressure = 3 atmospheres), the amount of dissolved O_2 is still a small fraction of the amount carried by hemoglobin under normal conditions.

Chemically Combined Oxygen (Oxyhemoglobin)

Hemoglobin and Oxygen Transport

Most blood O_2 is transported in chemical combination with Hb in the erythrocytes. Hb is a conjugated protein, consisting of four linked polypeptide chains (the *globin* portion), each of which is combined with a porphyrin complex called *heme*. The four polypeptide chains of Hb are coiled together into a ball-like structure, the shape of which determines its affinity for O_2.[5,8]

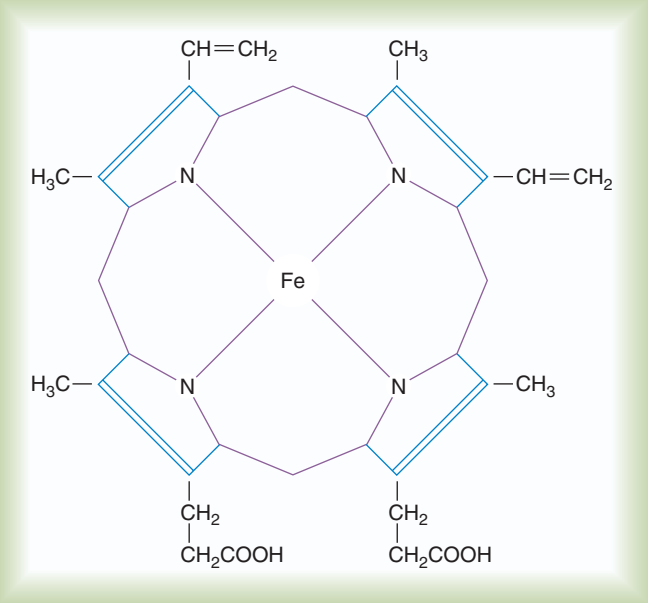

FIGURE 12-7 Structure of heme.

As shown in Figure 12-7, each heme complex contains a centrally located ferrous iron ion. When Hb is not carrying O_2, this ion has four unpaired electrons. In this deoxygenated state, the molecule exhibits the characteristics of a weak acid. Deoxygenated Hb serves as an important blood buffer for H+, a crucial factor in CO_2 transport.

When fully saturated, 4 O_2 molecules bind to the iron ion of Hb, one for each protein chain. With complete O_2 binding, all electrons become paired, and Hb is converted to its oxygenated state (**oxyhemoglobin** [HbO_2]).

In whole blood, 1 g of normal Hb can carry approximately 1.34 ml of O_2. Given an average blood Hb content of 15 g/dl, the O_2-carrying capacity of the blood can be calculated as follows:

$$1.34\ \text{ml/g} \times 15\ \text{g/dl} = 20.1\ \text{ml/dl}$$

The addition of Hb increases the O_2-carrying capacity of the blood nearly 70-fold compared with plasma alone. The amount of O_2 bound to Hb depends on its level of saturation with O_2 (see later).

Hemoglobin Saturation

Saturation is a measure of the proportion of available Hb that is carrying O_2. Saturation is computed as the ratio of HbO_2 (content) to total Hb (capacity). Hb arterial O_2 saturation (SaO_2) is usually expressed as a percentage of this ratio and calculated according to the following formula:

$$SaO_2 = (HbO_2 \div \text{Total Hb}) \times 100$$

where HbO_2 equals the oxyhemoglobin content. If there were a total of 15 g/dL Hb in the blood, of which 7.5 g was HbO_2, the SaO_2 would be calculated as follows:

$$SaO_2\ (\%) = (7.5 \div 15) \times 100 = 50\%$$

In this example, Hb is said to be 50% saturated: Only half of the available Hb is carrying O_2, and the remainder is unoxygenated. In clinical practice, both SaO_2 and total Hb content are measured directly to derive the HbO_2. Normal SaO_2 is 95% to 100% depending on the age of the patient.

Total Oxygen Content of the Blood

Total O_2 content of the blood equals the sum of O_2 dissolved and chemically combined with Hb.[2,7] For total O_2 content to be calculated, the following three values must be known: (1) PO_2, (2) total Hb content (g/dL), and (3) Hb saturation. Given these values, the following equation can be applied:

$$CaO_2 = (0.003 \times PaO_2) + (1.34 \times Hb \times SaO_2)$$

where:

CaO_2 = Total O_2 content (ml/dl)
PaO_2 = Partial pressure of O_2 in the blood
Hb = Hb content (in g/dl)
SaO_2 = Hb saturation with O_2 (as a decimal)

Typically, clinicians want to know the O_2 content of arterial blood (CaO_2). The ($0.003 \times PO_2$) component of the equation represents dissolved O_2, whereas the ($Hb \times 1.34 \times SO_2$) component represents the chemically combined oxyhemoglobin. For example, to compute the total O_2 content of normal arterial blood (assuming PaO_2 = 100, Hb = 15g/dl, SaO_2= 0.97):

$$CaO_2 = (0.003 \times PaO_2) + (1.34 \times Hb \times SaO_2)$$
$$CaO_2 = (0.003 \times 100) + (1.34 \times 15 \times 0.97)$$
$$CaO_2 = 0.3 + 19.5$$
$$CaO_2 = 19.8\ (\text{ml/dl})$$

The normal CaO_2 concentration is 16 to 20 ml/dl. Note that dissolved O_2 contributes a small fraction of blood's total O_2 carrying capacity (0.3/19.8 = 1.5%) and is often omitted from the practical discussions and calculations.

Oxyhemoglobin Dissociation Curve

Hb saturation with O_2 varies with changes in PO_2. Plotting the saturation (*y*-axis) against PO_2 (*x*-axis) yields the HbO_2 dissociation curve (Figure 12-8). In contrast to dissolved O_2, Hb saturation is not linearly related to PO_2.[4] Instead, the relationship forms an S-shaped curve. The flat upper part of this curve represents the normal operating range for arterial blood. Because the slope is minimal in this area, major changes in PaO_2 have little effect on SaO_2, indicating a strong affinity of Hb for O_2. With a normal PaO_2 of 100 mm Hg, SaO_2 is approximately 97%. If some abnormality (e.g., lung disease) reduced PaO_2 to 65 mm Hg, SaO_2 would still be approximately 90%.

However, with PO_2 less than 60 mm Hg, the curve steepens dramatically, which is why it is beneficial to keep PaO_2 greater than 60 mm Hg in clinical practice. With PO_2 less than 60 mm Hg, a small decrease in PO_2 causes a large decrease in SaO_2, indicating a lessening affinity for O_2. This normal decrease in the affinity of Hb for O_2 helps release large amounts of O_2 to the tissues, where PO_2 is low.

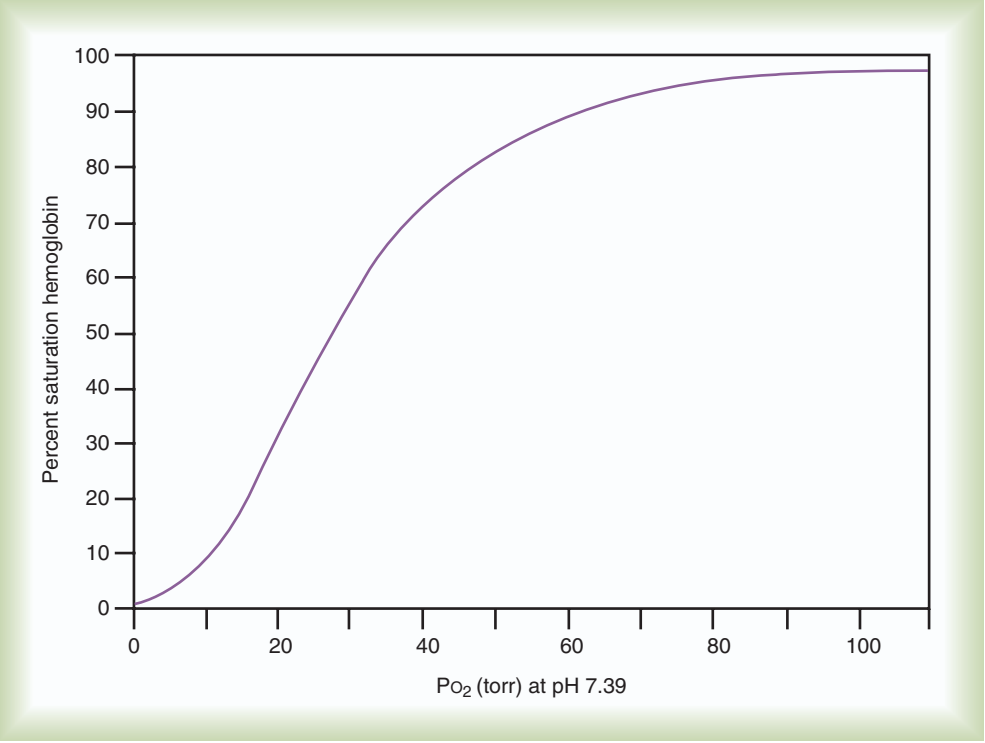

FIGURE 12-8 O_2 dissociation curve plots the relationship between plasma PO_2 (*x*-axis) and Hb saturation (*y*-axis).

MINI CLINI

Relating Hemoglobin Saturation and PaO_2

PROBLEM: Pulse oximeters are simple bedside devices that measure Hb saturation by way of a noninvasive probe taped to the patient's finger or forehead. Although oximeters measure Hb saturation percentage, blood oxygenation still tends to be quantified according to PaO_2. Is there a simple way to relate these two measures without carrying around an HbO_2 dissociation curve?

DISCUSSION: First, although extremely useful, pulse oximeters are relatively inaccurate (compared to other types of clinical measurement device) and they measure only normal Hb saturation. This limitation should be understood. The value of oximetry is in its ability to display trends and provide warning of significant changes in Hb saturation with O_2.

Even so, RTs often need to estimate PaO_2 from oximeter readings. The following simple rule, called the *40-50-60/70-80-90 rule*, should be helpful. Assuming normal pH, PCO_2, and Hb values, saturations of 70%, 80%, and 90% are roughly equivalent to PO_2 values of 40 mm Hg, 50 mm Hg, and 60 mm Hg:

Hb Saturation (%)	Approximate PaO_2 (mm Hg)
70	40
80	50
90	60

A patient with a pulse oximeter reading of 90% has a PaO_2 of approximately 60 mm Hg. If the saturation decreased to 80%, the PaO_2 would decrease to approximately 50 mm Hg. This rule works only in the middle range of PO_2 values, where the curve is most linear; it should not be applied with saturations greater than 90% or less than 70%.

Although SaO_2 plays a greater part in total blood O_2 content than PaO_2, it is often important to consider both when evaluating a patient's oxygenation. First, PaO_2 is a more accurate measurement than SaO_2, which is usually derived from pulse oximetry. In addition, a patient with an SaO_2 of 100% may have a PaO_2 between 100 and 600 mm Hg and the knowledge of exact PaO_2 value gives a clinician a better understanding of the patient's gas-exchange status.

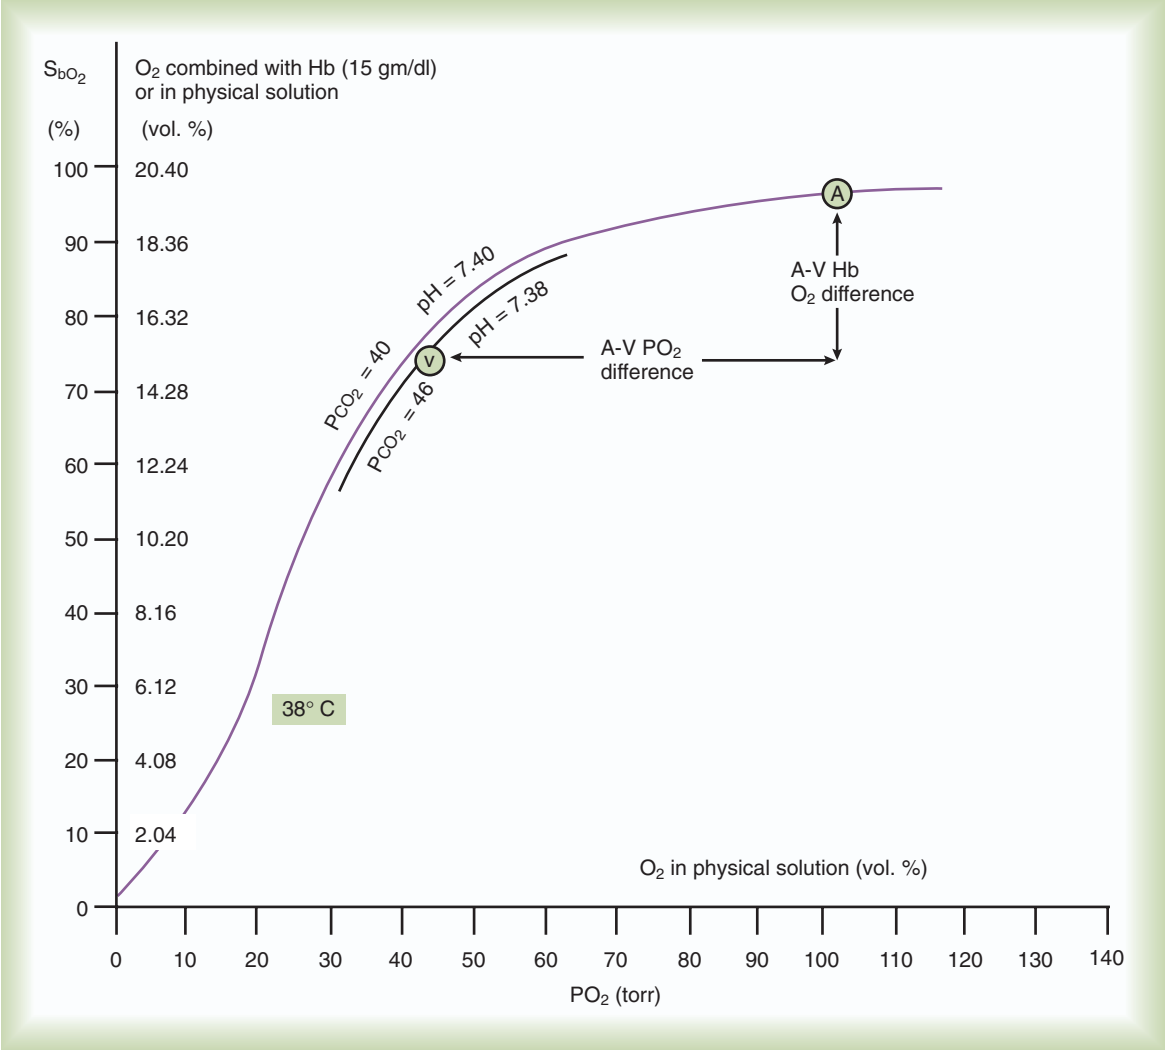

FIGURE 12-9 Normal oxyhemoglobin dissociation curve, showing the basic relationship of blood O_2 transport. Point *sA* represents normal values for arterial blood leaving the lungs (loading point). Point *sV* represents normal values for venous blood leaving the tissues (unloading point). The slight difference in curve position resulting from pH and CO_2 changes helps O_2 unloading at the tissues. Differences between O_2 content at these two points represent the amount of O_2 taken up by the tissues on one pass through the systemic circulation. (Modified from Slonim NB, Hamilton LH: Respiratory physiology, ed 5, St Louis, 1987, Mosby.)

Normal Loading and Unloading of Oxygen (Arteriovenous Differences)

Figure 12-9 uses the HbO_2 dissociation curve to show the effects of O_2 loading and unloading in the lungs and tissues. *Point A* represents freshly arterialized blood leaving the pulmonary capillaries, with PO_2 of approximately 100 mm Hg and Hb saturation of approximately 97%. As blood perfuses body tissues, O_2 uptake causes a decrease in both PO_2 and saturation, such that venous blood leaving the tissues *(point V)* has a PO_2 of approximately 40 mm Hg, with Hb saturation of approximately 75%.

Using a normal Hb content of 15 g/dl and knowing the saturation at each possible PO_2, the total O_2 content can be calculated at any PO_2 in the manner previously described. The *y*-axis of Figure 12-9 provides this information in SaO_2 increments of 10%. Table 12-2 summarizes the difference between the O_2 content of these normal arterial and venous points.

TABLE 12-2
Oxygen Content of Arterial and Venous Blood

O_2 Content	Arterial O_2 (ml/dl)	Venous O_2 (ml/dl)
Combined O_2 (1.34 × 15 × SO_2)	19.5	14.7
Dissolved O_2 (PO_2 × 0.003)	0.3	0.1
Total O_2 content	19.8	14.8

As indicated in Table 12-2, the difference between the arterial and venous O_2 contents is normally approximately 5 ml/dl. This is the arterial-to-venous O_2 content difference ($C_{a-v}O_2$). It is the amount of O_2 given up by every 100 ml of blood on each pass through the tissues.

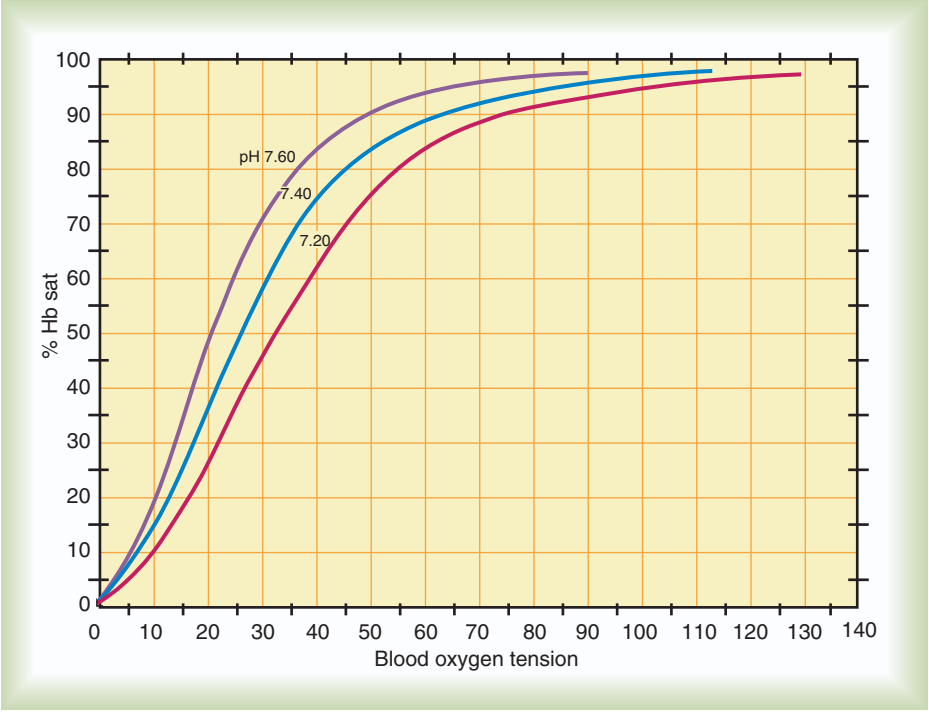

FIGURE 12-10 O_2 dissociation curve of blood at 37°C, showing variations at three pH levels. A right shift (lower pH) decreases Hb affinity for O_2, whereas a left shift (higher pH) increases Hb affinity for O_2.

Fick Equation

The Fick principle states that the total O_2 uptake by the peripheral tissues (O_2 consumption, or $\dot{V}_{O_2}$) is equal to the product of the blood flow to the peripheral tissues and the arterial-to-venous O_2 content difference ($C_{a-v}O_2$). The classic **Fick equation** is written as follows:

$$\dot{V}_{O_2} = CO \times (C_aO_2 - C_vO_2) \times 10$$

where

CO = cardiac output (ml/min)
$\dot{V}_{O_2}$ = whole-body O_2 consumption (ml/min)
C_aO_2 = arterial O_2 content (ml/dl)
C_VO_2 = venous O_2 content (ml/dl)

According to the Fick equation, if a patient becomes hypoxic (C_aO_2 falls), total-body O_2 consumption can be maintained by either increasing cardiac output. Also, hypoxic tissues compensate by vasodilation (increased blood flow to the tissues) or increasing O_2 extraction ($C_aO_2 - C_vO_2$). Although the Fick equation for calculating cardiac output has been replaced by other techniques, the principle relating O_2 extraction to perfusion is used to monitor tissue oxygenation at the bedside. More details on these methods are provided in Chapter 51.

Factors Affecting Oxygen Loading and Unloading

In addition to the shape of the HbO_2 curve, many other factors affect O_2 loading and unloading. Among the most important factors in clinical practice are blood pH, body temperature, and erythrocyte concentration of certain organic phosphates.[5]

Variations in the structure of Hb also affect O_2 loading and unloading, as can chemical combinations of Hb with substances other than O_2, such as CO.

pH (Bohr Effect)

The impact of changes in blood pH on Hb affinity for O_2 is called the **Bohr effect.** As shown in Figure 12-10, the Bohr effect alters the position of the HbO_2 dissociation curve. A low pH (acidity) shifts the curve to the right, whereas a high pH (alkalinity) shifts it to the left. These changes are a result of variations in the shape of the Hb molecule caused by fluctuations in pH.

As blood pH decreases and the curve shifts to the right, the Hb saturation for a given PO_2 decreases. This is important for the tissue O_2 delivery because acidic environment of the tissues allows O_2 to dissociate from Hb into the tissues. Conversely, as blood pH increases and the curve shifts to the left, the Hb saturation for a given PO_2 increases (increased affinity of Hb for O_2).[4,5,8] Therefore, when venous blood returns to the lungs, the pH increases and higher pH shifts the HbO_2 curve back to the left, increasing the affinity of Hb for O_2 and enhancing its uptake from the alveoli.

Body Temperature

Variations in body temperature also affect the HbO_2 dissociation curve. As shown in Figure 12-11, a decrease in body temperature shifts the curve to the left, increasing Hb affinity for O_2. Conversely, as body temperature increases, the curve shifts to the right, and the affinity of Hb for O_2 decreases. As with the

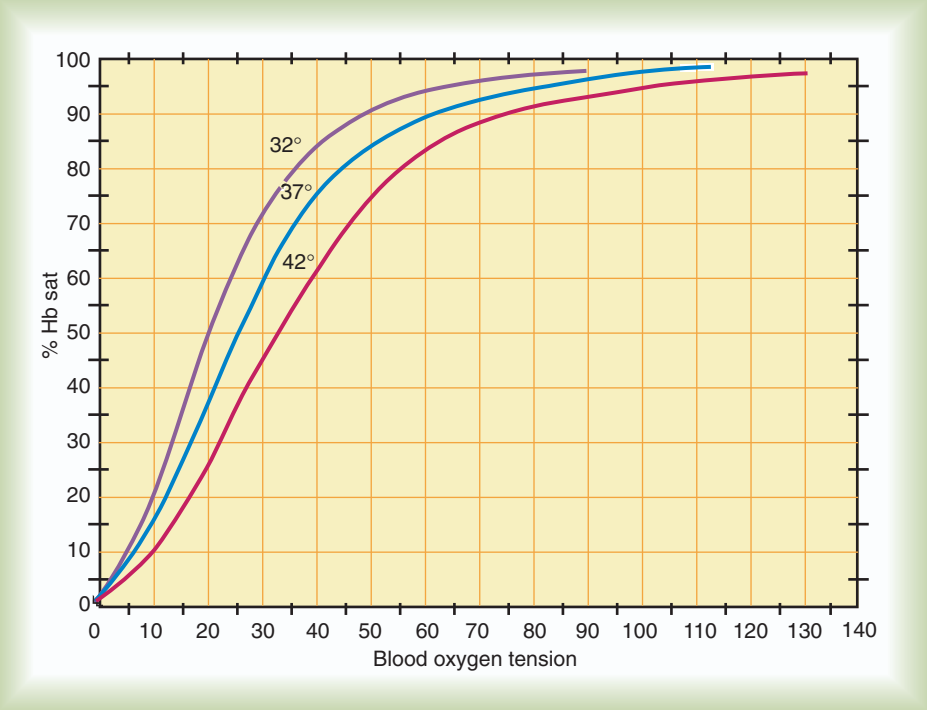

FIGURE 12-11 O_2 dissociation curve of blood at pH of 7.40, showing variations at three temperatures. For a given O_2 tension, the lower the temperature, the more the Hb holds onto O_2, maintaining a higher saturation.

Bohr effect, these changes enhance normal O_2 uptake and delivery. At the tissues, metabolic activity increases the temperature, which allows more O_2 to be released into the tissues.

Organic Phosphates (2,3-Diphosphoglycerate)

The organic phosphate 2,3-diphosphoglycerate (2,3-DPG) is found in abundance in the RBCs, where it forms a loose chemical bond with the globin chains of deoxygenated Hb. In this configuration, 2,3-DPG stabilizes the molecule in its deoxygenated state, reducing its affinity for O_2.[5-7] Without 2,3-DPG, Hb affinity for O_2 would be so great that normal O_2 unloading would be impossible. Increased 2,3-DPG concentrations shift the HbO_2 curve to the right, promoting O_2 unloading. Conversely, low 2,3-DPG concentrations shift the curve to the left, increasing Hb affinity for O_2.

Alkalosis, chronic hypoxemia, and anemia all tend to increase 2,3-DPG concentrations and promote O_2 unloading. Conversely, acidosis results in a lower intracellular level of 2,3-DPG and a greater affinity of Hb for O_2.

Erythrocyte concentrations of 2,3-DPG in banked blood decrease over time. After 1 week of storage, the 2,3-DPG level may be less than one-third of the normal value. This change shifts the HbO_2 curve to the left, decreasing the availability of O_2 to the tissues. Large transfusions of banked blood that is more than a few days old can severely impair O_2 delivery, even in the presence of normal PO_2. Improved maintenance levels of 2,3-DPG can be achieved with newer blood storage techniques.

Abnormal Hemoglobin

Structural or chemical abnormalities within the Hb also affect O_2 affinity. More than 120 abnormal HbS have been identified. In healthy individuals, 15% to 40% of the circulating Hb may be abnormal.

HbS (**sickle cell hemoglobin**) is less soluble than normal Hb, which causes it to become susceptible to polymerization and precipitation when deoxygenated. Certain events such as dehydration, hypoxia, and acidosis cause HbS to crystallize and the RBC to become hardened and curved like a sickle. Erythrocyte fragility is increased (leading to hemolysis), and the risk for thrombus formation is increased. Patients with sickle cell disease are prone to vasoocclusive disease and anemia. Some patients with sickle cell anemia develop **acute chest syndrome.** Acute chest syndrome is the most common cause of death in patients with sickle cell anemia. Patients usually complain of acute chest pain, cough, and shortness of breath. A new infiltrate is usually seen on the chest radiograph, and the patient often develops progressive anemia and hypoxemia. The causes of acute chest syndrome are multiple; the term *acute chest syndrome* does not indicate a definite diagnosis but rather indicates the clinical difficulty of defining a specific cause in most of such episodes.

Methemoglobin (metHb) is an abnormal form of the molecule, in which the heme-complex normal Fe^{++} loses an electron and is oxidized to its ferric state (Fe^{+++}). In the ferric state, the iron ion cannot combine with O_2. This is called **methemoglobinemia.** As with HbCO, clinical abnormalities come from the associated increased affinity for O_2 and loss of O_2-binding

capacity. The most common cause of methemoglobinemia is the therapeutic use of oxidant medications such as nitric oxide, nitroglycerin, and lidocaine. When using these therapeutic agents, frequent monitoring for metHb is important to weigh the risk against the benefit. The presence of metHb turns the blood brown, which can produce a slate-gray skin coloration that is often confused with cyanosis. The presence of metHb is confirmed by spectrophotometry (see Chapter 19). Methemoglobinemia is treated with reducing agents such as methylene blue or ascorbic acid when the blood level exceeds approximately 30%.

Carboxyhemoglobin (HbCO) is the chemical combination of Hb with CO. The affinity of Hb for CO is more than 200 times greater than it is for O_2. Extremely low concentrations of CO can quickly displace O_2 from Hb, forming HbCO. CO partial pressure of 0.12 mm Hg can displace half the O_2 from Hb. Because HbCO cannot carry O_2, each 1 g of Hb saturated with CO represents a loss in carrying capacity. The combination of CO with Hb shifts the HbO_2 curve to the left, impeding O_2 delivery to the tissues further. Treatment for CO poisoning involves giving the patient as much O_2 as possible because O_2 reduces the half-life of HbCO (Table 12-3). Sometimes a hyperbaric chamber is required to reverse rapidly the binding of CO with Hb.

During fetal life and for up to 1 year after birth, the blood has a high proportion of an Hb variant called **fetal hemoglobin (HbF).** HbF has a greater affinity for O_2 than normal adult Hb, as manifested by a leftward shift of the HbO_2 curve. Given the low PO_2 values available to the fetus in utero, this leftward shift aids O_2 loading at the placenta. Because of the relatively low pH of the fetal environment, O_2 unloading at the cellular level is not greatly affected. However, after birth, this enhanced O_2 affinity is less advantageous. Over the first year of life, HbF is gradually replaced with normal Hb.

Measurement of Hemoglobin Affinity for Oxygen

Variations in the affinity of Hb for O_2 are quantified by a measure called the **P50.**[2,8] The P_{50} is the partial pressure of O_2 at which the Hb is 50% saturated, standardized to a pH level of 7.40. A normal P_{50} is approximately 26.6 mm Hg. Conditions that cause a decrease in Hb affinity for O_2 (a shift of the HbO_2 curve to the right) increase the P_{50} to a value higher than normal. Conditions associated with an increase in affinity (a shift of the HbO_2 curve to the left) decrease the P_{50} to lower than normal. With 15 g/dl Hb, a 4-mm Hg increase in P_{50} results in approximately 1 to 2 ml/dl more O_2 being unloaded in the tissues than when the P_{50} is normal. Figure 12-12 shows the effect of changes in P_{50} and summarizes how the major factors previously discussed affect Hb affinity for O_2.

TABLE 12-3

Half-Life of Carboxyhemoglobin (HbCO) at Different Oxygen Exposures

HbCO Half-Life (min)	Inhaled FiO_2	PaO_2 (mm Hg)
280-320	0.21 at 1 atm	100
80-90	1.0 at 1 atm	673
20-30	1.0 at 3 atm	2193

CARBON DIOXIDE TRANSPORT

Figure 12-13 shows the physical and chemical events of gas exchange at the systemic capillaries. In the pulmonary capillaries, all events occur in the opposite direction. Although the primary focus is on CO_2 transport, Figure 12-13 also includes the basic elements of O_2 exchange. O_2 exchange is included here for completeness and to show that the exchange and transport of these two gases are closely related.

Transport Mechanisms

Approximately 45 to 55 ml/dl of CO_2 is normally carried in the blood in the following three forms: (1) dissolved in physical solution, (2) chemically combined with protein, and (3) ionized as bicarbonate.[5,7]

Dissolved in Physical Solution

As with O_2, CO_2 produced by the tissues dissolves in the plasma and erythrocyte intracellular fluid. However, in contrast to O_2, dissolved CO_2 plays an important role in transport, accounting for approximately 8% of the total released at the lungs; this is because of the higher solubility of CO_2 in plasma.

Chemically Combined With Protein

Molecular CO_2 has the capacity to combine chemically with free amino groups (NH_2) of protein molecules (Prot), forming a carbamino compound:

$$\text{Prot-NH}_2 + \text{CO}_2 = \text{Prot-NHCOO}^- + \text{H}^+$$

A small amount of the CO_2 leaving the tissues combines with plasma proteins to form these carbamino compounds. A larger fraction of CO_2 combines with erythrocyte Hb to form a carbamino compound called *carbaminohemoglobin*. As indicated in the previous equation, this reaction produces hydrogen ions. These H^+ ions are buffered by the reduced Hb, which is made available by the concurrent release of O_2.

The availability of additional sites for H^+ buffering increases the affinity of Hb for CO_2. Because reduced Hb is a weaker acid than HbO_2, pH changes associated with the release of the H^+ ions in the formation of carbaminohemoglobin are minimized. Carbaminohemoglobin constitutes approximately 12% of the total CO_2 transported.

Ionized as Bicarbonate

Approximately 80% of CO_2 in the blood is transported as bicarbonate. Of the CO_2 that dissolves in plasma, a small portion combines chemically with water in the process *hydrolysis.* Hydrolysis of CO_2 initially forms carbonic acid, which quickly ionizes into H^+ and bicarbonate ions:

$$\text{CO}_2 + \text{H}_2\text{O} = \text{H}_2\text{CO}_3 = \text{HCO}_3^- + \text{H}^+$$

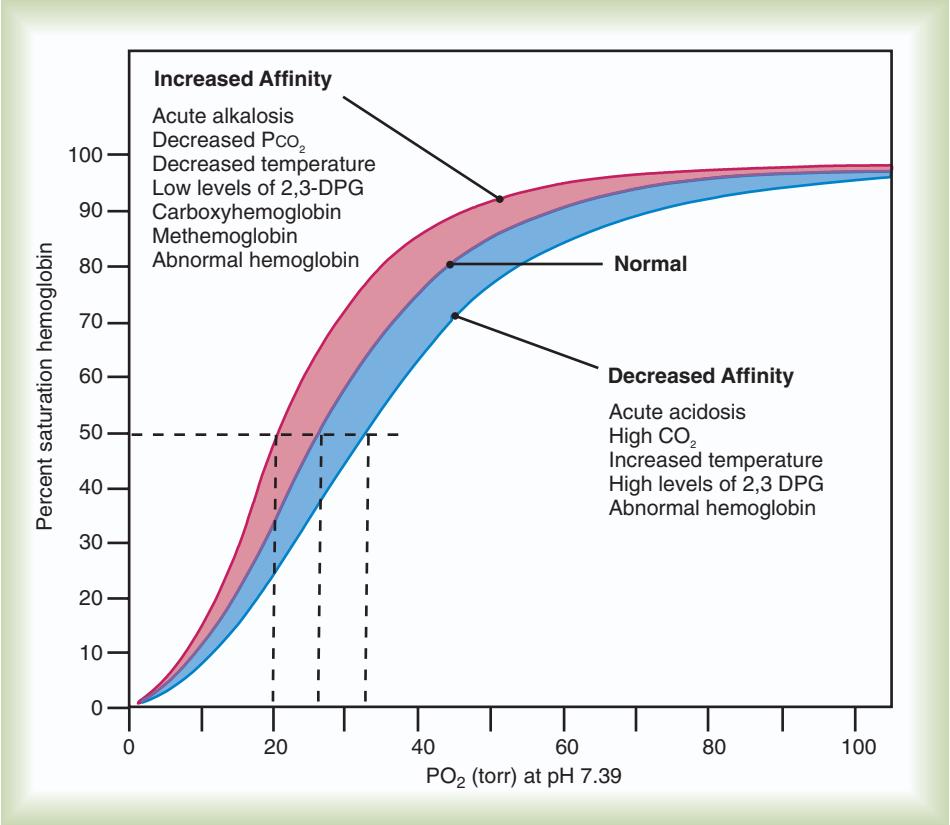

FIGURE 12-12 Conditions associated with altered affinity of Hb for O_2. P_{50} is PaO_2 at which Hb is 50% saturated (normally 26.6 mm Hg). A lower than normal P_{50} represents increased affinity of Hb for O_2. A high P_{50} is seen with decreased affinity. *2,3-DPG,* 2,3-Diphosphoglycerate. (Modified from Lane EE, Walker JF: Clinical arterial blood gas analysis, St Louis, 1987, Mosby.)

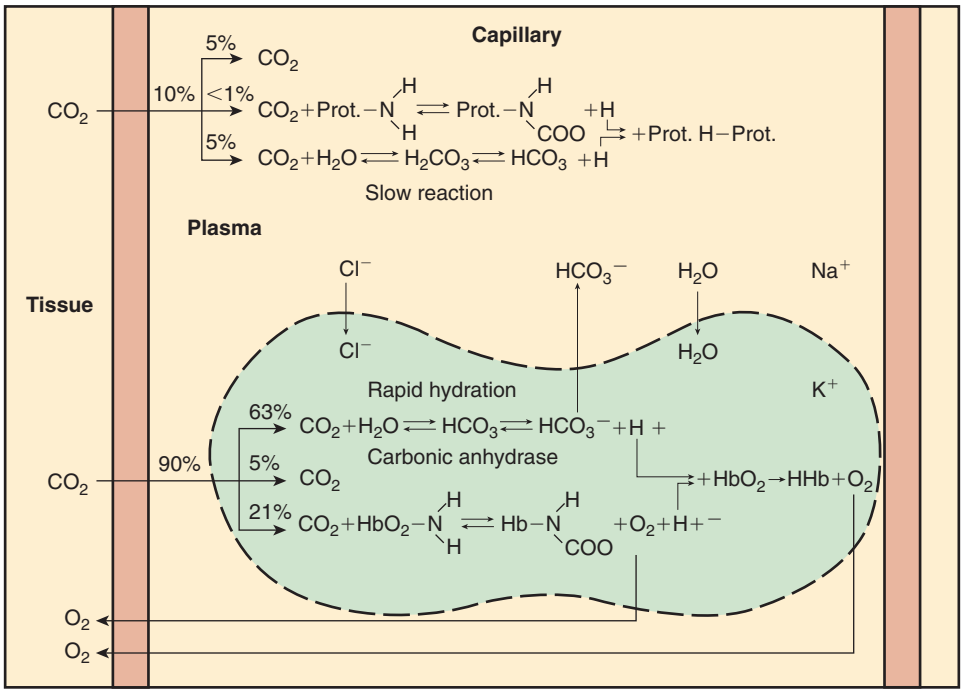

FIGURE 12-13 Summary diagram of various fates of CO_2 as it diffuses from the cells and interstitial spaces into the peripheral capillaries before its transport toward the venous circulation. (Modified from Martin DE, Youtsey JW: Respiratory anatomy and physiology, St Louis, 1988, Mosby.)

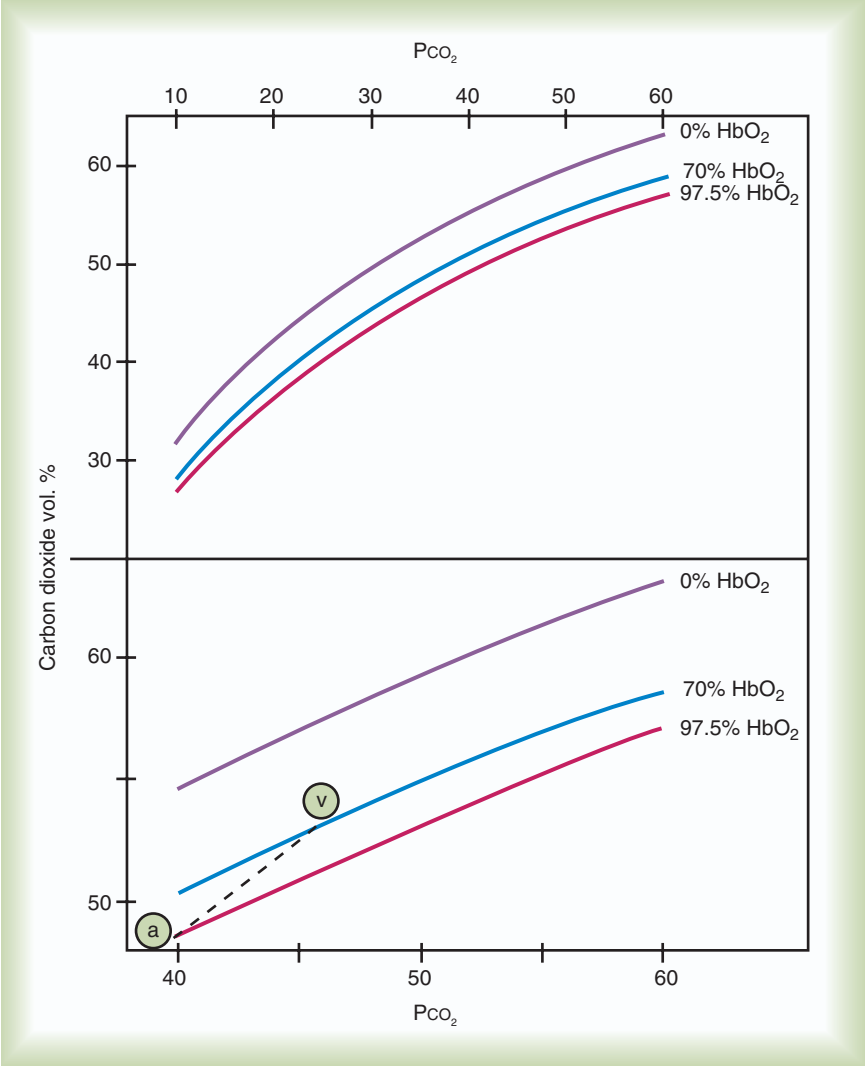

FIGURE 12-14 CO_2 dissociation curves. **A,** Relationship between CO_2 content and tension at three levels of Hb saturation. **B,** Close-up of curves between PCO_2 of 40 mm Hg and 60 mm Hg.

The H^+ ions produced in this reaction are buffered by the plasma proteins in much the same way as Hb buffers H^+ in the RBC. However, the rate of this plasma hydrolysis reaction is extremely slow, producing minimal amounts of H^+ and HCO_3^-.

Most CO_2 undergoes hydrolysis inside the erythrocyte. This reaction is greatly enhanced by an enzyme catalyst called *carbonic anhydrase.* The resulting H^+ ions are buffered by the imidazole group ($R\text{-}NHCOO^-$) of the reduced Hb molecule. The concurrent conversion of HbO_2 to its deoxygenated form helps buffer H^+ ions, enhancing the loading of CO_2 as carbaminohemoglobin.

As the hydrolysis of CO_2 continues, HCO_3^- ions begin to accumulate in the erythrocyte. To maintain a concentration equilibrium across the cell membrane, some of these anions diffuse outward into the plasma. Because the erythrocyte is not freely permeable by cations, electrolytic equilibrium must be maintained by way of an inward migration of anions. This migration is achieved by the shifting of chloride ions from the plasma into the erythrocyte—a process called the *chloride shift,* or the **Hamburger phenomenon.**

Carbon Dioxide Dissociation Curve

As with O_2, CO_2 has a dissociation curve. The relationship between blood PCO_2 and CO_2 content is depicted in Figure 12-14. The first point to note is the effect of Hb saturation with O_2 on this curve. As previously discussed, CO_2 levels, through their influence on pH, modify the O_2 dissociation curve (Bohr effect). Figure 12-14 shows that oxyhemoglobin saturation also affects the position of the CO_2 dissociation curve. The influence of oxyhemoglobin saturation on CO_2 dissociation is called the **Haldane effect.** As previously explained, this phenomenon is a result of changes in the affinity of Hb for CO_2, which occur as a result of its buffering of H^+ ions.[4-7]

Figure 12-14, *A* shows CO_2 dissociation curves for three levels of blood O_2 saturation. The first two are physiologic values, and the third extreme value is provided for contrast.

Figure 12-14, *B* amplifies selected segments of these curves in the physiologic range of PCO_2. Note first the arterial point *a* lying on the curve representing an SaO_2 of 97.5%. At this point, PCO_2 is 40 mm Hg and CO_2 content is approximately 48 ml/dl. The venous point *v* falls on the curve, representing SaO_2 of approximately 70%. At this point, PCO_2 is 46 mm Hg and CO_2 content is approximately 52 ml/dl. Because O_2 saturation changes from arterial to venous blood, the true physiologic CO_2 dissociation curve must lie somewhere between these two points. This physiologic curve is represented as the *dashed line* in Figure 12-14, B. At point *a,* the high SaO_2 decreases the capacity of the blood to hold CO_2, helping unload this gas at the lungs. At point *v,* the lower mixed venous O_2 saturation (S_vO_2) increases the capacity of the blood for CO_2, aiding uptake at the tissues.

The total CO_2 content of arterial and venous blood is compared in Table 12-4. The amounts of CO_2 are expressed in gaseous volume equivalents (milliliters per deciliter) and as millimoles per liter (mmol/L). This latter measure of the chemical combining power of CO_2 in solutions is critical in understanding the role of this gas in acid-base balance.

TABLE 12-4

Carbon Dioxide Content of Arterial and Venous Blood

Unit of Measure	Arterial	Venous
mmol/L	21.53	23.21
ml/dl	48.01	51.76

ABNORMALITIES OF GAS EXCHANGE AND TRANSPORT

Gas exchange is abnormal when either tissue O_2 delivery or CO_2 removal is impaired.

Impaired Oxygen Delivery

O_2 delivery (DO_2) to the tissues is a product of arterial O_2 content (CaO_2) and cardiac output (CO).

$$DO_2 = CaO_2 \times CO$$

When O_2 delivery is inadequate for cellular needs, **hypoxia** occurs. According to the preceding equation, hypoxia occurs if (1) the arterial blood O_2 content is decreased (*hypoxemia*), (2) cardiac output or perfusion is decreased (*shock* or *ischemia*). Table 12-5 summarizes causes, common clinical indicators, mechanisms, and examples of hypoxia.

Hypoxemia

Hypoxemia occurs when the partial pressure of O_2 in the arterial blood (PaO_2) is decreased to less than the predicted normal value based on the age of the patient. Impaired O_2 delivery also occurs in the presence of abnormalities that prevent saturation of Hb with O_2 (see subsequent discussion).

Decreased Partial Pressure of Oxygen in Arterial Blood. Decreased PaO_2 may be caused by a low ambient PO_2, hypoventilation, impaired diffusion, $\dot{V}_A/\dot{Q}$ imbalances, and right-to-left anatomic or physiologic shunting. PaO_2 also decreases normally with aging. The normal predicted PaO_2 decreases steadily with age, and the average is approximately 85 mm Hg at age 60 years (see later discussion).

TABLE 12-5

Causes of Hypoxia

Cause	Primary Indicator	Mechanism	Example
Hypoxemia			
Low PiO_2	Low P_AO_2 Low PaO_2	Reduced P_B	Altitude
Hypoventilation	High $PaCO_2$	Decreased $\dot{V}_A$	Drug overdose
$\dot{V}_A/\dot{Q}$ imbalance	Low PaO_2 High $D(A–a)O_2$; resolves with O_2	Decreased $\dot{V}_A$ relative to perfusion	COPD, aging
Anatomic shunt	Low PaO_2 High $D(A–a)O_2$; does not resolve with O_2	Blood flow from right to left side of heart	Congenital heart disease
Physiologic shunt	Low PaO_2 High D $(A–a)O_2$; does not resolve with O_2	Perfusion without ventilation	Atelectasis
Diffusion defect	Low PaO_2 High $D(A–a)O_2$; resolves with O_2	Damage to alveolar-capillary membrane	ARDS
Hb deficiency			
Absolute	Low Hb content Reduced CaO_2	Loss of Hb	Hemorrhage
Relative	Abnormal SaO_2 Reduced CaO_2	Abnormal Hb	Carboxyhemoglobin
Low blood flow	Increased $C(a–\bar{v})O_2$	Decreased perfusion	Shock, ischemia
Dysoxia	Normal CaO_2 Decreased $C(a–\bar{v})O_2$	Disruption of cellular enzymes	Cyanide poisoning

ARDS, Acute respiratory distress syndrome; *COPD,* chronic obstructive pulmonary disease.

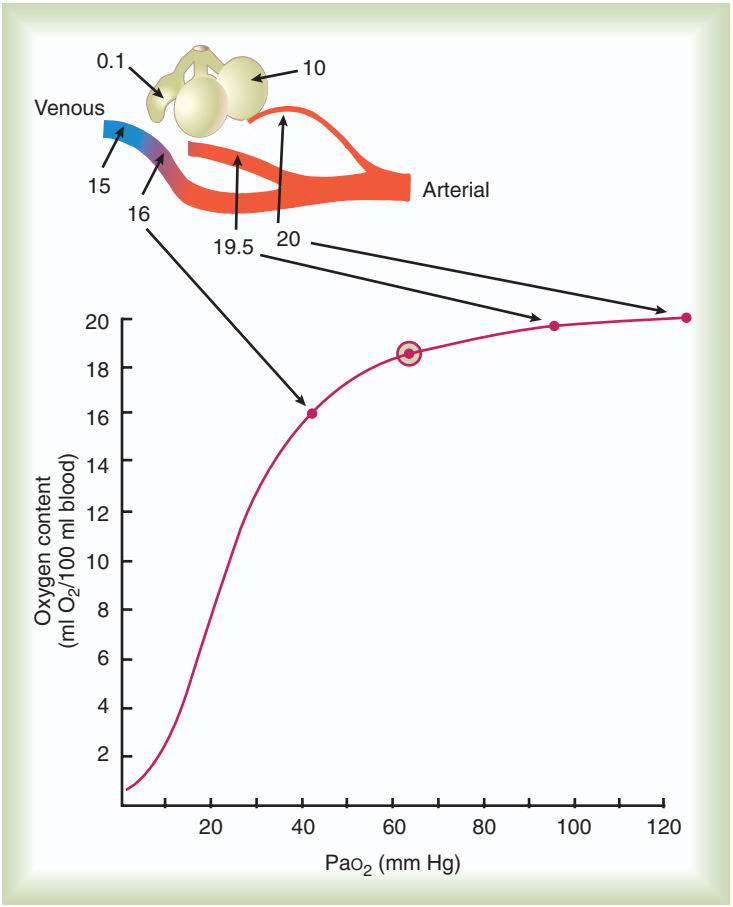

FIGURE 12-15 O_2 dissociation curve. PaO_2 versus O_2 content. O_2 content from alveolar-capillary units with $\dot{V}/\dot{Q}$ of 0.1, 1, and 10 is 16 ml/dl, 19.5 ml/dl, and 20 ml/dl. Lines are drawn for each O_2 content to its point on the dissociation curve. The average O_2 content, 18.5 ml/dl, is represented by a *circle* on the dissociation curve. (Modified from Martin L: Pulmonary physiology in clinical practice: the essentials for patient care and evaluation, St Louis, 1987, Mosby.)

Breathing gases with a low O_2 concentration (hypoxia chamber) or at pressures less than atmospheric (high altitude) lowers PiO_2, thus decreasing P_AO_2 and P_aO_2. A common example of this problem occurs during travel to high altitudes, where the visitor often experiences the ill effects of hypoxia for several days. This condition is called *mountain sickness.* In such cases, although P_aO_2 is reduced, the pressure gradient between the alveoli and the arterial blood for O_2 ($D_{A-a}O_2$) remains normal.

Assuming a constant FiO_2, P_AO_2 varies inversely with $PACO_2$. An increase in P_ACO_2 (hypoventilation) is always accompanied by a proportionate decrease in P_AO_2. $D_{A-a}O_2$ is normal in such cases. Conversely, hyperventilation decreases P_ACO_2 and helps compensate for hypoxemia (but only modestly, as discussed earlier in this chapter).

Even when P_AO_2 is normal, disorders of the alveolar-capillary membrane may limit diffusion of O_2 into the pulmonary capillary blood, decreasing P_aO_2. Examples are pulmonary fibrosis and interstitial edema. However, as previously noted, a pure diffusion limitation is an uncommon cause of hypoxemia at rest.

$\dot{V}_A/\dot{Q}$ imbalances are the most common cause of hypoxemia in patients with lung disease. A $\dot{V}_A/\dot{Q}$ imbalance is an abnormal deviation in the distribution of ventilation to perfusion in the lung. The normal lung has some $\dot{V}_A/\dot{Q}$ mismatch; however, in disease states, the degree of $\dot{V}_A/\dot{Q}$ imbalances becomes much greater. To understand how $\dot{V}_A/\dot{Q}$ imbalance causes hypoxemia, reinspect the normal oxyhemoglobin dissociation curve, with PO_2 plotted against O_2 content (Figure 12-15). The curve is nearly flat in the physiologic range of PaO_2 (>70 mm Hg) but falls steeply when PaO_2 is less than 60 mm Hg. Points representing O_2 content of three separate lung units also are shown. These units have $\dot{V}_A/\dot{Q}$ of 0.1, 1.0, and 10.0.

Blood leaving the normal unit ($\dot{V}_A/\dot{Q} = 1$) has a normal O_2 content (19.5 ml/dl). Blood leaving the unit with poor ventilation ($\dot{V}_A/\dot{Q} = 0.1$) has a low O_2 content (16.0 ml/dl). Because Hb is almost fully saturated at a normal PO_2 of 100 mm Hg, blood leaving the over ventilated unit ($\dot{V}_A/\dot{Q} = 10$) has an O_2 content that is just slightly greater than normal (20.0 ml/dl). When the blood from all three units mixes together, the result is O_2 content that is reduced (18.5 ml/dl). The decrease in oxygenation caused by the poorly ventilated unit is not fully compensated for by the high $\dot{V}_A/\dot{Q}$ unit.

$\dot{V}_A/\dot{Q}$ of zero represents a special type of imbalance. When $\dot{V}_A/\dot{Q}$ is zero, there is blood flow but no ventilation. The result

is equivalent to a right to left anatomic shunt, shown at the *bottom* of Figure 12-16. Here, venous blood bypasses ventilated alveoli and mixes with freshly oxygenated arterial blood, resulting in venous admixture.

RULE OF THUMB

Although $\dot{V}_A/\dot{Q}$ imbalances are the most common cause of hypoxemia in patients with respiratory diseases, physiologic shunting also can occur commonly, especially in patients who are critically ill. To differentiate between hypoxemia caused by a $\dot{V}_A/\dot{Q}$ imbalance and hypoxemia caused by shunting, apply the following 50/50 rule: If FiO_2 is greater than 50 (%) and P_aO_2 is less than 50 (mm Hg), significant shunting is present; otherwise, the hypoxemia is mainly caused by a simple $\dot{V}_A/\dot{Q}$ imbalance.

When a low P_aO_2 is observed, the RT must take into account the normal decrease in arterial O_2 tension that occurs with aging. As shown in Figure 12-17, for an individual breathing air at sea level, the "normal" $P_{A-a}O_2$ increases in a near-linear fashion with increasing age *(shaded area)*. This increase in $P_{A-a}O_2$ results in a gradual decline in P_aO_2 over time and is probably caused by reduced surface area in the lung for gas exchange

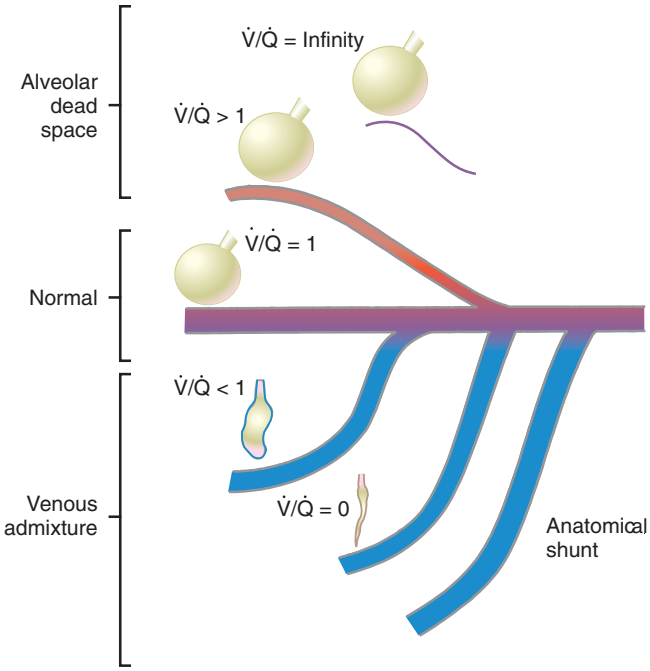

FIGURE 12-16 Range of $\dot{V}_A/\dot{Q}$ ratios. (Modified from Martin L: Pulmonary physiology in current practice: the essentials for patient care and evaluation, St Louis: 1987, Mosby).

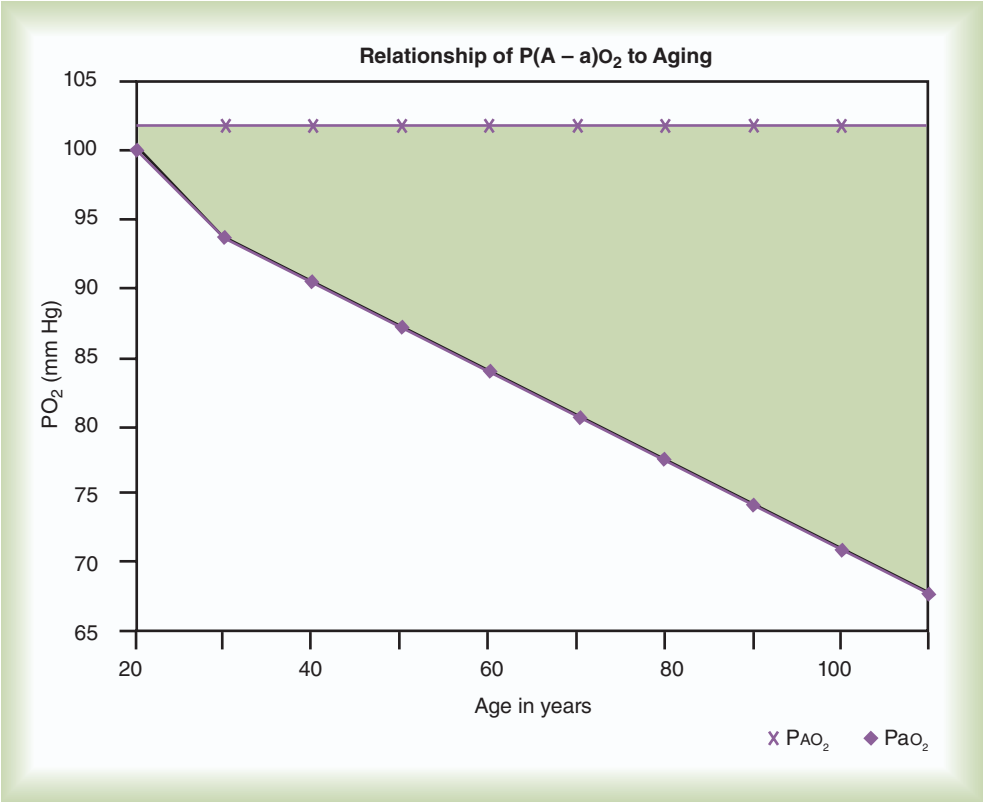

FIGURE 12-17 Relationship between $PA_{-a}O_2$ and aging. As P_aO_2 naturally decreases with age, $PA_{-a}O_2$ increases at the rate of approximately 3 mm Hg each decade beyond 20 years. (Modified from Lane EE, Walker JF: Clinical arterial blood gas analysis, St Louis, 1987, Mosby.)

and increases in $\dot{V}_A/\dot{Q}$ mismatching. P_aO_2 of 85 mm Hg in a 60-year-old adult would be interpreted as normal, but the same P_aO_2 in a 20-year-old adult would indicate hypoxemia. The expected P_aO_2 in older adults may be estimated by using the following formula:

$$\text{Expected } P_aO_2 = 100 - (0.323 \times \text{Age in years})$$

Hemoglobin Deficiencies. Normal P_aO_2 does not guarantee adequate arterial O_2 content or delivery. For arterial O_2 content to be adequate, there also must be enough normal Hb in the blood. If the blood Hb is low—even when PaO_2 is normal—hypoxia can occur because of low O_2 content in the arterial blood. Relative Hb deficiencies are caused by abnormal forms of Hb and have been discussed earlier in this chapter.

Hb deficiencies, or anemias, can be either absolute or relative. Absolute Hb deficiency occurs when the Hb concentration is lower than normal. Relative Hb deficiencies are caused by either the displacement of O_2 from normal Hb or the presence of abnormal Hb variants. A low blood Hb concentration may be caused either by a loss of RBCs, as with hemorrhage, or by inadequate erythropoiesis (formation of RBCs in the bone marrow). Regardless of the cause, a low Hb content can seriously impair the O_2-carrying capacity of the blood, even in the presence of a normal supply (P_aO_2) and adequate diffusion.[5]

Figure 12-18 plots the relationship between arterial O_2 content and PaO_2 as a function of Hb concentration. As can be seen, progressive decreases in blood Hb content causes large decreases in arterial O_2 content (CaO_2). A 33% decrease in Hb content (from 15 to 10 g/dl) reduces CaO_2 as much as would a decrease in PaO_2 from 100 mm Hg to 40 mm Hg.

Reduction in Blood Flow (Shock or Ischemia)

Because O_2 delivery depends on both arterial O_2 content and cardiac output, hypoxia can still occur when the CaO_2 is normal if blood flow is reduced. There are two types of reduced blood flow: (1) circulatory failure *(shock)* and (2) local reductions in perfusion *(ischemia)*.

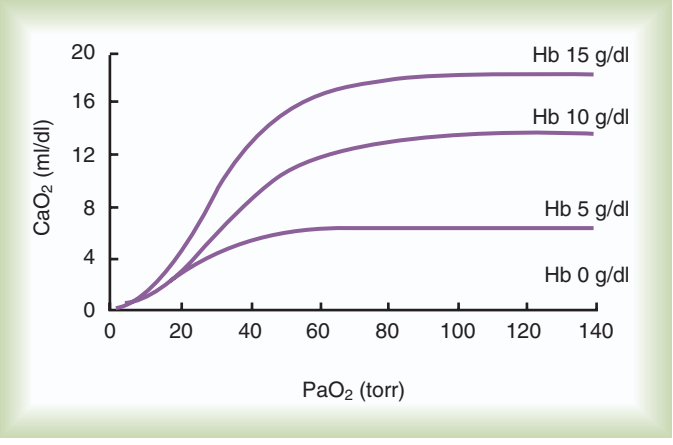

FIGURE 12-18 Relationship between CaO_2 and PaO_2 as a function of blood Hb concentration. Progressive decreases in Hb cause large decreases in CaO_2.

MINI CLINI

Effect of Anemia on Oxygen Content

In its most common form, anemia is a clinical disorder in which the number of RBCs is decreased. Because RBCs carry Hb, anemia decreases the amount of this O_2-carrying protein.

PROBLEM: What effect would anemia that causes a progressive decrease in Hb from (a) 15 g/dl, to (b) 12 g/dl, to (c) 8 g/dl, to (d) 4 g/dl, have on the amount of O_2 carried in a patient's blood? Assume that PO_2 and saturation stay normal at 100 mm Hg and 97%.

DISCUSSION: 1. Calculate dissolved O_2 the same way for all four examples as follows:

$$\text{Dissolved } O_2 = 100 \times 0.003 = 0.30 \text{ ml/dl}$$

2. Compute chemically combined O_2 as follows: Chemically combined O_2 = Hb (g/dl) × 1.34 ml/g × SaO_2
   a. 15 g/dl × 1.34 ml/g × 0.97 = 19.50 ml/dl
   b. 12 g/dl × 1.34 ml/g × 0.97 = 15.60 ml/dl
   c. 8 g/dl × 1.34 ml/g × 0.97 = 10.40 ml/dl
   d. 4 g/dl × 1.34 ml/g × 0.97 = 5.20 ml/dl
3. Compute total O_2 content as follows:

$$CaO_2 = \text{Dissolved } O_2 + \text{Chemically combined } O_2$$

   a. 0.30 + 19.50 = 19.80 ml/dl
   b. 0.30 + 15.60 = 15.90 ml/dl
   c. 0.30 + 10.40 = 10.70 ml/dl
   d. 0.30 + 5.20 = 5.50 ml/dl

Loss of Hb decreases the amount of O_2 carried in a patient's blood, even though PO_2 and saturation remain normal. With Hb concentration of 4 g/dl, the amount of O_2 carried in a patient's blood is only approximately one-fourth the normal concentration (5.50 vs. 19.80 ml/dl).

Circulatory Failure (Shock). In circulatory failure, tissue O_2 deprivation is widespread. Although the body tries to compensate for the lack of O_2 by directing blood flow to vital organs, this response is limited. Prolonged shock ultimately causes irreversible damage to the central nervous system and eventual cardiovascular collapse.

Local Reductions in Perfusion (Ischemia). Even when whole-body perfusion is adequate, local reductions in blood flow can cause localized hypoxia. Ischemia can result in anaerobic metabolism, metabolic acidosis, and eventual death of the affected tissue. Myocardial infarction and stroke are examples of ischemic conditions that can cause hypoxia and tissue death.

Dysoxia

Dysoxia is a form of hypoxia in which the cellular uptake of O_2 is abnormally decreased. The best example of dysoxia is cyanide poisoning. Cyanide disrupts the intracellular cytochrome oxidase system, preventing cellular use of O_2. Dysoxia also may occur when tissue O_2 consumption becomes dependent on O_2 delivery.

Figure 12-19 plots tissue O_2 consumption ($\dot{V}_2$) against O_2 delivery (DO_2) in both normal and pathologic states. Normally, the tissues extract as much O_2 as they need from what is

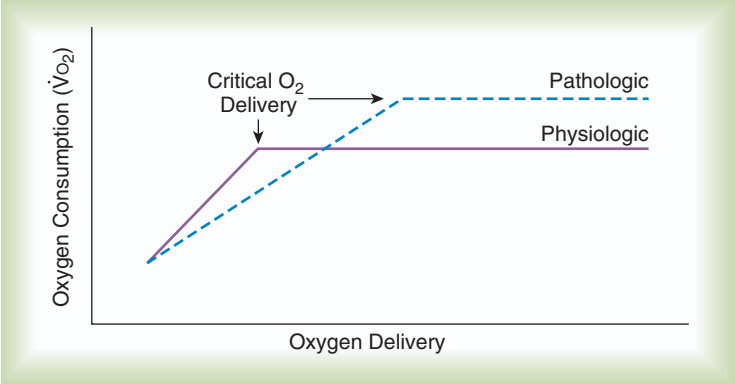

FIGURE 12-19 Physiologic versus pathologic O_2 consumption–delivery relationship. Critical O_2 delivery occurs at higher O_2 delivery in a pathologic state. The slope of the pathologic consumption curve below the critical delivery point reflects the decrease in O_2 extraction ratio that exists in these situations. (Modified from Pasquale MD, Cipolle MD, Cerra FB: Oxygen transport: does increasing supply improve outcome? Respir Care 38:800, 1993.)

delivered and O_2 consumption equals O_2 demand (flat portion of *solid line*). However, if delivery decreases, conditions begin to change *(solid line)*. At a level called the *point of critical delivery,* tissue extraction reaches a maximum. Further decreases in delivery result in an O_2 "debt," which occurs when O_2 demand exceeds O_2 delivery. Under conditions of O_2 debt, O_2 consumption becomes dependent on O_2 delivery *(sloped line)*. This dependence leads to lactic acid accumulation and metabolic acidosis.

In pathologic conditions such as septic shock and ARDS *(dotted line)*, this critical point may occur at levels of O_2 delivery considered normal. In addition, the slope of the curve below the point of critical delivery may be less than normal, indicating a decreased extraction ratio ($\dot{V}_2/DO_2$).[6] In combination, these findings indicate that O_2 demands are not being met and that a defect exists in the cellular mechanisms regulating O_2 uptake.

Impaired Carbon Dioxide Removal

Any disorder that decreases alveolar ventilation ($\dot{V}_A$) relative to metabolic need impairs CO_2 removal. Impaired CO_2 removal by the lung causes hypercapnia and respiratory acidosis (see Chapter 14). A decrease in alveolar ventilation occurs when (1) the minute ventilation is inadequate, (2) the dead space ventilation per minute is increased, or (3) a $\dot{V}_A/\dot{Q}$ imbalance exists.[4-8]

Inadequate Minute Ventilation

Clinically, inadequate minute ventilation is caused by decreased tidal volume, or respiratory rate. Inadequate minute ventilation occurs in restrictive conditions, such as atelectasis, neuromuscular disorders, or impeded thoracic expansion (e.g., kyphoscoliosis). A decrease in respiratory rate is less common but may be present with respiratory center depression, as in drug overdose.

Increased Dead Space Ventilation

An increase in dead space ventilation, or V_D/V_T, is caused by either (1) decreased tidal volume (as with rapid, shallow breathing) or (2) increased physiologic dead space as in various lung diseases. In either case, wasted ventilation increases. Without compensation, alveolar ventilation per minute is decreased, and CO_2 removal is impaired.

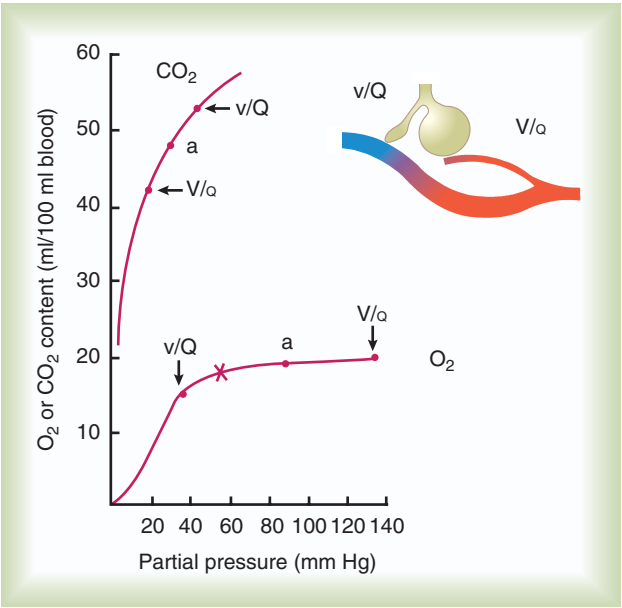

FIGURE 12-20 $\dot{V}_A/\dot{Q}$ imbalance and dissociation curves for CO_2 and O_2. v/Q represents low $\dot{V}_A/\dot{Q}$ units, and V/Q represents high $\dot{V}_A/\dot{Q}$ units. See text for discussion.

Ventilation-Perfusion Imbalances

Theoretically, any $\dot{V}_A/\dot{Q}$ imbalance should cause an increase in P_aCO_2. However, P_aCO_2 does not always increase in these cases. Many patients who are hypoxemic because of a $\dot{V}_A/\dot{Q}$ imbalance have a low or normal P_aCO_2. This common clinical finding suggests that $\dot{V}_A/\dot{Q}$ imbalances have a greater effect on oxygenation than on CO_2 removal.

Careful inspection of the O_2 and CO_2 dissociation curves supports this finding. The O_2 and CO_2 dissociation curves are plotted on the same scale in Figure 12-20. The upper CO_2 curve is nearly linear in the physiologic range. The lower O_2 curve is almost flat in the physiologic range. Point *a* on each curve is the normal arterial point for both content and partial pressure. To

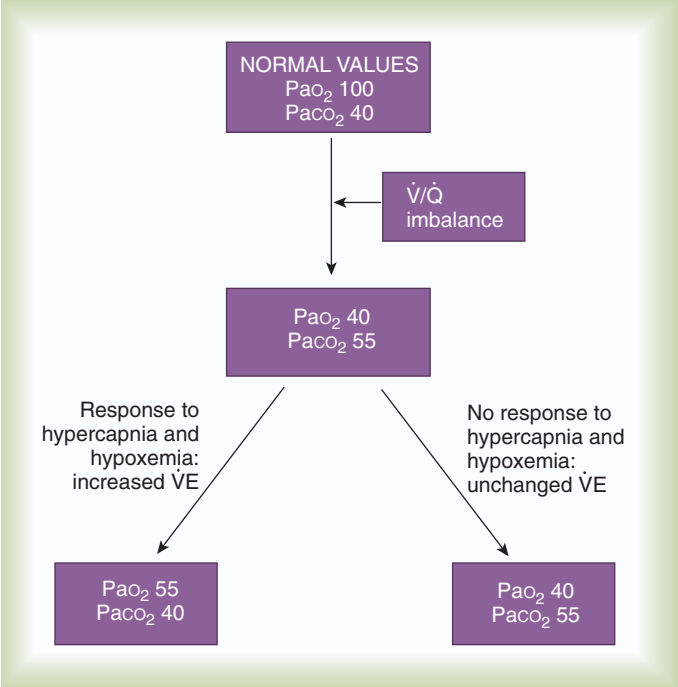

FIGURE 12-21 Changes in PaO_2 and $PaCO_2$ caused by $\dot{V}_A/\dot{Q}$ imbalance. All values are given in millimeters of mercury (mm Hg).

the right of the graph are two lung units, one with a low $\dot{V}_A/\dot{Q}$ and the other with a high $\dot{V}_A/\dot{Q}$. The blood O_2 and CO_2 contents from each unit are plotted on the curves. The final CO_2 content, arrived at by averaging the high and low $\dot{V}_A/\dot{Q}$ points, is shown as point *a* on the CO_2 curve. This point is the same as the normal arterial point for CO_2.

Patients with significant $\dot{V}_A/\dot{Q}$ imbalances must compensate for high PCO_2 coming from underventilated units. To compensate for these high PCO_2 values, the patient's minute ventilation must increase (Figure 12-21). Patients who can increase their minute ventilation tend to have either normal or low P_aCO_2, combined with hypoxemia.

Conversely, patients with $\dot{V}_A/\dot{Q}$ imbalance who cannot increase their minute ventilation are hypercapnic. Hypercapnia generally occurs only when the $\dot{V}_A/\dot{Q}$ imbalance is severe and chronic, as in COPD. Such a patient must sustain a higher than normal minute ventilation just to maintain normal $PaCO_2$. If the energy costs required to sustain a high minute ventilation are prohibitive, the patient opts for less work—and hence elevated P_aCO_2.

SUMMARY CHECKLIST

- Movement of gases between the lungs and the tissues depends mainly on diffusion.
- P_ACO_2 varies directly with CO_2 production and inversely with alveolar ventilation.
- P_AO_2 is computed using the alveolar air equation.
- With a constant FiO_2, P_AO_2 varies inversely with P_ACO_2.
- Normal P_AO_2 averages 100 mm Hg, with mean P_ACO_2 of approximately 40 mm Hg.
- Normal mixed venous blood has PO_2 of approximately 40 mm Hg and PCO_2 of approximately 46 mm Hg.
- $\dot{V}_A/\dot{Q}$ must be in balance for pulmonary gas exchange to be effective. Because of normal anatomic shunts and $\dot{V}_A/\dot{Q}$ imbalances, pulmonary gas exchange is imperfect.
- In disease, $\dot{V}_A/\dot{Q}$ can range from zero (perfusion without ventilation or physiologic shunting) to infinity (pure alveolar dead space).
- Blood carries a small amount of O_2 in physical solution, and larger amounts are carried in chemical combination with erythrocyte Hb.
- Hb saturation is the ratio of oxyhemoglobin to total Hb, expressed as a percentage.
- To compute total O_2 contents of the blood, add the dissolved O_2 content ($0.003 \times PO_2$) to the product of Hb content × Hb saturation × 1.34.
- Arteriovenous O_2 content difference, $C_{a-v}O_2$, is the amount of O_2 given up by every 100 ml of blood on each pass through the tissues. All else being equal, $C_{a-v}O_2$ varies inversely with cardiac output.
- Hb affinity for O_2 increases with high PO_2, high pH, low temperature, and low levels of 2,3-DPG.
- Hb abnormalities can affect O_2 loading and unloading and can cause hypoxia.
- Most CO_2 (approximately 80%) is transported in the blood as ionized bicarbonate; other forms include carbamino compounds in physical solution.
- Changes in CO_2 levels modify the O_2 dissociation curve (Bohr effect). Changes in Hb saturation affect the CO_2 dissociation curve (Haldane effect). These changes are mutually beneficial, assisting in gas exchange at the lung and the cellular level.
- Hypoxia occurs if (1) the arterial blood O_2 content is decreased, (2) blood flow is decreased, or (3) abnormal cellular function prevents proper uptake of O_2.
- Decreased PaO_2 level may be a result of a low ambient PO_2, hypoventilation, impaired diffusion, $\dot{V}_A/\dot{Q}$ imbalances, and right-to-left anatomic or physiologic shunting.
- A decrease in alveolar ventilation occurs when (1) the minute ventilation is inadequate, (2) dead space ventilation is increased, or (3) a $\dot{V}_A/\dot{Q}$ imbalance exists.

CHAPTER 13

Solutions, Body Fluids, and Electrolytes

DANIEL F. FISHER

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the characteristics of and key terms associated with solutions, colloids, and suspensions.
- Describe the five factors that influence the solubility of a substance in a solution.
- Describe how osmotic pressure functions and what its action is in relation to cell membranes.
- Describe how to calculate the solute content of a solution using ratio, weight/volume, and percent methods.
- State the ionic characteristics of acids, bases, and salts.
- Describe how proteins can function as bases.
- Describe how to calculate the pH of a solution when given the $[H^+]$ in nanomoles per liter.
- Identify where fluid compartments are located in the body and their volumes.
- Describe how water loss and replacement occur.
- Define the roles played by osmotic and hydrostatic pressure in edema.
- Identify clinical findings associated with excess or deficiency of the seven basic electrolytes.

CHAPTER OUTLINE

KEY TERMS

acid

anions
base
buffering
cations
colloids
diluent
dilute solution
dilution equation
equivalent weight
hydrostatic pressure
hyperkalemia
hypertonic
hypotonic
ionic
interstitial fluid
isotonic
nanomole
normal solution
osmolality
osmotic pressure (oncotic pressure)
plasma colloid osmotic pressure (oncotic pressure)
saturated solution
solute
solution
solvent
Starling equilibrium
suspensions

In healthy individuals, body water and various chemicals are regulated to maintain an environment in which biochemical processes can continue. Imbalances in the amount or concentration of chemicals in the body occur in many diseases. The nature and importance of body fluids and electrolytes require an understanding of physiologic chemistry. This chapter provides the reader with the background knowledge needed to understand body chemistry.

SOLUTIONS, COLLOIDS, AND SUSPENSIONS

Definition of a Solution

The body is based on liquid water chemistry and the interaction of various substances either dissolved or suspended within the fluid. Water itself is a polar (having two sides with positive and negative charges) covalent (capable of forming bonds by sharing electrons) molecule and is referred to in chemistry as a *universal solvent*. Water is the primary component of any liquid within the body and has a great influence on the behavior of other materials as they are introduced. These substances and particles combine with water in the following three ways: as (1) colloids, (2) suspensions, or (3) solutions.

A **solution** is a stable mixture of two or more substances in a single phase that cannot be separated using a centrifuge. One substance is evenly distributed between the molecules of the other. The substance that dissolves is called the **solute.** The medium in which it dissolves is called the **solvent.** Gases, liquids, and solids can dissolve to become solutes; for example, carbon dioxide, alcohol, and salt can be dissolved in water. The process of dissolving involves breaking the (relatively weak) bonds between the solute-solute molecules and the solvent-solvent molecules. These intermolecular forces must be broken before a new solute-solvent bond can be formed. A solute dissolves in a solvent if the solute-solvent forces of attraction are great enough to overcome the solute-solute and solvent-solvent forces of attraction. If the solute-solvent force is less than the solute-solute or solvent-solvent force, the solute does not dissolve. When all three sets of forces are approximately equal, the two substances typically are soluble in each other.

In electrochemical terms, there are three basic types of physiologic solutions. Depending on the solute, solutions are **ionic** (electrovalent), *polar covalent,* or *nonpolar covalent* (Table 13-1). In ionic and polar covalent solutions, some of the solute ionizes into separate particles known as *ions.* A solution in which this dissociation occurs is called an *electrolyte solution* (Figure 13-1). If an electrode is placed in such a solution, positive ions migrate to the negative pole of the electrode (the cathode). These ions are called **cations.** Negative ions migrate to the positive pole of the electrode (the anode); they are called **anions.** In nonpolar covalent solutions, molecules of solute remain intact and do not carry electrical charges; these solutions are referred to as *nonelectrolytes.* These nonelectrolytes are not attracted to either the positive or the negative pole of an electrode (hence the designation *nonpolar*). All three types of solutions coexist in the body. These solutions also serve as the media in which colloids and simple suspensions are dispersed. Gases such as oxygen and CO_2

TABLE 13-1

Types of Physiologic Solutions

Type	Characteristics	Physiologic Example
Ionic (electrovalent)	Ionic compounds dissolved from crystalline form, usually in water (hydration); form strong electrolytes with conductivity dependent on concentration of ions	Saline solution (0.9% NaCl)
Polar covalent	Molecular compounds dissolved in water or other solvents to produce ions (ionization); electrolytes may be weak or strong, depending on degree of ionization; solutions polarize and are good conductors	Hydrochloric acid (HCl) (strong electrolyte); acetic acid (CH_3COOH) (weak electrolyte)
Nonpolar covalent	Molecular compounds dissolved into electrically neutral solutions (do not polarize); solutions are not good conductors; nonelectrolytes	Glucose ($C_6H_{12}O_6$)

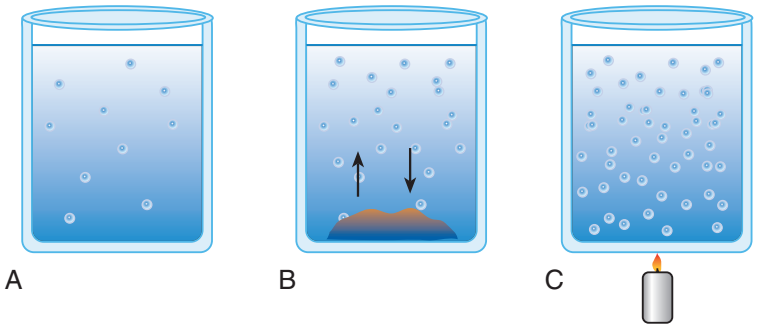

FIGURE 13-1 **A,** In the dilute solution, there are relatively few solute particles. **B,** In the saturated solution, the solvent contains all the solute it can hold in the presence of excess solute. **C,** Heating the solution dissolves more solute particles, which may remain in the solution if cooled gently, creating a state of supersaturation.

are nonpolar molecules (along with nitrogen) and do not dissolve very well in water, which is a polar solvent.

Colloids (sometimes called *dispersions* or *gels*) consist of large molecules that attract and hold water (*hydrophilic:* "water loving"). These molecules are uniformly distributed throughout the dispersion, and they tend not to settle. The protoplasm inside cells is a common example of a colloid. Physiologically, colloids provide very little free water to the patient's system, and care should be taken not to create a hypotonic environment.[1]

Suspensions are composed of large particles that float in a liquid. Suspensions can be physically separated by centrifugation and do not possess the same interactions between solvent and solute that are found in a true solution. Red blood cells in plasma are an example of a suspension. Dispersion of suspended particles depends on physical agitation. Particles settle because of gravity when the suspension is motionless.

The ease with which a solute dissolves in a solvent is its *solubility,* which is influenced by the following five factors:

1. *Nature of the solute*. The ease with which substances go into a solution (dissociation) in a given solvent depends on the forces of the solute-solute molecules and varies widely.
2. *Nature of the solvent*. The ability of a solvent to dissolve a solute depends on the bonds of the solvent-solvent molecules and varies widely. The electrical properties of the solvent molecules determine how soluble a substance is for a particular solvent. Polar solvents, such as water, dissolve other polar covalent bonds; nonpolar solvents dissolve nonpolar solutes: "Like dissolves like."
3. *Temperature*. The solubility of most solids increases with increased temperature. However, the solubility of gases varies inversely with temperature.
4. *Pressure*. The solubility of solids and liquids is not greatly affected by pressure. However, the solubility of gases in liquids varies directly with pressure.
5. *Concentration.* The concentration of a solute or available solvent affects how much of the substance goes into solution.

The effects of temperature and pressure on the solubility of gases are important. More gas dissolves in a liquid at lower temperatures. As the temperature of a liquid increases, gas dissolved in that liquid comes out of solution. Henry's law describes the effect of pressure on solubility of a gas in a liquid. At a given temperature, the volume of a gas that dissolves in a liquid is proportional to the solubility coefficient of the gas and the partial pressure of gas to which the liquid is exposed. O_2 and CO_2 transport can change significantly with changes in body temperature or atmospheric pressure (see Chapter 6).

Concentration of Solutions

The term *concentration* refers to the amount of solute dissolved into the solvent. Concentration can be described either qualitatively or quantitatively. Calling something a **dilute solution** is an example of a qualitative description. Stating that a specific container holds 50 ml of 0.4 molar solution of sodium hydroxide is a quantitative description (Figure 13-2, *A*). **Saturated solutions** occur when the solvent has dissociated the maximal amount of solute into itself. Additional solute added to a saturated solution does not dissociate into solution but remains at the bottom of the container (see Figure 13-2, *B*). Solute particles precipitate into the solid state at the same rate at which other particles go into solution. This equilibrium characterizes a saturated solution.

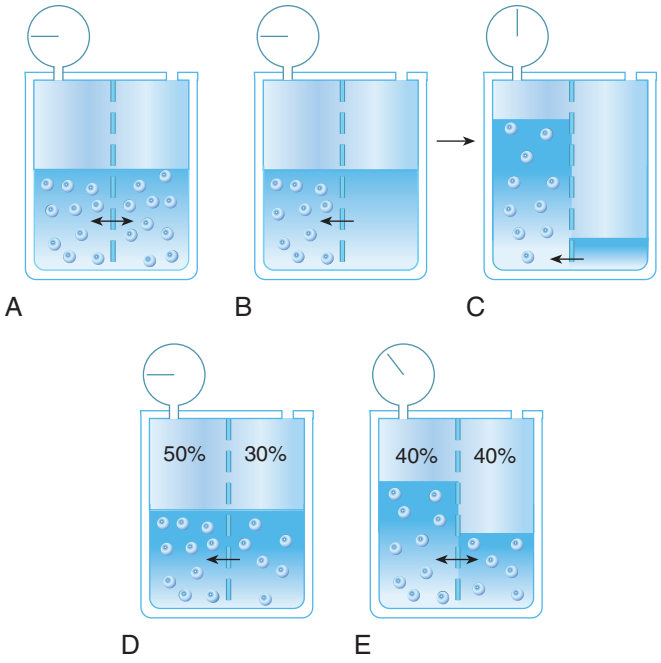

FIGURE 13-2 Osmotic pressure is illustrated by the solutions in the five containers. Each container is divided into two compartments by a semipermeable membrane, which permits passage of solvent molecules but not solute *(circles).* The number of solute particles represents relative concentrations of the solutions. Solute particles are fixed in number and are confined by the membranes. Volume changes are a function of the diffusible solvent. Solvent movement is indicated by *arrows* through the membranes. Container **A** shows a state of equilibrium, in which solute and solvent are equally distributed on either side of the membrane. Containers **B** and **C** show diffusion of solvent through the membrane as a result of solvent on only one side of the membrane and the resulting pressure change (osmotic pressure indicated by the gauge). Containers **D** and **E** show what happens when different concentrations exist on either side of a semipermeable membrane. Solvent moves from the lower concentration toward the higher concentration to establish an equilibrium because of osmotic pressure.

A solution is characterized as being *supersaturated* when the solvent contains more solute than a saturated solution at the same temperature and pressure. If a saturated solution is heated, the solute equilibrium is disturbed and more solute goes into solution. This is because of the space between the solvent molecules increases. If undissolved solute is removed and the solution is cooled gently, there is an excess of dissolved solute (see Figure 13-2, *C*). The excess solute of supersaturated solutions may be precipitated out if the solution is vibrated or if a "seed crystal" is introduced.

Starling Forces

Ernest Starling, a nineteenth-century British physiologist studied fluid transport across membranes. He described that the

driving force for fluid filtration across the wall of the capillary is determined by four separate pressures: hydraulic (hydrostatic) and colloid osmotic pressure both within the vessel and in the tissue space.[2] This process can be described mathematically using the following equation:

$$Jv = Lp\,[Pc - Pi - s\,(pc - pi)]$$

where:

J_v = Fluid filtration flux across the capillary wall per unit area
L_p = Permeability of the capillary wall
s = Oncotic reflection coefficient
P_c, P_i, p_c, p_i = Global values for the hydrostatic and colloid osmotic pressures in the capillary and interstitial compartments

Osmotic Pressure of Solutions

Most of the solutions of physiologic importance in the body are dilute. Solutes in dilute solution resemble gases. This behavior results from the relatively large distances between the molecules of solute in dilute solutions. The most important physiologic characteristic of solutions is their ability to exert pressure.

Osmotic pressure (oncotic pressure)[3] is the force produced by solvent particles under certain conditions. A membrane that permits passage of solvent molecules but not solute is called a *semipermeable membrane*. If such a membrane divides a solution into two compartments, molecules of solvent can pass (diffuse) through it from one side to the other (Figure 13-3, *A*). The number of solvent molecules diffusing in one direction must equal the number of solute molecules passing in the opposite direction. An equal ratio of solute to solvent particles (i.e., the concentration of the solution) is maintained on both sides of the membrane. A capillary wall is an example of a semipermeable membrane.[4,5]

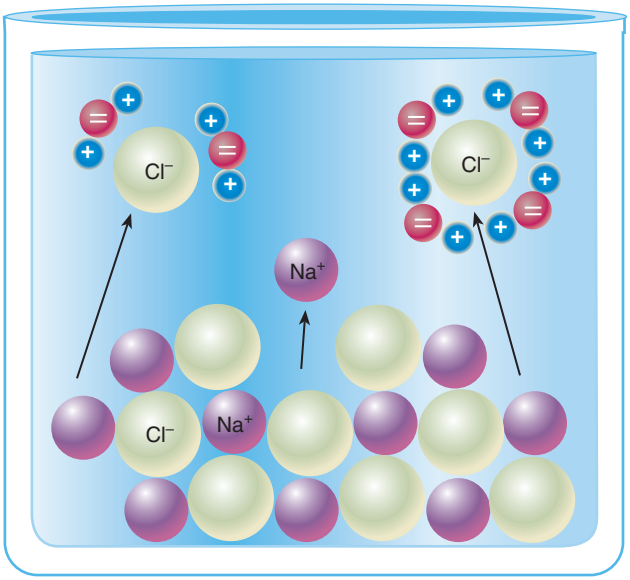

FIGURE 13-3 Sodium chloride (NaCl) is shown as a crystalline mass of ions being dissociated by the attraction of water dipoles.

If a solution is placed on one side of a semipermeable membrane and pure solvent is placed on the other, solvent molecules move through the membrane into the solution. The force driving solvent molecules through the membrane is called *osmotic pressure*. Osmotic pressure tries to redistribute solvent molecules so that the same concentration exists on both sides of the membrane. Osmotic pressure may be measured by connecting a manometer to the expanding column of the solution (see Figure 13-3, *B* and *C*).

Osmotic pressure also can be visualized as an attractive force of solute particles in a concentrated solution. If 100 ml of a 50% solution is placed on one side of a membrane and 100 ml of a 30% solution is placed on the other side, solvent molecules move from the dilute to the concentrated side (see Figure 13-3, *D* and *E*). The particles in the concentrated solution attract solvent molecules from the dilute solution until equilibrium occurs. Equilibrium exists when the concentrations (i.e., ratio of solute to solvent) in the two compartments are equal (40% in Figure 13-3).

Osmolality is defined as the ratio of solute to solvent. In physiology, the solvent is water.[1,4,6] Osmotic pressure depends on the number of particles in solution but not on their charge or identity. A 2% solution has twice the osmotic pressure of a 1% solution under similar conditions. For a given amount of solute, osmotic pressure is inversely proportional to the volume of solvent. Most cell walls are semipermeable membranes. Through osmotic pressure, water is distributed throughout the body within certain physiologic ranges. Tonicity is the relative concentration of solutions that determine the direction and extent of diffusion. Tonicity is a way of describing the response of cells immersed in an external solution. Tonicity is influenced by the concentration of solutes that cannot cross the membrane. Average body cellular fluid has a tonicity equal to a 0.9% solution of sodium chloride (sometimes referred to as *physiologic* or *normal saline*). Solutions with similar tonicity are called **isotonic.** Compared to body fluid, solutions with more tonicity (more oncotic pressure and higher concentration as a result of less water) are **hypertonic,** and solutions with less tonicity (less oncotic pressure and lower concentration as a result of more water) are **hypotonic.** For example, a hypotonic solution has a lower concentration of solutes outside the cell than inside the cell. In an attempt to balance the concentrations of solutes inside and outside the cell, water will move into the cell, causing it to enlarge. Pressure increases inside the cell to counteract osmotic pressure. This pressure is called *turgor*. Some cells have selective permeability, allowing passage not only of water but also of specific solutes. Through these mechanisms, nutrients and physiologic solutions are distributed throughout the body.

Quantifying Solute Content and Activity

The amount of solute in a solution can be quantified in two ways: (1) by actual weight (grams or milligrams) and (2) by chemical combining power *(electronegativity)*. The weight of a solute is easy to measure and specify. However, it does not indicate chemical combining power. The sodium ion (Na^+) has a gram ionic weight of 23. The bicarbonate ion (HCO_3^-) has a

RULE OF THUMB

Solutions that have osmotic pressures equal to the average intracellular pressure in the body are called *isotonic*. This is roughly equivalent to a saline solution (NaCl) of 0.9%. Solutions with higher osmotic pressure are called *hypertonic,* whereas solutions with lower osmotic pressure are called *hypotonic*. Administration of isotonic solutions usually causes no net change in cellular water content. Hypertonic solutions draw water out of cells. Hypotonic solutions usually cause water to be absorbed from the solution into cells.

MINI CLINI

Sputum Induction and Hypertonic Saline

PROBLEM: To obtain samples of respiratory secretions, aerosol therapy is sometimes used to increase the volume of secretions and promote coughing to recover sputum or cells or both from the respiratory tract. Sputum induction combines the effect of hypertonic aerosols on the lining of the respiratory tract and with the normal cough reflex.

DISCUSSION: Sputum induction is usually performed by having the patient inhale a sterile hypertonic saline solution. Isotonic saline is approximately 0.9% (i.e., normal saline); concentrations greater than 0.9% are considered hypertonic. In clinical practice, concentrations of 3% to 10% have been used. When the particles of hypertonic saline are deposited in the airway, osmotic pressure is thought to play a key role. When hypertonic saline comes into contact with the respiratory mucosa, water moves from the cells lining the airway into the sol-gel matrix that lines the airways, increasing its volume. The combination of increased volume of respiratory secretions with irritation of the epithelial cells themselves promotes reflex coughing. The volume of sputum and the rate of clearance from the lungs seem to depend on the osmolarity of the inhaled aerosol. Exposure of mast cells normally present in the airways to hypertonic aerosols results in the release of mediators (e.g., histamine) and bronchospasm. These effects may be related to the stimulation of the cough reflex. For the same reason, hypertonic saline is also sometimes used for bronchial challenge testing.

gram ionic weight of 61. Both ions have equal electronegativities (+1 for Na^+, −1 for HCO_3^-). The number of chemically reactive units is usually more meaningful than their weight.

Equivalent Weights

In medicine, it is customary to refer to physiologic substances in terms of chemical combining power. The measure commonly used is **equivalent weight.** Equivalent weights are amounts of substances that have equal chemical combining power. For example, if chemical *A* reacts with chemical *B,* by definition, 1 equivalent weight of *A* reacts with exactly 1 equivalent weight of *B*. No excess reactants of *A* or *B* remain.

Two magnitudes of equivalent weights are used to calculate chemical combining power: gram equivalent weight (gEq) and milligram equivalent weight, or milliequivalent (mEq). One milliequivalent (1 mEq) is $\frac{1}{1000}$ of 1 gEq.

Gram Equivalent Weight Values. A gram equivalent weight of a substance is calculated as its gram molecular (formula) weight divided by its valence. *Valence* refers to the number of electrons that need to be added or removed to make the substance electrically neutral. The valence signs (+ or −) are disregarded.

$$\text{gEq} = \text{Gram molecular weight}/\text{Valence}$$

The gram equivalent weight of N^+, with a valence of 1, equals its gram atomic weight of 23 g. The gram equivalent weight of calcium (Ca^{++}) is its atomic weight (i.e., 40) divided by 2, or 20 g. The gram equivalent weight of ferric iron (Fe^{+++}) is its atomic weight (i.e., 55.8) divided by 3, or approximately 18.6 g.

For radicals such as sulfate (SO_4^{2-}), the formula for sulfuric acid (H_2SO_4) shows that one SO_4^{2-} group combines with two atoms of H_2. Half (0.5) of a mole of SO_4^{2-} is equivalent to 1 mole of H atoms. The gram equivalent weight of SO_4^{2-} is half its gram formula weight, or 48 g. If an element has more than one valence, the valence must be specified or must be apparent from the observed chemical combining properties.

Gram Equivalent Weight of an Acid. The gram equivalent weight of an acid is the weight of the acid (in grams) that contains 1 mole of replaceable H. The gram equivalent weight of an acid may be calculated by dividing its gram formula weight by the number of H^+ atoms in its formula, as shown in the following reaction:

$$HCl + Na^+ \rightarrow NaCl + H^+$$

The single H^+ of hydrochloric acid (HCl) is replaced by Na^+. In 1 mole of HCl, there is 1 mole of replaceable H^+. By definition, the gram equivalent weight of HCl must be the same as its gram formula weight, or 36.5 g. The two H_2 of H_2SO_4 are both considered to be replaceable. In 1 mole of H_2SO_4, there are 2 moles of replaceable H^+, and the gram equivalent weight of H_2SO_4 is half its gram formula weight, or 48 g.

Acids in which H^+ atoms are not completely replaceable are exceptions to the rule. In some acids, H^+ replacement varies according to specific reactions. Carbonic acid (H_2CO_3) and phosphoric acid (H_3PO_4) are examples of such exceptions. Their equivalent weights are determined by the conditions of their chemical reactions.

For example, H_2CO_3 has two H^+ atoms. In physiologic reactions, only one is considered replaceable:

$$H_2CO_3 + Na^+ \rightarrow NaHCO_3 + H^+$$

Only one H^+ atom is released; the other remains bound. In 1 mole of H_2CO_3, there is only 1 mole of replaceable H^+. The gram equivalent weight of H_2CO_3 is the same as its gram formula weight, or 61 g.

Gram Equivalent Weight of a Base. The equivalent weight of a base is its weight (grams) containing 1 mole of replaceable hydroxyl (OH^-) ions. Similar to acids, the gram equivalent weight of bases is calculated by dividing gram formula weight by the number of OH^- groups in its formula.

Conversion of Gram Weight to Equivalent Weight. To determine the number of gram equivalent weights in a substance, the gram weight is divided by its calculated equivalent weight, as shown in the following example:

$$58.5 \text{ g NaCl/gEq } 58.5 \text{ g} = 1 \text{ gEq}$$
$$29.25 \text{ g NaCl/gEq } 58.5 = 0.5 \text{ gEq}$$

Milligram Equivalent Weights. The concentrations of most chemicals in the body are quite small. The term *milligram equivalent weight (milliequivalent)* is preferred for expressing these minute values; 1 mEq is simply 0.001 gEq:

$$\text{mEq} = \text{gEq}/1000$$

The normal concentration of potassium in plasma ranges from 0.0035 to 0.005 gEq/L. These values may be converted to milliequivalents by multiplying by a factor of 1000. The normal concentration of K^+ in the plasma would be expressed as ranging from 3.5 to 5.0 mEq/L.

Solute Content by Weight

The measurement of many electrolytes is based on actual weight rather than on milliequivalents. This weight is often expressed as milligrams per 100 ml of blood or body fluid. The units for this measurement are abbreviated as mg% (milligram percent) or mg/dl (milligrams per deciliter). This text uses the modern designation *mg/dL*. Some substances present in blood or body fluid are present in extremely small amounts and are expressed in *micrograms* ($\frac{1}{1000}$ of a milligram) per deciliter (µg/dl or mcg/dl).

Values stated in milligrams per deciliter may be converted into their corresponding equivalent weights and reported as milliequivalents per liter. Conversion between mEq/L and mg/dl may be calculated as follows:

(1) $$\text{mEq/L} = \frac{\text{mg/dl} \times 10}{\text{Equivalent weight}}$$

(2) $$\text{mEq/L} = \frac{\text{mEq/L} \times \text{Equivalent weight}}{10}$$

To convert a serum Na^+ value of 322 mg/dl to mEq/L, the equation is used as follows:

$$\text{mEq/L} = \text{mg/dl} \times 10/\text{Equivalent weight}$$
$$= 322 \times 10/23$$
$$= 140 \text{ mEq/L}$$

In clinical practice, electrolyte replacement is common when a laboratory test identifies a significant deficiency. The electrolyte content of intravenous solutions is usually stated in milligrams per deciliter or in milliequivalents per liter. Lactated Ringer's solution is one such infusion used for electrolyte replacement (Table 13-2).

Calculating Solute Content

In addition to gEq, mEq, mg/dl, and µg/dl (mcg/dl), several other methods of calculating solute content exist. These common chemical standards are used to compute solute content and dilution of solutions.

TABLE 13-2

Concentration of Ingredients in Lactated Ringer's Solution

Substance	mg/dl	Approximate mEq/L
NaCl (sodium chloride)	600 Na	130
	310 Cl	109
$NaC_3H_5O_3$ (sodium lactate)	30 $C_3H_5O_3$	28
KCl (potassium chloride)	30 K	4
$CaCl_2$ (calcium chloride)	20 Ca	27

Quantitative Classification of Solutions

The amount of solute in a solution may be quantified by the following six methods:

1. *Ratio solution*. The amount of solute to solvent is expressed as a proportion (e.g., 1:100). Ratio solutions are sometimes used in describing concentrations of drugs.
2. *Weight-per-volume (W/V) solution*. The W/V solution is commonly used for solids dissolved in liquids. It is defined as weight of solute per volume of solution. This method is sometimes erroneously described as a percent solution. W/V solutions are commonly expressed in grams of solute per 100 ml of solution. For example, 5 g of glucose dissolved in 100 ml of solution is properly called a *5% solution,* according to the W/V scheme. A liquid dissolved in a liquid is measured as volumes of solute to volumes of solution.
3. *Percent solution*. A percent solution is weight of solute per weight of solution. For example, 5 g of glucose dissolved in 95 g of water is a true percent solution. The glucose is 5% of the total solution weight of 100 g.
4. *Molal solution*. A molal solution contains 1 mole of solute per kilogram of solvent, or 1 mmol/g solvent. The concentration of a molal solution is independent of temperature.
5. *Molar solution*. A molar solution has 1 mole of solute per liter of solution, or 1 mmol/ml of solution. The solute is measured into a container, and solvent is added to produce the solution volume desired.
6. *Normal solution*. A **normal solution** has 1 gEq of solute per liter of solution, or 1 mEq/ml of solution. For all monovalent solutes, normal and molar solutions are the same. The equivalent weights of their solutes equal their gram formula weights. Equal volumes of solutions of the same normality contain chemically equivalent amounts of their solutes. If the solutes react chemically with one another, equal volumes of the solutions react completely. Neither substance remains in excess. In the analytic process of titration, normal solutions are often used as standards to determine the concentrations of other solutions.

Dilution Calculations

Dilute solutions are made from a stock preparation. Preparation of medications often involves dilution. Dilution calculations are based on the weight-per-unit volume principle (the aforementioned W/V solution method).

Diluting a solution increases its volume without changing the amount of solute it contains, and this reduces the concentration of the solution. The amount of solute in a solution can be expressed as volume times concentration. For example, 50 ml of a 10% solution (10 g/dl) contains 50 × 0.1, or 5 g. In the dilution of a solution, initial volume (V_1) multiplied by initial concentration (C_1) equals final volume multiplied by final concentration. This can be expressed as follows:

$$V_1C_1 = V_2C_2$$

This equation is sometimes referred to as the **dilution equation.** Whenever three of the variables are known, the fourth can be calculated as in the following examples:

1. Diluting 10 ml of a 2% (0.02) solution to a concentration of 0.5% (0.005) requires finding the new volume (V_2) by rearranging the dilution equation as follows:

$$V_2 = V_1C_1/C_2$$
$$V_2 = 10\text{ ml} \times 0.02/0.005$$
$$V_2 = 40\text{ ml}$$

2. If 50 ml of water is added to 150 ml of a 3% (0.03) solution, the new concentration is calculated by rearranging the dilution equation to find C_2 as follows:

$$C_2 = V_1C_1/V_2$$
$$C_2 = 150\text{ ml} \times 0.02/(50\text{ ml} + 150\text{ ml})$$
$$C_2 = 0.0225 \text{ or } (2.25\%)$$

3. To dilute 50 ml of a 0.33 normal (N) solution to a 0.1 N concentration, concentration is given as normality, but it can be used similar to a percentage. The new volume (V_2) can be calculated by rearranging the dilution equation as follows:

$$V_2 = V_1C_1/C_2$$
$$V_2 = 50\text{ ml} \times 0.33/0.1$$
$$V_2 = 165\text{ ml}$$

In the last example, the volume needed to produce a 0.1 N solution would be 165 ml – 50 ml (the original volume), or 115 ml. In other words, 115 ml of solvent would have to be added to the original 50 ml of 0.33 N solution to produce the desired concentration. The added solvent is called the **diluent** because it dilutes the original concentration to a lower concentration.

ELECTROLYTIC ACTIVITY AND ACID-BASE BALANCE

Acid-base balance depends on the concentration and activity of electrolytic solutes in the body. Clinical application of acid-base homeostasis is discussed in detail in Chapter 14.

Characteristics of Acids, Bases, and Salts

Acids

The term **acid** refers to either compounds that can donate [H^+] (Brönsted-Lowry acid) or any compound that accepts an electron pair (Lewis acid). Although these two theories of acids differ in which is being transferred, both theories attempt to describe how reactive groups perform within an aqueous solution[7,8]:

$$NH_4Cl + NaOH \rightarrow NH_3 + NaCl + HOH$$

In this reaction, Na^+ and Cl^- ions are not involved in the proton transfer. The equation can be rewritten ionically as follows to show the acidity of the ammonium ion:

$$NH_4^+ + OH^- \rightarrow NH_3 + HOH$$

The ammonium ion donates a H^+ ion (proton) to the reaction. The H^+ combines with the hydroxide ion (OH^-), and this converts the former into ammonia gas and the latter into water.

Acids With Single Ionizable Hydrogen. Simple compounds such as hydrochloric acid (HCl) ionize into one cation and one anion:

$$HCl \rightarrow H^+ + Cl^-$$

Acids With Multiple Ionizable Hydrogens. The H^+ ions in an acid may become available in stages. The degree of ionization increases as an electrolyte solution becomes more dilute. Concentrated sulfuric acid ionizes only one of its two H^+ atoms per molecule, as follows:

$$H_2SO_4 \rightarrow H^+ + HSO_4^-$$

With further dilution, second-stage ionization occurs:

$$H_2SO_4 \rightarrow H^+ + H^+ + SO_4^-$$

Bases

A **base** is a compound that yields hydroxyl ions (OH^-) when placed into aqueous solution. A substance capable of inactivating acids is also considered a base. These compounds, called *hydroxides,* consist of a metal that is ionically bound to a OH^- ion or ions. The OH^- may also be bound to an ammonium cation (NH_4^+). An example of this type of base is sodium hydroxide (NaOH). The Brönsted-Lowry definition of a base is any compound that accepts a proton; bases are paired with acids that donate the proton, and these are called *conjugate pairs.* This definition includes substances other than hydroxides, such as ammonia, carbonates, and certain proteins.

Hydroxide Bases. In aqueous solution, the following are typical dissociations of hydroxide bases:

$$Na^+OH \rightarrow Na^+ + OH^-$$
$$K^+OH \rightarrow K^+ + OH^-$$
$$Ca^{++}(OH^-)2 \rightarrow Ca^{++} + 2(OH^-)$$

Inactivation of an acid is part of the definition of a base. This inactivation is accomplished by OH^- reacting with H^+ to form water:

$$NaOH + HCl \rightarrow NaCl + HOH$$

Nonhydroxide Bases. Ammonia and carbonates are examples of nonhydroxide bases. Proteins, with their amino groups, also can serve as nonhydroxide bases.

MINI CLINI

Methacholine Dilution

The dilution equation ($V_1C_1 = V_2C_2$) is commonly used to calculate volumes or concentrations of medications when a specific dosage needs to be administered to a patient. If three of the variables are known, the fourth can be determined.

PROBLEM: Methacholine is a drug used to induce airway constriction in patients suspected of having. In healthy subjects, only higher doses of methacholine cause bronchospasm. In asthmatics, very low doses can precipitate a 20% decrease in the forced expiratory volume in 1 second (FEV_1). The methacholine challenge test begins with a low dose and increases the concentration (either doubling or quadrupling) until the patient has a significant change in FEV_1 or the highest dose has been given. Methacholine is supplied in vials that contain 100 mg of the active substance to which 6.25 ml of diluent (saline) can be added to produce a concentration of 16 mg/ml. This is the highest dosage administered to the patient. How can you make serial dilutions of the drug so that five different dosages are available and each one is four times more concentrated than the previous dose?

SOLUTION: Starting with a 16 mg/ml stock solution of methacholine, how much diluent needs to be added to 3 ml of the stock to make a 4 mg/ml dose (one-fourth of the original concentration)?

Using the dilution equation:

$$C_1V_1 = C_2V_2$$
$$(16)(3.0) = (4)V_2$$
$$48/4 = V_2$$
$$12 = V_1$$

Because there was 3 ml of the stock solution to begin with, the amount of diluent to add is the difference between 12 (V_2) and 3, or 9 ml. Adding 9 ml of diluent to the original 3 ml of stock (16 mg/ml) provides 12 ml of methacholine with a concentration of 4 mg/ml, exactly one-fourth of the highest dose. Additional dilutions can be prepared using 3 ml of solution according to the following table:

Start With		To Make
3 ml of 4 mg/ml	9 ml	1 mg/ml
3 ml of 1 mg/ml	9 ml	0.25 mg/ml
3 ml of 0.25 mg/ml	9 ml	0.0625 mg/ml

Each of these dilutions uses the same proportions used in the first dilution as determined by the dilution equation. Methacholine is administered by nebulizer to the patient, starting with the lowest concentration (0.0625 mg/ml) and increasing until a change in FEV_1 is observed. (See Chapter 20 for additional information on pulmonary function testing.)

Ammonia. Ammonia qualifies as a base because it reacts with water to yield OH^-:

$$NH_3 + HOH \rightarrow NH_4^+ + OH^-$$

and neutralizes H^+ directly:

$$NH^3 + H^+ \rightarrow NH_4^+$$

In both instances, NH_3 accepts a proton to become NH_4^+. Ammonia plays an important role in renal excretion of acid (see Chapter 14).

Carbonates. The carbonate ion (CO_3^{2-}), can react with water in the following way to produce OH^-:

(1) $$Na_2CO_3 \rightleftharpoons 2Na^+ + CO_3^{2-}$$

(2) $$CO_3^{2-} + HOH \rightleftharpoons HCO_3^- + OH^-$$

In this reaction, CO_3^{2-} accepts a proton from water, becoming the HCO_3^- ion. It simultaneously produces a hydroxide ion. The CO_3^{2-} ion also can react directly with H^+ to inactivate it:

$$CO_3^{2-} + H^+ \rightleftharpoons HCO_3^-$$

Protein Bases. Proteins are composed of amino acids bound together by peptide links. Physiologic reactions in the body occur in a mildly alkaline environment. This environment allows proteins to act as H^+ receptors, or bases. Cellular and blood proteins acting as bases are transcribed as $prot^-$.

The imidazole group of the amino acid histidine is an example of an H^+ acceptor on a protein molecule (Figure 13-4). The ability of proteins to accept H^+ ions limits H^+ activity in solution, which is called **buffering.** The buffering effect of hemoglobin (Hb) is produced by imidazole groups in the protein. Each Hb molecule contains 38 histidine residues. Each O_2-carrying component (heme group) of Hb is attached to a histidine residue. The ability of Hb to accept (i.e., buffer) H^+ ions depends on its oxygenation state. Deoxygenated (reduced) Hb is a stronger base (i.e., a better H^+ acceptor) than oxygenated Hb. This difference partially accounts for the ability of reduced Hb to buffer more acid than oxygenated Hb can (see Chapter 14). Plasma proteins also act as buffers, although with less buffering power than Hb, which contains more histidine.

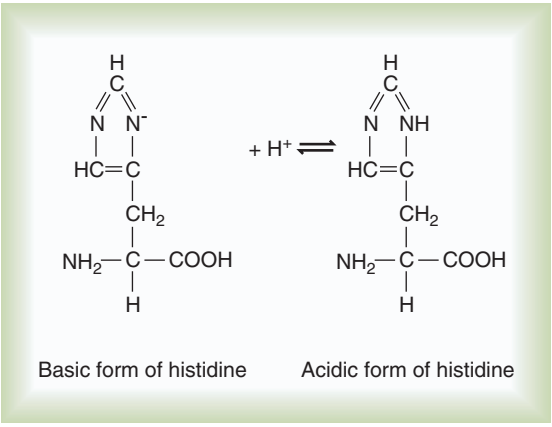

FIGURE 13-4 Histidine portion of a protein molecule (at *top*) serving as a proton acceptor (base).

Designation of Acidity and Alkalinity

Pure water can be used as a reference point for determining acidity or alkalinity. The concentration of both H^+ and OH^- in pure water is 10^{-7} mol/L. A solution that has a greater H^+ concentration or lower OH^- concentration than water acts as an acid. A solution that has a lower H^+ concentration or a greater OH^- concentration than water is alkaline, or basic.

The H^+ concentration $[H^+]$ of pure water has been adopted as the standard for comparing reactions of other solutions. Electrochemical techniques are used to measure the $[H^+]$ of unknown solutions. Acidity or alkalinity is determined by variation of the $[H^+]$ greater than or less than 1×10^{-7}. For example, a solution with a $[H^+]$ of 89.2×10^{-4} has a higher $[H^+]$ than water and is acidic. A solution with a $[H^+]$ of 3.6×10^{-8} has fewer H^+ ions than water and is by definition alkaline. Two related techniques are used for expressing the acidity or alkalinity of solutions using the $[H^+]$ of water (i.e., 10^{-7}) as a neutral factor: (1) the $[H^+]$ in nanomoles per liter and (2) the logarithmic pH scale.

Nanomolar Concentrations

The acidity or alkalinity of solutions may be reported using the molar concentration of H^+ compared with that of water. The $[H^+]$ of water is 1×10^{-7} mol/L, or 0.0000001 (one ten-millionth of a mole). The unit for one-billionth of a mole is a **nanomole** (nmol). The $[H^+]$ of water can be expressed as 100 nmol/L. A solution that has a $[H^+]$ of 100 nmol/L is neutral. A solution with an $[H^+]$ greater than 100 nmol/L is acidic; one with an $[H^+]$ less than 100 nmol/L is alkaline. This system is limited because of the wide range of possible $[H^+]$ but is applicable in clinical medicine because the physiologic range of $[H^+]$ is narrow. $[H^+]$ in healthy individuals is usually 30 to 50 nmol/L.

pH Scale

The pH scale is used to describe the concentration of H^+, ($[H^+]$), (i.e., Brönsted-Lowry acid) in a solution. Rather than expressing the $[H^+]$ in nanomoles, it is more convenient to describe it in terms of the negative logarithm of the nanomolar $[H^+]$. The equation for calculating pH is:

$$pH = -\log[H^+]$$

The pH of pure water is 7.0: The $[H^+]$ of water is 1×10^{-7} mol/L. The logarithm of 1×10^{-7} is -7, so the negative logarithm of 1×10^{-7} is 7.

Using this scheme, in a solution with a pH of 7.00, the $[H^+]$ is the same as would be seen in pure water, so by convention this is called "neutral." As the pH decreases below 7.00, the solution is termed *acidic*. When the pH increases above 7.00, the solution is considered to be *basic*. With a whole number change in pH (i.e., pH decreasing from 7.00 to 6.00), the $[H^+]$ is a factor of 10 less. With a pH increase from 7.00 to 8.00, the $[H^+]$ is 10 times greater (Figure 13-5). A pH of 7.00 is equivalent to a $[H^+]$ of 100 nmol. A pH of 8.00 is equivalent to a $[H^+]$ concentration of 10 nmol. Similarly, a change in pH of 0.3 units equals a twofold change in $[H^+]$.

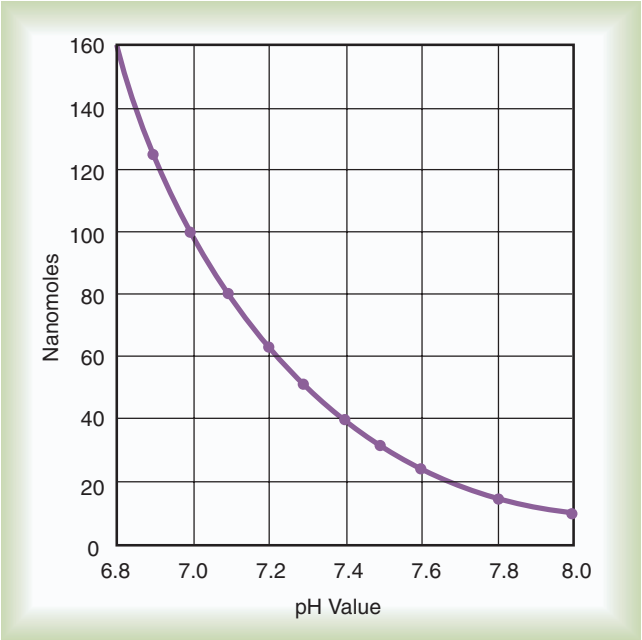

FIGURE 13-5 Relationship between pH scale and $[H^+]$ concentrations in nanomoles per liter (nmol/L). pH of 7.00 equals 100 nmol/L H^+, whereas the normal human pH (arterial blood) of 7.40 is equal to about 40 nmol/L.

Applying these concepts in an example pertinent to clinical medicine yields the following:

$$\begin{aligned}[H^+]\text{ in blood} &= 4.0\times10^{-8}\text{ mol/L}\\ pH &= -\log(4.0\times10^{-8})\\ &= -\log 4.0 + -\log 10^{-8}\\ &= -\log 4.0 + \log 10^{8}\\ &= -0.602 + 8\\ &= 7.40\end{aligned}$$

In this example, the $[H^+]$ in arterial blood of a healthy adult is approximately 4.0×10^{-8} mol/L, or 40 nmol/L.

RULE OF THUMB

The pH scale is logarithmic. pH is a positive number representing the negative log of the hydrogen ion concentration $[H^+]$ of a solution. To visualize changes in acidity or alkalinity, the following two rules are helpful:

1. A pH change of 0.3 unit equals a 2-fold change in $[H^+]$.
2. A pH change of 1 unit equals a 10-fold change in $[H^+]$.

For example, if a patient's blood pH decreased from 7.40 (normal) to 7.10, the $[H^+]$ concentration would be twice as high. If a patient's urine pH decreased from 7.00 to 6.00, the $[H^+]$ would have increased by 10 times.

BODY FLUIDS AND ELECTROLYTES

Body Water

Water constitutes 45% to 80% of an individual's body mass, depending on the mass, gender, and age of the individual. Obese individuals have a lower percentage of body water (≤30% less) than normal-weight individuals. Men have a slightly higher percentage of total-body water than women. Total percentage of body water in infants and children is substantially greater, with water accounting for 80% of a newborn's total-body weight (Table 13-3).

Distribution

Body water is divided into the following two major compartments: (1) *intracellular* ("within the cells") and (2) *extracellular* ("outside the cells"). Intracellular water accounts for approximately two-thirds of the total-body water, and extracellular water accounts for the remaining one-third. Extracellular water is found in three sub-compartments: (1) intravascular water (plasma), (2) interstitial water, and (3) transcellular fluid. Intravascular water constitutes approximately 5% of the body weight. Interstitial water is water in the tissues between the cells. It constitutes approximately 15% of the body weight. The proportion of *transcellular fluid* is quite small in proportion to plasma and **interstitial fluid.** Interstitial fluid is a matrix—a collagen/gel substance that allows the interstitium to provide structural support during times of extracellular volume depletion.[10] Examples of transcellular fluid include cerebrospinal fluid, digestive juices, and mucus. Transcellular fluid can become an important third space in some pathologic conditions, such as *ascites* (excess fluid in the peritoneal cavity) or *pleural effusion* (fluid collection in the pleural space).

Composition

The concentration of ionic solutes in intracellular and extracellular fluids differs significantly. Sodium (Na^+), chloride (Cl^-), and bicarbonate (HCO_3^-) are predominantly extracellular electrolytes. Potassium (K^+), magnesium (Mg^{++}), phosphate (PO_4^{3-}), sulfate (SO_4^{2-}), and protein constitute the main intracellular electrolytes. Although protein does not dissociate ionically, it can create H^+ and other weak bonds and distribute net extra charge within its molecule. Intravascular and interstitial fluids have similar electrolyte compositions. Plasma contains substantially more protein than interstitial fluid. Proteins, chiefly albumin, account for the high osmotic pressure of plasma. Osmotic pressure is an important determinant of fluid distribution between vascular and interstitial compartments.

TABLE 13-3
Distribution of Body Fluids

Body Water	Man (% Body Weight)	Woman (% Body Weight)	Infant (% Body Weight)
Total body Water	60 ± 15	50 ± 15	80
Intracellular	45	40	50
Extracellular	15-20	15-20	30
Interstitial	11-15	11-15	24
Intravascular	4.5	4.5	5.0
Transcellular	<1	<1	<1

Regulation

As discussed, movement of certain ions and proteins between body compartments is restricted yet water diffuses freely. Control of total-body water occurs through regulation of water intake (thirst) and water excretion (urine production, insensible loss, and stool water). The kidneys are mainly responsible for water excretion. If water intake is low, the kidneys reduce urine volume. Solutes in the urine can be concentrated up to four times the concentration of solutes in the plasma. If water intake is high, the kidneys can excrete large volumes of dilute urine.

The kidneys maintain the volume and composition of body fluids via two related mechanisms. First, filtration and reabsorption of Na^+ adjust urinary Na^+ excretion to match changes in dietary intake. Second, water excretion is regulated by osmoreceptors that are located in the hypothalamus and modulate secretion of antidiuretic hormone (ADH, also known as *vasopressin*).[6,11,12] These receptors are exceptionally sensitive; in vivo studies have shown that a single neuron can respond to either an osmotic or a nonosmotic baroreceptor simulus.[12] These mechanisms allow the kidneys to maintain the volume and concentration of body fluid despite variations in salt and water intake. Analysis of the urine (urinalysis) often provides diagnostic clues in disorders of body fluid volume.

Water Losses. Water may be lost from the body through the skin, lungs, kidneys, and gastrointestinal (GI) tract. Water loss can be *insensible,* such as evaporation of water from the skin and lungs, or *sensible,* such as losses from urine and the GI tract (Table 13-4).[13] Fluid losses from the body also may occur during vomiting, diarrhea, or suctioning from the stomach. Fever, in conjunction with sweating, also can cause significant losses.

The GI tract manufactures 8 to 10 L of fluid per day. More than 98% of this volume is reclaimed in the large intestine. In

TABLE 13-4
Daily Water Exchange

Regulation	Average Daily Volume (ml)	Maximum Daily Volume
Water Losses		
Insensible		
Skin	700	1500 ml
Lung	200	
Sensible		
Urine	1000-1200	>2000 ml/hr
Intestinal	200	8000 ml
Sweat	0	>2000 ml/hr
Water Gain		
Ingestion		
Fluids	1500-2000	1500 ml/hr
Solids	500-600	1500 ml/hr
Body metabolism	250	1000 ml

patients who are vomiting or have diarrhea, water losses through the GI tract can be considerable. Individuals with severe burns or open wounds can lose large quantities of water.

Other causes of abnormal fluid loss include certain renal and respiratory disorders. Patients with renal disease may have to excrete larger quantities of urine to get rid of extra nitrogenous wastes. Patients with increased ventilation also have increased water losses through increased evaporation from the respiratory tract. Patients with artificial airways are prone to evaporative water loss if inspired air is not adequately humidified. Infants have a greater proportion of body water than adults, particularly in the extracellular compartments (see Table 13-3). Water loss in infants may be twice the water loss in adults. Infants also have a greater body surface area (in proportion to body volume) than adults, making their basal heat production twice as high. Higher metabolic rates in infants necessitate greater urinary excretion. Infants turn over approximately half of their extracellular fluid volume daily versus one-seventh for adults. Fluid loss or lack of intake can rapidly deplete an infant of water.

Water Replacement. Water is replenished in two major ways: ingestion and metabolism (see Table 13-4).

Ingestion. Water is replaced mainly by ingestion, through the consumption of liquids. An average adult drinks 1500 to 2000 ml of water per day. An additional 500 to 600 ml of water is ingested from solid food.

Metabolism. Water also is gained from the oxidation of fats, carbohydrates, and proteins in the body; the destruction of cells also releases some water. During total starvation, 2000 ml of water can be produced daily by the metabolism of 1 kg of fat. Recovery after surgery or trauma may be similar to starvation; under such conditions, approximately 500 mg of protein and a similar amount of fat are metabolized. This metabolism yields approximately 1 L of water per day.

Transport Between Compartments

Homeostasis depends largely on the total volume of body fluids and on fluid transport between body compartments. The first stage of homeostasis is fluid exchange between systemic capillaries and interstitial fluid via passive diffusion. Capillary walls are permeable to crystalline electrolytes. This allows equilibrium between the two extracellular compartments to occur quickly. Except for the large protein molecules, plasma also can move through capillary walls into the tissue spaces. Because water and small molecules can cross the capillary membranes, they produce little or no osmotic effect.

Movement of fluid and solutes from capillary blood to interstitial spaces is enhanced by the difference in **hydrostatic pressure** (pressure exerted by a liquid at rest with respect to adjacent bodies) between compartments. Hydrostatic pressure difference depends on blood pressure, blood volume, and the vertical distance of the capillary from the heart (i.e., the effects of gravity). Hydrostatic pressure tends to cause fluid to leak out of capillaries into the interstitial spaces.

Osmotic pressure differences between interstitial and intravascular compartments oppose hydrostatic pressure; that is, osmotic pressure tends to keep fluid in the capillaries. Proteins with molecular weights greater than approximately 70,000 in colloidal suspension in the plasma cause this difference in osmotic pressure. Proteins such as albumin are too large to pass through the pores of the capillary. Instead, these proteins remain in the intravascular compartment and exert osmotic pressure, which draws water and small solute molecules back into the capillaries; this is called **plasma colloid osmotic pressure (oncotic pressure).** Because these large proteins are negatively charged, they attract (but do not bind) an equivalent amount of cations to the intravascular compartment. These cations have the effect of increasing osmotic pressure within the capillary *(Donnan effect)*.

In a typical capillary, blood pressure is approximately 30 mm Hg at the arterial end and approximately 20 mm Hg at the venous end (Figure 13-6). Colloid osmotic pressure of the intravascular fluid remains constant at approximately 25 mm Hg. Hydrostatic pressure along the capillary continually decreases. At the arterial end, hydrostatic pressure normally exceeds osmotic pressure, and water flows out of the vascular space into the interstitial space. At the venous end, colloidal osmotic pressure exceeds hydrostatic forces. Water is pulled back into the vascular compartment.

The outflow of water and electrolytes from the capillary at the arterial end is not completely balanced by the return on the venous end. Slightly more water diffuses out than is reabsorbed. This slight outward excess is balanced by fluid return through the lymphatic circulation (see Chapter 9). Fluid return via lymphatic channels also depends on pressure differences. The pressure in the interstitial space is determined by the volume of interstitial fluid and its electrolyte content. Interstitial fluid moves from a region of higher pressure (interstitial space) to a region of lower pressure (lymphatic channels). This lymph fluid moves into larger lymphatic spaces, where the pressure is continuously decreasing.

Three examples of the forces in Starling's equation are fluid return from gravity-dependent areas of the body, fluid exchange in the lung, and tissue edema.

Because of hydrostatic effects, capillary pressure in the feet can reach 100 mm Hg when an individual is standing. Reabsorption of tissue fluid can be accomplished, although hydrostatic pressure greatly exceeds colloidal osmotic pressure. Three factors favor reabsorption under these circumstances:

1. High intravascular hydrostatic pressure is balanced by a proportionally greater interstitial pressure.
2. The "pumping" action of the skeletal muscles surrounding leg veins reduces venous pressures.
3. Lymph flow back to the thorax is enhanced via a similar mechanism; this facilitates clearance of excess interstitial fluid.

However, when an imbalance results from changes in the basic pressures (e.g., arterial hypertension), edema tends to occur in the dependent limbs.

The lungs present a different situation. In systemic tissues, a constant exchange of interstitial fluid is essential. In the lungs, the alveoli must be kept relatively dry. Otherwise, interstitial

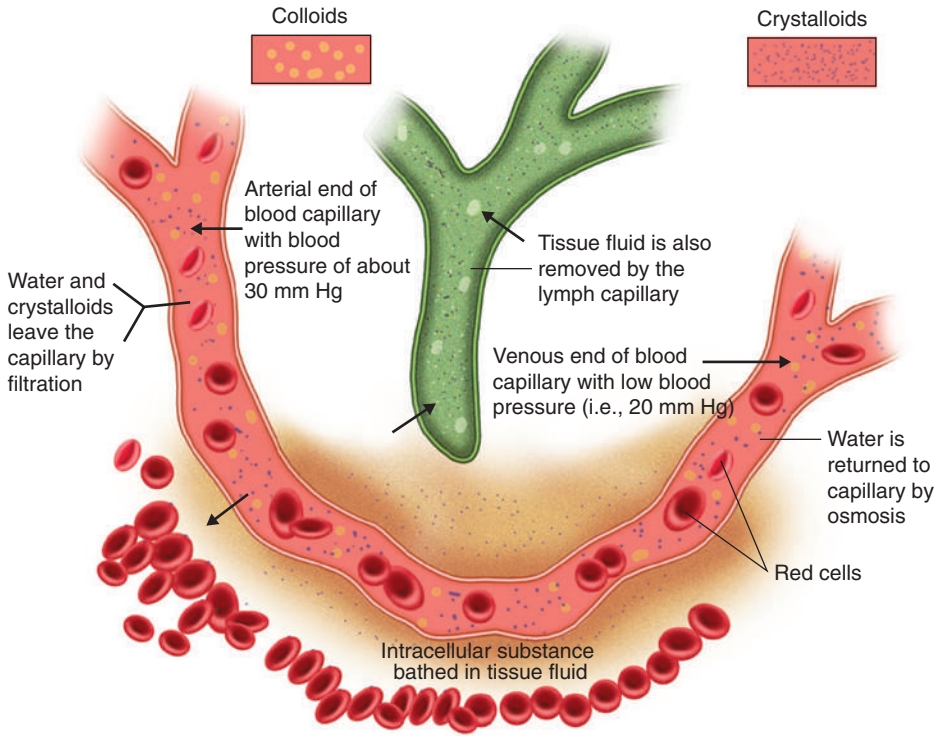

FIGURE 13-6 Tissue fluid is formed by a process of filtration at the arterial end of a systemic capillary *(left),* in which blood pressure exceeds colloid osmotic pressure. The fluid is absorbed by the blood capillaries and lymphatic vessels. It returns to the venous end of the capillary *(right)* when colloid osmotic pressure exceeds blood pressure. Fluid is absorbed into the lymphatic capillary system when interstitial fluid pressure is greater than the pressure within the lymphatic capillary. Normally, little colloid escapes from the capillary. Colloid that does escape is returned to the blood circulation by the lymphatic vessels. (Modified from Burke SR: The composition and function of body fluids, ed 3, St Louis, 1980, Mosby.)

fluid in the alveolar-capillary spaces would impede the diffusion of gas. Colloid osmotic pressure in pulmonary blood vessels is the same as it is in the systemic circulation. To minimize interstitial fluid in the alveolar-capillary region, the hydrostatic pressure difference must be kept low. The pulmonary circulation is a low-pressure system. The mean pulmonary vascular pressures are approximately one-sixth of those in the systemic circulation. Colloid osmotic pressure exceeds hydrostatic forces across the entire length of the pulmonary capillaries in healthy individuals. The alveoli are relatively free of excess interstitial water.

If hydrostatic pressure increases in the pulmonary circulation, this balance can be upset. This causes fluid movement into the alveolar-capillary spaces. Excess fluid in the interstitial space is called *edema*. In the lungs, edema caused by increased hydrostatic pressure often is a result of backpressure from a failing left ventricle (e.g., in congestive heart failure).

Edema can be caused by other factors. The **Starling equilibrium** equation given earlier shows that edema can be caused by a decrease in colloid osmotic pressure or an increase in capillary permeability. If albumin is depleted in the blood, the balance of forces is upset, favoring increased movement of fluid into the interstitium. Likewise, an increase in capillary permeability results in more fluid leaving the capillaries. Increased capillary permeability is a major factor in certain types of acute lung injuries (see Chapter 29).[14]

Electrolytes

Electrolytes in the various body fluids are not passive solutes. Electrolytes maintain the internal environment while making possible essential chemical and physiologic events. There are seven major electrolytes: sodium, chloride, bicarbonate, potassium, calcium, magnesium, and phosphorus (phosphate).

Sodium (Na^+)

Na^+ is the major circulating cation within the body.[15] Regulation of Na^+ concentration in plasma and urine is related to regulation of total-body water. Of the total-body stores of Na^+, 50% is extracellular. The remaining Na^+ is found in bone (40%) and in cells (10%). The normal serum concentration of Na^+ is 136 to 145 mEq/L. In cells, the Na^+ concentration is much lower, averaging only 4.5 mEq/L.

The average adult ingests and excretes approximately 100 mEq of Na^+ every 24 hours. Children require approximately half this amount, and infants typically exchange 20 mEq of Na^+ per day. Most Na^+ is reabsorbed through the kidney. Approximately 80% of the Na^+ in the body is reclaimed passively in the proximal tubules. The remainder is actively reabsorbed in the distal tubules. Na^+ reabsorption in the kidneys is governed mainly by the level of aldosterone, which is secreted by the adrenal cortex. Na^+ reabsorption in the distal tubules of the

TABLE 13-5

Electrolyte Disorders and Clinical Findings

Electrolyte	Imbalance	Causes	Symptoms
Sodium (Na^+)	Hyponatremia	GI loss, sweating, fever, diuretics, ascites, congestive heart failure, kidney failure	Weakness, lassitude, apathy, headache, orthostatic hypotension, tachycardia
	Hypernatremia	Net sodium gain, net water loss, increased aldosterone, steroid therapy	Tremulousness, irritability, ataxia, confusion, seizures, coma
Chloride (Cl^-)	Hypochloremia	GI loss, diuretics	Metabolic alkalosis, muscle spasm, coma (severe cases)
	Hyperchloremia	Dehydration, metabolic acidosis, respiratory alkalosis	(Minimal)
Potassium (K^+)	Hypokalemia	Diuretics, steroid therapy, renal tubular disease, vomiting, diarrhea, malnutrition, trauma	Muscle weakness, paralysis, ECG abnormalities, supraventricular arrhythmias, circulatory failure, cardiac arrest
	Hyperkalemia	Chronic renal disease, hemorrhage, tissue necrosis, nonsteroidal antiinflammatory drugs, ACE inhibitors, cyclosporine, K^+-sparing diuretics	ECG changes, ventricular arrhythmias, cardiac arrest
Calcium (Ca^{++})	Hypocalcemia	Hyperparathyroidism, pancreatitis, renal failure, trauma	Hyperactive tendon reflexes, muscle twitching, spasm, abdominal cramps, ECG changes, seizures (rarely)
	Hypercalcemia	Hyperthyroidism, hyperparathyroidism, metastatic bone cancer, sarcoidosis	Fatigue, depression, muscle weakness, anorexia, nausea, vomiting, constipation
Magnesium (Mg^{++})	Hypomagnesemia	Inadequate intake/impaired absorption of Mg^{++}, pancreatitis, alcoholism	Muscle weakness, irritability, tetany, ECG changes, arrhythmias, delirium, seizures
	Hypermagnesemia	Dehydration, renal insufficiency, tissue trauma, lupus erythematosus	ECG changes (along with hyperkalemia, cardiac arrest, respiratory muscle paralysis)
Phosphate (HPO_4^{2-})	Hypophosphatemia	Starvation, malabsorption, hyperparathyroidism, hyperthyroidism, uncontrolled diabetes mellitus	Diaphragmatic weakness
	Hyperphosphatemia	Endocrine disorders, acromegaly, chronic renal insufficiency, acute renal failure, tissue trauma	(Minimal)

ACE, Angiotensin-converting enzyme; *ECG,* electrocardiogram.

kidney occurs in exchange for other cations. Na^+ balance is involved in acid-base homeostasis (i.e., H^+ exchange) and the regulation of K^+. Abnormal losses of Na^+ can lead to *hyponatremia* (low Na^+ concentration in the plasma) and may occur for numerous reasons, as shown in Table 13-5.

Hyponatremia, which is the most common electrolyte imbalance found in hospitalized patients, is defined as having serum Na^+ levels less than 135 mEq/L.[6] Previously considered to be benign, mild hyponatremia has been shown in more recent studies to have a significant impact on a patient's cognitive function and gait stability, and it is thought to be a contributing factor in falls.[16] Hyponatremia can lead to cerebral edema owing to a change in osmotic pressure; the two most common causes for acute hyponatremia are postoperative iatrogenic and self-induced secondary to water intoxication.[16] One type of normal-volume (euvolemic) hyponatremia is known as the *syndrome of inappropriate antidiuretic hormone secretion* (SIADH).[15-17]

Treatment of hypovolemic hyponatremia can have dire consequences as well. If fluid is administered too quickly, damage to the central nervous system occurs. With significant fluid shifts in Na^+ concentrations, rapid changes in cellular volume can lead to cell damage and cell death (apoptosis).[6] Osmotic demyelination syndrome occurs when serum Na^+ concentration changes more than 10 mEq/L in chronic hyponatremia or 18 mEq/L over 48 hours.[16]

Chloride (Cl^-)

Cl^- is the most prominent anion in the body. Two-thirds of the body's store of Cl^- is extracellular; the remainder is intracellular. Intracellular Cl^- is present in significant amounts in red and white blood cells. It also is present in cells that have excretory functions, such as the GI mucosa.

Normal serum levels of Cl^- are 98 to 106 mEq/L. The concentration of extracellular Cl^- is inversely proportional to the concentration of the other major anion, HCO_3^-. Cl^- is regulated by the kidney in much the same manner as Na^+ (80% reabsorbed in the proximal tubules and 20% reabsorbed in the distal tubules). Cl^- is usually excreted with K^+ in the form of KCl. An imbalance in one of these electrolytes usually affects both. Replacement therapy usually includes both K^+ and Cl^-. The stomach and the small bowel also affect the balance of Cl^-, and sweat contains hypotonic quantities of Cl^-. Abnormal Cl^- levels may occur for various reasons (see Table 13-5).

Bicarbonate (HCO_3^-)

After Cl^-, HCO_3^- is the most important body fluid anion. It plays an important role in acid-base homeostasis and is the strong base in the HCO_3–H_2CO_3 buffer pair (see Chapter 14). HCO_3^- is the primary means for transporting CO_2 from the tissues to the lungs. The ratio of HCO_3^- to H_2CO_3 in healthy individuals is maintained near 20 : 1; this results in a pH of close

to 7.40. HCO_3^- stores are evenly divided between intracellular and extracellular compartments. Normal serum HCO_3^- levels in arterial blood range from 22 to 26 mEq/L. HCO_3^- levels are slightly higher in venous blood as CO_2 is being transported to the lungs.

In acid-base disorders, the kidneys regulate HCO_3^- levels to maintain a near-normal pH. In healthy individuals, more than 80% of blood HCO_3^- is reabsorbed in the proximal tubules of the kidneys. The remainder is reclaimed in the distal tubules. In respiratory acidosis, the kidneys retain or produce HCO_3^- to buffer the additional acid caused by CO_2 retention. In respiratory alkalosis, the opposite occurs. A reciprocal relationship exists between Cl^- and HCO_3^- concentrations. HCO_3^- retention is associated with Cl^- excretion, and vice versa (Chapter 14).

MINI CLINI

Water, Salt, and Congestive Heart Failure

PROBLEM: Why do patients who have congestive heart failure (CHF) need to adhere to a low-salt diet?

SOLUTION: CHF occurs when the left ventricle cannot pump all of the blood presented to it. This situation leads to pooling of blood in the lungs and venous circulation and an increase in peripheral venous pressure. Normally, the ventricle pumps most of the blood entering it. This volume is the "preload" of the heart. The volume of extracellular water partially determines the preload of the ventricle.

The ventricle can fail as a pump either because of intrinsic heart disease, such as infarction or ischemia, or because of elevated distal pressures against which it must pump (hypertension). In addition to pooling of blood in the systemic venous circulation, blood can back up in the lungs, resulting in congestion and edema.

The most important determinant of the extracellular water volume is its Na^+ content. Changes in extracellular water are dictated by the net gain or loss of Na^+, with an accompanying gain or loss of water. To reduce the work of the heart, fluid volume must be carefully regulated. By restricting Na^+ intake, extracellular fluid volume can be reduced, allowing the heart to function more effectively as a pump. Treatment of CHF must address not only excess fluid volume but also the underlying cause.

Diuretics are often used to help reduce fluid volume. Many diuretics cause the kidney to excrete Na^+, causing water to follow and reducing the extracellular fluid load. Because some diuretics also cause K^+ to be excreted, care must be taken in the management of CHF not to cause electrolyte imbalances. K^+ supplements may be used so that diuresis does not result in hypokalemia. Because of the central role of extracellular water in CHF, weighing the patient is a simple yet sensitive means of detecting excess fluid volume.

Potassium (K^+)

K^+ is the main cation of the intracellular compartment. Most of the K^+ (98%) in the body is found in cells. **Active transport** of K^+ into the cells occurs through an ionic pump mechanism. An electrical differential across the cell membrane also facilitates K^+ movement into the cell. For every three K^+ ions that enter a cell, two Na^+ ions and one H^+ ion must leave. This transfer maintains electrical neutrality in the cell.

The difference in K^+ distribution is evident when comparing concentrations between fluid compartments. Intracellular K^+ concentration is approximately 150 mEq/L, whereas serum K^+ concentration normally ranges from 3.5 to 5.0 mEq/L. Serum K^+ is an indirect indicator only of the total-body K^+. Serum K^+ is usually analyzed by assessing both intake and excretion.

The average adult excretes 40 to 75 mEq of K^+ in the urine every 24 hours. An additional 10 mEq is excreted in the stool. The average dietary intake of K^+ ranges from 50 to 85 mEq/day. Patients who have undergone surgery, have sustained trauma, or have renal disease often have greater K^+ losses. Consequently, such patients may need K^+ replacement averaging 100 to 120 mEq/day.

Serum K^+ concentration is determined primarily by the pH of extracellular fluid and the size of the intracellular K^+ pool. In extracellular acidosis, excess H^+ ions are exchanged for intracellular K^+. Movement of K^+ from intracellular to extracellular spaces may produce dangerous levels of *hyperkalemia* (elevated K^+). Alkalosis has the opposite effect. When pH increases, K^+ moves into cells. In the absence of acid-base disturbances, serum K^+ reflects total-body K^+. With excessive loss of K^+ from the GI tract, serum K^+ decreases. A 10% loss of total-body K^+ causes the serum K^+ level to decrease approximately 1 mEq/L.

Renal excretion of K^+ is controlled by aldosterone levels.[18] Aldosterone inhibits the enzyme responsible for K^+ transport in the distal renal tubular cells of the kidney. Metabolic acidosis also inhibits the transport system. Na^+ and H^+ ions enter cells at the expense of increased K^+ excretion. Alkalosis has the reverse effect. It stimulates cellular retention of K^+. Kidney failure results in K^+ retention and hyperkalemia.

Hypokalemia (reduced serum K^+) disturbs cellular function in numerous organ systems, including the GI, neuromuscular, renal, and cardiovascular systems (see Table 13-5), and is one of the most common electrolyte abnormalities within the hospital environment.[18] Management of hypokalemia involves replacement of K^+ losses and treatment of the underlying disorder. To manage the associated Cl^- deficit, K^+ is given with Cl^-. Caution is required in the administration of intravenous K^+ because cardiac muscle is very sensitive to extracellular concentrations of this electrolyte.

Hyperkalemia (elevated serum K^+) is most common in patients with renal insufficiency (see Table 13-5). The primary treatment of hyperkalemia is restriction of K^+ intake. The processes that precipitated the hyperkalemia also must be controlled. Temporary measures for reducing serum K^+ levels include administration of insulin, calcium gluconate, Na^+ salts, or large volumes of hypertonic glucose. Cation exchange resins may be given orally or rectally. If these measures fail, peritoneal or renal dialysis can aid in K^+ removal.

Calcium (Ca^{++})

Ca^{++} is an important mediator of neuromuscular function and cell enzyme processes. Most of the Ca^{++} in the body is contained in the bones. The normal serum calcium is 8.7 to 10.4 mg/dl, or approximately 4.5 to 5.25 mEq/L. This concentration is maintained by the interaction of parathyroid hormone, vitamin D (calcitriol), and calcitonin.

Ca^{++} is present in the blood in the following three forms: ionized, protein bound, and complex. The proportion of Ca^{++} in each form is affected by blood pH, concentration of plasma proteins, and presence of Ca^{++}-combining anions (e.g., HCO_3^- and hydrogen phosphate [HPO_4^{2-}]). Approximately 50% of serum Ca is ionized (Ca^{++}) and is physiologically active. An additional 10% forms Ca-anion complexes. The remaining 40% is bound to plasma proteins, primarily albumen. Ionized Ca^{++} is physiologically active in processes such as enzyme activity, blood clotting, neuromuscular irritability, and bone calcification. Acidemia increases the concentration of Ca^{++} in the serum, and alkalemia decreases the concentration.

Abnormal levels of Ca^{++} can cause various serious symptoms (see Table 13-5). Treatment of *hypocalcemia* (low serum levels of Ca^{++}) consists of correcting the underlying cause and replacing Ca^{++} either orally or intravenously. *Hypercalcemia* (increased levels of Ca^{++}) can result from numerous disorders. The most common causes are hyperparathyroidism and malignancies (e.g., multiple myeloma, lung cancer). Acute hypercalcemia requires emergency treatment because death may occur quickly if serum Ca^{++} increases to more than 17 mg/L (8.5 mEq/L). In such cases, there is usually an associated deficit of extracellular fluid. Volume replacement reduces serum Ca^{++} by dilution.

Magnesium (Mg^{++})

Mg^{++} is the second most abundant intracellular cation after K^+. Mg^{++} plays an important role in cellular functions, including energy transfer; metabolism of protein, carbohydrate, and fat; and maintenance of normal cell membrane function (see Table 13-5). Systemically, Mg^{++} decreases blood pressure and alters peripheral vascular resistance. Abnormalities of Mg^{++} levels can result in disturbances in nearly every organ system and can cause potentially fatal complications (e.g., ventricular arrhythmia, coronary artery vasospasm, sudden death). Hypomagnesemia is also associated with multiple neuromuscular symptoms, such as muscular weakness, tetany, coma, and seizures. There is some evidence that intercellular Mg^{++} levels may be related to bronchial hyperresponsiveness.

Normal values for serum Mg^{++} range from 1.7 to 2.1 mg/dl (1.7 to 1.4 mEq/L) in healthy adults. Most (99%) of the Mg^{++} in the body is intracellular. Of the small portion in extracellular spaces, 80% is ionized or bound to other ions (e.g., phosphate) and the remaining 20% bound to proteins. Extracellular Mg^{++} is in equilibrium with Mg^{++} in the bone, kidneys, intestine, and other soft tissues. In contrast to most electrolytes, Mg^{++} excretion in urine is not regulated hormonally, and circulating Mg^{++} in the extracellular fluid does not exchange readily with its main repository—the bones. Serum levels of Mg^{++} may remain normal even if total-body stores are depleted by 20%. Conversely, when there is a negative Mg^{++} balance, most of the losses come from the extracellular spaces.

Phosphorus (P)

An average adult has approximately 1 kg (1000 g) of P, of which 80% to 90% is in bone and teeth in the form of apatite. The remaining P is mostly present in the viscera and skeletal muscle, with a very small amount (<0.1%) in the extracellular fluids.[19] Of this total, 10% to 17% is combined with proteins, carbohydrates, and lipids in muscle tissue and blood, and the remainder is incorporated into complex organic compounds. Only about 1% of the total-body P is available as free serum compounds, so the serum level (1.2 to 2.3 mEq/L) does not reflect total-body content. Serum P levels are influenced by several factors (see Table 13-5), including the serum Ca^{++} concentration and the pH of blood.

Organic phosphate (HPO_4^{2-}) is the main anion within cells, with 20% present in the mitochondria. Approximately 30% of cellular HPO_4^{2-} is stored in the endoplasmic reticulum and is used in the phosphorylation of various proteins.[19] Inorganic phosphate plays a primary role in the metabolism of cellular energy, being the source from which adenosine triphosphate is synthesized. In acid-base homeostasis, phosphate is the main urinary buffer for titratable acid excretion (see Chapter 14).

P homeostasis depends on balance between GI absorption and urinary excretion. The parathyroid hormone provides hormonal regulation. *Hyperphosphatemia* (elevated serum levels of P) can occur when the load (e.g., GI absorption, cellular release) exceeds renal excretion and tissue uptake. Hyperphosphatemia precipitates Ca^{++}, causing hypocalcemia, which can be life-threatening if severe. Central nervous system symptoms such as altered mental status, paresthesias, and seizures can result from hyperphosphatemia. Prolonged hyperphosphatemia can result in abnormal deposition of calcium phosphate in previously healthy connective tissues, such as cardiac valves, and in solid organs, such as muscles.

SUMMARY CHECKLIST

- The body is a water-based organism in which chemical substances and particles exist in solution or suspension.
- The concentration of solutes in a solution may be quantified (1) by actual weight (grams, milligrams, or micrograms) or (2) by chemical combining power (equivalents or milliequivalents). The weight of a solute does not give an indication of its chemical combining power, but gram equivalent weights do.
- Solutions commonly involve the action of osmotic pressure. Body cell membranes are semipermeable, and osmotic pressure maintains the distribution of water and solutes in physiologic ranges.
- Concentrations of solutions may be calculated using ratio, weight/volume, or percent methods.
- Physiologically active compounds in the body are mostly weak electrolytic covalent substances. In aqueous solutions, some molecules ionize, leaving the remainder

intact. Equilibrium is maintained between the ions and un-ionized molecules.

- Proteins made up of amino acids can function as bases in the mildly alkaline environment of the body; this allows Hb and plasma proteins to function as buffers.
- Acidity or alkalinity is determined by variation of $[H^+]$ greater than or less than 1×10^{-7} mol/L. Two methods for recording acidity or alkalinity use H^+ concentration of water as the neutral standard: (1) the actual measured molar concentration of H^+ in nanomoles per liter and (2) the logarithmic pH scale.
- Water makes up 45% to 80% of an individual's body weight. Percentage of total-body water depends on weight, gender, age, and adipose tissue. Total-body water is divided into intracellular and extracellular water. Extracellular water is divided further into intravascular and interstitial water, with a small component of transcellular fluids.
- Control of total-body water is regulated by water intake and excretion. The kidneys maintain the volume and composition of body fluids by two related mechanisms: (1) filtration and reabsorption of Na^+ and (2) regulation of water excretion in response to changes in secretion of ADH.
- A balance between hydrostatic and osmotic pressure keeps water in the appropriate body compartments. Plasma proteins account for the high colloid osmotic pressure of plasma. Colloid osmotic pressure determines distribution of fluid between vascular and interstitial compartments. Imbalances in osmotic and hydrostatic pressures can result in edema.
- Electrolytes help maintain the internal environment and make important chemical and physiologic events possible. The concentrations of electrolytes in the intracellular and extracellular fluid compartments differ markedly. Increased or decreased concentrations of any electrolytes can result in disease and sometimes death.

CHAPTER 14

Acid-Base Balance

WILL BEACHEY

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe how the lungs and kidneys regulate volatile and fixed acids.
- Describe how the equilibrium constant of an acid is related to its ionization and strength.
- Define open and closed buffer systems.
- Explain why open and closed buffer systems differ in their ability to buffer fixed and volatile acids.
- Explain how to use the Henderson-Hasselbalch equation in hypothetical clinical situations.
- Describe how the kidneys and lungs compensate for each other when the function of one is abnormal.
- Explain how renal absorption and excretion of electrolytes affect acid-base balance.
- Classify and interpret arterial blood acid-base results.
- Explain how to use arterial acid-base information to decide on a clinical course of action.
- Explain why acute changes in the carbon dioxide levels of the blood affect plasma bicarbonate ion concentration.
- Calculate the anion gap and use it to determine the cause of metabolic acidosis.
- Describe how standard bicarbonate and base excess measurements are used to identify the nonrespiratory component of acid-base imbalances.

CHAPTER OUTLINE

KEY TERMS

acidemia
alkalemia
base excess (BE)
buffer base
closed buffer system
conjugate base
equilibrium constant
fixed (nonvolatile) acids
Henderson-Hasselbalch (H-H) equation
hypercapnia
hypocapnia
isohydric buffering
metabolic acidosis
metabolic alkalosis
open buffer system
paresthesia
respiratory acidosis
respiratory alkalosis
standard bicarbonate
volatile acid

Even small changes in hydrogen ion concentration [H^+] can cause vital metabolic processes in the body to fail. Note that brackets [ ] around the abbreviation for a substance indicate concentration. Normal metabolism continually generates H^+, which means H^+ regulation is extremely important. Several physiologic mechanisms work together to keep [H^+] of body fluids in a range that supports life. This chapter will help respiratory therapists (RTs) understand how these mechanisms work and how to spot abnormalities in their function. This knowledge will help RTs and other members of the patient care team make informed decisions about treating the underlying causes of acid-base disturbances.

HYDROGEN ION REGULATION IN BODY FLUIDS

Acid-base balance refers to physiologic mechanisms that keep [H^+] of body fluids in a range that supports life. H^+ ions react readily with the protein molecules of important cellular catalytic enzymes. These reactions change the physical shape of the protein molecule, which may inactivate enzymes. Body fluids must be kept in a narrow pH range of 7.35 to 7.45 to function normally. This corresponds to [H^+] of 45 to 35 nmol/L.

H^+ ions formed in the body come from either *volatile* or *fixed* (nonvolatile) acids. **Volatile acids** are in equilibrium with a dissolved gas. The only volatile acid of physiologic importance in the body is carbonic acid (H_2CO_3), which is in equilibrium with dissolved carbon dioxide. Normal aerobic metabolism generates approximately 13,000 mmol/L of CO_2 each day, which produces an equal amount of H^+ as shown by the CO_2 hydration reaction:

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow HCO_3^- + H^+$$
$$\uparrow$$
Aerobic metabolism

As CO_2 diffuses into the blood at the tissue level, this reaction occurs mostly in the erythrocyte, where it is catalyzed by carbonic anhydrase, an intracellular enzyme. In a process called **isohydric buffering**,[1] most H^+ produced in this way causes no change in pH because hemoglobin (Hb) in the erythrocyte immediately buffers the H^+. When blood reaches the lungs, Hb releases H^+ to form CO_2 as shown:

Ventilation
$$\uparrow$$
$$CO_2 + H_2O \leftarrow H_2CO_3 \leftarrow HCO_3^- + H^+$$
$$\uparrow$$
$$HHb \rightarrow H^+ + Hb^-$$

In this way, ventilation gets rid of H_2CO_3 just as fast as it is produced. Isohydric buffering and ventilation are the two major ways the body keeps the blood's pH constant regardless of how much CO_2 is produced.

Catabolism—the breakdown of proteins—continually produces **fixed (nonvolatile) acids** such as sulfuric and phosphoric acids. In addition, anaerobic metabolism produces lactic acid, another fixed acid. In contrast to H_2CO_3, these nonvolatile acids are not in equilibrium with a gas. However, the H^+ of fixed acids can be buffered by bicarbonate ions (HCO_3^-), which produce CO_2 and water (H_2O) (see the previous CO_2 hydration reaction); the CO_2 formed is removed from the body in exhaled gas. Compared with daily CO_2 production, fixed acid production is small, averaging only approximately 50 to 70 mEq/day.[2] Certain diseases, such as untreated diabetes, increase fixed acid production. H^+ ions produced in this way stimulate respiratory centers in the brain, increasing ventilation; this eliminates more CO_2, which pulls the CO_2 hydration reaction to the left and removes H^+ from the blood (refer to the CO_2 hydration reaction). In this way, the respiratory system *compensates* for increases in fixed acid; that is, it prevents [H^+] from rising as sharply as it otherwise would when fixed acids are produced.

Strong and Weak Acids and Bases: Equilibrium Constants

Strong acid and base molecules dissociate or ionize almost completely in an aqueous (liquid) solution. Weak acids and bases ionize only to a small extent. An example of a strong acid is hydrochloric acid. Nearly 100% of the HCl molecules dissociate to form H^+ and Cl^-:

(1) $$HCl \rightarrow H^+ + Cl^-$$

At *equilibrium,* when all dissociation stops, the concentration of HCl is extremely small compared with either [H^+] or [Cl^-]. There is no arrow pointing to the left in Reaction 1, emphasizing that HCl ionizes almost completely in solution. In contrast, H_2CO_3 is an example of a relatively weak acid:

(2) $$H_2CO_3 \rightleftharpoons HCO_3^- + H^+$$

The long arrow pointing to the left indicates that at *equilibrium,* the concentration of undissociated H_2CO_3 molecules is far greater than the concentration of either HCO_3^- or H^+.

The **equilibrium constant** of an acid is a measure of the extent to which the acid molecules dissociate (ionize). At equilibrium, the number of dissociating H_2CO_3 molecules in Reaction 2 is equal to the number of associating HCO_3^- and H^+, even though the concentrations of reactants and products are unequal. In this state, no further change occurs in [H_2CO_3], [HCO_3^-], or [H^+]. The following reaction expresses the state of affairs at equilibrium:

(3) $$\frac{[H^+] \times [HCO_3^-]}{[H_2CO_3]} = K_A \ (Small)$$

where K_A is the equilibrium constant for H_2CO_3. (K_A is also known as the acid's *ionization* or *dissociation* constant.)

K_A is a small number because [H_2CO_3] is quite large with respect to the numerator of Reaction 3 ([H^+] × [HCO_3^-]). The

value of K_A is always the same for H_2CO_3 at equilibrium, regardless of the initial concentration of H_2CO_3.

A strong acid, such as HCl, has a *large* K_A because the denominator [HCl] is extremely small compared with the numerator ($[H^+] \times [Cl^-]$):

$$\frac{[H^+]\times[Cl^-]}{[HCl]} = K_A\ (Large) \quad (4)$$

As shown by Equations 3 and 4, K_A is a measure of the strength of an acid—that is, how much the acid molecule dissociates.

Buffer Solution Characteristics

A buffer solution resists changes in pH when an acid or a base is added to it. Buffer solutions are aqueous mixtures of acids and bases. The acid component is the H^+ cation (positively charged ion), formed when a weak acid dissociates in solution. The base component is the remaining anion (negatively charged ion) portion of the acid molecule, known as the **conjugate base**. An important blood buffer system is a solution of carbonic acid and its conjugate base, HCO_3^-:

$$H_2CO_3(\text{Acid}) \rightleftharpoons HCO_3^-\ (\text{Conjugate base}) + H^+$$

In the blood, HCO_3^- combines with sodium ions to form sodium bicarbonate ($NaHCO_3$). If hydrogen chloride, a strong acid, is added to the $H_2CO_3/NaHCO_3$ buffer solution, HCO_3^- reacts with the added H^+ to form weaker H_2CO_3 molecules and a neutral salt:

$$HCl + H_2CO_3/Na^+HCO_3^- \rightarrow 2H_2CO_3 + NaCl$$

The strong acidity of HCl is converted to the relatively weak acidity of H_2CO_3, preventing a large decrease in pH.

Similarly, if sodium hydroxide, a strong base, is added to this buffer solution, it reacts with the H_2CO_3 molecule to form the weak base, $NaHCO_3$, and H_2O:

$$NaOH + H_2CO_3/NaHCO_3 \rightarrow 2NaHCO_3 + H_2O$$

The strong alkalinity of NaOH is changed to the relatively weak alkalinity of $NaHCO_3$. Again, pH change is minimized.

Bicarbonate and Nonbicarbonate Buffer Systems

Blood buffers are classified as bicarbonate or nonbicarbonate buffer systems. The bicarbonate buffer system consists of H_2CO_3 and its conjugate base, HCO_3^-. The nonbicarbonate buffer system consists mainly of phosphate and protein molecules, including the Hb molecule. The blood buffer base is the sum of bicarbonate and nonbicarbonate bases measured in millimoles per liter of blood.

The bicarbonate system is called an **open buffer system** because H_2CO_3 is in equilibrium with dissolved CO_2, which is readily removed by ventilation. That is, when H^+ is buffered by HCO_3^-, the product, H_2CO_3, is broken down into H_2O and CO_2 as long as ventilation removes CO_2. The removal of CO_2 from the reaction prevents the reaction from reaching equilibrium among its reactants. For this reason, buffering activity can continue without being slowed or stopped, as long as ventilation continues:

$$HCO_3^- + H^+ \rightarrow H_2CO_3 \rightarrow H_2O + CO_2\ (\text{Exhaled gas})$$

A nonbicarbonate buffer system is called a **closed buffer system** because all the components of acid-base reactions remain in the system. (In the following discussions, all nonbicarbonate buffer systems are grouped together and represented as *Hbuf/Buf*$^-$, where Hbuf is the weak acid, and Buf^- is the conjugate base.) When H^+ is buffered by Buf^-, the product, HBuf, builds up and eventually reaches equilibrium with the reactants, preventing further buffering activity:

$$Buf^- + H^+ \leftrightarrow Hbuf$$

Box 14-1 summarizes the characteristics and components of bicarbonate and nonbicarbonate buffer systems.

Open and closed buffer systems play different roles in buffering fixed and volatile acids, and they differ in their ability to function in wide-ranging pH environments. Volatile acid (H_2CO_3) accumulates in the body only if ventilation cannot eliminate CO_2 fast enough to keep up with the body's CO_2 production. In such a case, CO_2 builds up, continually pushing the hydration reaction (the reaction between CO_2 and H_2O) to the right, creating more H_2CO_3 and, ultimately, more H^+ and HCO_3^-. Because the HCO_3^- is co-produced with the H^+, the only buffer system that can buffer the H^+ of volatile acid is the nonbicarbonate buffer system. However, both nonbicarbonate and bicarbonate buffer systems can buffer the H^+ produced by fixed acids; this is true of the bicarbonate buffer system only if ventilation is normal and CO_2 can be adequately eliminated. Both systems are physiologically important, each playing a unique and essential role in maintaining pH homeostasis. Table 14-1 summarizes the approximate contributions of various blood buffers to the total buffer base. Bicarbonate buffers have the greatest buffering capacity because they function in an open system.

Of course, bicarbonate and nonbicarbonate buffer systems do not function in isolation from one another because they are intermingled in the same solution (whole blood) and are in equilibrium with the same $[H^+]$ (Figure 14-1). Increased

ventilation increases the CO_2 removal rate, causing blood $[H^+]$ to fall, which causes nonbicarbonate buffers (Hbuf) to release more H^+. By the same token, decreased ventilation ultimately causes Hbuf to accept more H^+.

pH of a Buffer System: Henderson-Hasselbalch Equation

Buffer solutions in body fluids consist of mostly undissociated acid molecules and only a small amount of H^+ and conjugate base anions. The $[H^+]$ of a buffer solution can be calculated if the concentrations of the buffer's components and each acid's equilibrium constant are known. Consider the bicarbonate buffer system. As described earlier, the equilibrium constant (K_A) for H_2CO_3 is as follows:

$$K_A = \frac{[H^+] \times [HCO_3^-]}{[H_2CO_3]}$$

TABLE 14-1

$[H^+]$ can be calculated by algebraic rearrangement of this equation, as follows:

$$[H^+] = K_A \times \frac{[H_2CO_3]}{[HCO_3]}$$

This equation shows that $[H^+]$ is determined by the ratio between undissociated acid molecules $[H_2CO_3]$ and base anions $[HCO_3^-]$. This equation is the basis for deriving the **Henderson-Hasselbalch (H-H) equation**:

$$pH = 6.1 + \log \frac{[HCO_3^-]}{PaCO_2 \times 0.03}$$

pH is a logarithmic expression of $[H^+]$, and the term 6.1 is the logarithmic expression of the H_2CO_3 equilibrium constant. Because dissolved CO_2 ($PCO_2 \times 0.03$) is in equilibrium with and directly proportional to blood $[H_2CO_3]$, and because blood PCO_2 is more easily measured than $[H_2CO_3]$, dissolved CO_2 is used in the denominator of the H-H equation. The H-H equation is specific for calculating the pH of the bicarbonate buffer system of the blood. The calculation of this pH is important because it equals the pH of blood plasma; because all buffer systems in the blood are in equilibrium with the same pH, the pH of one buffer system is the same as the pH of the entire plasma solution (the isohydric principle).[1]

Clinical Use of Henderson-Hasselbalch Equation

The H-H equation allows the pH, $[HCO_3^-]$, or PCO_2 to be computed if two of these three variables are known (shown as follows for PCO_2 and HCO_3^-):

$$[HCO_3^-] = \text{antilog}\,(pH - 6.1) \times (PCO_2 \times 0.03)$$

$$PCO_2 = \frac{[HCO_3^-]}{(\text{antilog}\,[pH - 6.1] \times 0.03)}$$

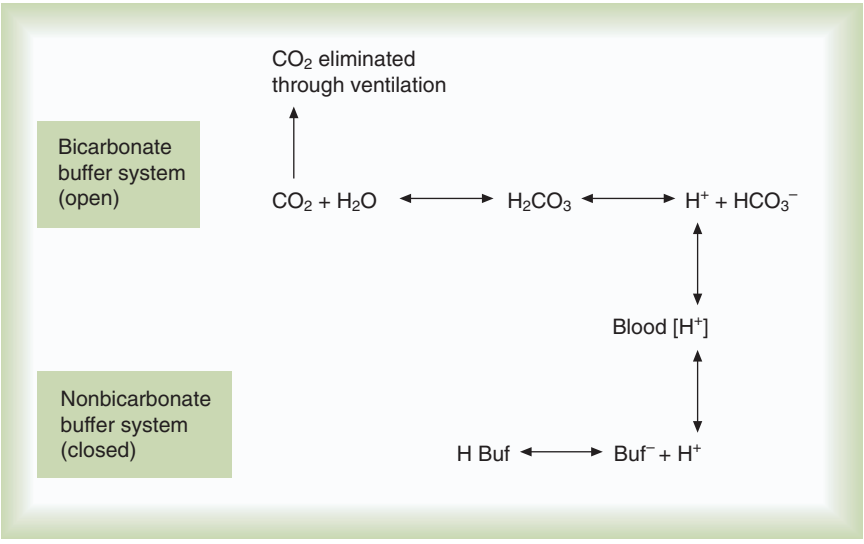

FIGURE 14-1 The bicarbonate and nonbicarbonate buffer systems exist in equilibrium in the plasma. (Modified from Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.)

Blood gas analyzers *measure* pH and PCO_2 but *compute* $[HCO_3^-]$. Assuming a normal arterial pH of 7.40 and a $PaCO_2$ of 40 mm Hg, arterial $[HCO_3^-]$ can be calculated as follows:

$$pH = 6.1 + \log\left(\frac{[HCO_3^-]}{PCO_2 \times 0.03}\right)$$

$$7.40 = 6.1 + \log\left(\frac{[HCO_3^-]}{[40 \times 0.03]}\right)$$

$$7.40 = 6.1 + \log\left(\frac{[HCO_3^-]}{1.2}\right)$$

Solving for $[HCO_3^-]$:

$$\begin{aligned}[HCO_3^-] &= \text{antilog}\,(7.40 - 6.1) \times 1.2 \\ &= \text{antilog}\,(1.3) \times 1.2 \\ &= 20 \times 1.2 \\ &= 24\ \text{mEq/L}\end{aligned}$$

The H-H equation is useful for checking a clinical blood gas report to see if the pH, PCO_2, and $[HCO_3^-]$ values are compatible with one another. In this way, transcription errors and analyzer inaccuracies can be detected. It is also clinically useful to predict what effect changing one H-H equation component will have on the other components. For example, a clinician may want to know how low the arterial blood pH will fall for a given increase in $PaCO_2$.

Physiologic Roles of Bicarbonate and Nonbicarbonate Buffer Systems

The functions of bicarbonate and nonbicarbonate buffer systems are summarized in Table 14-2.

TABLE 14-2

Buffering Functions

Buffer	Type of System	Acids Buffered
Bicarbonate	Open	Fixed (nonvolatile)
Nonbicarbonate	Closed	Volatile (carbonic)
		Fixed

From Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.

Bicarbonate Buffer System

The bicarbonate buffer system is particularly effective in the body because it is an open system—that is, one of its components (CO_2) is continually removed through ventilation:

$$(\text{Exhaled gas}) \leftarrow CO_2 + H_2O \leftarrow H_2CO_3 \leftarrow HCO_3^- + H^+$$

In this way, HCO_3^- continues to buffer H^+ as long as ventilation continues. Hypothetically, this buffering activity can continue until all body sources of HCO_3^- are used up in binding H^+.

The bicarbonate buffer system can buffer only fixed acid. An increased fixed acid load in the body (e.g., lactic acid) reacts with HCO_3^- of the bicarbonate buffer system:

$$\begin{array}{c} \text{Ventilation} \\ \uparrow \\ H^+ + HCO_3^- \rightarrow H_2CO_3 \rightarrow H_2O + CO_2 \\ \uparrow \\ \text{Fixed acid} \end{array}$$

As shown, the process of buffering fixed acid produces CO_2, which is eliminated in exhaled gas. Large amounts of acid are

MINI CLINI

Applying the Henderson-Hasselbalch Equation in a Clinical Setting

PROBLEM: The RT is caring for a mechanically ventilated patient. The patient has a tidal volume (V_T) of 800 ml and a breathing frequency of 10/min, yielding a minute ventilation ($\dot{V}_E$) of 8 L/min. The patient's $PaCO_2$ is 55 mm Hg, pH is 7.30, and bicarbonate is 26 mEq/L, and the RT wishes to maintain a pH of 7.35. How much does the RT need to change the $PaCO_2$ to achieve this desired pH, and what change in the patient's V_T does this require?

SOLUTION: First, the therapist needs to calculate the $PaCO_2$ required to achieve a pH of 7.35 using the known values:

$$PaCO_2 = \frac{26\ \text{mEq/L}}{1.003 \times \text{antilog}\,(7.35 - 6.1)}$$

$$PaCO_2 = \frac{26}{0.53}$$

$$PaCO_2 = 49\ \text{mm Hg}$$

Next, the RT must calculate the $\dot{V}_E$ required to produce a $PaCO_2$ of 49 mm Hg. Because $\dot{V}_E$ is inversely proportional to $PaCO_2$ (assuming that tidal volume remains constant), the following can be stated:

$$(\dot{V}_E)_1 \times (PaCO_2)_1 = (\dot{V}_E)_2 \times (PaCO_2)_2$$

where subscripts 1 and 2 represent current and future values. The RT then solves for $(\dot{V})_2$ as follows:

$$(8\ \text{L/min}) \times 55\ \text{mm Hg} = (\dot{V}_E)_2 \times 49\ \text{mm Hg}$$

$$\frac{(8 \times 55)}{49} = (\dot{V}_E)_2$$

$$8.98\ \text{L/min} = (\dot{V}_E)_2$$

Increasing the patient's $\dot{V}_E$ from 8 L/min to approximately 9 L/min yields a $PaCO_2$ of 49 mm Hg and a pH of approximately 7.35. Now the RT divides the new $\dot{V}_E$ of 9 L/min by the respiratory frequency to calculate the new V_T required:

$$9\ \text{L/min}/10 = 900\ \text{ml}$$

A V_T of 900 ml at a rate of 10 breaths/min should produce an arterial pH of 7.35, according to the H-H equation.

normally buffered in this fashion. If ventilation cannot keep up with the body's CO_2 production, this type of buffering cannot occur.

The bicarbonate buffer system cannot buffer carbonic (volatile) acid, which accumulates in the blood whenever ventilation fails to eliminate CO_2 as fast as it is produced (hypoventilation). The resulting accumulation of CO_2 drives the hydration reaction in the direction that produces more carbonic acid, H^+, and HCO_3^-, as shown:

$$\text{Hypoventilation} \downarrow \quad CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow HCO_3^- + H^+$$

H^+ produced by dissociating H_2CO_3 molecules cannot be buffered by the simultaneously produced HCO_3^- because hypoventilation prevents the reaction from reversing its direction. The closed nonbicarbonate buffer systems are the only buffers that can buffer H_2CO_3.

Nonbicarbonate Buffer System

Table 14-1 lists the nonbicarbonate buffers in the blood. Of these, Hb is the most important simply because it is the most abundant. As mentioned, these buffers are the only ones available to buffer H_2CO_3. However, they can buffer H^+ produced by any acid, fixed or volatile. Because nonbicarbonate buffers (Buf^-/HBuf) function in closed systems, the products of their buffering activity eventually accumulate and approach equilibrium, slowing or stopping further buffering activity:

$$H^+ + Buf^- \leftrightarrow HBuf$$

This slowing or stopping of buffering activity means that not all of the Buf^- reserves are available for buffering activity. At equilibrium (denoted by the *double arrow*), Buf^- still exists in solution but cannot combine further with H^+. In contrast, most of the HCO_3^- in the bicarbonate buffer system is available for buffering activity because it functions in an open system in which equilibrium between reactants and products does not occur as long as ventilation continues. Both open and closed systems function in a common fluid compartment (blood plasma), as illustrated in the following equation:

$$\begin{array}{l} (CO_2 \text{ removed by ventilation}) \quad (\text{from body's } HCO_3^- \text{ stores}) \\ \uparrow \qquad\qquad\qquad \downarrow \\ \text{Open system: } CO_2 + H_2O \leftarrow H^+ + HCO_3^- \\ \qquad\qquad\qquad\quad \uparrow \\ \qquad\qquad\quad \text{Added fixed acid} \\ \qquad\qquad\qquad\quad \downarrow \\ \text{Closed system: } HBuf \leftrightarrow H^+ + Buf^- \\ \qquad\qquad\qquad\qquad\quad \uparrow \\ \qquad\qquad\quad (\text{from body's } Buf^- \text{ stores}) \end{array}$$

Most of the added fixed acid is buffered by HCO_3^- because ventilation continually pulls the reaction to the left. Smaller amounts of H^+ react with Buf^- because equilibrium is approached, slowing the reaction.

ACID EXCRETION

Bicarbonate and nonbicarbonate buffer systems are the immediate defense against the accumulation of H^+. However, if the body fails to eliminate the remaining acids, these buffers are soon exhausted and the pH of body fluids quickly decreases to life-threatening levels.

The lungs and kidneys are the primary acid-excreting organs. The lungs can excrete only volatile acid (i.e., the CO_2 from dissociating H_2CO_3). However, as discussed previously, bicarbonate buffers effectively buffer the H^+ originating from fixed acid, converting it to H_2CO_3 and to CO_2 and H_2O. By eliminating the CO_2, the lungs can rapidly remove large quantities of fixed acid from the blood. The kidneys also remove fixed acids but at a slow pace. In healthy individuals, the acid excretion mechanisms of lungs and kidneys are delicately balanced. In individuals affected by disease, failure of one system can be partially offset by a compensatory response of the other.

Lungs

Because the volatile acid H_2CO_3 is in equilibrium with dissolved CO_2, the lungs can decrease blood H_2CO_3 concentration through ventilation. The elimination of CO_2 is crucial because normal aerobic metabolism produces large quantities of CO_2, which reacts with H_2O to form large quantities of H_2CO_3. The reaction between fixed acids and bicarbonate buffers also produces H_2CO_3. H_2CO_3 generated by both pathways is eliminated as CO_2 through the lungs. Approximately 24,000 mmol/L of CO_2 is removed from the body daily through normal ventilation. CO_2 excretion of the lungs does not remove H^+ from the body. Instead, the chemical reaction that breaks down H_2CO_3 to form CO_2 binds H^+ in the harmless H_2O molecule:

$$H^+ + HCO_3^- \rightarrow H_2CO_3 \rightarrow H_2O + CO_2$$

Kidneys

The kidneys physically remove H^+ from the body. The following terms refer to certain kidney functions:

- *Excretion* is the elimination of substances from the body in the urine.
- *Secretion* is the process by which renal tubule cells actively transport substances into the fluid inside the tubule lumen (i.e., the *filtrate*).
- *Reabsorption* is the active or passive transport of filtrate substances back into the tubule cell and into the blood of nearby capillaries.

The amount of H^+ the kidney tubules secrete into the filtrate depends on the blood's pH. Secreted H^+ may originate from H_2CO_3 (when the blood PCO_2 is increased) or from fixed acids. The kidneys excrete less than 100 mEq of fixed acid per day, which is a small amount compared with volatile H_2CO_3 elimination by the lungs.[3] In addition to excreting H^+, the kidneys influence blood pH by reabsorbing or excreting HCO_3^-. If the blood PCO_2 is high, creating high levels of H_2CO_3, the kidneys excrete greater amounts of H^+ and reabsorb all of the tubule filtrate's HCO_3^- back into the blood. The opposite happens

when the blood PCO_2 is low. The kidneys excrete less H^+ and more HCO_3^-. Compared with the ability of the lungs to change blood PCO_2 in seconds, the renal process is slow, requiring hours to days.

Basic Kidney Function

To understand how the kidneys determine whether to excrete acidic or basic urine, some fundamental facts about renal function must be understood. The *glomerulus* is the component of the renal nephron responsible for filtering the blood. Hydrostatic blood pressure forces water, electrolytes, and other nonprotein substances through semipermeable glomerular capillary endothelium. The resulting filtrate is greatly modified in volume and composition as it flows through the nephron tubules. Excreted filtrate is called *urine*.

HCO_3^- is one of the electrolytes filtered from the blood at the glomerulus to become part of the tubular filtrate. In this way, base (HCO_3^-) is removed from the blood. This loss of base is offset by the nephron's simultaneous secretion of H^+ into the filtrate of the tubular lumen. Under normal conditions, the rate of H^+ secretion is almost the same as the rate of HCO_3^- filtration.[4] In this way, the kidneys titrate H^+ and HCO_3^- against each other to form CO_2 and H_2O.

H^+ secretion begins with the diffusion of blood CO_2 into the tubule cell (Figure 14-2). Aided by the enzyme carbonic anhydrase, CO_2 reacts with H_2O to form H_2CO_3, which instantly forms HCO_3^- and H^+. The tubule cell actively secretes H^+ into the filtrate by means of *counter-transport,* in which Na^+ and H^+ are simultaneously transported in opposite directions. That is, Na^+ and H^+ combine with opposite ends of a carrier protein in the luminal border of the tubule cell membrane. Sodium ions move from the filtrate into the cell down its high concentration gradient, providing the energy to secrete H^+ back into the tubular filtrate (see Figure 14-2).[4]

The rate of tubular H^+ secretion increases if the concentration of H^+ in the blood plasma increases. Conversely, the rate of H^+ secretion decreases if blood plasma $[H^+]$ decreases (Figure 14-3). Any factor that increases $PaCO_2$, such as hypoventilation, increases $[H^+]$ in the blood and thus $[H^+]$ secretion; any factor that decreases $PaCO_2$, such as hyperventilation, decreases H^+ secretion.

HCO_3^- formed in the tubule cell from the reaction between CO_2 and H_2O (see Figure 14-2) diffuses back into the blood plasma because the luminal side of the tubule cell is relatively impermeable to HCO_3^-. HCO_3^- and Na^+ are reabsorbed whenever H^+ is secreted into the tubular filtrate.

Reabsorption of Bicarbonate Ion

Because the luminal side of the renal tubule cell is relatively impermeable to HCO_3^-, these ions are reabsorbed indirectly, as

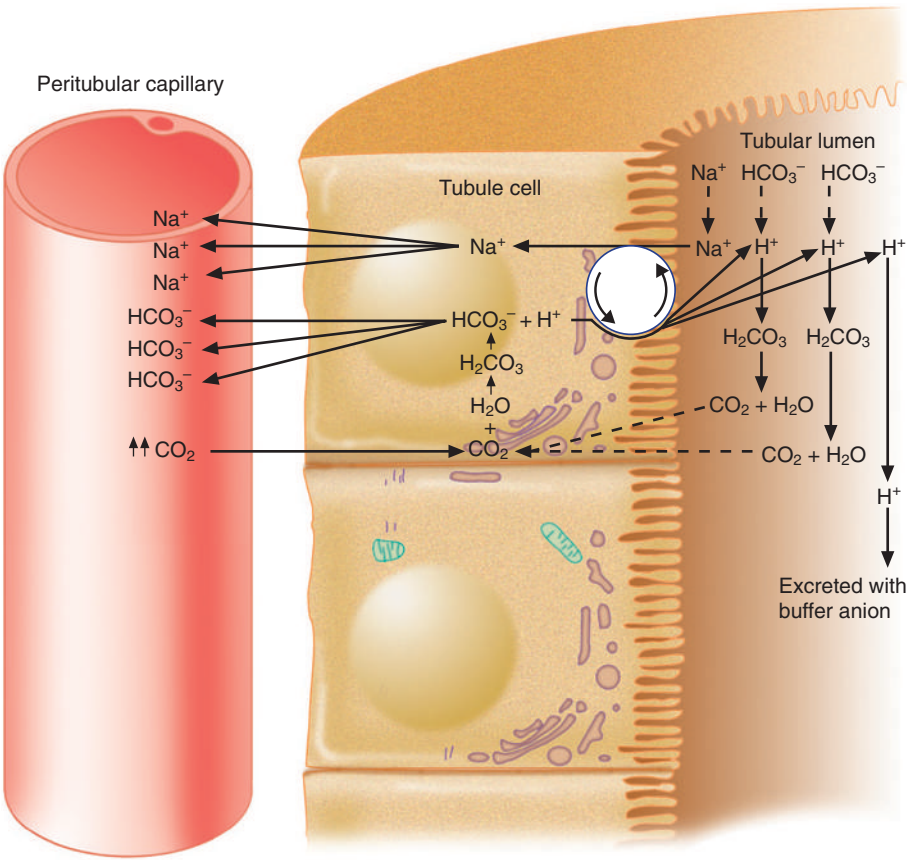

FIGURE 14-2 Renal response to respiratory acidosis. Filtrate HCO_3^- is reabsorbed by first reacting with secreted H^+. (Modified from Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.)

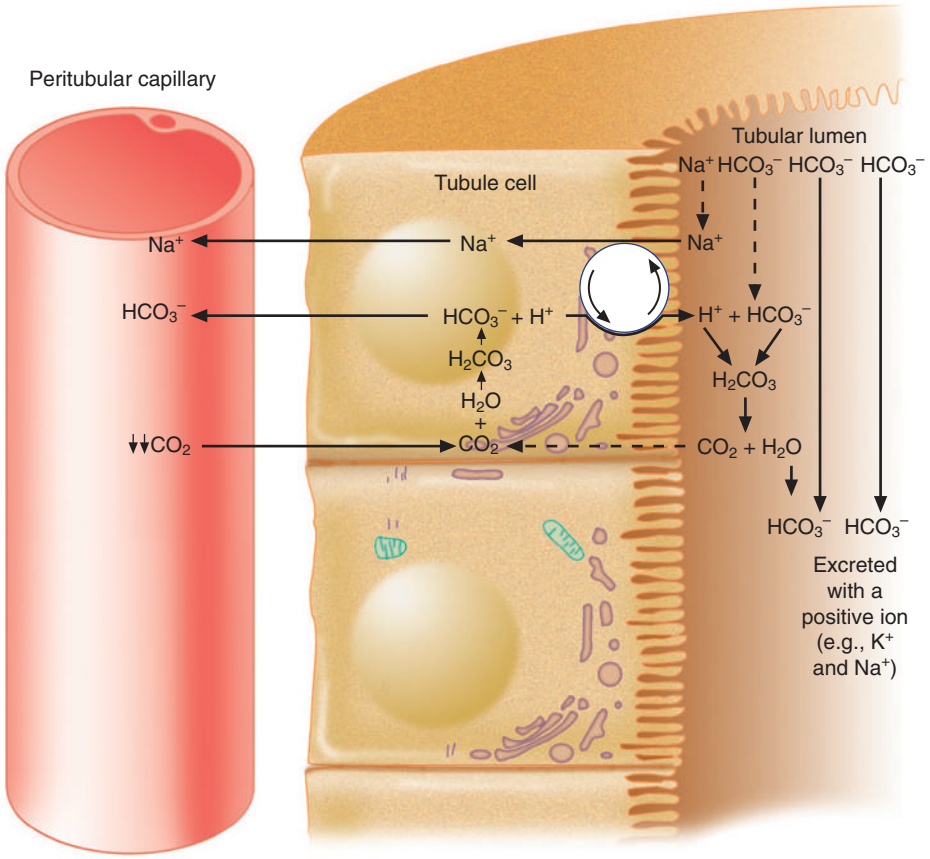

FIGURE 14-3 Renal response to respiratory alkalosis. Excess HCO_3^- is excreted in the urine with a positive ion. (Modified from Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.)

shown in Figure 14-2. The HCO_3^- in the tubular filtrate reacts with the H^+ secreted by the tubular cells. The resulting H_2CO_3 breaks down into CO_2 and H_2O. Because CO_2 is extremely diffusible through biologic membranes, it diffuses instantly from the filtrate into the tubule cell. There CO_2 reacts rapidly with H_2O in the presence of carbonic anhydrase, instantly forming HCO_3^- and H^+. The HCO_3^- thus created diffuses back through the nonluminal side of the tubule cell into the blood. Although the reabsorbed HCO_3^- ion is not the same HCO_3^- ion that existed in the tubular fluid, the net result is the same as if HCO_3^- were directly reabsorbed. If the tubule cells secrete sufficient H^+, all HCO_3^- in the tubular fluid is reabsorbed in this manner.

The net effect of secreting H^+ (caused by high blood CO_2 or *hypoventilation,* as shown in Figure 14-2) is to reabsorb all filtrate HCO_3^-, increasing the quantity of HCO_3^- in the blood. According to the H-H equation, this brings blood pH up toward the normal range.

If blood CO_2 is low, as is the case in a state of *hyperventilation* (see Figure 14-3), the ratio of HCO_3^- to dissolved CO_2 molecules increases, and the renal filtrate ends up with more HCO_3^- than secreted H^+. Because HCO_3^- cannot be reabsorbed from the filtrate without first reacting with H^+, the extra HCO_3^- is excreted in the urine, which requires positive ions such as Na^+ or K^+ to also be excreted to maintain tubular electrical neutrality. The net effect of secreting less H^+ is to increase the quantity of HCO_3^- (base) lost in the urine. According to the H-H equation, this brings blood pH down toward the normal range. These renal responses to high and low blood PCO_2 are the mechanisms by which the kidneys compensate for or offset respiratory acid-base disturbances.

Excess Hydrogen Ion Excretion and Role of Urinary Buffers

If no buffers existed in the filtrate to react with H^+, the H^+-secreting mechanism would soon cease to function because when the filtrate pH decreases to 4.5, H^+ secretion stops.[4] In other words, buffers in the tubular filtrate are essential for the secretion and elimination of excess H^+ in acidotic states.

In Figure 14-2, more H^+ than HCO_3^- is present in the filtrate. After all available HCO_3^- reacts with H^+, the remaining H^+ reacts with two other filtrate buffers, phosphate and ammonia, as illustrated in Figures 14-4 and 14-5. In Figure 14-4, phosphate and H^+ react to form $H_2PO_4^-$, which must be excreted with a positive ion to maintain tubular electroneutrality. Figure 14-5 shows that when urinary buffers are depleted, the resulting fall in filtrate pH stimulates the tubules to secrete ammonia. The NH_3 molecule buffers H^+ by reacting with it to form the positively charged ammonium ion (NH_4^+). To maintain

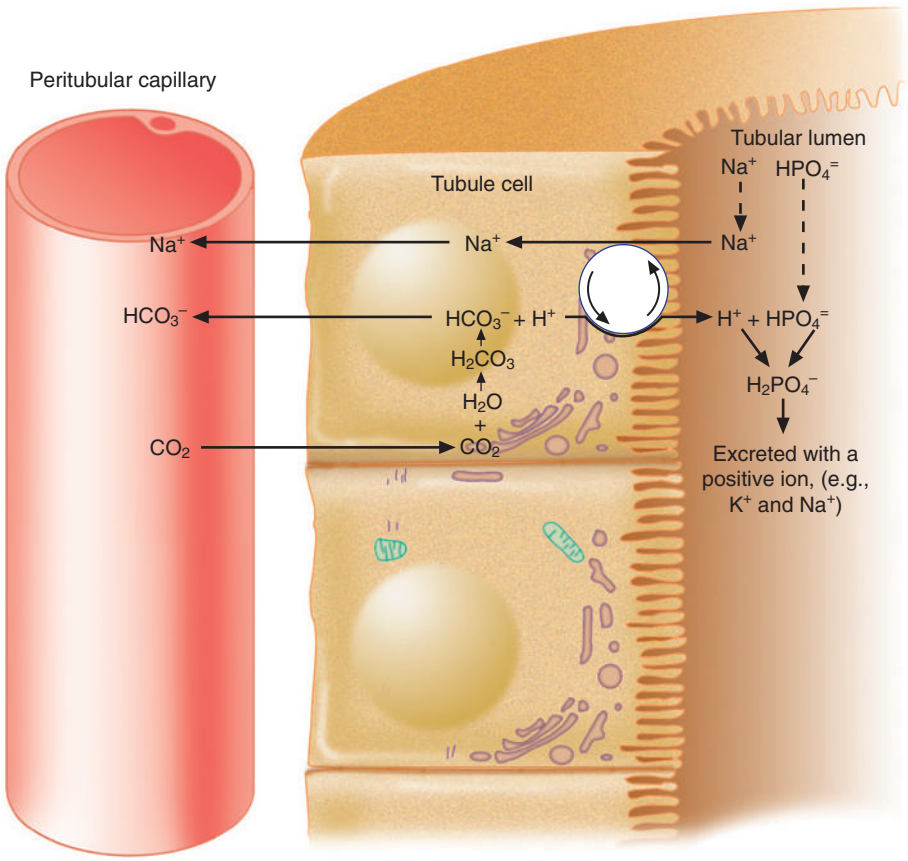

FIGURE 14-4 Phosphate buffer system. After HCO_3^- buffers are exhausted, the remaining H^+ reacts with urinary phosphate buffers. (Modified from Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.)

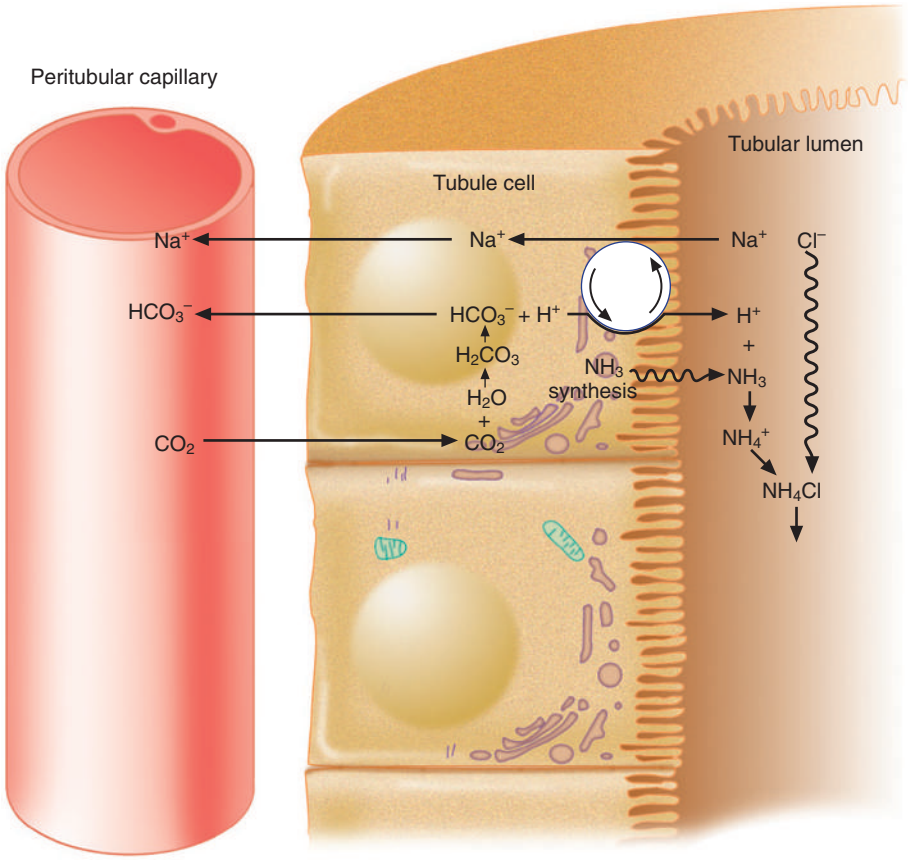

FIGURE 14-5 Tubule cells secrete ammonia in response to low-filtrate pH. NH_3 molecules buffer H^+, forming NH_4^+, which is excreted with Cl^-. (Modified from Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.)

electroneutrality, the kidney excretes a negatively charged ion to accompany NH_4^+. This negative ion is chloride, the most abundant filtrate anion.

When NH_4^+ reacts with H^+, HCO_3^- diffuses from the tubule cell into the blood (see Figure 14-5). The net effect of ammonia buffer activity is to cause more HCO_3^- to be reabsorbed into the blood, counteracting the acidic state of the blood. Figure 14-5 shows that when Cl^- is excreted in combination with NH_4^-, the blood gains HCO_3^-. Blood $[Cl^-]$ and $[HCO_3^-]$ are reciprocally related (i.e., when one is high, the other is low). This relationship explains why people with chronically high blood PCO_2 tend to have low blood $[Cl^-]$ or *hypochloremia*. Activation of the ammonia buffer system enhances Cl^-loss and HCO_3^- gain.

ACID-BASE DISTURBANCES

In healthy individuals, the body buffer systems, the lungs, and the kidneys work together to maintain acid-base homeostasis under various conditions.

Normal Acid-Base Balance

Normally, the kidneys keep the arterial $[HCO_3^-]$ in the range of 22 to 26 mEq/L, while lung ventilation keeps the arterial PCO_2 in the range of 35 to 45 mm Hg. These normal values produce an arterial pH range of 7.35 to 7.45; as shown by the H-H equation, when $[HCO_3^-]$ is 24 mEq/L and $PaCO_2$ is 40 mm Hg, the pH is exactly 7.40:

$$pH = 6.1 + \log \frac{[HCO_3^-]}{PCO_2 \times 0.03}$$

$$pH = 6.1 + \log \frac{24}{1.2}$$

$$pH = 6.1 + \log[20]$$

$$pH = 7.40$$

The H-H equation shows that plasma pH is determined by the *ratio* of $[HCO_3^-]$ to dissolved CO_2, not the absolute values of these components. As long as the ratio of HCO_3^- buffer to dissolved CO_2 is 20:1, the pH is normal, or 7.40. Because the kidneys control blood $[HCO_3^-]$ and the lungs control blood CO_2 levels, the H-H equation can be conceptually rewritten as follows:

$$pH \propto \frac{\text{Kidney control of } [HCO_3^-]}{\text{Lung control of } PCO_2}$$

An increase in $[HCO_3^-]$ or a decrease in PCO_2 increases the pH, leading to **alkalemia**. This condition produces an $[HCO_3^-]/(PCO_2 \times 0.03)$ ratio greater than 20:1 (e.g., 25:1). A decreased $[HCO_3^-]$ or an increased PCO_2 decreases the pH, leading to **acidemia**. This condition produces an $[HCO_3^-]/(PCO_2 \times 0.03)$ ratio less than 20:1 (e.g., 15:1). The normal ranges for arterial pH, PCO_2, and $[HCO_3^-]$ are as follows:

$$pH = 7.35 \text{ to } 7.45$$

$$PaCO_2 = 35 \text{ to } 45 \text{ mm Hg}$$

$$[HCO_3^-] = 22 \text{ to } 26 \text{ mEq/L}$$

Alkalemia is defined as a blood pH greater than 7.45. *Acidemia* is defined as a blood pH less than 7.35. *Hyperventilation* is defined as $PaCO_2$ less than 35 mm Hg. *Hypoventilation* is defined as $PaCO_2$ greater than 45 mm Hg.

Primary Respiratory Disturbances

Abnormal arterial pH levels caused by changes in $PaCO_2$ are called *primary respiratory disturbances* because the lungs control $PaCO_2$. Respiratory disturbances affect the denominator of the H-H equation. A high $PaCO_2$ increases dissolved CO_2, decreasing the pH:

$$\downarrow pH \propto \frac{\rightarrow HCO_3^-}{\uparrow PaCO_2}$$

where ↓ means decreased, → means no change, and ↑ means increased. Respiratory disturbance causing acidemia is called **respiratory acidosis**. On the other hand, a low $PaCO_2$ decreases dissolved CO_2, raising the pH; this is called **respiratory alkalosis**:

$$\uparrow pH \propto \frac{\rightarrow HCO_3^-}{\downarrow PaCO_2}$$

*Hypo*ventilation causes respiratory acidosis, whereas *hyper*ventilation causes respiratory alkalosis.

Primary Metabolic (Nonrespiratory) Disturbances

Nonrespiratory processes change arterial pH, manifested by changes in $[HCO_3^-]$. These are called *primary metabolic disturbances*. Although the term *nonrespiratory* is more accurate, the term *metabolic* is, by convention, used to refer to all nonrespiratory acid-base disturbances. These kinds of disturbances involve a gain or loss of fixed acids or HCO_3^-. Such processes affect the numerator of the H-H equation. The build-up of a fixed acid in the body is buffered by HCO_3^-, decreasing the plasma $[HCO_3^-]$ and the pH:

$$\downarrow pH \propto \frac{\downarrow HCO_3^-}{\rightarrow PaCO_2}$$

The same effect is created by a loss of HCO_3^-. Nonrespiratory processes causing acidemia are traditionally called **metabolic acidosis**.

In contrast, ingesting too much alkali (e.g., $NaHCO_3$ or other antacids) increases $[HCO_3^-]$ and pH:

$$\uparrow pH \propto \frac{\uparrow HCO_3^-}{\rightarrow PaCO_2}$$

Plasma $[HCO_3^-]$ can be increased by its *addition,* as in the previous example, or by its *generation,* as occurs when fixed acid is lost from the body.[5] An individual may lose HCl from the body by vomiting large amounts of gastric juice. This loss generates HCO_3^-, as discussed later (see Figure 14-8, later).

Processes that increase arterial pH by losing fixed acid or gaining HCO_3^- produce a condition called **metabolic alkalosis**. Table 14-3 shows the four primary acid-base disturbances causing alkalemia and acidemia.

TABLE 14-3

Primary Acid-Base Disorders and Compensatory Responses

Acid-Base Disorder	Primary Defect	Compensatory Response
Respiratory acidosis	$\begin{bmatrix}\rightarrow HCO_3^-\\ \uparrow \mathbf{PaCO_2}\end{bmatrix} = \downarrow pH$	$\begin{bmatrix}\uparrow \mathbf{HCO_3^-}\\ \uparrow PaCO_2\end{bmatrix} = \rightarrow pH$
Respiratory alkalosis	$\begin{bmatrix}\rightarrow HCO_3^-\\ \downarrow \mathbf{PaCO_2}\end{bmatrix} = \uparrow pH$	$\begin{bmatrix}\downarrow \mathbf{HCO_3^-}\\ \downarrow PaCO_2\end{bmatrix} = \rightarrow pH$
Metabolic acidosis	$\begin{bmatrix}\downarrow \mathbf{HCO_3^-}\\ \rightarrow PaCO_2\end{bmatrix} = \downarrow pH$	$\begin{bmatrix}\downarrow HCO_3^-\\ \downarrow \mathbf{PaCO_2}\end{bmatrix} = \rightarrow pH$
Metabolic alkalosis	$\begin{bmatrix}\uparrow \mathbf{HCO_3^-}\\ \rightarrow PaCO_2\end{bmatrix} = \uparrow pH$	$\begin{bmatrix}\uparrow HCO_3^-\\ \uparrow \mathbf{PaCO_2}\end{bmatrix} = \rightarrow pH$

NOTE: Primary defects and compensatory responses appear in boldface type.
→, No change; ↓, decrease; ↑, increase.

Compensation: Restoring pH to Normal

When any primary acid-base defect occurs, the body immediately reacts to make up for the defect; that is, the body initiates a *compensatory* response. If a person hypoventilates (respiratory acidosis), the kidneys bring the pH back toward normal by returning the filtrate's HCO_3^- ions back to the blood, a process called *reabsorption*. In contrast, the compensatory renal response to hyperventilation (respiratory alkalosis) is urinary elimination of HCO_3^- (bicarbonate diuresis).

Similarly, if a nonrespiratory (metabolic) process decreases or increases $[HCO_3^-]$, the lungs compensate by hyperventilating (eliminating CO_2) or hypoventilating (retaining CO_2), restoring the pH to near normal. Consider the following example of pure (uncompensated) respiratory acidosis in which the PCO_2 level increases to 60 mm Hg:

$$pH = 6.1 + \log \frac{(24\ mEq/L)}{(60\ mm\ Hg \times 0.03)}$$
$$pH = 6.1 + \log(13.3)$$
$$pH = 7.22$$

The kidneys compensate by reabsorbing HCO_3^- from the filtrate into the blood, returning the plasma HCO_3^-/dissolved CO_2 ratio to almost 20 : 1, as shown:

$$pH = 6.1 + \log \frac{(34\ mEq/L)}{(60\ mm\ Hg \times 0.03)}$$
$$pH = 6.1 + \log(18.9)$$
$$pH = 7.38$$

pH is restored to the normal range of 7.35 to 7.45, although the PCO_2 level remains abnormally high. This compensatory response of the kidney produces a high plasma $[HCO_3^-]$, *not to be confused with primary metabolic alkalosis;* compensatory renal HCO_3^- retention is a normal secondary response to the primary event of respiratory acidosis.

The lungs normally compensate quickly for metabolic acid-base defects because ventilation can change the $PaCO_2$ within seconds. The kidneys require more time to retain or excrete significant amounts of HCO_3^- and compensate for respiratory defects at a much slower pace. Table 14-3 summarizes the four primary acid-base disturbances and the body's compensatory responses.

Effect of the Carbon Dioxide Hydration Reaction on $[HCO_3^-]$

In the previous examples of pure (uncompensated) respiratory acidosis and alkalosis, it was assumed that $[HCO_3^-]$ did not change when the $PaCO_2$ level increased or decreased. However, arterial $[HCO_3^-]$ does increase slightly as the $PaCO_2$ increases because the CO_2 hydration reaction generates HCO_3^-. This reaction occurs primarily in the red blood cell because the catalytic enzyme, carbonic anhydrase, is present:

$$CO_2 + H_2O - (\text{carbonic anhydrase}) \rightarrow H_2CO_3 \rightarrow H^+ + HCO_3^-$$

As H^+ and HCO_3^- are rapidly produced in the erythrocyte, Hb immediately buffers H^+, pulling the reaction to the right, generating more plasma HCO_3^-.

The amount of HCO_3^- generated by this buffering action depends on the amount of buffer available to accept the H^+ produced by the hydration reaction. Generally, when the nonbicarbonate buffer concentration is normal, and the PCO_2 increase is acute, the hydration reaction increases the plasma $[HCO_3^-]$ approximately 1 mEq/L for every 10-mm Hg increase in PCO_2 higher than 40 mm Hg. Figure 14-6 illustrates this hydration reaction effect. Normal status is represented by point *A:* $PaCO_2$ of 40 mm Hg, pH of 7.40, and plasma HCO_3^- of 24 mEq/L. An acute increase in $PaCO_2$ from 40 to 80 mm Hg proceeds from point *A,* moving to the left, up the normal blood buffer line (line *BAC*) to point *D,* where the buffer line intersects the $PaCO_2$ = 80 mm Hg isopleth. Point *D* indicates an HCO_3^- of approximately 28.5 mEq/L and a pH of approximately 7.18. This small change in $[HCO_3^-]$ is a natural result of the Hb buffering action and should not be wrongly interpreted as early renal compensation.

RULE OF THUMB

For an acute increase in PCO_2, the plasma $[HCO_3^-]$ increases by approximately 1 mEq/L for every 10 mm Hg PCO_2 rise above 40 mm Hg.

CLINICAL ACID-BASE STATES

Systematic Acid-Base Classification

In analyzing an acid-base problem, it is helpful to use a series of systematic steps. Consistently applying them to all acid-base disturbances helps one avoid the tendency to jump to conclusions. Four steps in arterial blood acid-base classification are outlined in Box 14-2. After the pH is categorized, the order of

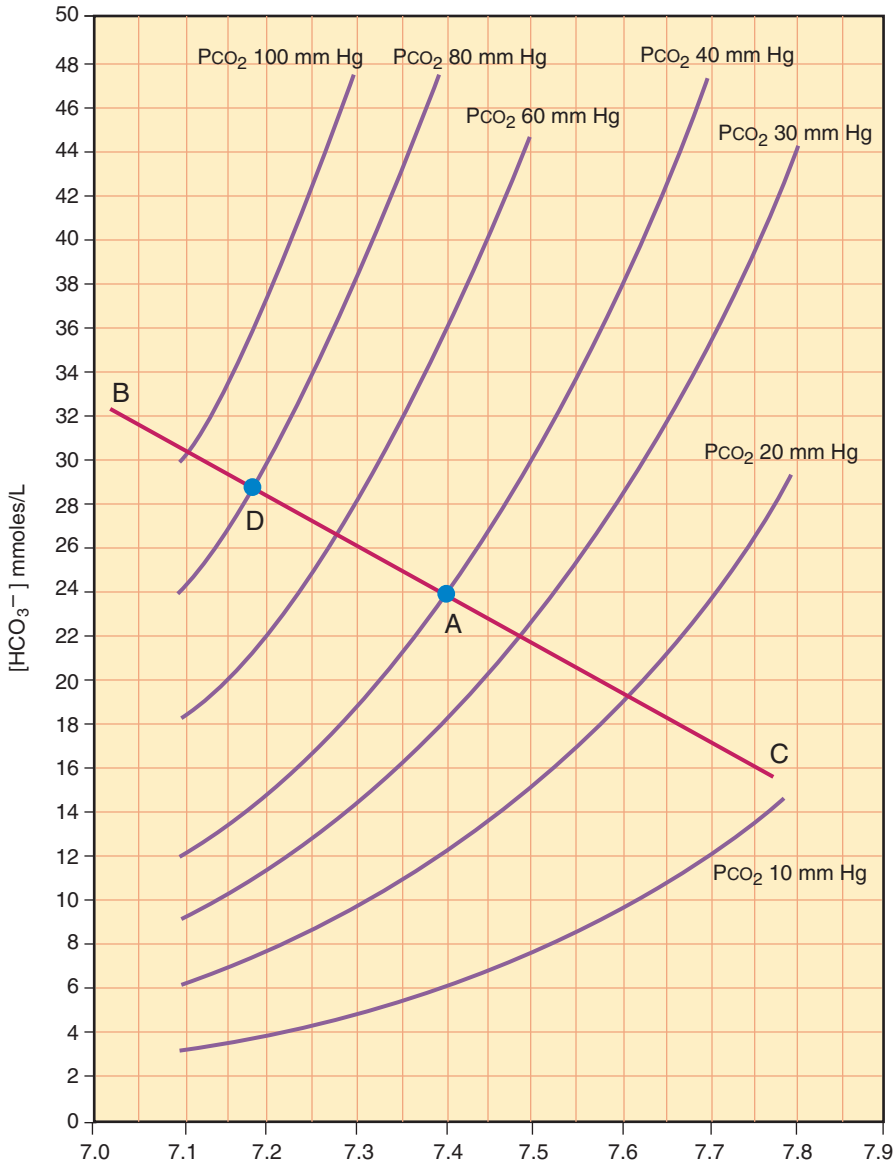

FIGURE 14-6 pH-PCO_2 diagram. Because of the hydration reaction between CO_2 and H_2O, acute increases in PCO_2 increase the plasma HCO_3^- concentration along line *CADB*. An acute increase in PCO_2 from 40 mm Hg to 80 mm Hg (point *A* to point *D*) increases [HCO_3^-] from 24 mEq/L to approximately 29 mEq/L. (Modified from Masoro EJ, Siegel PD: Acid-base regulation: its physiology and pathophysiology, Philadelphia, 1971, Saunders.)

Box 14-2 Systematic Acid-Base Classification

- Inspect the pH (acidemia, alkalemia, or normal).
- Inspect $PaCO_2$ (respiratory component). Can it explain the pH?
- Inspect HCO_3^- (metabolic component). Can it explain the pH?
- Check for compensation. Did the noncausative component respond appropriately?

From Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.

the steps is not as important as following the same procedure for each situation.

Step 1: Categorize pH

If the arterial pH is greater than 7.45, a state of alkalemia exists. If the pH is less than 7.35, a state of acidemia exists. Steps 2 through 4 help the clinician determine whether an acid-base abnormality is of respiratory or metabolic (nonrespiratory) origin.

Step 2: Determine Respiratory Involvement

$PaCO_2$ is the marker for respiratory involvement because the lungs control the level of CO_2 in the arterial blood. (The normal

range for $PaCO_2$ is 35 to 45 mm Hg.) If the arterial pH is abnormal, the clinician should determine whether the observed $PaCO_2$ could cause the abnormality by itself. If the pH was less than 7.35 (denoting an acidosis) and $PaCO_2$ was greater than 45 mm Hg, according to the H-H equation, the high $PaCO_2$ would lower the pH (i.e., produce an acidemia). In this case, the respiratory system would be at least partly, if not entirely, responsible for the acidemia. If the pH is less than 7.35 and $PaCO_2$ is in the normal range, the acidemia is of nonrespiratory, or metabolic origin.

Step 3: Determine Metabolic (Nonrespiratory) Involvement

Plasma $[HCO_3^-]$ is the marker for metabolic involvement because $[HCO_3^-]$ is controlled by nonrespiratory factors. (The normal plasma $[HCO_3^-]$ of arterial blood is 22 to 26 mEq/L.) If the arterial pH is abnormal, the clinician must determine whether the observed $[HCO_3^-]$ could cause the abnormality by itself. If the pH was less than 7.35 (denoting an acidemia) and the $[HCO_3^-]$ was less than 22 mEq/L, according to the H-H equation, the low $[HCO_3^-]$ would produce an acidosis. Nonrespiratory (metabolic) factors would be partly, if not entirely, responsible for the acidemia. If $[HCO_3^-]$ is in the normal range in the presence of this acidemia, the acidemia is of respiratory origin.

Step 4: Assess for Compensation

The system (respiratory or nonrespiratory) that is not primarily responsible for the acid-base imbalance usually attempts to return the pH to the normal range. Compensation may be complete (pH is brought into the normal range) or partial (pH is still out of the normal range but is in the process of moving toward the normal range). In a pure respiratory acidosis, the kidneys compensate by reabsorbing more $[HCO_3^-]$, restoring the pH to normal. Similarly, respiratory alkalosis elicits a compensatory loss of $[HCO_3^-]$, decreasing its plasma concentration. A pure metabolic acidosis normally stimulates a compensatory increase in ventilation, decreasing the $PaCO_2$. A pure metabolic alkalosis causes a compensatory decrease in ventilation, increasing the $PaCO_2$. All compensatory responses work to restore the pH to the normal range.

In cases in which compensation has occurred, if the pH is on the acidic side of the normal range (7.35 to 7.39), the event that would cause an acidosis (either increased $PaCO_2$ or decreased plasma HCO_3^-) is generally the primary cause of the original acid-base imbalance. If compensation is present but pH is on the alkalotic side of the normal range (7.41 to 7.45), the component that would cause an alkalosis (either decreased $PaCO_2$ or increased HCO_3^-) is generally the primary cause of the original acid-base disturbance.

Complete compensation refers to any case in which the compensatory response returns the pH to the normal range (7.35 to 7.45). *Partial compensation* refers to instances in which the expected compensatory response has begun but has not had sufficient time to return the pH into the normal range. For example, suppose a patient has a partially compensated respiratory acidosis. This condition is characterized by high $PaCO_2$ (>45 mm Hg), pH less than 7.35, and plasma $[HCO_3^-]$ greater than 26 mEq/L. The compensatory response (increased HCO_3^-) is not yet sufficient to return the pH into the normal range, although the expected compensatory activity has begun. By comparison, a completely compensated respiratory acidosis might be shown by the same patient several hours later, when the kidneys have had enough time to retain sufficient plasma HCO_3^- to bring the pH into the normal range. This completely compensated respiratory acidosis is characterized by the same originally observed high $PaCO_2$, pH that is in the 7.35 to 7.39 range, and plasma $[HCO_3^-]$ that is greater than it was before *complete compensation* took place. The pH remains on the acidic side of 7.40 because the primary disturbance (high $PaCO_2$) originally created an acidotic environment. Generally, the body does not overcompensate for an acid-base disturbance. Table 14-4 summarizes acid-base and ventilatory classification. Table 14-5 classifies the degree of compensation for acid-base disturbances.

Respiratory Acidosis

Any physiologic process that increases $PaCO_2$ (>45 mm Hg) with an accompanying decreased arterial pH (<7.35) produces respiratory acidosis. Increased $PaCO_2$ (**hypercapnia**) lowers the arterial pH because dissolved CO_2 produces H_2CO_3:

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow HCO_3^- + H^+$$

TABLE 14-4

Acid-Base and Ventilatory Classification

Component	Classification	Range

MINI CLINI

Acute (Uncompensated) Respiratory Acidosis

PROBLEM: A 35-year-old woman was admitted to the emergency department with a diagnosis of heroin overdose. Her breathing was shallow and slow. Arterial blood gas analysis showed a pH of 7.30, PCO_2 of 55 mm Hg, and HCO_3^- of 26 mEq/L. How would the RT assess this patient's respiratory condition?

SOLUTION: The RT should follow these steps:

1. Categorize the pH. The pH is below normal, indicating the presence of acidemia.
2. Determine respiratory involvement. $PaCO_2$ is elevated above normal (hypercapnea), consistent with a low pH, indicating hypoventilation as a contributing factor to acidemia (respiratory acidosis).
3. Determine metabolic involvement. HCO_3^- is elevated slightly above normal. However, this is in the expected range for acute respiratory acidosis (1 mEq for each 10-mm Hg increase in PCO_2).
4. Assess for compensation. As explained in step 3, HCO_3^- is within the expected range for acute respiratory acidosis. There is no evidence of metabolic compensation. Therefore the condition is interpreted as an uncompensated respiratory acidosis.

ABNORMAL LUNGS
Chronic obstructive pulmonary disease
Acute airway obstruction (late phase)

Causes

Any process in which alveolar ventilation fails to eliminate CO_2 as rapidly as the body produces it causes respiratory acidosis. This acidosis could occur in two different ways. A person's ventilation may be decreased from a drug-induced central nervous system depression, or a person with limited ventilatory reserve may have a normal $PaCO_2$ at rest but cannot accommodate the increased CO_2 production associated with increased physical activity. Box 14-3 summarizes causes of respiratory acidosis.

If hypercapnia is uncompensated, respiratory acidosis occurs with decreased pH, increased $PaCO_2$, and normal or slightly increased $[HCO_3^-]$.

Compensation

Renal compensation for respiratory acidosis begins as soon as $PaCO_2$ increases. The kidney reabsorbs HCO_3^- from the renal tubular filtrate, bringing the arterial pH into the normal range (see Figure 14-2). However, this process is slow and cannot keep pace with an acutely increasing $PaCO_2$. Full compensation may take several days.

Partly compensated respiratory acidosis is characterized by increased $PaCO_2$, increased $[HCO_3^-]$, and an acid pH—still not quite up in the normal range. *Fully compensated* respiratory acidosis is characterized by a pH on the acidic side of the normal (<7.40 but >7.35), increased $PaCO_2$, and increased $[HCO_3^-]$. Increased $[HCO_3^-]$ in the presence of increased $PaCO_2$ is a sign that the $PaCO_2$ has been elevated for a considerable time (i.e., the kidneys have had sufficient time to compensate). The underlying pathologic process that produced hypercapnia is still present; the kidneys simply mask the problem by maintaining a normal-range pH. Because hypercapnia is still present, the term *acidosis* is retained in classifying this condition (fully compensated respiratory *acidosis*). This terminology emphasizes that lung function is still abnormal, and, if it were unopposed by the renal compensatory mechanism, it would still produce an acidosis.

Correction

The main goal in correcting respiratory acidosis is to treat the underlying problem—to improve alveolar ventilation. Various respiratory care modalities may be used, ranging from bronchial hygiene and lung expansion techniques to mechanical ventilation. If hypoventilation is chronic and compensation has restored pH to the normal range, action aimed at decreasing $PaCO_2$ to the normal range is inappropriate and possibly harmful, because the high level of $[HCO_3^-]$ in the blood created by the kidney's compensation would produce an alkalosis (Table 14-6).

Respiratory Alkalosis

Any physiologic process that decreases $PaCO_2$ (<35 mm Hg) and increases arterial pH (>7.45) produces respiratory alkalosis. A low $PaCO_2$ (**hypocapnia**) forces the hydration reaction to the left, decreasing H_2CO_3 concentration and increasing the pH:

$$CO_2 + H_2O \leftarrow H_2CO_3 \leftarrow HCO_3^- + H^+$$

Hypocapnia is synonymous with respiratory alkalosis.

Causes

Any process in which ventilatory elimination of CO_2 exceeds the body's production of CO_2 causes respiratory alkalosis. The

MINI CLINI

Chronic (Compensated) Respiratory Acidosis

PROBLEM: A 73-year-old man is being treated on an outpatient basis for pulmonary emphysema, which was diagnosed 7 years earlier. His breathing is labored at rest, with marked use of accessory muscles. Arterial blood gas analysis showed a pH of 7.36, PCO_2 of 64 mm Hg, and HCO_3^- of 35 mEq/L. How would the RT assess this patient's arterial blood gas results?

SOLUTION: The RT should follow these steps:

1. Categorize the pH. The pH is on the acidic side of the normal range, but it is still normal.
2. Determine respiratory involvement. $PaCO_2$ is higher than normal, indicating hypoventilation as a contributing factor to the low-normal pH (respiratory acidosis).
3. Determine metabolic involvement. HCO_3^- is substantially elevated. By itself, this would cause alkalemia, but because pH is on the acidic side of normal, primary metabolic alkalosis is ruled out. Compensation for the respiratory acidosis has occurred.
4. Assess for compensation. HCO_3^- is approximately 8 to 10 mEq higher than normal. This is consistent with a compensatory response by the kidneys to offset the acidosis. In addition, the expected pH for a $PaCO_2$ of 64 mm Hg is [7.40 − (64 mm Hg − 40 mm Hg) × 0.006], or 7.26 (see Table 14-6). Because the actual pH is 7.36, metabolic compensation (retention of HCO_3^-) must have occurred. Therefore the interpretation is a fully compensated respiratory acidosis.

most common cause of hyperventilation in patients with pulmonary disease is decreased PaO_2 (hypoxemia). Hypoxemia causes specialized neural structures to signal the brain, increasing ventilation (see Chapter 15). Anxiety, fever, stimulatory drugs, pain, and central nervous system injuries are possible causes of hyperventilation. Other possible causes include stimulation of irritant receptors in the lung parenchyma, which may occur in pneumonia or pulmonary edema.

MINI CLINI

Acute (Uncompensated) Respiratory Alkalosis

PROBLEM: A distraught 77-year-old man experiencing anxiety of apparent psychosomatic origin was brought to the hospital by his wife. The patient exhibited rapid and deep breathing, had slurred speech, and complained about tingling in his extremities. Arterial blood gas analysis showed a pH of 7.57, PCO_2 of 23 mm Hg, and HCO_3^- of 22 mEq/L. How would the RT interpret this patient's acid-base condition?

SOLUTION: The RT should follow these steps:

1. Categorize the pH. The pH is substantially higher than normal, indicating the presence of an alkalemia.
2. Determine respiratory involvement. $PaCO_2$ is well below normal, which is consistent with the high pH, indicating hyperventilation as a contributing factor in alkalemia (respiratory alkalosis).
3. Determine metabolic involvement. HCO_3^- is slightly lower than normal. However, this is within the expected range for acute respiratory alkalosis (CO_2 hydration reaction's effect).
4. Assess for compensation. The decrease in HCO_3^- is within the expected range for acute respiratory alkalosis (1 mEq for each 5-mm Hg decline in PCO_2). Therefore the interpretation is an uncompensated respiratory alkalosis.

Hyperventilation and respiratory alkalosis also may be *iatrogenically* induced (induced by medical treatment). Iatrogenic hyperventilation is most commonly associated with overly aggressive mechanical ventilation. It may also be associated with aggressive deep breathing and lung expansion respiratory care procedures. Decreased $PaCO_2$, increased pH, and normal-range [HCO_3^-] characterize acute respiratory alkalosis. A slight decrease in [HCO_3^-] is expected from the effect of the hydration reaction. Box 14-4 summarizes causes of respiratory alkalosis.

Clinical Signs

An early sign of respiratory alkalosis is **paresthesia** (numbness or a tingling sensation in the extremities). Severe hyperventilation is associated with hyperactive reflexes and possibly tetany (seizures). The low $PaCO_2$ may constrict the brain's cerebral vessels enough to reduce cerebral circulation, causing lightheadedness and dizziness.

Compensation

The kidneys compensate for respiratory alkalosis by excreting more HCO_3^- in the urine (HCO_3^- diuresis; see Figure 14-3). This activity brings arterial pH down toward the normal range. As with respiratory acidosis, renal compensation is a slow process. Complete compensation may take days.

Partly compensated respiratory alkalosis is characterized by decreased $PaCO_2$, decreased $[HCO_3^-]$, and a high pH—still not quite down to the normal range. Fully compensated respiratory alkalosis is characterized by decreased $PaCO_2$, decreased $[HCO_3^-]$, and pH on the alkaline side of normal (pH > 7.40 but ≤ 7.45). Compensated respiratory alkalosis is sometimes called *chronic respiratory alkalosis* or *chronic alveolar hyperventilation*. The underlying hyperventilation and hypocapnia are still present. The terminology *respiratory alkalosis* is retained in classifying this condition, because although the pH is within the normal range, the $PaCO_2$ is still below normal.

Correction

Correcting respiratory alkalosis involves removing the stimulus that caused the hyperventilation. If hypoxemia is the stimulus, oxygen therapy is needed.

Alveolar Hyperventilation Superimposed on Compensated Respiratory Acidosis

Consider a patient with a compensated respiratory acidosis who has an arterial pH of 7.38, $PaCO_2$ of 58 mm Hg, and HCO_3^- of 33 mEq/L. If this patient becomes severely hypoxic, the hypoxia may stimulate increased alveolar ventilation if lung mechanics are not too severely impaired. If increased alveolar ventilation acutely lowers the $PaCO_2$ from 58 to 50 mm Hg, the pH could possibly increase to the alkalotic side of the normal range. For example, the patient's blood gas values might now be pH of 7.44, $PaCO_2$ of 50 mm Hg, and HCO_3^- of 33 mEq/L.

The inexperienced clinician might wrongly interpret these values as compensated metabolic alkalosis. This example shows that blood gas data alone are not enough to make an accurate acid-base assessment. Knowledge of the patient's medical history and the nature of the current problem are essential to evaluate this problem accurately. The blood gas values in this example would be properly classified as acute alveolar hyperventilation (even though the $PaCO_2$ is >45 mm Hg) superimposed on chronic alveolar hypoventilation (i.e., compensated respiratory acidosis).

Metabolic (Nonrespiratory) Acidosis

Any nonrespiratory process that decreases plasma $[HCO_3^-]$ causes metabolic acidosis. A reduction in $[HCO_3^-]$ decreases blood pH because it decreases the amount of base compared to the amount of acid in the blood.

MINI CLINI

Compensated (Chronic) Respiratory Alkalosis

PROBLEM: A 27-year-old man was admitted to the hospital with a persistent case of bacterial pneumonia, which had not responded to 6 days of ambulatory care with antimicrobial drugs. He exhibited mild cyanosis and labored breathing. Arterial blood gas analysis (with the patient breathing room air) showed a pH of 7.44, $PaCO_2$ of 26 mm Hg, HCO_3^- of 17 mEq/L, and PaO_2 of 53 mm Hg. How would the RT interpret this patient's acid-base condition?

SOLUTION: The RT should follow these steps:

1. Categorize the pH. The pH is on the alkalotic side of the normal range, but it is still normal.
2. Determine respiratory involvement. PCO_2 is well below normal, indicating hyperventilation as a contributing factor to the high-normal pH (respiratory alkalosis).
3. Determine metabolic involvement. HCO_3^- is substantially lower than normal, but because the pH is on the alkalotic side of normal, primary metabolic acidosis is ruled out. Compensation for the respiratory alkalosis has occurred.
4. Assess for compensation. HCO_3^- is approximately 7 mEq below normal. This is consistent with a compensatory response by the kidneys. In addition, the expected pH for $PaCO_2$ of 26 mm Hg is [7.40 + (40 mm Hg − 26 mm Hg) × 0.01], or 7.54 (see Table 14-6). Because the actual pH is 7.44, metabolic compensation (excretion of HCO_3^-) must have occurred. Therefore the interpretation is a fully compensated respiratory alkalosis.

Causes

Metabolic acidosis can occur in one of the following two ways: (1) fixed (nonvolatile) acid build-up in the blood or (2) an excessive loss of HCO_3^- from the body. An example of fixed acid build-up is a state of low blood flow in which tissue hypoxia and anaerobic metabolism produce lactic acid. The resulting H^+ accumulates and reacts with HCO_3^-, which reduces blood $[HCO_3]$. On the other hand, an example of HCO_3^- loss is severe diarrhea, in which large stores of HCO_3^- are eliminated from the body, also producing a nonrespiratory (metabolic) acidosis.

Because these two kinds of metabolic acidosis are treated differently, it is important to identify the underlying cause. Analysis of the plasma electrolytes is helpful in distinguishing between these two types of metabolic acidosis. Specifically, measuring the anion gap is helpful in making this distinction.

Anion Gap

The *law of electroneutrality* states that the total number of positive charges must equal the total number of negative charges in the body's fluids. *Cations* (positively charged ions) in the plasma produce a charge exactly balanced by plasma *anions* (negatively

charged ions). Plasma electrolytes (cations and anions) *routinely* measured in clinical medicine are Na^+, potassium, Cl^-, and HCO_3^-. Normal plasma concentrations of these electrolytes are such that the cations (Na^+ and K^+) outnumber the anions (Cl^- and HCO_3^-), which leads to what seems to be an *anion gap.* Generally, K^+ is ignored in calculating this apparent anion gap:

$$\text{Anion gap} = [Na^+] - ([Cl^-] + [HCO_3^-])$$

Figure 14-7, *A* shows that normal concentrations of these ions in the plasma are as follows: 140 mEq/L for Na^+, 105 mEq/L for Cl^-, and 24 mEq/L for HCO_3^-, yielding an "anion gap" of 11 mEq/L (140 mEq/L − [105 mEq/L + 24 mEq/L] = 11 mEq/L). The normal anion gap range is 9 to 14 mEq/L.[6]

An increased anion gap (>14 mEq/L) is caused by a metabolic acidosis in which abnormal fixed acids accumulate in the body. The H^+ of these acids reacts with plasma HCO_3^-, lowering its concentration; this leads to a further increase in the anion gap (i.e., an increase in *unmeasured anions*) (see Figure 14-7, *B*). (When the H^+ of fixed acids is buffered by HCO_3^-, the anion portion of the fixed acid remains in the plasma, increasing unmeasured anion concentration.) A high anion gap indicates that fixed acid concentration in the body has increased.

Metabolic acidosis caused by HCO_3^- loss from the body does not cause a further increase in the anion gap. HCO_3^- loss is accompanied by Cl^- gain, which keeps the anion gap within normal limits (see Figure 14-7, *C*). The law of electroneutrality helps explain the reciprocal nature of $[HCO_3^-]$ and $[Cl^-]$ in this instance. With a constant cation concentration, losing HCO_3^- means that another anion must be gained to maintain electroneutrality. In this case, the kidney increases its reabsorption of the most abundant anion in the tubular filtrate, the Cl^- ion. The kind of metabolic acidosis in which HCO_3^- is lost from the body is sometimes called *hyperchloremic acidosis* because of the characteristic increase in plasma $[Cl^-]$. Box 14-5 summarizes causes of anion gap and non–anion gap metabolic acidosis.

Box 14-5 Causes of Anion Gap and Non–Anion Gap Metabolic Acidosis

HIGH ANION GAP

Metabolically Produced Acid Gain

Lactic acidosis
Ketoacidosis
Renal failure (e.g., retained sulfuric acid)

Ingestion of Acids

Salicylate (aspirin) intoxication
Methanol (formic acid)
Ethylene glycol (oxalic acid)

NORMAL ANION GAP (HYPERCHLOREMIC ACIDOSIS)

Gastrointestinal Loss of HCO_3^-

Diarrhea
Pancreatic fistula

Renal Tubular Loss: Failure to Reabsorb HCO_3^-

Renal tubular acidosis

Ingestion

Ammonium chloride
Hyperalimentation intravenous nutrition

From Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.

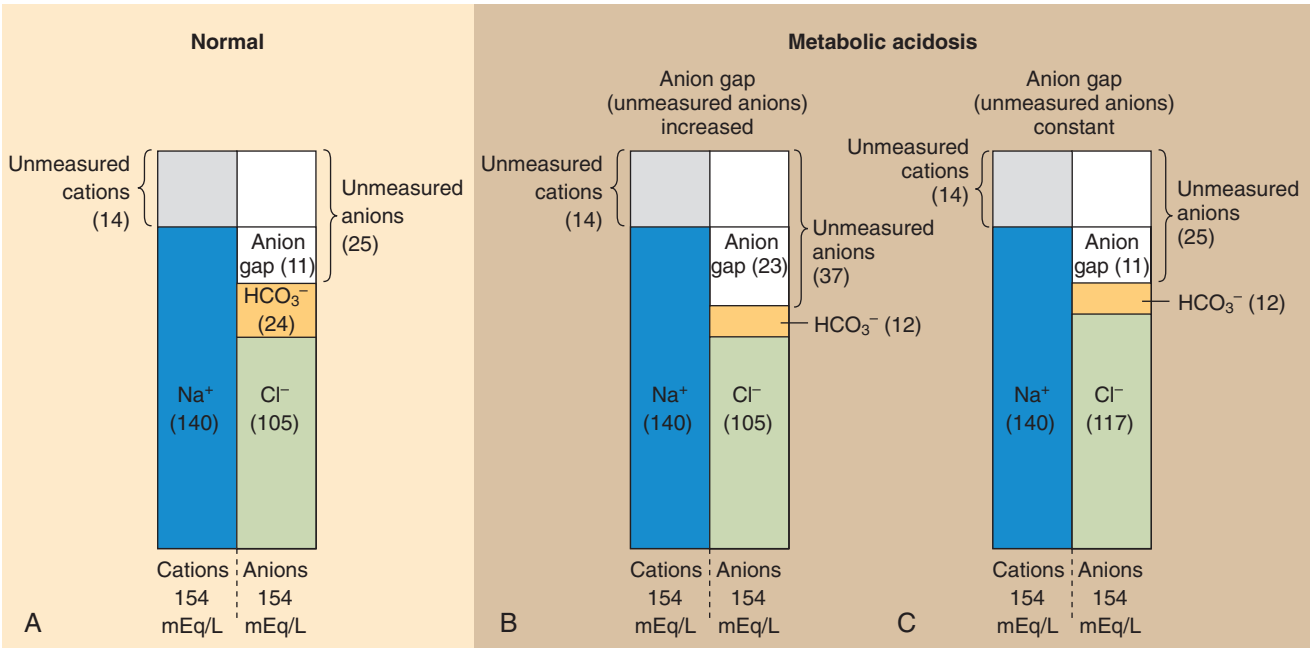

FIGURE 14-7 The anion gap in normal **(A)** and metabolic acidosis (**B** and **C**). Fixed acid accumulation increases the anion gap **(B),** whereas HCO_3^- loss is accompanied by an equal Cl^- gain, keeping the anion gap within the normal range. (Modified from Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.)

RULE OF THUMB

Metabolic acidosis accompanied by a higher than normal anion gap means that the body has accumulated an unusual fixed acid. A metabolic acidosis accompanied by a normal anion gap means that the body has lost a greater than normal amount of base.

Compensation

Hyperventilation is the main compensatory mechanism for metabolic acidosis. The increased plasma $[H^+]$ of metabolic acidosis is buffered by plasma HCO_3^-, which reduces plasma $[HCO_3^-]$ and pH. The low pH activates sensitive receptors in the brain that signal the respiratory muscles to increase ventilation. This increased ventilation lowers the blood's CO_2 levels, and thus it's volatile acid (H_2CO_3), which returns the pH toward the normal range. Uncompensated metabolic acidosis suggests that a ventilatory defect must be present, because ventilation usually responds to this stimulus immediately. Metabolic acidosis accompanied by $PaCO_2$ of 40 mm Hg means that something prevents the lungs from responding appropriately to the brain's stimulation. The defect may lie in nerve impulse transmission, the respiratory muscles, or the lungs.

Symptoms

Respiratory compensation in metabolic acidosis means there is a great increase in minute ventilation, which may cause patients to report dyspnea. Hyperpnea (increased tidal volume depth) is a common finding during physical examination of patients with metabolic acidosis. In patients with severe diabetic ketoacidosis, a very deep, fast breathing develops, called *Kussmaul respiration.* Neurologic symptoms of severe metabolic acidosis range from lethargy to coma.

Correction

The initial goal in severe acidemia is to increase the arterial pH greater than 7.20, a level below which serious cardiac arrhythmias become more likely, and treating them becomes more challenging. If respiratory compensation maintains the pH at or above this level, immediate corrective action is usually not indicated. Treatment of the underlying cause of acid gain or base loss is the reasonable approach.

In cases of severe metabolic acidosis, intravenous infusion of $NaHCO_3$ may be indicated. If respiratory compensation is under way, only small amounts of $NaHCO_3$ are required to attain an arterial pH of 7.20. In any case, rapid correction of an arterial pH greater than 7.20 by $NaHCO_3$ infusion is undesirable.

Metabolic Alkalosis

Metabolic alkalosis is characterized by increased plasma $[HCO_3^-]$ or a loss of H^+ and a high pH. One must keep in mind that increased $[HCO_3^-]$ is not always diagnostic of a primary metabolic alkalosis because it may be caused by renal compensation for respiratory acidosis.

MINI CLINI

Partially Compensated Metabolic Acidosis

PROBLEM: A 42-year-old woman in a diabetic coma was taken to the emergency department. She exhibited fast and deep respirations. Arterial blood gas analysis showed a pH of 7.22, PCO_2 of 20 mm Hg, HCO_3^- of 8 mEq/L, and base excess (BE) of −16 mEq/L. How would the RT interpret this patient's acid-base condition?

SOLUTION: The RT should follow these steps:

1. Categorize the pH. The pH is below the normal range, indicating the presence of acidemia.
2. Determine respiratory involvement. $PaCO_2$ is well below normal, indicating severe hyperventilation. By itself, this would cause alkalosis, but the presence of acidemia rules out primary respiratory alkalosis. The low $PaCO_2$ is probably a compensatory response to primary metabolic acidosis, although this response is currently insufficient to restore pH to the normal range.
3. Determine metabolic involvement. HCO_3^- is severely reduced, consistent with the low pH. In the presence of low pH and low $PaCO_2$, a low HCO_3^- signals primary metabolic acidosis. This is confirmed by the large BE.
4. Assess for compensation. The severe hyperventilation represents a compensatory response to primary metabolic acidosis, although compensation is far from complete. Nevertheless, the pH level would be even lower if the $PaCO_2$ were normal. Hence, the interpretation is a partially compensated metabolic acidosis.

MINI CLINI

Fully Compensated Metabolic Acidosis

PROBLEM: A 38-year-old man had severe diarrhea for weeks without receiving medical attention. Arterial blood gas analysis showed a pH of 7.36, PCO_2 of 24 mm Hg, HCO_3^- of 13 mEq/L, and BE of −11 mEq/L. How would the RT assess this patient's acid-base condition?

SOLUTION: The RT should follow these steps:

1. Categorize the pH. The pH is on the acidic side of the normal range, but it is still normal.
2. Determine respiratory involvement. $PaCO_2$ is below normal, indicating hyperventilation. By itself, this would cause alkalosis; however, because the pH is on the acidic side of normal, the presence of primary respiratory alkalosis is ruled out. The low $PaCO_2$ is likely a compensatory response to a primary metabolic acidosis.
3. Determine metabolic involvement. HCO_3^- level is substantially lower than normal, consistent with a low pH. Given that the pH level is on the acidic side of normal, the low HCO_3^- level signals a possible metabolic acidosis. This is confirmed by the large BE.
4. Assess for compensation. The hyperventilation previously described must represent a compensatory response to primary metabolic acidosis. The pH is in the normal range. Hence, the interpretation is a fully compensated metabolic acidosis.

MINI CLINI

Metabolic Alkalosis

PROBLEM: An 83-year-old woman with heart disease had been taking a powerful diuretic to remove excess edematous fluid from her legs and help keep her free of pulmonary edema. Blood gas and serum electrolyte analyses showed a pH of 7.58, $PaCO_2$ of 46 mm Hg, HCO_3^- of 44 mEq/L, BE of +19 mEq/L, serum K^+ of 2.5 mEq/L, and serum Cl^- of 95 mEq/L. How would the RT assess this patient's acid-base condition?

SOLUTION: The RT should follow these steps:

1. Categorize the pH. The pH level is substantially above normal, indicating the presence of alkalemia.
2. Determine respiratory involvement. $PaCO_2$ is slightly higher than normal, indicating mild hypoventilation. However, because alkalemia is present, the existence of primary respiratory acidosis is ruled out. The elevated $PaCO_2$ may be a compensatory response to a primary metabolic alkalosis.
3. Determine metabolic involvement. HCO_3^- is substantially higher than normal. Given the high pH, the elevated HCO_3^- signals a metabolic alkalosis. This is confirmed by the large BE. In addition, the low serum K^+ and Cl^- values indicate hypokalemic/hypochloremic metabolic alkalosis.
4. Assess for compensation. Although $PaCO_2$ is slightly elevated, compensation for metabolic alkalosis is minimal and the interpretation would be an uncompensated metabolic alkalosis.

Causes

Metabolic alkalosis can occur in one of the following two ways: (1) loss of fixed acids or (2) gain of blood buffer base. Both processes increase plasma $[HCO_3^-]$. To explain why losing fixed acid increases the plasma $[HCO_3^-]$, consider a situation in which vomiting removes gastric HCl from the body (Figure 14-8). In response to HCl loss, H^+ diffuses out of the gastric cell into the gastric fluid, where Cl^- accompanies it; this forces the CO_2 hydration reaction in the gastric cell to the right, which generates HCO_3^-. The HCO_3^- enters the blood in exchange for the Cl^-. The plasma gains an HCO_3^- for each Cl^- (or H^+) that is lost (see Figure 14-8).[6]

The causes of metabolic alkalosis are summarized in Box 14-6. Metabolic alkalosis is common in acutely ill patients and is probably the most complicated acid-base imbalance to treat because it involves fluid and electrolyte imbalances. Metabolic alkalosis is often iatrogenic, resulting from the use of diuretics, low-salt diets, and gastric drainage.

To understand how the loss of Cl^-, K^+, and fluid volume may cause alkalosis, one needs to understand how the kidney regulates Na^+. Approximately 26,000 mEq of Na^+ passes through the glomerular membrane daily, but the body's daily Na^+ intake averages only approximately 150 mEq.[4] The kidney's main job is to reabsorb Na^+, not to excrete it. For this reason, and because Na^+ has a major role in maintaining fluid balance, the kidney places a greater priority on reabsorbing Na^+ than on maintaining Cl^-, K^+, or acid-base balance.

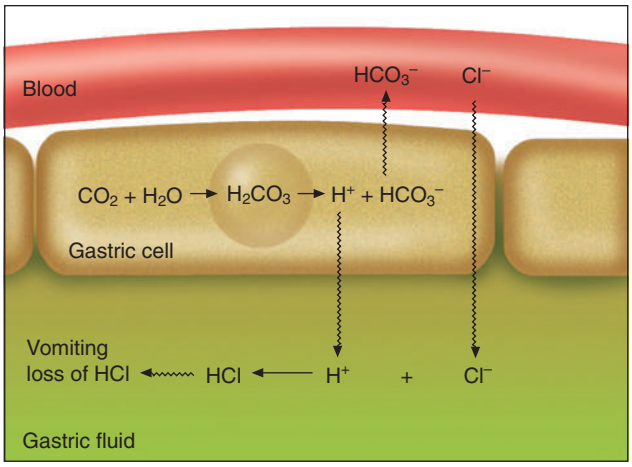

FIGURE 14-8 Gastric H^+ loss generates HCO_3^-, creating metabolic alkalosis. (Modified from Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.)

Box 14-6 Causes of Metabolic Alkalosis (Increased Plasma HCO_3^-)

LOSS OF HYDROGEN IONS

Gastrointestinal

Vomiting
Nasogastric drainage

Renal

Diuretics (loss of Cl^-, K^+ fluid volume)
Hypochloremia (increased H^+ secretion and HCO_3^- reabsorption)
Hypokalemia (increased H^+ secretion and HCO_3^- reabsorption)
Hypovolemia (increased H^+)

RETENTION OF BICARBONATE ION

$NaHCO_3$ infusion or ingestion

From Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.

Normally, Na^+ is reabsorbed through *primary active transport* (Figure 14-9), in which the sodium-potassium–adenosine triphosphatase (Na^+,K^+-ATPase) pump actively transports Na^+ out of the renal tubule cell into the blood. This process causes Na^+ to diffuse continually from the filtrate into the tubule cell. Cl^- (the most abundant anion in the filtrate) accompanies Na^+ because of electrostatic forces—that is to maintain electroneutrality in the filtrate. If blood Cl^- concentration is much below normal (hypochloremia), less Cl^- is available for reabsorption with Na^+, which means that the kidney relies more on other mechanisms to reabsorb Na^+. These other mechanisms, called *secondary active secretion,* require the kidney to secrete either H^+ or K^+ into the filtrate in exchange for Na^+. In this way, Na^+ is reabsorbed, and filtrate electroneutrality is preserved. Figures 14-10 and 14-11 illustrate the secondary active secretion process for H^+ and Na^+, which may lead to loss of plasma H^+ (alkalemia)

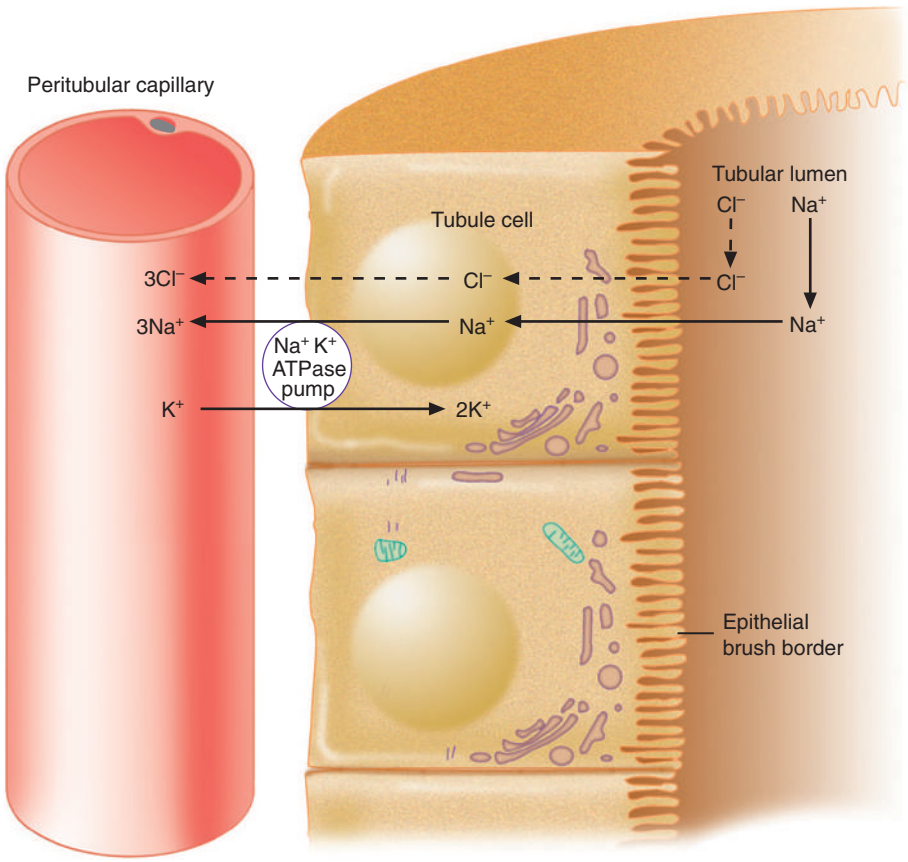

FIGURE 14-9 N^+ reabsorption through primary active transport. The sodium-potassium-adenosine triphosphatase (Na^+,K^+-ATPase) pump generates tubular cell electronegativity by pumping out more Na^+ than it pumps in K^+. This creates both electrostatic and concentration gradients favoring Na^+ diffusion from the filtrate into the tubular cell. Normally, negatively charged Cl^- passively follows Na^+ (cotransport). (Modified from Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.)

and K^+ (hypokalemia). Preexisting hypokalemia (e.g., from inadequate K^+ intake) in the presence of hypochloremia places an even greater demand on the kidney to secrete H^+ to reabsorb Na^+; that is, hypokalemia leads to alkalosis. Dehydration (fluid volume depletion or hypovolemia) further aggravates alkalosis and hypokalemia because hypovolemia profoundly increases the kidney's stimulus to reabsorb Na^+, which means the kidney depends even more on these secondary mechanisms for Na^+ reabsorption.

Compensation

The expected compensatory response to metabolic alkalosis is hypoventilation (CO_2 retention). Traditionally, it was thought that the hypoxemia accompanying hypoventilation greatly limited respiratory compensation for metabolic alkalosis (i.e., hypoxemia itself stimulates ventilation and should prevent compensatory hypoventilation). However, metabolic alkalosis blunts the hypoxemic stimulus to ventilation; that is, neurologic receptors sensitive to hypoxemia become less sensitive in the presence of alkalemia. Individuals with PaO_2 levels of 50 mm Hg may still hypoventilate to $PaCO_2$ levels of 60 mm Hg to compensate for metabolic alkalosis.[6] Nevertheless, significant CO_2 retention is not seen often in cases of metabolic alkalosis, probably because metabolic alkalosis commonly coexists with other conditions that may cause hyperventilation, such as anxiety, pain, infection, fever, or pulmonary edema.

Correction

Correction of metabolic alkalosis is aimed at restoring normal fluid volume and electrolyte concentrations, especially K^+ and Cl^- levels. Inadequate fluid volume, especially if coupled with hypochloremia, causes excessive secretion and loss of H^+ and K^+ because of the great need to reabsorb Na^+. In treating this type of alkalosis, it is important to supply adequate fluids containing Cl^-. If hypokalemia is a primary factor, potassium chloride (KCl) is the preferred corrective agent. In rare cases of very severe metabolic alkalosis, acidifying agents, such as dilute HCl may be infused directly into a large central vein.[7]

Metabolic Acid-Base Indicators

Standard Bicarbonate

To eliminate the influence of the hydration reaction on plasma bicarbonate concentration, some laboratories report **standard bicarbonate**. The standard bicarbonate is the plasma concentration of HCO_3^- (in mEq/L) obtained from a blood sample that has been equilibrated (at body temperature) with a PCO_2

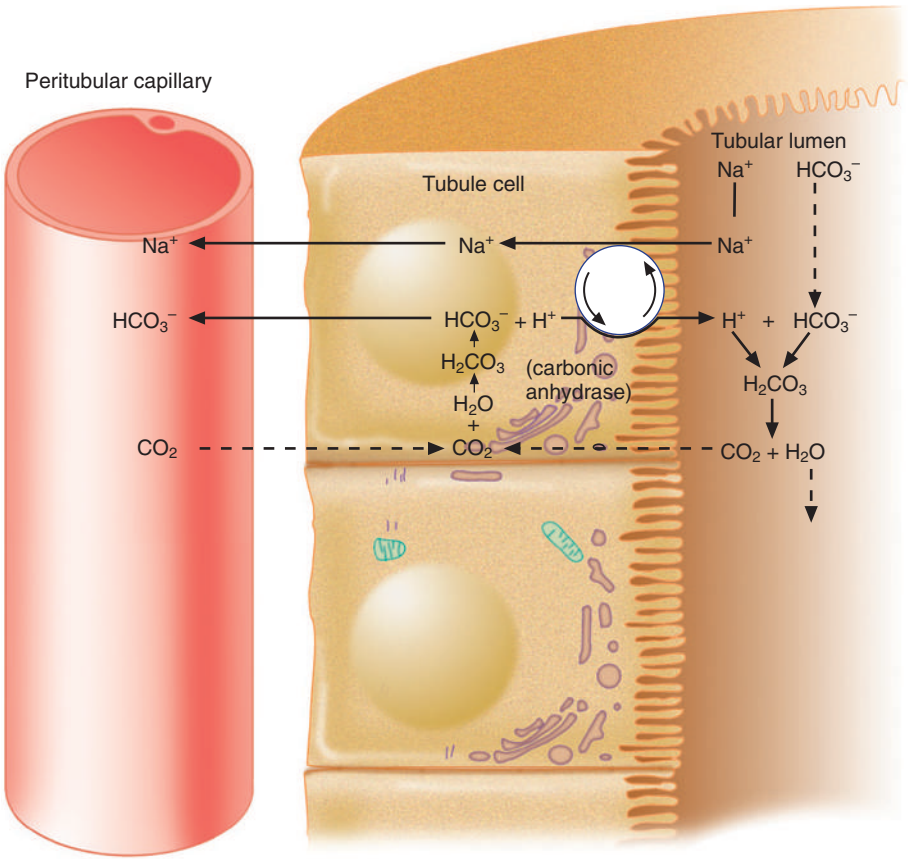

FIGURE 14-10 Na^+ reabsorption through secondary active H^+ secretion. Through the countertransport process, Na^+ is reabsorbed as H^+ is secreted into the filtrate. HCO_3^- ion is reabsorbed with Na^+ instead of Cl^-. This process becomes more predominant when Cl^- is scarce, and it leads to alkalosis. (Modified from Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.)

of 40 mm Hg. This HCO_3^- measurement presumably reflects only the metabolic component of acid-base balance, unhampered by the influence that CO_2 changes have on HCO_3^-. However, the process of standardizing the bicarbonate under in vitro laboratory conditions creates an artificial situation not present in the patient's body. The blood in the patient's vascular system is separated from the extravascular fluid (fluid outside of the vessels) by a thin capillary endothelial membrane, readily permeable to HCO_3^-. When a patient hypoventilates and the blood $PaCO_2$ increases, the plasma HCO_3^- also increases because of the hydration reaction. Consequently, plasma HCO_3^- diffuses out of the capillary into the extravascular fluid until HCO_3^- equilibrium is established between the blood and extravascular fluid. If the patient were now to hyperventilate so that the $PaCO_2$ again was 40 mm Hg, blood HCO_3^- would decrease, and extravascular HCO_3^- would diffuse down its concentration gradient back into the blood until an HCO_3^- equilibrium was established again. This diffusion of HCO_3^- between vascular and extravascular spaces cannot occur in a laboratory blood sample when the blood PCO_2 of a hypercapnic patient is artificially lowered to 40 mm Hg. Thus, even the standard bicarbonate is not a perfect measure of purely nonrespiratory factors that influence blood pH.

Base Excess

Base excess (BE) is determined by equilibrating a blood sample in the laboratory to a PCO_2 of 40 mm Hg (at 37° C) and recording the amount of acid or base needed to titrate 1 L of blood to a pH of 7.40. A normal BE is ±2 mEq/L. A positive BE (>+2 mEq/L) indicates a gain of base or loss of acid from nonrespiratory causes. A negative BE (<–2 mEq/L) indicates a loss of base or a gain of acid from nonrespiratory causes. The BE measurement suffers from the same limitation as the standard bicarbonate because it is an in vitro, rather than in vivo, measurement. That is, in hypercapnia, the **buffer base** that diffused into the extravascular fluid in vivo cannot be recovered during laboratory in vitro titrations.

Further, the reliance on BE to quantify metabolic acid-base abnormalities can be misleading. In cases of acute (uncompensated) respiratory acidosis, the BE commonly would be within the normal range, indicating correctly that the disturbance is purely respiratory in origin. However, when renal compensation has occurred to offset chronic hypercapnia, the BE measurement is elevated above the normal range because of the compensatory increase in plasma HCO_3^-.

To illustrate, consider the accompanying Mini Clini in which the patient has respiratory acidosis for which the body has

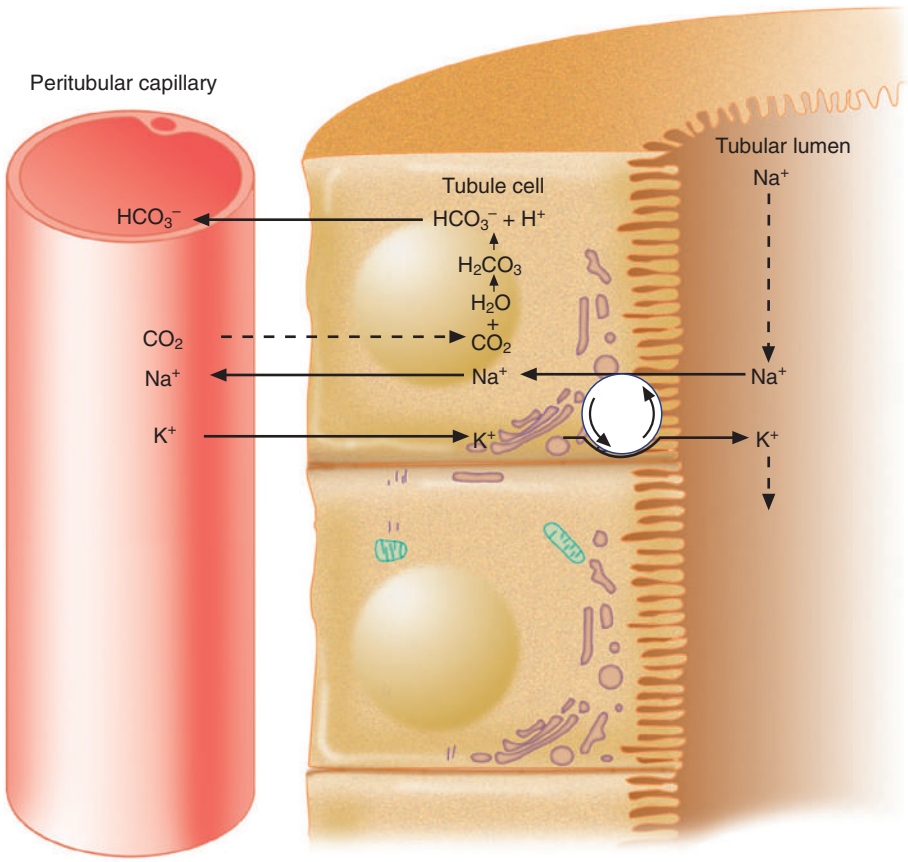

FIGURE 14-11 Na^+ reabsorption through secondary active K^+ secretion. This mechanism is more likely to occur when Cl^- is scarce and an alkalemia (low H^+) exists. In such instances, hypokalemia develops. (Modified from Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.)

compensated by renal retention of HCO_3^-. If this patient's blood were equilibrated in vitro to a $PaCO_2$ of 40 mm Hg, the HCO_3^- would decrease by only 2 to 3 mEq/L to 32 to 33 mEq/L and the pH would increase to much greater than 7.45. This patient's BE would be well above normal. The high BE may lead the clinician to conclude incorrectly that this patient has a primary metabolic alkalosis. However, in this instance, the high BE does not indicate the presence of a pathologic process; it merely reflects the fact that renal compensation has occurred.

Mixed Acid-Base States

Combinations of acid-base disorders may occur in the same patient. A combined disturbance is one in which both respiratory and metabolic disturbances exist and promote the same acid-base disturbance. For example, consider the following arterial blood gas results: a pH of 7.62, $PaCO_2$ of 32 mm Hg, and HCO_3^- of 29 mEq/L. The pH indicates alkalemia, consistent with both the low $PaCO_2$ and the elevated HCO_3^-. This is a combined alkalosis, which means that the patient has two primary acid-base problems (i.e., respiratory and metabolic alkalosis combined); compensation cannot occur in this case. Further, consider the patient in cardiopulmonary arrest whose arterial blood gas results are pH of 7.09, $PaCO_2$ of 77 mm Hg, and HCO_3^- of 11 mEq/L, in all likelihood a result of cessation of breathing resulting in hypercapnia, an uncompensated respiratory acidosis, and moderate to severe hypoxemia, which lead to anaerobic metabolism, which produce a lactic (metabolic) acidosis and thus a combined respiratory and metabolic acidosis.

SUMMARY CHECKLIST

- The lungs regulate the volatile acid content (CO_2) of the blood, and the kidneys control the fixed acid concentration of the blood.
- The larger the equilibrium constant of an acid, the more the acid molecule dissociates and yields H^+.
- In the *open* bicarbonate buffer system, H^+ is buffered to form the volatile acid, H_2CO_3, which dissociates to form H_2O and CO_2; the CO_2 is exhaled into the atmosphere. In the *closed* nonbicarbonate buffer system, H^+ is buffered to form fixed acids, which accumulate in the body.
- Bicarbonate buffers can buffer only fixed acids, but nonbicarbonate buffers can buffer both fixed and volatile acids.
- The ratio between the plasma [HCO_3^-] and dissolved CO_2 determines the blood pH, according to the H-H equation; a ratio of 20:1 [HCO_3^-] to dissolved CO_2 always yields a normal arterial pH of 7.40.

- The kidneys respond to hypoventilation by reabsorbing HCO_3^-, and they respond to hyperventilation by excreting HCO_3^-.
- The lungs respond to metabolic acidosis by hyperventilating, and they respond to metabolic alkalosis by hypoventilating.
- $PaCO_2$ abnormalities characterize respiratory acid-base disturbances, and $[HCO_3^-]$ abnormalities characterize metabolic acid-base disturbances.
- Hypochloremia forces the kidneys to excrete increased amounts of H^+ and K^+ to reabsorb Na^+, causing alkalosis and hypokalemia.
- Hypokalemia forces the kidneys to excrete increased amounts of H^+ to reabsorb Na^+, causing alkalosis.
- Standard bicarbonate and BE measurements are made under conditions of a normal $PaCO_2$ (40 mm Hg), which means that any abnormality in these measurements reflects only nonrespiratory influences.

CHAPTER 15

Regulation of Breathing

WILL BEACHEY

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Identify where the structures that regulate breathing are located.
- Explain how the inspiratory and expiratory neurons in the medulla establish the basic pattern of breathing.
- Describe the effect that impulses from the pneumotaxic and apneustic centers in the pons have on the medullary centers of breathing.
- Describe the effect of various reflexes on breathing.
- Explain how the central and peripheral chemoreceptors differ in the way they regulate breathing.
- Compare and contrast central chemoreceptors response to respiratory and nonrespiratory acid-base disorders.
- Contrast the regulation of breathing in individuals with chronic hypercapnia with the regulation of breathing in healthy individuals.
- Explain why administering high concentrations of oxygen to patients with chronic hypercapnia poses a special risk that is not present in healthy individuals.
- Describe why ascending to a high altitude has different immediate and long-term effects on ventilation.
- Explain why mechanically ventilated patients with head injuries may benefit from deliberate hyperventilation.
- Characterize various abnormal breathing patterns.

CHAPTER OUTLINE

KEY TERMS

apnea
apneustic breathing
apneustic center
Biot respiration
blood-brain barrier
chemoreceptors
Cheyne-Stokes respiration
dorsal respiratory groups (DRGs)
Hering-Breuer inflation reflex
J-receptors
pneumotaxic center
vagovagal reflexes
ventral respiratory groups (VRGs)

Breathing, similar to the heartbeat, is an automatic activity requiring no conscious awareness. In contrast to the heartbeat, breathing patterns can be consciously changed, although powerful neural control mechanisms overwhelm conscious control soon after one willfully stops breathing. The normal unconscious cycle of breathing is regulated by complex mechanisms that are still not completely understood. The rhythmic cycle of breathing comes from the brainstem, mainly from neurons located in the medulla. Higher brain centers and many systemic receptors and reflexes change the output of the medulla. These different structures function in harmony, precisely controlling ventilatory rate and depth to meet the gas exchange needs of the body. This chapter helps the respiratory therapist (RT) understand basic physiologic mechanisms that regulate breathing. With this knowledge, the RT and other members of the patient care team can help predict the effects that various therapies and disease processes have on ventilation.

MEDULLARY RESPIRATORY CENTER

Animal experiments show that cutting through the brainstem just below the medulla (Figure 15-1, *level IV*) stops all ventilatory activity. However, breathing continues rhythmically after the brainstem is cut just above the pons (see Figure 15-1, *level I*). Physiologists used to believe that separate inspiratory and expiratory neuron "centers" in the medulla were responsible for the cyclic pattern of breathing. Researchers believed that inspiratory and expiratory neurons fired by self-excitation and that they mutually inhibited one another. More recent evidence shows that inspiratory and expiratory neurons are anatomically mixed together and do not inhibit one another.[1] No clearly separate inspiratory and expiratory centers exist. Instead, the medulla contains widely scattered groups of respiratory-related neurons, as shown in Figure 15-1. The **dorsal respiratory groups (DRGs)** contain mainly inspiratory neurons, whereas the **ventral respiratory groups (VRGs)** contain both inspiratory and expiratory neurons.

Dorsal Respiratory Groups

As shown in Figure 15-1, DRG neurons are mainly inspiratory neurons located on both sides of the medulla. These neurons send the major inspiratory stimuli to the motor nerves of the diaphragm and external intercostal muscles.[1] Many DRG nerves extend into the VRGs, but few VRG nerve fibers extend into the DRGs. Mutual inhibition is an unlikely explanation for rhythmic, spontaneous breathing.[1]

The vagus and glossopharyngeal nerves transmit many sensory impulses to the DRGs from the lungs, airways, peripheral chemoreceptors, and joint proprioceptors. These impulses change the basic breathing pattern generated in the medulla.

Ventral Respiratory Groups

VRG neurons are located bilaterally in the medulla in two different nuclei and contain inspiratory and expiratory neurons (see Figure 15-1). Some inspiratory VRG neurons send motor impulses through the vagus nerve to the laryngeal and pharyngeal muscles, abducting the vocal cords and increasing the diameter of the glottis. Other VRG inspiratory neurons transmit impulses to the diaphragm and external intercostal muscles. Still other VRG neurons have mostly expiratory discharge patterns and send impulses to the internal intercostal and abdominal expiratory muscles.

The exact origin of the basic rhythmic pattern of ventilation is unknown. No single group of pacemaker cells has been identified. Two predominant theories of rhythm generation are

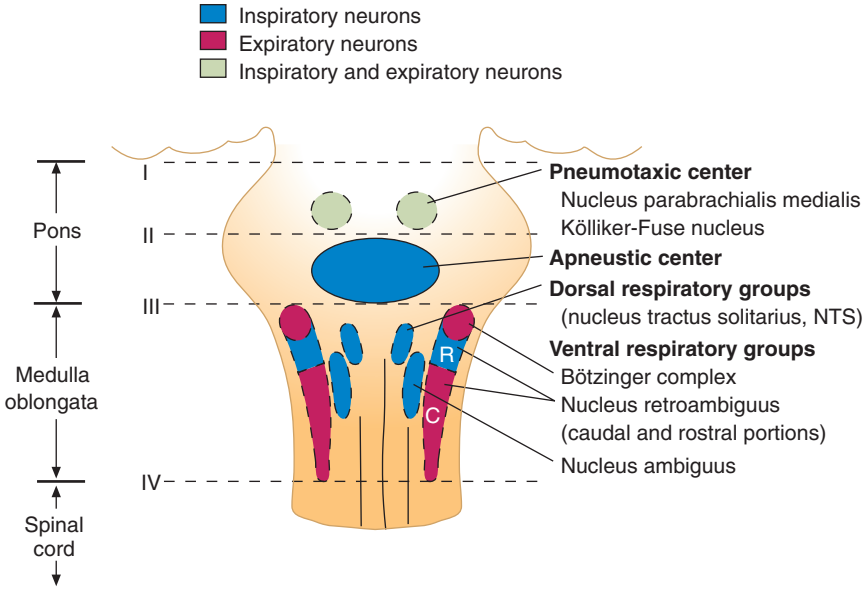

FIGURE 15-1 Dorsal view of the brainstem. Dashed lines *I* to *IV* refer to transections at different levels. (Modified from Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.)

the *pacemaker hypothesis* and the *network hypothesis*.[2] The pacemaker hypothesis holds that certain medullary cells have intrinsic pacemaker properties (i.e., rhythmic self-exciting characteristics) and that these cells drive other medullary neurons. The network hypothesis suggests that rhythmic breathing is the result of a particular pattern of interconnections between neurons dispersed throughout the upper part of the VRG, the pre-Bötzinger complex, and the Bötzinger complex. This hypothesis assumes that certain populations of inspiratory and expiratory neurons inhibit one another and that one of the neuron types fires in a self-limiting way, such that it becomes less responsive the longer it fires. There is no definitive proof of either hypothesis; the precise origin of respiratory rhythm generation remains mysterious.[2]

Inspiratory Ramp Signal

The inspiratory muscles do not receive an instantaneous burst of signals from the dorsal and ventral inspiratory neurons. Rather, the firing rate of DRG and VRG inspiratory neurons increases gradually at the end of the expiratory phase, creating a ramp signal (Figure 15-2). The inspiratory muscles contract steadily and smoothly, gradually expanding the lungs rather than filling them in an abrupt inspiratory gasp. During exercise, various reflexes and receptors influence the medullary neurons, making the ramp signal much steeper, filling the lungs more rapidly.

During quiet breathing, inspiratory neurons fire with an increasing rate for approximately 2 seconds and then abruptly switch off, allowing expiration to proceed for approximately 3 seconds.[3] At the start of expiration, inspiratory neurons again fire briefly, holding back the early phase of expiration (see Figure 15-2). The inhibitory neurons that switch off the inspiratory ramp signal are controlled by the pneumotaxic center and pulmonary stretch receptors, which are discussed later in this chapter.

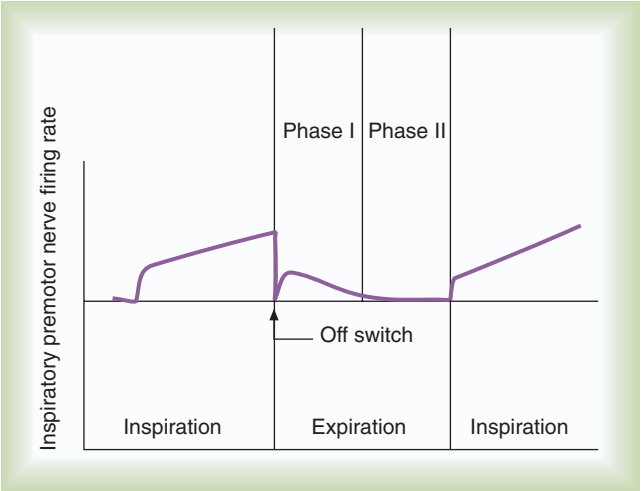

FIGURE 15-2 Inspiratory neural activity during breathing. Note the inspiratory ramp signal *(left)* and the braking action of inspiratory signals in the early part *(phase I)* of expiration. (Redrawn from Leff AR, Shumacher PT: Respiratory physiology: basics and applications, Philadelphia, 1993, Saunders.)

PONTINE RESPIRATORY CENTERS

If the brainstem is cut above the medulla (see Figure 15-1, *level III*), spontaneous respiration continues, although in an irregular pattern. The pons does not make breathing rhythmic; rather, it modifies the output of the medullary centers. Figure 15-1 shows two groups of neurons in the pons: (1) the apneustic center and (2) the pneumotaxic center.

Apneustic Center

The **apneustic center** does not occupy a well-defined anatomic location; its existence and function can be shown only if its connections to the higher pneumotaxic center and vagus nerves are severed. Under such circumstances, the DRG inspiratory neurons fail to switch off, causing prolonged inspiratory gasps interrupted by occasional expirations (**apneustic breathing**). Vagal and pneumotaxic center impulses hold the apneustic center's stimulatory effect on DRG neurons in check.

Pneumotaxic Center

The **pneumotaxic center** is a group of neurons located on both sides of the upper pons (see Figure 15-1). The pneumotaxic center controls the "off-switch" point of the inspiratory ramp, controlling inspiratory time. Strong pneumotaxic signals increase the respiratory rate, and weak signals prolong inspiration and increase tidal volumes. The exact nature of the interaction between the pneumotaxic and apneustic centers is poorly understood. They apparently work together to control the depth of inspiration.[3]

REFLEX CONTROL OF BREATHING

Hering-Breuer Inflation Reflex

The **Hering-Breuer inflation reflex**, described by Hering and Breuer in 1868, is generated by stretch receptors located in the smooth muscle of both large and small airways. When lung inflation stretches these receptors, they send inhibitory impulses through the vagus nerve to the DRG neurons, stopping further inspiration. In this way, the Hering-Breuer reflex has an effect similar to that of the pneumotaxic center. In adults, the Hering-Breuer reflex is activated only at large tidal volumes (≥800 to 1000 ml) and apparently is not an important control mechanism in quiet breathing.[2] This reflex is important, however, in regulating respiratory rate and depth during moderate to strenuous exercise.

Deflation Reflex

Sudden collapse of the lung stimulates strong inspiratory effort. This inspiratory effort may be the result of decreased stretch receptor activity, or it may be caused by the stimulation of other receptors, such as the irritant receptors and J-receptors (discussed later). Although it is unclear which receptors are involved, it is clear that the vagus nerve is the pathway (as it is for the Hering-Breuer reflex) and that the effect is hyperpnea.[1] The

deflation reflex is probably responsible for the hyperpnea observed with pneumothorax (air in the pleural space).

Head Paradoxical Reflex

In 1889, Head observed that if the Hering-Breuer reflex is blocked by cooling the vagus nerve, lung hyperinflation causes a further increase in inspiratory effort—the opposite of the Hering-Breuer reflex. The receptors for this reflex are called *rapidly adapting receptors* because they stop firing promptly after a volume change occurs. The Head reflex may help maintain large tidal volumes during exercise and may be involved in periodic deep sighs during quiet breathing. Periodic sighs help prevent alveolar collapse, or atelectasis. The Head reflex also may be responsible for the first breaths of a newborn.[1]

Irritant Receptors

Rapidly adapting irritant receptors in the epithelium of the larger conducting airways have vagal sensory nerve fibers. Their stimulation, whether by inhaled irritants or by mechanical factors, causes reflex bronchoconstriction, coughing, sneezing, tachypnea, and narrowing of the glottis. Some of these reflexes, called **vagovagal reflexes,** have both sensory and motor vagal components; they are responsible for laryngospasm, coughing, and slowing of the heartbeat. Endotracheal intubation, airway suctioning, and bronchoscopy readily elicit vagovagal reflexes. Physical stimulation of the conducting airways, as with suctioning or bronchoscopy, may cause a severe case of bronchospasm, coughing, and laryngospasm.

J-Receptors

C fibers in the lung parenchyma near the pulmonary capillaries are called *juxtacapillary receptors,* or **J-receptors.** Alveolar inflammatory processes (pneumonia), pulmonary vascular congestion (congestive heart failure), and pulmonary edema stimulate these receptors. This stimulation causes rapid, shallow breathing; a sensation of dyspnea; and expiratory narrowing of the glottis.

Peripheral Proprioceptors

Proprioceptors in muscles, tendons, and joints and pain receptors in muscles and skin send stimulatory signals to the medullary respiratory center. Such stimuli increase medullary inspiratory activity and cause hyperpnea.[4] For this reason, moving the limbs, slapping or splashing cold water on the skin, and other painful stimuli stimulate ventilation in patients with respiratory depression.

Proprioceptors in joints and tendons may be important in initiating and maintaining increased ventilation at the beginning of exercise. Passive limb movement around a joint increases breathing rate in both anesthetized animals and unanesthetized humans.[4]

Muscle Spindles

Muscle spindles in the diaphragm and intercostal muscles are part of a reflex arc that helps the muscles adjust to an increased load. Muscle spindles are sensing elements located on intrafusal muscle fibers, arranged parallel to the main extrafusal muscle fibers (Figure 15-3). The extrafusal fibers that elevate the ribs are innervated by motor fibers (alpha fibers) different from the fibers that innervate the intrafusal spindle fibers (gamma fibers). When the main extrafusal muscle fiber and the intrafusal fibers contract simultaneously, the sensing element *(spindle)* of the intrafusal muscle fiber stretches and sends impulses over spindle afferent nerves directly to the spinal cord (see Figure 15-3). The spindle's afferent (sensory) nerve synapses directly with the alpha motor neuron in the spinal cord, sending impulses back to the main extrafusal muscle. A single synapse reflex arc is created. Alpha motor neuron impulses cause the main extrafusal muscle fibers to contract with greater force, shortening the nearby intrafusal fibers. The stretch-sensitive spindle is thus unloaded, and its impulses cease. In this way, inspiratory muscle force adjusts to the load imposed by decreased lung compliance or increased airway resistance.

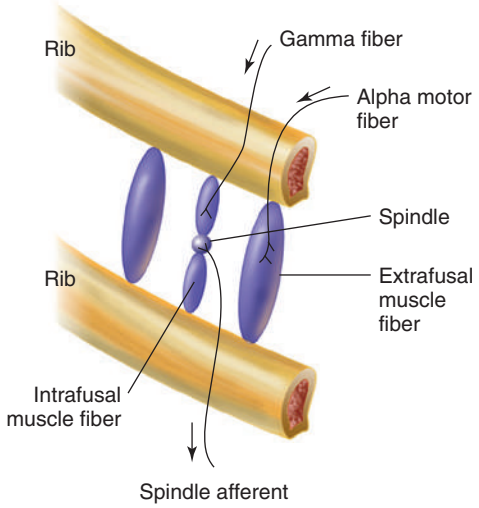

FIGURE 15-3 Stretch-sensitive muscle spindle located on the intrafusal fibers of intercostal muscles. Motor innervation for intrafusal fibers (gamma nerve fibers) is different than for extrafusal fibers (alpha nerve fibers). Spindle afferent nerve fibers synapse with alpha motor neurons in the spinal cord, creating a single synapse reflex arc.

CHEMICAL CONTROL OF BREATHING

The body maintains the proper amounts of oxygen (O_2), carbon dioxide (CO_2), and hydrogen ions (H^+) in the blood mainly by regulating ventilation. Physiologic mechanisms that monitor these substances in the blood allow ventilation to respond appropriately to maintain homeostasis. An increase in blood H^+ concentration stimulates specialized nerve structures called **chemoreceptors.** As a result, the chemoreceptors transmit impulses to the medulla, increasing ventilation. Centrally located chemoreceptors in the medulla respond to H^+, which normally arises from dissolved CO_2 in the cerebrospinal fluid (CSF). Peripherally located chemoreceptors in the fork of the common carotid arteries and the aortic arch are also sensitive

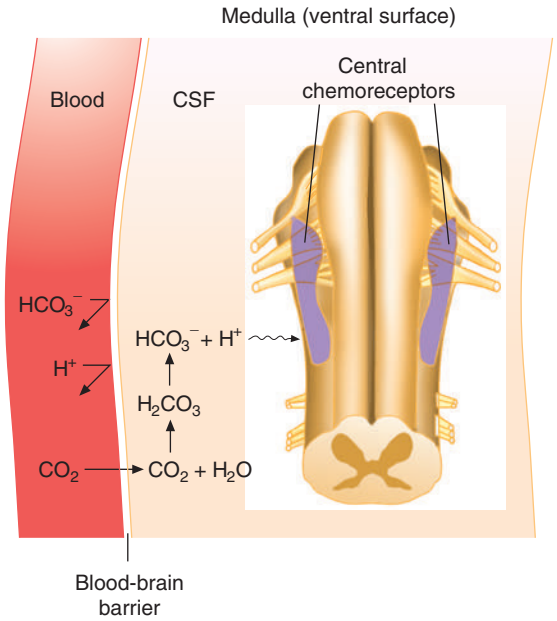

FIGURE 15-4 CO_2 stimulates the medullary chemoreceptors by forming H^+ in the cerebrospinal fluid (CSF). The blood-brain barrier is almost impermeable to H^+ and HCO_3^- but is freely permeable to CO_2. (Modified from Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.)

to H^+ and indirectly to CO_2. These receptors are also indirectly sensitive to hypoxemia because hypoxemia increases the sensitivity of the peripheral chemoreceptors to H^+.[2]

Central Chemoreceptors

H^+ ions, not CO_2 molecules, stimulate highly responsive chemosensitive nerve cells, located on both sides of the medulla. Nevertheless, these central chemoreceptors are extremely sensitive to CO_2 in an indirect fashion. These chemoreceptors are not in direct contact with arterial blood (Figure 15-4). Instead, they are bathed in the CSF, separated from the blood by a semipermeable membrane called the **blood-brain barrier.** This membrane is almost impermeable to H^+ and HCO_3^-, but it is freely permeable to CO_2. When $PaCO_2$ increases, CO_2 diffuses rapidly through the blood-brain barrier into the CSF. In the CSF, CO_2 reacts with water (H_2O) to form H^+ and HCO_3^- (see Figure 15-4). The H^+ ions generated in this fashion stimulate the central chemoreceptors, which stimulate the medullary inspiratory neurons. In this way, $PaCO_2$ is indirectly the primary minute-to-minute controller of ventilation. CO_2 diffusing from the blood into the CSF increases $[H^+]$ almost instantly, exciting the chemoreceptors within seconds. Alveolar ventilation increases by approximately 2 to 3 L/min for each 1-mm Hg increase in $PaCO_2$.[5]

The stimulatory effect of chronically high CO_2 on the central chemoreceptors gradually declines over 1 or 2 days because the kidneys reabsorb HCO_3^- ions in response to respiratory acidosis, bringing the blood pH level back toward normal. The increased number of HCO_3^- ions in the blood eventually diffuses across the blood-brain barrier into the CSF, where they buffer H^+ and bring the CSF pH level back to normal. This activity removes the stimulus to the chemoreceptors, and ventilation decreases. Thus an acute increase in $PaCO_2$ has a powerful effect on ventilation, which is greatly weakened after 1 or 2 days of adaptation.

Peripheral Chemoreceptors

The peripheral chemoreceptors are small, highly vascular structures known as the *carotid* and *aortic bodies*. The carotid bodies are located bilaterally in the bifurcations of the common carotid arteries. The aortic bodies are found in the arch of the aorta. These neural structures increase their firing rates in response to increased arterial $[H^+]$ regardless of its origin (i.e., whether from fixed acid accumulation or increased CO_2). The carotid bodies send their impulses to the respiratory centers in the medulla via the glossopharyngeal nerve, whereas the aortic bodies send their impulses over the vagus nerve. The carotid bodies exert much more influence over the respiratory centers than the aortic bodies do, especially with respect to arterial hypoxemia and acidemia.[1]

Because the carotid bodies receive an extremely high rate of blood flow, they have little time to remove O_2 from the blood. Therefore venous blood leaving the carotid bodies has almost the same O_2 content as the arterial blood entering them. The carotid bodies are exposed at all times to arterial blood, not venous blood, and they sense arterial (not venous) $[H^+]$.

Response to Decreased Arterial Oxygen

Traditionally, it was believed that the carotid bodies directly sense low PaO_2, implying that arterial hypoxemia is an independent stimulus to breathe—the so-called *hypoxic drive*. Although the peripheral chemoreceptors fire more frequently in the presence of arterial hypoxemia, they do so only because hypoxemia makes them more sensitive to H^+.[2] In other words, when PaO_2 is low, carotid body sensitivity to a given $[H^+]$ increases; in this way, hypoxia increases ventilation for any given pH. On the other hand, elevated PaO_2 (hyperoxia) decreases carotid body sensitivity to $[H^+]$. The carotid bodies respond to arterial hypoxemia only because hypoxia makes them more sensitive to $[H^+]$. This means that if the arterial $[H^+]$ is extremely low (high pH), as in severe alkalemia, hypoxemia has little effect on the carotid bodies.[2] Simply stated, the ultimate effect of hypoxemia is to increase the sensitivity of the peripheral chemoreceptors to the given blood $[H^+]$, which increases their firing rate and brings about increased ventilation.

Because of their extremely high blood flow rates, the carotid bodies respond to decreased arterial *partial pressure* of O_2 (in the indirect way just described) rather than to an actual decrease in arterial O_2 *content*. That is, the amount of O_2 the carotid bodies extract from each unit of rapidly flowing blood is so small that their O_2 needs are met entirely by dissolved O_2 in the plasma—which depends on the PaO_2. This is why conditions associated with low arterial O_2 content but normal PaO_2 (e.g., anemia and carbon monoxide poisoning) do not stimulate ventilation.[5]

When pH and $PaCO_2$ are normal (pH = 7.40 and $PaCO_2$ = 40 mm Hg), the nerve-impulse transmission rate of the carotid bodies does not increase significantly until the PaO_2 decreases to approximately 60 mm Hg.[5] If PaO_2 decreases further from 60 mm Hg to 30 mm Hg, the rate of impulse transmission increases sharply because hypoxemia makes the carotid bodies much more sensitive to a pH of 7.40. A decrease in PaO_2 from 60 mm Hg to 30 mm Hg corresponds to the sharpest decrease in O_2 content on the O_2-Hb equilibrium curve (i.e., the steepest part of the curve). Arterial hypoxemia does not stimulate ventilation greatly until the PaO_2 decreases to less than 60 mm Hg.

O_2 plays no role in the drive to breathe in healthy individuals at sea level. High altitude causes a healthy person's ventilation to increase because low barometric pressure decreases the inspired PO_2 and the arterial PO_2, which increases the sensitivity of peripheral chemoreceptors to their H^+ environment. The resulting increase in ventilation is less than expected, however, because hyperventilation decreases $PaCO_2$ and increases arterial pH. The increased pH depresses the medullary respiratory center, counteracting the excitatory effect of a low PaO_2 on peripheral chemoreceptors. Hypoxemia-induced hyperventilation may be impossible in certain conditions, such as severe chronic obstructive pulmonary disease (COPD), in which lung mechanics are so deranged that the stimulatory effect of hypoxemia on ventilation fails to decrease $PaCO_2$ regardless of the patient's effort. In such instances, there is no alkalosis to counteract the stimulatory effects of hypoxemia on ventilation.

RULE OF THUMB

Hypoxemia is not associated with an increased drive to breathe until PaO_2 is less than 60 mm Hg, after which the drive to breathe increases proportionally with the decrease in PaO_2.

Response to Increased $PaCO_2$ and Hydrogen Ions

For a given increase in $PaCO_2$ or $[H^+]$, the carotid bodies are less responsive than the central chemoreceptors. The peripheral chemoreceptors account for only 20% to 30% of the ventilatory response to hypercapnia.[5] However, they respond to increased arterial $[H^+]$ more rapidly than the central chemoreceptors. The explanation is that, in contrast to the central chemoreceptors, the carotid bodies are exposed directly to arterial blood. The body's initial ventilatory response to metabolic acidosis is fairly quick, even though H^+ crosses the blood-brain barrier with difficulty.

As stated earlier, hypoxemia increases the sensitivity of the peripheral chemoreceptors to H^+ and indirectly to $PaCO_2$. Conversely, high PaO_2 (hyperoxia) *decreases* the peripheral chemoreceptors' PCO_2 sensitivity to almost zero.[2] This means that when the PaO_2 is high, the ventilatory response to $PaCO_2$ is mainly due to the central chemoreceptors, which are unaffected by hypoxemia.

Because the only effect of hypoxia on the peripheral chemoreceptors is to increase their sensitivity to arterial $[H^{++}]$—and indirectly to $PaCO_2$—the following statements are true: (1) High PO_2 renders the peripheral chemoreceptors almost unresponsive to PCO_2, and (2) low $PaCO_2$ renders the peripheral chemoreceptors almost unresponsive to hypoxemia.[2] Coexisting arterial hypoxemia, acidemia, and high $PaCO_2$ (i.e., asphyxia) maximally stimulate the peripheral chemoreceptors.

MINI CLINI

Delayed Hyperventilation at High Altitude

PROBLEM: If a person ascends to an elevation of 10,000 feet above sea level, his or her inspired PO_2 decreases because of low barometric pressure; this excites the peripheral chemoreceptors and causes an increase in ventilation. Why must a day or so pass at this altitude before ventilation increases to its maximal level?

SOLUTION: Hypoxia-induced hyperventilation reduces $PaCO_2$ and creates alkalemia. This condition produces an alkalotic CSF because the blood-brain barrier is nearly impermeable to HCO_3^- ions; that is, as CO_2 diffuses out of the CSF in response to the low arterial blood PCO_2, HCO_3^- remains behind in the CSF. The central chemoreceptors are exposed to an alkalotic environment, diminishing the effect of the hypoxic ventilatory stimulus on peripheral chemoreceptors. In other words, the development of respiratory alkalosis limits the degree of hypoxia-induced hyperventilation. Over the first 24 hours or so of hyperventilation, HCO_3^- gradually diffuses out of the CSF across the blood-brain barrier, restoring the CSF pH level to normal. In addition, the kidneys excrete HCO_3^- to compensate for the respiratory alkalemia. Consequently, the blood pH level decreases toward normal, and the hypoxic ventilatory stimulus keeps the $PaCO_2$ low. As the CSF pH level returns to normal, the progressively unrestrained hypoxic stimulus increases ventilation further. It takes approximately 24 hours of high-altitude exposure before ventilation increases to its maximal level.

Individuals with chronic hypercapnia secondary to advanced COPD have depressed ventilatory responses to acute increases in arterial CO_2, partly because of their altered acid-base status and partly because their deranged lung mechanics prevents them from increasing their ventilation adequately.[1] The altered acid-base status arises from the preexisting high levels of blood buffer base, a compensatory response to chronic respiratory acidosis (see Chapter 14).

RULE OF THUMB

The ventilatory response to hypoxemia is greatly enhanced by hypercapnia and acidemia.

Control of Breathing in Chronic Hypercapnia

A sudden increase in arterial PCO_2 causes an immediate increase in ventilation because CO_2 rapidly diffuses from the blood into

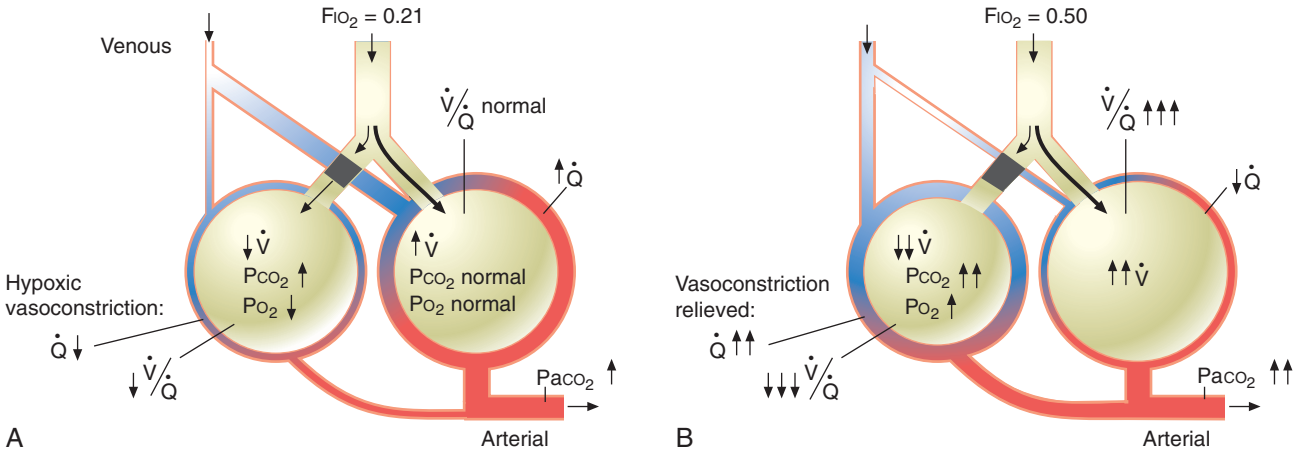

FIGURE 15-5 Proposed mechanism whereby O_2 administration in chronically hypercapnic individuals induces further hypercapnia by creating $\dot{V}/\dot{Q}$ mismatches. **A,** Low $\dot{V}/\dot{Q}$ unit *(left)* is hypoxic and hypercapnic while breathing ambient air; this induces pulmonary vasoconstriction. **B,** Breathing 50% O_2 predisposes the poorly ventilated unit to absorption atelectasis, further decreasing its ventilation, and simultaneously relieves hypoxic vasoconstriction, increasing its blood flow. These events (1) lower the poorly ventilated unit's $\dot{V}/\dot{Q}$ ratio further and (2) divert blood flow away from and ventilation toward already well-ventilated units. The latter increases alveolar dead space (high $\dot{V}/\dot{Q}$). (Modified from Beachey W: Respiratory care anatomy and physiology: foundations for clinical practice, ed 2, St Louis, 2007, Mosby.)

the CSF, increasing the $[H^+]$ surrounding central chemoreceptors. If $PaCO_2$ increases gradually over many years, as might occur in the development of severe COPD and worsening lung mechanics, the kidneys compensate by increasing the plasma $[HCO_3^-]$, which keeps arterial pH within normal limits. As plasma HCO_3^- levels increase, HCO_3^- ions slowly diffuse across the blood-brain barrier, keeping CSF pH within its normal range. Because the central chemoreceptors respond to $[H^+]$, not the CO_2 molecule, they sense a normal pH environment, even though the $PaCO_2$ is abnormally high.

This adaptation explains why the chronically high $PaCO_2$ of people with severe COPD does not overly stimulate their ventilation. Instead, the hypoxemia that accompanies chronic hypercapnia becomes a major part of the minute-to-minute breathing stimulus in the roundabout way discussed previously; hypoxemia increases the sensitivity of the peripheral chemoreceptors to $[H^+]$, increasing the nerve impulses they transmit to the medulla, which stimulates ventilation. Patients with severe COPD are invariably hypoxemic when breathing room air because their lungs have ventilation and blood flow mismatches. It stands to reason that breathing supplemental O_2 would increase the PaO_2 and make the carotid bodies less sensitive to $[H^+]$, which would decrease ventilation further and increase the $PaCO_2$.

Oxygen-Associated Hypercapnia

The $PaCO_2$ of chronically hypercapnic patients with COPD sometimes increases acutely after these patients are given supplemental O_2. The reason for this phenomenon has been a subject of much debate and misunderstanding. The traditional explanation for this phenomenon has been that O_2 breathing removes the hypoxic ventilatory stimulus and induces hypoventilation, but this explanation is probably overly simplified. The reduction in minute ventilation after O_2 breathing in patients with advanced COPD is generally severe enough to account for the increased $PaCO_2$. The most significant reason for hypercapnia following O_2 breathing in severe COPD is that it worsens the ventilation-perfusion ($\dot{V}/\dot{Q}$) relationships in the lungs.

When patients with severe COPD breathe supplemental O_2 it abolishes the hypoxic pulmonary vasoconstriction present in poorly ventilated lung regions. As a result, vascular resistance of underventilated regions decreases, and these areas receive more blood flow, drawing blood away from well-ventilated regions (Figure 15-5). At the same time that poorly ventilated regions receive more blood flow, they become even less ventilated as O_2-rich inspired gas washes out resident nitrogen gas, making these alveoli more subject to absorption atelectasis (i.e., O_2 may be absorbed by the pulmonary circulation more rapidly than the slowed ventilation can replenish it—notice the further decreased $\dot{V}$ in Figure 15-5, *B*). As a result, inspired gas flows preferentially to the compliant, already well-ventilated alveoli (see Figure 15-5, *B*), increasing their $\dot{V}/\dot{Q}$. The increased $\dot{V}/\dot{Q}$ in these alveoli is exaggerated further as a greater proportion of the cardiac output than before is redirected to poorly ventilated alveoli, because their vascular resistance was reduced by O_2 breathing.

To summarize, O_2 breathing causes more blood flow to be directed to poorly ventilated alveoli, which takes blood flow away from well-ventilated alveoli. The key point is that already underventilated alveoli receive additional blood flow, which causes blood PCO_2 to increase further. These events can occur without a decrease in overall minute ventilation.

It is important to keep in mind that the diagnosis of COPD on a patient's medical record does not mean the patient has a chronically high $PaCO_2$ or that O_2 administration may be associated with hypercapnia. These characteristics are present only in severe end-stage disease, which includes only a small percentage of patients with a COPD diagnosis. Concern about

O_2-associated hypercapnia and acidemia is not justifiable in most patients with a diagnosis of COPD. O_2 should never be withheld from acutely hypoxemic patients with COPD for fear of inducing hypoventilation and hypercapnia. Tissue oxygenation is the overriding priority; O_2 must never be withheld from exacerbated, hypoxemic patients with COPD for any reason. The clinician must be prepared to support ventilation mechanically if O_2 administration is accompanied by severe hypoventilation.

Central Chemoreceptor Response to Acute Carbon Dioxide Increase in Chronic Hypercapnia

As discussed earlier, the kidneys compensate for the acidic effects of chronic hypercapnia by increasing the plasma HCO_3^- level, keeping the medullary chemoreceptor pH environment in the normal range. This does not mean that the medullary chemoreceptors cannot respond to further *acute* increases in $PaCO_2$. A sudden elevation in $PaCO_2$ immediately crosses the blood-brain barrier into the CSF, generating H^+ that then stimulates the medullary chemoreceptors. The resulting ventilatory response is depressed, however, for chemical and mechanical reasons: (1) The blood's increased buffering capacity (high HCO_3^- level) in chronic hypercapnia prevents arterial pH from decreasing as sharply as it would in normal conditions, and (2) abnormal breathing mechanics hamper the lung's ability to increase ventilation appropriately. To illustrate the blood's changed buffering capacity, compare a healthy person (pH = 7.40, $PaCO_2$ = 40 mm Hg, HCO_3^- = 24 mEq/L) with a chronically hypercapnic person (pH = 7.38, $PaCO_2$ = 60 mm Hg, HCO_3^- = 34 mEq/L). A sudden increase of 30 mm Hg in $PaCO_2$ of both individuals causes the healthy person's arterial pH to decrease to 7.21 and the hypercapnic person's pH to decrease to only 7.24. (These values are calculated using the Henderson-Hasselbalch equation, assuming a 1-mEq/L increase in plasma HCO_3^- concentration for each acute increase of 10 mm Hg in $PaCO_2$.) The central chemoreceptors of a chronically hypercapnic patient experience less stimulation than the central chemoreceptors of normal individuals for the same increase in $PaCO_2$.

RULE OF THUMB

Tissue oxygenation is of overriding importance and must not be sacrificed because of concern about hypercapnia and acidemia in a patient with exacerbated COPD.

VENTILATORY RESPONSE TO EXERCISE

Strenuous exercise can increase CO_2 production and O_2 consumption by 20-fold.[3] Ventilation normally keeps pace with CO_2 production, keeping $PaCO_2$, PaO_2, and arterial pH constant. Because arterial blood gases do not change during normal exercise, some other mechanism must be responsible for the increased ventilation in healthy individuals during exertion.

The exact mechanism responsible for this increase in ventilation is not well understood. Especially mysterious is the abrupt increase in ventilation at the onset of exercise, long before any chemical or humoral changes can occur in the body. Two predominating theories for this phenomenon are: (1) When the cerebral motor cortex sends impulses to exercising muscles, it apparently sends collateral excitatory impulses to the medullary respiratory centers; (2) exercising limbs moving around their joints stimulate proprioceptors, which transmit excitatory impulses to the medullary centers.[1,3] Evidence also suggests that the sudden increase in ventilation at the onset of exercise is a learned response.[1,3] With repeated experience, the brain may learn to anticipate the proper amount of ventilation required to maintain normal blood gases during exercise.

ABNORMAL BREATHING PATTERNS

Commonly described abnormal breathing patterns include Cheyne-Stokes respiration, Biot respiration, apneustic breathing, and central neurogenic hypoventilation and hyperventilation. In **Cheyne-Stokes respiration,** respiratory rate and tidal volume gradually increase and then gradually decrease to complete **apnea** (absence of ventilation), which may last several seconds. Tidal volume and breathing frequency gradually increase again, repeating the cycle. This pattern occurs when cardiac output is low, as in congestive heart failure, delaying the blood transit time between the lungs and the brain.[4] In this instance, changes in respiratory center PCO_2 lag behind changes in arterial PCO_2.

For example, when an increased $PaCO_2$ from the lungs reaches the respiratory neurons, ventilation is stimulated; this lowers the $PaCO_2$ level. By the time the reduced $PaCO_2$ reaches the medulla to inhibit ventilation, hyperventilation has been in progress for an inappropriately long time. When blood from the lung finally does reach the medullary centers, the low $PaCO_2$ greatly depresses ventilation to the point of apnea. $PaCO_2$ increases, but an increase in respiratory center PCO_2 is delayed because of low blood flow rate. The brain eventually does receive the high $PaCO_2$ signal, and the cycle is repeated. Cheyne-Stokes respiration may also be caused by brain injuries in which the respiratory centers over-respond to changes in the PCO_2 level.

Biot respiration is similar to Cheyne-Stokes respiration except that tidal volumes are of identical depth. It occurs in patients with increased intracranial pressure (ICP), but the mechanism for this pattern is unclear.[4]

Apneustic breathing indicates damage to the pons. Central neurogenic hyperventilation is characterized by persistent hyperventilation driven by abnormal neural stimuli. It is related to midbrain and upper pons damage associated with head trauma, severe brain hypoxia, or lack of blood flow to the brain.[6] Conversely, central neurogenic hypoventilation means the respiratory centers do not respond appropriately to ventilatory stimuli, such as CO_2. It also is associated with head trauma and brain hypoxia as well as narcotic suppression of the respiratory center.[6]

CARBON DIOXIDE AND CEREBRAL BLOOD FLOW

CO_2 plays an important role in regulating cerebral blood flow. Its effect is mediated through the formation of H^+ by CO_2.[7] Increased PCO_2 dilates cerebral vessels, increasing cerebral blood flow, whereas decreased PCO_2 constricts cerebral vessels and reduces cerebral blood flow. In patients with traumatic brain injury (TBI), the brain swells acutely; this increases the ICP in the rigid skull to such high levels that blood supply to the brain might be cut off, causing cerebral hypoxia *(ischemia)*. That is, high ICP may exceed cerebral arterial pressure and stop blood flow to the brain.

Although controversial, mechanical hyperventilation has been used for many years in selected patients with TBI to decrease $PaCO_2$ and reduce the cerebral blood flow and ICP. In patients with TBI, a cerebral blood volume reduction of only 0.5 to 0.7 ml reduces the ICP by 1 mm Hg; for every 1-mm Hg acute reduction in $PaCO_2$ (between 20 mm Hg and 60 mm Hg), there is a 3% reduction in cerebral blood flow. Although an acute reduction in $PaCO_2$ reduces ICP, it also reduces cerebral blood flow and potentially causes cerebral ischemia. For this reason, the practice of inducing mechanical hyperventilation in patients with TBI is debatable primarily because it may well reduce blood flow and O_2 to an injured organ. On the other end of the spectrum; however, *hypoventilation* in a head trauma patient with an already high ICP is especially dangerous because hypercapnia dilates cerebral vessels and elevates the ICP even more.

The debate centers around the question of whether a hyperventilation-induced decrease in cerebral blood flow creates an additional hypoxic insult to the already ischemic brain and whether patients managed in this way have better clinical outcomes than patients in whom hyperventilation is not instituted. A comprehensive review of the subject published in 2005 concluded that hyperventilation produced no advantage in long-term clinical outcome of TBI compared with ventilation that maintained $PaCO_2$ in the normal range.[7] The authors concluded that in TBI, hyperventilation therapy should be considered only for patients with high ICPs; no benefit can be expected if ICP is normal. They further concluded that hyperventilation is most appropriate in the second or third day after injury because cerebral blood flow is lowest in the first 24 hours after injury, and the risk for inducing ischemia through hyperventilation is greatest during this time. The authors advise against the hyperventilation of patients with TBI to $PaCO_2$ less than 30 mm Hg because of the increased danger of cerebral ischemia. Finally, hyperventilation is effective for only approximately 24 to 48 hours because compensatory renal elimination of HCO_3^- in the face of alkalemia restores the acid-base balance, negating the vasoconstrictive effect of hypocapnia. In any case, *hypoventilation* in patients with head trauma and increased ICP is especially dangerous because hypercapnia dilates cerebral vessels and increases ICP further. Even opponents of hyperventilation generally maintain $PaCO_2$ of patients with TBI in the low to normal range at approximately 35 mm Hg.[8]

MINI CLINI

Mechanical Hyperventilation of a Patient With Traumatic Brain Injury

PROBLEM: An automobile accident victim, previously healthy, sustained a closed head injury with accompanying high ICP. Mechanical ventilation in the intensive care unit is required, and the physician asks the RT for input regarding ventilator strategies and what $PaCO_2$ should be targeted?

DISCUSSION: More than 40 years ago, clinical investigators showed that the volume of the swollen brain could be reduced by decreasing the $PaCO_2$. Since then, mechanical hyperventilation has been a cornerstone in managing increased ICP associated with TBI.[7] Hyperventilation decreases ICP by causing cerebral vasoconstriction, ultimately reducing cerebral blood volume. This subject is not without controversy because hyperventilation-induced cerebral vasoconstriction has the potential to reduce cerebral blood flow to levels that cause cerebral hypoxia *(ischemia)*. This concern has dampened enthusiasm for hyperventilation in TBI. Both the proponents and the opponents of hyperventilation recognize that TBI poses an ischemic threat to the brain; proponents believe that the reduction of cerebral blood flow ultimately improves cerebral oxygenation by reducing the ICP, which helps sustain the cerebral perfusion pressure. Opponents point out that no other hypoxic organ in the body is treated by reducing its blood flow and O_2 supply. (Hyperventilation in this context is generally defined as $PaCO_2 < 35$ mm Hg.[7])

SUMMARY CHECKLIST

- The DRGs and VRGs of neurons in the medulla generate the basic cyclic breathing pattern.
- Apneustic center impulses prevent medullary inspiratory neurons from switching off, creating a prolonged, gasping inspiration.
- Impulses from the pneumotaxic center inhibit the apneustic center and inspiratory neurons of the DRGs, shortening inspiratory time and increasing respiratory rate.
- Various reflexes from peripheral sources affect the breathing pattern by altering the output of the medullary center.
- Central chemoreceptors in the medulla are bathed in the CSF, separated from arterial blood by a semipermeable membrane called the *blood-brain barrier*.
- The blood-brain barrier is almost impermeable to arterial H^+ and HCO_3^- ions, but it is freely permeable to arterial CO_2.
- Central chemoreceptors stimulate increased ventilation in response to the H^+ formed in the CSF by the reaction between arterial CO_2 and H_2O.
- Peripheral chemoreceptors, located mainly in the carotid bodies, respond to arterial $[H^+]$; hypoxemia increases the sensitivity of chemoreceptors to a given arterial pH.
- The peripheral chemoreceptors are indirectly stimulated by arterial CO_2 to the extent that CO_2 reacts with H_2O to form H^+.

- The primary stimulus for breathing in healthy individuals is arterial CO_2, mediated through the central chemoreceptors via H^+ formed by the reaction between H_2O and CO_2 molecules.
- The secondary stimulus for breathing in healthy individuals is arterial hypoxemia, which is not clinically significant until PaO_2 is less than 60 mm Hg.
- Breathing of patients with chronic, compensated hypercapnia is driven more by the hypoxic stimulus than when acid-base status is normal.
- O_2 therapy is associated with acute arterial CO_2 retention and acidosis in patients with chronic hypercapnia.
- O_2 should never be withheld for any reason from patients with severe hypoxemia.
- CO_2 dilates cerebral blood vessels and increases ICP; reducing arterial CO_2 constricts cerebral vessels and decreases ICP.

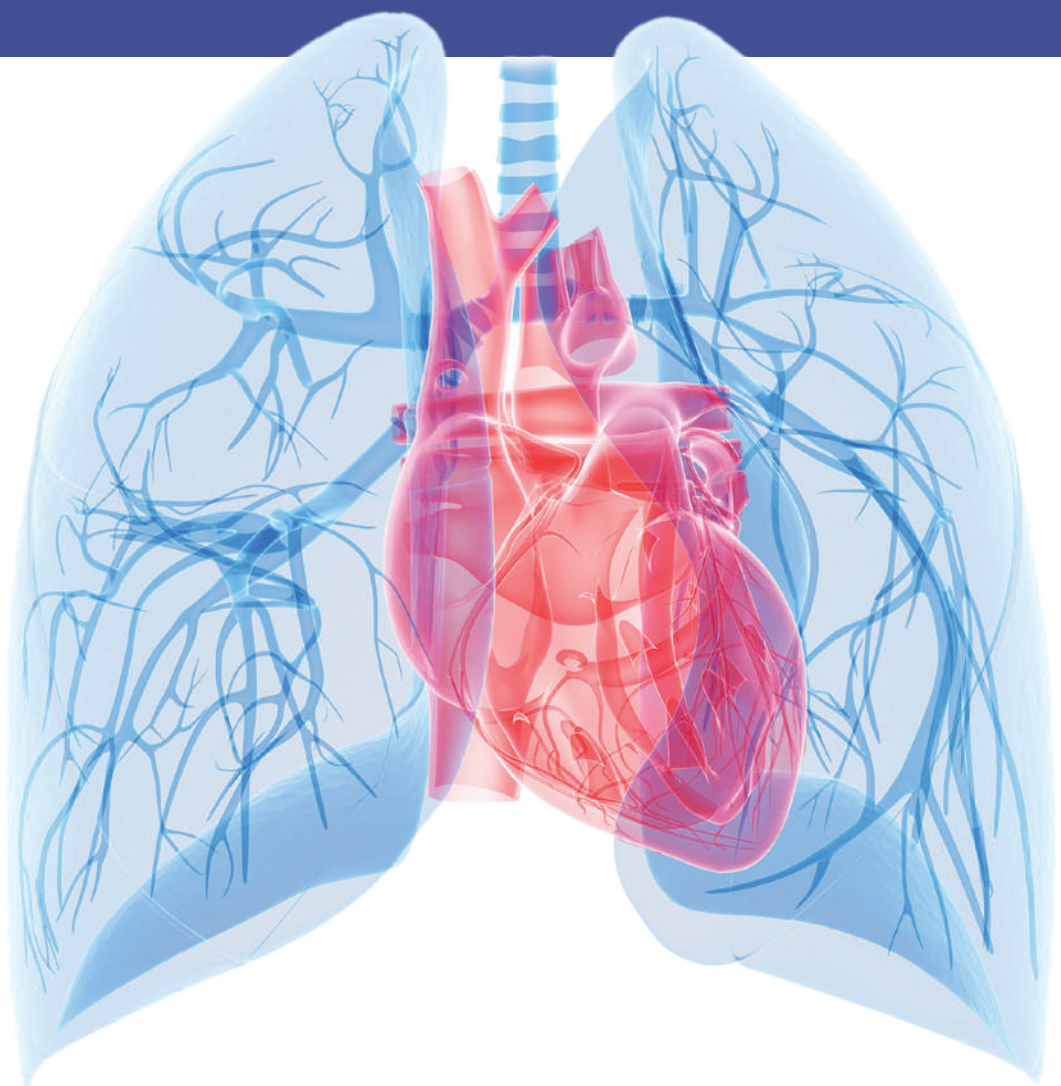
SECTION III

ASSESSMENT OF RESPIRATORY DISORDERS



CHAPTER 16

Bedside Assessment of the Patient

RICHARD H. KALLET

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe why patient interviews are necessary and the appropriate interview techniques.
- Identify abnormalities in lung function associated with common pulmonary symptoms.
- Identify breathing patterns associated with pulmonary disease.
- Differentiate between dyspnea and breathlessness.
- Identify terms describing normal and abnormal lung sounds.
- Describe the mechanisms causing normal and abnormal lung sounds.
- Review the importance of examining the precordium, abdomen, and extremities to identify abnormalities associated with cardiopulmonary disease.

CHAPTER OUTLINE

KEY TERMS

abdominal compartment syndrome
abdominal paradox
advance directive
adventitious lung sounds
angina
barrel chest
bradycardia
bradypnea
breathlessness
bronchophony
cachexia
central cyanosis
clubbing
cough
crackles
diagnosis
differential diagnosis
diaphoresis
diastolic pressure
dyspnea
febrile
fetid
fever
gallop rhythm
heave
hematemesis
hemoptysis
hepatomegaly
Hoover sign
hypertension
hypotension
hypothermia
hypovolemia
jugular venous distention
Kussmaul breathing
Kussmaul sign
loud P_2
lymphadenopathy
mucoid
murmurs
orthodeoxia
orthopnea
pack-years
pedal edema
peripheral cyanosis
phlegm
platypnea
pneumothorax
postural hypotension
pulse pressure
pulsus alternans

pulsus paradoxus
purulent
rales
respiratory alternans
retractions
sensorium
shock
signs
sputum
stridor
subcutaneous emphysema
symptoms
syncope
systolic pressure
tachycardia
tachypnea
thrills
tracheal tugging
trepopnea
tripodding
wheezes

Decisions regarding when to initiate, change, or discontinue therapy depend on accurate clinical assessments. The physician is ultimately responsible for these decisions. But because respiratory therapists (RTs) often participate in clinical decision making, they must develop competent bedside assessment skills. To do this effectively, the RT must assume responsibility for gathering and interpreting relevant bedside patient data.

Bedside assessment is the process of interviewing and examining a patient for signs and symptoms of disease, as well as evaluating the effects of treatment. Very often bedside assessment provides initial evidence that something is wrong. In contrast to some diagnostic tests, bedside assessment techniques are of little risk to the patient.

Two key sources of patient data are the medical history and the physical examination. Data gathered during the initial interview and physical examination help identify the need for subsequent diagnostic tests. After a tentative diagnosis is made, these assessment skills help the clinician in selecting the best therapy. These assessment skills are used repeatedly to monitor the patient's response to therapy, and make any necessary adjustments.

The patient initially is assessed to identify the correct diagnosis. **Diagnosis** (from the Greek *to know thoroughly*), is the process of identifying the nature and cause of illness. It is a disciplined, systematic approach based on careful history taking, physical examination and testing (e.g., laboratory analysis of blood or tissue samples, radiologic examinations, etc.). **Differential diagnosis** is the term used when signs and symptoms are shared by many diseases and the exact cause is unclear. For example a cough can be a symptom of a common cold, pneumonia, bronchitis, or congestive heart failure (CHF). **Signs** refer to the *objective manifestation* of illness (e.g., increased respiratory rate) whereas **symptoms** refer the sensation or *subjective experience* of some aspect of an illness (e.g., breathlessness). Symptoms must always be stated by the patient and never inferred from observed signs. Common symptoms and signs associated with cardiopulmonary disease are discussed in this chapter.

Diagnosis is performed primarily by a physician. Exceptions may occur in emergency situations when a physician is unavailable. In such cases, nurses and RTs may evaluate the patient to rapidly implement appropriate lifesaving therapy (e.g., cardiopulmonary resuscitation).

The mastery of bedside assessment skills described here requires practice. Initially, students should practice these skills on healthy individuals. This helps improve technique and provides an understanding of normal variations. The ability to discriminate abnormal findings from the range of normal findings is an important skill that requires experience to master.

INTERVIEWING THE PATIENT AND TAKING A MEDICAL HISTORY

Interviewing furnishes unique information because it provides the patient's perspective. It serves the following three related purposes:

1. To establish a rapport between the clinician and patient.
2. To obtain information essential for making a diagnosis.
3. To help monitor changes in the patient's symptoms and response to therapy.

MINI CLINI

Bedside Assessment of the Postoperative Patient

PROBLEM: The RT is called to see a 54-year-old woman who underwent abdominal surgery 2 days earlier. She is currently afebrile, alert, and oriented but is complaining of dyspnea. Her resting respiratory rate is 34 breaths/min, and the breaths are shallow. Her heart rate is 110 beats/min. She is 5 feet tall and weighs approximately 185 lb. During the brief interview, the RT identifies that the dyspnea has gradually increased over the past 12 hours and increases with exertion. The RT auscultates diminished breath sounds in the bases, with some fine, late inspiratory crackles. The remainder of the physical examination is normal. What is the most likely cause of this patient's dyspnea, and what should be done?

SOLUTION: The findings indicate a loss of lung volume as the cause of the sudden dyspnea. The rapid, shallow breathing; fine, late inspiratory crackles; and history of recent abdominal surgery suggest atelectasis. Patients who undergo abdominal surgery are prone to developing atelectasis in the postoperative period. The differential diagnosis would include CHF and pulmonary thromboembolism. The RT should ask the attending physician to order a chest radiograph and begin lung expansion therapy if the chest film confirms the presence of atelectasis.

Principles of Interviewing

Interviewing is the process of gathering relevant information from a patient, an essential element of which involves establishing rapport. Building rapport with a patient requires basic

human skills of communicating concern, warmth, and empathy. Illness serious enough to require hospitalization causes stress. Meaningful human contact lessens a patient's sense of isolation and helps reduce stress. Factors affecting communication between the RT and the patient include the following:

- Sensory and emotional factors
- Environmental factors
- Verbal and nonverbal components of the communication process
- Cultural and other internal values, beliefs, feelings, habits, and preoccupations of *both* the RT and the patient.

Because of these factors, no two interviews are the same. Developing interview skills takes time and experience. This requires adherence to some basic interview techniques and becoming knowledgeable about the causes and characteristics of common cardiopulmonary symptoms. The following discussion provides some guidelines for interviewing and discusses common symptoms associated with diseases of the chest.

Structure and Technique for Interviewing

The ideal interview makes the patient feel secure enough to talk openly about important personal matters. Each interview should begin with the RT introducing himself or herself to the patient, and stating the purpose of the visit. To begin the process of establishing rapport, the introduction is done from the nonthreatening position referred to as *social space,* approximately 4 to 12 feet from the patient. Bear in mind that the perception of "appropriate" space varies across individuals and particularly those of different cultural backgrounds. Pulling the curtain between the beds of a semiprivate room also may be helpful in making the patient feel more at ease with the interview (Box 16-1).

Next, the RT might be able to move into what is considered *personal space* (2 to 4 feet from the patient) to begin the interview. In this space, the patient does not have to speak loudly in response to questions. The RT should assume a physical position at the same level with the patient (e.g., by sitting in a chair) before beginning the formal interview. Avoid standing over the patient, because this may feel intimidating and foster uneasiness. Appropriate eye contact with the patient is essential for a high-quality interview. Eye contact gives the patient more confidence in the interviewer. It also allows the interviewer to observe facial expressions that may communicate a patient's confusion, fear, frustration, or other emotions in response.

Use neutral questions and avoid leading questions during the interview. For example, asking the patient, "Is your breathing better now?" leads the patient toward a desired response and may elicit false information. Rather ask the patient, "How is your breathing now?" Often this gets more accurate information (Box 16-2).

Common characteristics of symptoms can be identified by asking the following questions during the interview:

- When did the symptom start?
- How severe is it? (This can be rated on a scale of 1 to 10.)
- Where on the body is it? (This is especially important for chest pain.)

Box 16-1 Guidelines for Effective Patient Interviewing

PROJECT A SENSE OF UNDIVIDED INTEREST IN THE PATIENT

- Provide for privacy and do not permit interruptions.
- Review records and prepare materials before entering the room.
- Listen and observe carefully.
- Use appropriate eye contact.
- Be attentive and respond to the patient's priorities, concerns, feelings, and comfort.

ESTABLISH YOUR PROFESSIONAL ROLE DURING THE INTRODUCTION

- Dress and groom professionally.
- Enter the room with a smile and unhurried manner.
- Make immediate eye contact.
- If the patient is well enough, introduce yourself with a firm handshake.
- State your role and the purpose of your visit, and define the patient's involvement in the interaction.
- Address adult patients by title (e.g., Mr., Mrs., Ms.) and their last name. Using these formal terms of address alerts the patient to the importance of the interaction.

SHOW YOUR RESPECT FOR THE PATIENT'S BELIEFS, ATTITUDES, AND RIGHTS

- Ensure the patient is appropriately covered.
- Position yourself so that eye contact is comfortable for the patient. (Ideally, patients should be sitting up, with their eye level at or slightly above yours.)
- Avoid standing at the foot of the bed or with your hand on the door because this may send the nonverbal message that you do not have time for the patient.
- Ask the patient's permission before moving any personal items or making adjustments in the room.
- Remember that the patient's dialogue with you and his or her medical record are confidential. Share this information only with other health care providers who need to know about it, and do not share the information in a place where others can overhear the conversation.
- Be honest; never guess at an answer or information that you do not know; do not provide information beyond your scope of practice; providing new information to the patient is the privilege and responsibility of the attending physician.
- Make no moral judgments about the patient; set your values for patient care according to the patient's values, beliefs, and priorities.
- Expect the patient to have an emotional response to illness and the health care environment.
- Listen, and then clarify and teach, but never argue.
- Adjust the time, length, and content of the interview to the patient's needs.

USE A RELAXED, CONVERSATIONAL STYLE

- Ask questions and make statements that communicate empathy.
- Encourage the patient to express his or her concerns.
- Expect and accept some periods of silence.
- Close even the briefest interview by asking whether there is anything the patient needs or wants to discuss.
- Tell the patient when you will return.

Box 16-2 Types of Questions Used in Patient Interviews

- *Open-ended questions* encourage patients to describe events and priorities as they see them, helping to bring out concerns and attitudes and to promote understanding. Questions such as "What brought you to the hospital?" or "What happened next?" encourage conversational flow and rapport, while giving patients enough direction to know where to start.
- *Closed questions,* such as "When did your cough start?" or "How long did the pain last?" focus on specific information and provide clarification.
- *Direct questions* can be open-ended or closed and always end in a question mark. Although they are used to obtain specific information, a series of direct questions or frequent use of the question "Why?" can be intimidating and cause the patient to minimize his or her responses to questions.
- *Indirect questions* are less threatening than direct questions because they sound like statements (e.g., "I gather your doctor told you to take the treatments every 4 hours"). Inquiries of this type also work well to confront discrepancies in the patient's statements (e.g., "If I understood you correctly, it is harder for you to breathe now than it was before your treatment").
- *Neutral questions* and statements are preferred for all interactions with the patient. "What happened next?" and "Can you tell me more about … ?" are neutral, open-ended questions. A neutral, closed question may give the patient a choice of responses, while focusing on the type of information desired (e.g., "Would you say there was a teaspoon, a tablespoon, or a half cup?"). Leading questions, such as "You didn't cough up blood, did you?" should be avoided because they imply an answer.

- What seems to make it better or worse?
- Has it occurred before? (If so, how long did it last?)

Identifying characteristics of any new symptom may be helpful in determining the cause and selecting appropriate therapy. Once therapy is started, further questions are used to evaluate the changes in the symptoms over the course of treatment. For example, the clinician may ask, "Has the symptom changed in any way since admission?" or, "Does the therapy seem to make a difference?"

The best interview techniques are worthless if the interviewer lacks knowledge about the pathophysiology and characteristic symptoms of common cardiopulmonary diseases. Essentially the interview is a series of focused questions pursuing specific information related to a tentative diagnosis. The ability to ask key questions at the right time comes from experience and familiarity with the signs and symptoms of lung disease.

Common Cardiopulmonary Symptoms

Dyspnea

Dyspnea is a *general term* describing the sensation of breathing discomfort. It is the most important symptom that the RT is called upon to assess and treat. Dyspnea is a *subjective experience* and should never be inferred from observing a patient's breathing pattern. Dyspnea and pain are similar in that both sensations possess qualitatively distinct features and have varying intensity. Similar to pain, dyspnea causes suffering. *As breathing is the primordial sensation of life,* dyspnea often is perceived as life-threatening and may provoke a profound sense of dread.

The term *dyspnea* also is used *specifically* to describe *difficulty in the mechanical act of breathing*. In essence, dyspnea occurs when the effort to breathe is disproportionately greater than the tidal volume achieved. The perception of breathing is a complex balance among three factors:

1. The neural drive to breathe emanating from the respiratory centers in the brainstem
2. The tension developed in the respiratory muscles
3. The corresponding displacement of the lungs and chest wall

When the neuronal signals governing these sensations become unbalanced, breathing is perceived to be abnormal and unpleasant. The technical name for this imbalance is *neuromechanical dissociation*. A normal individual experiences dyspnea only in unusual circumstances, such as trying to breathe through a straw or when wearing a restrictive garment.

Breathlessness. In contrast, **breathlessness** is an *unpleasant urge to breathe*. It is believed to be the conscious perception of intense neural discharge from the brainstem to the respiratory muscles. Breathlessness can be triggered by acute hypercapnia, acidosis, or hypoxemia. A normal experience of breathlessness is the unpleasant "throbbing" sensation induced by breath holding, or feeling "winded" during strenuous exercise. However, it is unknown whether these normal encounters with breathlessness actually resemble the sensation that arises in patients with cardiopulmonary disease. This is because dyspnea and breathlessness are influenced by other stimuli, including those arising from irritant receptors in the lungs and airways, as well as receptors in the blood vessels and heart. These various stimuli shape both the quality and intensity of the sensation.

Moreover, dyspnea and breathlessness are perpetuated and magnified by the emotional distress that accompanies them. This emotional distress is influenced by the situation, knowledge, and control. For example, a healthy person can quickly identify the source of breathlessness and arrest the symptom simply by stopping exercise or the breath hold. But a patient with cardiopulmonary disease often cannot control the symptom, let alone identify the source. This has a profound emotional impact that must be appreciated.

Positional Dyspnea. Dyspnea that is triggered when the patient assumes the reclining position is called **orthopnea** and is common in patients with CHF, mitral valve disease, and superior vena cava syndrome. **Platypnea** is dyspnea triggered by assuming the upright position. It typically occurs after pneumonectomy and in patients with chronic liver disease (hepatopulmonary syndrome). It is sometimes observed during hypovolemia and in some neurologic diseases. Platypnea may be accompanied by **orthodeoxia,** which is oxygen desaturation on assuming an upright position. **Trepopnea** is when lying on one side relieves dyspnea, It is usually associated with either CHF or pleural effusion.

Language of Dyspnea. Because dyspnea is a subjective experience, patients possess a nuanced language to describe their sensations. RTs should ask specific questions about the quality and characteristics of the patient's dyspnea. In this way, the RT might gain insight into the mechanism provoking dyspnea. The RT should try to categorize each sensation according to a particular aspect of breathing: inspiration, expiration, respiratory drive, or lung volume. A remark such as, "I feel that my breath stops," reflects a problem with inspiration, whereas the remark, "my breath does not go all the way out," suggests a problem with expiration. Statements such as, "I can't catch my breath," suggest elevated respiratory drive (i.e., breathlessness).

Different lung diseases often evoke unique sensations. Patients with asthma frequently complain of chest tightness, whereas, patients with interstitial lung disease tend to focus on the sensations of increased work of breathing, shallow breathing, and gasping. Unique to patients with CHF is the feeling of suffocation. However, the RT should keep in mind that many lung diseases evoke common sensations.

Patients with cardiopulmonary disease frequently experience several unpleasant breathing sensations simultaneously. A particular sensation may be more prominent than others and may change over time. For example, patients with asthma typically complain first about the sensation of chest tightness. As bronchoconstriction worsens and the lungs become more hyperinflated, patients often begin to focus more on the sensation of excessive work of breathing, air hunger, and the inability to take a deep breath.

Assessing Dyspnea in the Interview. Assessing dyspnea is largely determined by the situation. During the interview, the RT should pay particular attention to whether the patient can speak in full sentences. Patients with severe dyspnea often cannot speak more than a few words at a time. In this situation, the initial interview should be curtailed, and treatment should be initiated as soon as possible. Questions should be brief and when possible structured to elicit a yes or no response. Questions should be limited to the quality and intensity of dyspnea, the circumstances surrounding the onset, and current duration of dyspnea. The assessment of dyspnea should occur simultaneously with a gross examination of the patient's breathing pattern (see later section of this chapter). Assessment of acute dyspnea in patients without a prior history of cardiopulmonary disease does not require the same detail as in patients with long-standing cardiopulmonary or neurologic disease.

In patients with chronic cardiopulmonary disease, a detailed and systematic history should cover four major areas, as follows:

1. The RT should ask what activities of daily living tend to trigger episodes of dyspnea. For example, is dyspnea triggered by walking on flat surfaces, by climbing stairs, by bathing, by dressing?
2. The RT should ask how much exertion makes the patient to stop to catch his or her breath with different activities. Does the patient need to stop after walking up one flight of stairs or one step? Dyspnea provoked by less strenuous activities indicates more advanced disease.

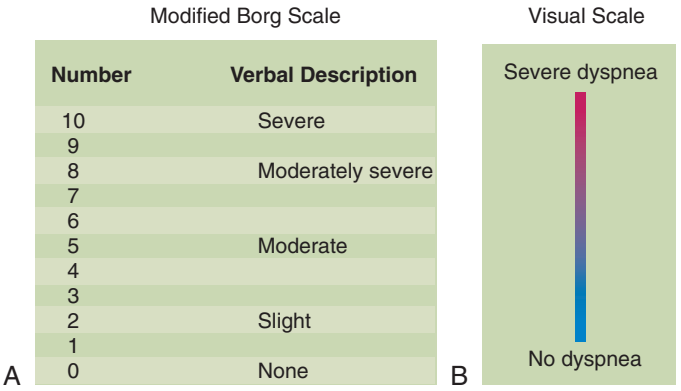


FIGURE 16-1 **A,** Modified Borg scale. **B,** Visual analogue scale for measuring the degree of dyspnea.

3. The RT should ask whether the quality or the sensation of breathing discomfort varies with different activities.
4. To gain a better understanding of the patient's history, ask the patient to recall when dyspnea first began and how it has evolved over time. Has dyspnea progressed slowly or rapidly? How long has this progression taken place: over a period of months or years? Has there been a dramatic change in the intensity of dyspnea over the recent past?

Beyond the information gleaned, a detailed conversation about patients' dyspnea allows them to share their experience and may decrease their sense of isolation.

The intensity of dyspnea can be documented using a numeric intensity or visual analogue scale (Figure 16-1). Such scales provide a way to evaluate the patient's response to treatment over time. These scales are important because, in many patients, objective measurements of lung function (e.g., pulmonary function tests, PaO_2) seldom correlate with the degree of dyspnea.

Psychogenic Dyspnea: Panic Disorders and Hyperventilation. There are perplexing situations in which a patient with normal cardiopulmonary function complains of dyspnea or suffocation. This is known as *psychogenic hyperventilation syndrome* and is associated with panic disorders. Hyperventilation may coincide with other symptoms such as chest pain, anxiety, palpitations, and *paresthesia* (the sensation of tingling and numbness in the extremities that accompanies respiratory alkalosis). This syndrome may be either sporadic or chronic and often is self-perpetuating.

Anxiety often is accompanied by breathlessness and hyperventilation. The resulting respiratory alkalosis amplifies the sensation of breathlessness and provokes more anxiety. This in turn increases the intensity of hyperventilation. The classic homespun remedy of slowly rebreathing into a paper bag holds merit, because this arrests respiratory alkalosis and helps break the cycle. However, rebreathing techniques may require formal behavioral therapy and may not be appropriate in the hospital setting. This condition usually is treated clinically by administering judicious amounts of anxiolytic agents.

The RT *always* must approach any situation involving hyperventilation or dyspnea as if it had a pathogenic basis. The first

priority is to measure the vital signs, including SaO_2, and perhaps a 12-lead electrocardiogram and arterial blood gases. A psychogenic source is considered *only* after a pathogenic source for hyperventilation or dyspnea has been ruled out. Intense pain or fear often provokes anxiety and hyperventilation. The RT must work in concert with nurses and the physician to determine the root-cause of any hyperventilation syndrome.

Cough

A **cough** is the most common, yet nonspecific symptom observed in patients with pulmonary disease. Coughing is a forceful expiratory maneuver that expels mucus and foreign material from the airways. It usually occurs when cough receptors are stimulated by inflammation, mucus, foreign materials, or noxious gases. Cough receptors are located primarily in the larynx, trachea, and larger bronchi. The effectiveness of a cough depends on (1) the ability of the individual to take a deep breath, (2) lung elastic recoil, (3) expiratory muscle strength, and (4) level of airway resistance. The ability to take a deep breath and exhale forcefully is often impaired in patients with cardiopulmonary, neurologic, or neuromuscular diseases.

Effective coughing also is impaired in the early postoperative period after upper abdominal surgery or thoracic surgery or after trauma because of pain. Often, expiratory flow is limited by factors such as bronchospasm (e.g., asthma), reduced lung elastic recoil (as in emphysema) and muscle weakness. Patients with an inadequate ability to cough often have problems with atelectasis, retained secretions, and therefore are more prone to developing pneumonia and/or hypoxemia.

It is important for the RT to note several characteristics of the patient's cough. This includes whether it is dry or loose, productive or nonproductive, acute or chronic, and whether it occurs more frequently at particular times (i.e., day or night). Knowledge of such details may help in determining the cause of the cough. A dry, nonproductive cough is typical for restrictive lung diseases such as CHF or pulmonary fibrosis. A loose, productive cough is more often associated with inflammatory obstructive diseases such as bronchitis and asthma. The most common cause of an acute, self-limited cough is a viral infection of the upper airway.

A **chronic cough** is one lasting 8 weeks or longer.[1] It carries with it considerable frustration and anxiety for patients, with decreased quality of life and depression commonly reported. When a thorough examination and history fail to find evidence of disease (e.g., cancer, human immunodeficiency virus [HIV] disease) and the chest radiograph is normal, more than 90% of chronic cough cases are accounted for by upper airway cough syndrome (formerly called postnasal drip), asthma, and gastroesophageal reflux. Chronic coughing has numerous common and uncommon causes that sometimes may have multiple sources (Box 16-3).[1]

Box 16-3 Evaluating Chronic Cough in the Adult (>8 Weeks Duration)[1]

COMMON SOURCES
- Upper airway cough syndrome (formerly known as "postnasal drip")
- Asthma
- Gastroesophageal reflux
- Chronic bronchitis associated with cigarette smoking
- Angiotensin-converting enzyme–1 cough (caused by the antihypertensive drug angiotensin-converting enzyme inhibitor)
- Nonasthmatic eosinophilic bronchitis

LESS COMMON SOURCES
- Postinfection (e.g., pertussis, mycoplasma)
- Interstitial lung disease
- Bronchiectasis
- Obstructive sleep apnea
- Primary lung cancer
- Heart failure
- Pulmonary tuberculosis
- Environmental exposures

UNCOMMON SOURCES
- Sarcoidosis
- Recurrent aspiration
- Chronic tonsillar enlargement
- Chronic auditory canal irritation
- Foreign body aspiration
- Endemic fungi
- Peritoneal dialysis
- Cystic fibrosis
- Tracheomalacia
- Habit or "tic cough"

Sputum Production

Healthy airways produce mucus daily. Normally, the quantity of this mucus is minimal, and it is not enough to stimulate the cough receptors. Mucus is gradually moved to the hypopharynx by the mucociliary escalator, where it is either swallowed or expectorated. Disease of the airways (e.g., bronchitis or acute asthma attacks), may cause mucous glands located in the airways to produce abnormal amounts of mucus. This stimulates the cough receptors and causes a loose, productive cough.

RULE OF THUMB

Ineffective coughing is common in patients with cardiopulmonary, neurologic, or neuromuscular diseases, as well as in the early postoperative period after thoracic and upper abdominal surgery or trauma. Ineffective coughing places patients at increased risk for developing atelectasis, retained secretions, pneumonia, and hypoxemia.

RTs need to be aware of the terminology associated with sputum. Mucus from the tracheobronchial tree, *uncontaminated* by oral secretions, is called **phlegm.** Mucus from the lungs that passes through the mouth as it is expectorated is **sputum.** Because this is how most mucus samples from the lung are

obtained, the term *sputum* is used in this chapter. Sputum that contains pus cells is said to be **purulent,** suggesting a bacterial infection. Purulent sputum appears thick, colored, and sticky. Sputum that is foul-smelling is said to be **fetid.** Sputum that is *clear and thick* is **mucoid** and commonly is seen in patients with asthma. Changes in the color, viscosity, or quantity of sputum produced are often signs of infection and must be documented and reported to the physician.

Hemoptysis

Coughing up blood or blood-streaked sputum from the lungs is common in patients with pulmonary disease and is called **hemoptysis.** *Frank hemoptysis* is the *primary* presence of blood in the expectorant. *Massive hemoptysis* is when more than 300 ml of blood is expectorated over 24 hours and represents a medical emergency. Common causes include bronchiectasis, lung abscess, and acute or chronic tuberculosis.

Nonmassive hemoptysis is observed in many conditions such as airway infections, pneumonia, lung cancer, tuberculosis, blunt or penetrating chest trauma, and pulmonary embolism. Infection-associated hemoptysis usually presents as blood-streaked, purulent sputum. Hemoptysis from bronchogenic carcinoma often is chronic and may be associated with a monophonic wheeze and cough.

Hemoptysis must be distinguished from **hematemesis,** which is vomiting blood from the gastrointestinal tract and is a common finding in patients with gastrointestinal disease. Whereas blood from the lungs often is mixed with sputum, blood from the stomach may be mixed with food particles.

Chest Pain

Chest pain is categorized as either pleuritic or nonpleuritic. *Pleuritic chest pain* usually is located *laterally or posteriorly* and typically worsens when taking a deep breath. Patients often describe it as a *sharp, stabbing* type of pain. It manifests primarily in chest diseases that cause the pleural lining of the lung to become inflamed (such as pneumonia, empyema, pleural effusion), but also is a common symptom in pulmonary embolism.

Nonpleuritic chest pain is located typically in the *center* of the anterior chest and may *radiate* to the shoulder, neck, or back. It is *not affected by breathing*, and is often described as a *dull ache* or *pressure* type of pain. A common cause of nonpleuritic chest pain is **angina.** It is classically described as a pressure sensation with exertion or stress that results from coronary artery occlusion. Other common causes of nonpleuritic chest pain include gastroesophageal reflux, esophageal spasm, chest wall pain (e.g., costochondritis), and gallbladder disease.

Fever

Fever is an elevated body temperature greater than 38.3°C (101°F),[2] with the most common sources being a bacterial, viral, or fungal infection. There are, however, numerous noninfectious causes of fever such as drug reaction (e.g., sulfa drugs), malignancies (e.g., lymphomas, metastatic cancer), head trauma (e.g., damage to the hypothalamus), burns, alcoholic cirrhosis, thromboembolic disorders (e.g., pulmonary embolism), and noninfectious inflammatory diseases (e.g., rheumatoid arthritis, systemic lupus erythematosus).[3] Therefore all patients with fever need further assessment to determine the cause. Sustained (e.g., >3 weeks), unexplained fever despite a comprehensive work-up is called a **fever of unknown origin (FUO)** and is a common finding in patients with HIV disease.[3]

The magnitude of temperature elevation during fever may indicate the type and virulence of the infection. Low-grade fever typically accompanies common upper respiratory tract infections, whereas a high fever occurs with viral influenza infection.

Fever that occurs with a cough suggests a respiratory tract infection. An infection is even more likely to be the cause of the fever if the patient is producing purulent sputum. In this situation, a persistent fever of 38.9°C (102°F) or greater for 2 days accompanied by chills is suggestive of pneumonia. However, the absence of coughing or sputum production does not rule out lung infection.

For many years it was believed that a link existed between fever and atelectasis in postoperative surgical patients. However, we now know that no such link exists.[4]

Patients with a significant fever have an increased metabolic rate that increases both O_2 consumption and carbon dioxide production and may cause tachypnea. Fever is particularly dangerous for patients with severe chronic cardiopulmonary disease because the increased ventilatory demand may induce acute respiratory failure.

Pedal Edema

Swelling of the lower extremities is known as **pedal edema** and often most occurs with heart failure. The diminished ability of the heart to effectively pump blood causes venous congestion. Increased hydrostatic pressure from blood pooling in the gravity-dependent lower extremities causes fluid to leak into the interstitial spaces. Afflicted patients often complain of "swollen ankles" in such cases. The degree of pedal edema depends on the severity of heart failure. There are two subtypes of pedal edema. *Pitting edema* is when finger pressure applied on a swollen extremity leaves an indentation mark on the skin. The height at which pitting edema occurs can indicate the severity of heart failure. Pitting edema that extends to the knee signifies a more significant problem than edema limited to the ankles. Furthermore, a standard scale may be used to quantify the severity of pitting edema, with "1" equating to a trace with rapid refill and "4" meaning severe pitting with refill time in excess of 2 minutes. Any patient who is suspected to have right-sided or left-sided heart failure is examined for pedal edema. *Weeping edema* occurs when the applied finger pressure causes a small fluid leak.

Patients with chronic hypoxemic lung disease are especially prone to right-sided heart failure (cor pulmonale) that also causes pedal edema. Chronic hypoxia causes severe pulmonary vasoconstriction and pulmonary hypertension. This places a heavy demand on the thin-walled right ventricle, which can eventually fail, resulting in venous congestion.

Format for the Medical History

All health care practitioners must be familiar with the medical history of the patients they are treating, even if their reason for contact is simply to provide intermittent therapy. The medical history familiarizes clinicians with the signs and symptoms the patient exhibited on admission and the reason the therapy is being administered.

The first priority of the RT reviewing the medical record is to ensure that all respiratory care procedures are supported by a physician order that is current, clearly written, and complete. Afterward, the RT should review the patient's medical record by reading about the patient's current medical problems. This information is found under the headings of *chief complaint* and *history of present illness*. This presents a detailed, systematic account of the patient's major complaints written by a physician after the postadmission interview with the patient.

The next step is to review the patient's *past medical history,* which describes all past major illnesses, injuries, surgeries, hospitalizations, allergies, and health-related habits. This information provides a basic understanding of the patient's previous experiences with illness and the health care system. The nature of past history may influence decisions made during the current hospitalization.

The *past medical history* is where the interviewer records the patient's cigarette and alcohol consumption. Accurate determination of a patient's smoking history is extremely important in assessing pulmonary health. The smoking history is often recorded in **pack-years.** This is determined by *multiplying the number of packs smoked per day by the number of years smoked*. Typically, a patient is asked how many cigarettes (on average) he or she smokes per day. If a patient states that he or she has smoked a pack of cigarettes a day for 20 years, the patient has a 20 pack-year smoking history.

If patients describe their smoking in terms of the number of cigarettes, or fractions of a pack, the calculation is slightly more difficult. Two examples may help illustrate how to calculate pack-years of smoking. There are 20 cigarettes per pack. If a patient states he or she has smoked a pack and a half of cigarettes per day for 20 years, the smoking history is calculated as follows:

$$30 \text{ cigarettes}/20 \text{ cigarettes per pack} = 1.5 \text{ packs} \times 20 \text{ years}$$
$$= 30 \text{ pack years smoking history}$$

If the patient states that he or she has smoked 15 cigarettes per day for 20 years:

$$15 \text{ cigarettes}/20 \text{ cigarettes per pack} = 0.75 \text{ packs} \times 20 \text{ years}$$
$$= 15 \text{ pack years smoking history}$$

Next, the *family* and *social/environmental history* should be reviewed. This focuses on potential genetic or occupational links to disease and the patient's current life situation. In many cases, there is a genetic predisposition to pulmonary disorders such as asthma, lung cancer, and cystic fibrosis. A detailed occupational history is important in establishing acquired pulmonary disorders resulting from inhaling dusts in the workplace, either organic (i.e., containing protein) or nonorganic (e.g., asbestos, silica). There is a strong link between many chronic pulmonary diseases and air pollution which predominantly effects those living in urban poverty.[5]

The *review of systems* is designed to uncover problem areas the patient forgot to mention or may have omitted. This information is usually obtained in a head-to-toe review of all body systems. For each body system, the interviewer obtains information about current, pertinent symptoms. During a review of the respiratory system, questioning would determine the presence or history of cough, hemoptysis, sputum production, chest pain, shortness of breath, and fever (Box 16-4).

Finally, the medical record should be examined for information indicating any limits on the extent of care to be provided in the event of cardiac or respiratory arrest. This information is known as an **advance directive,** whereby the patient (or a legally authorized representative) has formalized his or her wishes for resuscitative efforts; this is typically referred to as the *DNR status* ("do not resuscitate") or may be expressed as DNI ("do not intubate"). A less ambiguous acronym *AND* ("allow for natural death") is used to emphasize that care is primarily focused on patient comfort. This information may be found either in the admission note or within the body of the physician progress notes. In addition to this descriptive note, there must be an order written by the physician clearly specifying how care should be limited in the event of a medical emergency.

PHYSICAL EXAMINATION

A careful physical examination of the patient is essential for evaluating the patient's problem(s) and determining the effects of therapy. The physical examination consists of the following four general steps: (1) inspection (visually examining), (2) palpation (touching), (3) percussion (tapping), and (4) auscultation (listening with a stethoscope).

General Appearance

The first moments of an encounter with the patient may reveal the severity of the current problem. These initial impressions determine the course of subsequent assessment. If the patient's general appearance indicates an acute problem, the examination may be abbreviated and focused until the patient's condition is stabilized. When the initial impression indicates that the patient is stable, a more complete assessment can be conducted (Box 16-5). Several indicators are important in assessing the patient's overall appearance, including the patient's level of consciousness (see later discussion), facial expression, level of anxiety or distress, positioning, and personal hygiene.

The RT should look for specific characteristics when observing the patient's body. Does the patient appear well nourished or emaciated? Weakness and emaciation (**cachexia**) are signs of general ill health and malnutrition that increases susceptibility to infection. Is the patient sweating? **Diaphoresis** (sweating) can indicate fever, pain, severe stress, increased metabolism, or acute anxiety.

Box 16-4 Outline of a Complete Health History

Demographic data (obtained from admission interview): Name, address, age, birth date, place of birth, race, nationality, marital status, religion, occupation, and source of referral
Date and source of history and estimate of the reliability of the historian
Brief description of the patient's condition at the time the history or patient profile was taken
Chief complaint and reason for seeking treatment
History of present illness: Chronologic description of each symptom
- Onset: Time, type, source, setting
- Frequency and duration of symptoms
- Location and radiation of pain
- Severity (quantity)
- Quality (character)
- Aggravating and alleviating factors
- Associated manifestations

Past medical history
- Childhood diseases and development
- Hospitalizations, surgeries, injuries, accidents, and major illnesses
- Allergies
- Medications

Family history
- Familial disease history
- Marital history
- Family relationships

Social and environmental history
- Education
- Military experience
- Occupational history
- Religious and social activities
- Alcohol and cigarette consumption
- Living arrangements
- Hobbies and recreation
- Satisfaction with and stresses of life situation, finances, and relationships
- Recent travel or other event that might affect health

Review of systems: Respiratory system
- Cough
- Hemoptysis
- Sputum (amount and consistency)
- Chest pain
- Shortness of breath
- Hoarseness or changes in voice
- Dizziness or fainting
- Fever or chills
- Peripheral edema

Patient's printed name and signature

Box 16-5 Typical Format for Recording the Physical Examination

INITIAL IMPRESSION
- Age, height, weight, sensorium, and general appearance

VITAL SIGNS
- Pulse rate, respiratory rate, temperature, and blood pressure

HEAD, EARS, EYES, NOSE, AND THROAT
- Inspection findings

NECK
- Inspection and palpation findings

THORAX
- Lungs: Inspection, palpation, percussion, and auscultation findings
- Heart: Inspection, palpation, and auscultation findings

ABDOMEN
- Inspection, palpation, percussion, and auscultation findings

EXTREMITIES
- Inspection and palpation findings

The general facial expression may help reveal pain or anxiety, as well as in evaluating alertness, mood, and mental capacity. Simple observation of the patient's anxiety level can indicate the severity of the current problem and whether cooperation can be expected. The patient's position also may be useful in assessing the severity of the problem and the patient's response to it. For example, a patient with severe pulmonary hyperinflation tends to sit upright while bracing his or her elbows on a table. This position helps the accessory muscles gain a mechanical advantage for breathing and is called **tripodding.** Finally, personal hygiene indicators may help determine both the duration and severity of the illness.

Level of Consciousness

While observing the patient's overall appearance, the RT should assess the patient's level of consciousness (alertness). Evaluating the patient's alertness is a simple but important task (Box 16-6). If the patient appears conscious, the RT should assess the patient's orientation to time, place, person, and situation. This assessment often is called evaluating the **sensorium.** The sensorium is considered normal if the patient can correctly tell the interviewer his or her name, the current date, location, and situation (e.g., "I'm in the hospital because I fell and broke my hip") and this is typically documented as "oriented × 4." If the patient is not alert, the level of consciousness is assessed. The simple rating scale shown in Box 16-6 allows clinicians to describe the patient's level of consciousness objectively, using common clinical terms.

Depressed consciousness may occur with poor cerebral blood flow (e.g., hypotension, neurovascular lesion) or when poorly oxygenated blood perfuses the brain. As cerebral oxygenation acutely decreases, the patient initially becomes restless, confused, or disoriented. If hypoxia worsens, the patient may become comatose. However, patients with chronic hypoxia may adapt well and may have normal mental status despite significant hypoxemia. Abnormal consciousness also may occur in chronic degenerative brain disorders, as a side effect of certain medications, and in cases of drug overdose. The Glasgow Coma Scale score is used to assess the level of consciousness and neurologic function (see Chapter 51).

Vital Signs

Vital signs—the body temperature, pulse rate, respiratory rate, and blood pressure—are the most frequently used clinical

Box 16-6 Levels of Consciousness

CONFUSED
The patient
- Exhibits slight decrease of consciousness
- Has slow mental responses
- Has decreased or dulled perception
- Has incoherent thoughts

DELIRIOUS
The patient
- Is easily agitated
- Is irritable
- Exhibits hallucinations

LETHARGIC
The patient
- Is sleepy
- Arouses easily
- Responds appropriately when aroused

OBTUNDED
The patient
- Awakens only with difficulty
- Responds appropriately when aroused

STUPOROUS
The patient
- Does not awaken completely
- Has decreased mental and physical activity
- Responds to pain and exhibits deep tendon reflexes
- Responds slowly to verbal stimuli

COMATOSE
The patient
- Is unconscious
- Does not respond to stimuli
- Does not move voluntarily
- Exhibits possible signs of upper motor neuron dysfunction, such as Babinski reflex or hyperreflexia
- Loses reflexes with deep or prolonged coma

measurements because they are easy to obtain and provide useful information about the patient's clinical condition. Abnormal vital signs may reveal the first clue of adverse reactions to treatment. In addition, improvement in a patient's vital signs is strong evidence that a treatment is having a positive effect. For example, a decrease in the patient's breathing and heart rate toward normal after the application of O_2 therapy suggests a beneficial effect.

Body Temperature

The average body temperature for adults is approximately 37° C (98.6° F), with daily variations of approximately 0.5° C (1° F). Body temperature normally is lowest in the early morning and highest in the late afternoon. Body temperature is kept normal by balancing heat production with heat loss. The hypothalamus regulates heat loss by initiating peripheral vasodilation and sweating *(diaphoresis)* to dissipate body heat or vasoconstriction to preserve it. The respiratory system also helps remove excess heat through ventilation by warming the inspired air, which is subsequently exhaled.

Box 16-7 Key Characteristics of the Pulse

- Is the pulse rate normal, high, or low?
- Is the rhythm regular, consistently irregular, or irregularly irregular?
- Are there any changes in the amplitude (strength) of the pulse in relation to respiration? Are there changes in amplitude from one beat to another?
- Are there any other abnormalities, such as palpable vibrations (thrills or bruits)?

Elevated body temperature (*hyperthermia* or *hyperpyrexia*) can result from disease or from normal activities such as exercise. Temperature elevation caused by disease is called *fever,* and the patient is said to be **febrile.** Fever increases metabolism, causing both increased O_2 consumption and CO_2 production. Increased metabolism induces both increased circulation and ventilation to maintain homeostasis. This is why febrile patients often have increased heart and breathing rates. Fever increases the demand placed on the heart and lungs. This often complicates clinical management because some patients have limited ability to increase their circulation and ventilation. Thus respiratory failure can result.

A body temperature below normal is called **hypothermia.** The most common cause of hypothermia is prolonged exposure to cold, to which the hypothalamus responds by initiating shivering (to generate heat) and vasoconstriction (to conserve heat). Other, less common causes of hypothermia include head injury or stroke, causing dysfunction of the hypothalamus; decreased thyroid activity; and overwhelming infection, such as sepsis.

Because hypothermia reduces O_2 consumption and CO_2 production, patients with hypothermia may exhibit slow, shallow breathing and reduced pulse rate.

Body temperature is measured most often at one of the following four sites: mouth, axilla, ear (tympanic membrane), or rectum. The oral site is the most acceptable for an alert, adult patient, but it cannot be used with infants, comatose patients, or orally intubated patients. If a patient ingests hot or cold liquid or has been smoking, oral temperature measurement should be delayed for 10 to 15 minutes for accuracy. The axillary site is acceptable for infants or small children who do not tolerate rectal thermometers, but this site may underestimate core temperature by 1° to 2° C. The body temperature can also be assessed accurately with the use of a hand-held device to measure the temperature of the eardrum (tympanic membrane). Rectal temperatures are closest to actual core body temperature.

Pulse Rate

The peripheral pulse is evaluated for rate, rhythm, and strength (Box 16-7). The normal adult pulse rate is 60 to 100 beats/min, with a regular rhythm. A condition in which the pulse rate is greater than 100 beats/min is called **tachycardia.** Common causes of tachycardia are exercise, fear, anxiety, low blood

pressure, anemia, fever, reduced arterial blood O_2 levels *(hypoxemia),* elevated CO2 (*hypercapnia*) and certain medications. A condition in which the pulse rate is less than 60 beats/min is called **bradycardia.** Bradycardia is less common than tachycardia but can occur with hypothermia, as a side effect of medications, with certain cardiac arrhythmias, and with traumatic brain injury.

The radial artery is the most common site used to palpate the pulse. The second and third fingertip pads (but not the thumb) are used to palpate the radial pulse. Ideally, the pulse rate is counted for 1 minute, especially if the pulse is irregular. Essential pulse characteristics that should be noted and documented are described in Box 16-7.

Spontaneous ventilation can influence pulse strength, or amplitude. A slight decrease in pulse pressure is normally present with each inspiratory effort. This decrease is caused by negative intrathoracic pressure from inspiratory muscle contraction. The decrease in blood pressure is the result of decreased left ventricular filling. This occurs by two mechanisms. First, negative intrathoracic pressure causes blood to pool in the pulmonary circulation, thereby reducing left heart filling. Second, negative intrathoracic pressure simultaneously increases both venous return and right ventricular volume. The engorged right ventricle limits left ventricular expansion and filling during diastole. The end result is a brief reduction in left ventricular stroke volume and decreases systolic blood pressure during inspiration.

Pulse pressure normally decreases slightly with inspiration (<10 mm Hg) and may not be noticeable with palpation. **Pulsus paradoxus** *("paradoxical pulse")* is a *significant* decrease in pulse strength (>10 mm Hg) during spontaneous inspiration. Pulsus paradoxus can be quantified with a blood pressure cuff (see later section) and is common in patients with acute obstructive pulmonary disease, especially patients experiencing an asthma attack. During respiratory distress, vigorous inspiratory efforts decrease stroke volume by impeding the strength of left ventricular contraction.[6] Pulsus paradoxus also may signal a mechanical restriction of the pumping action of the heart, as can occur with constrictive pericarditis or cardiac tamponade. **Pulsus alternans** is an alternating succession of strong and weak pulses. Pulsus alternans suggests left-sided heart failure and usually is not related to respiratory disease.

The pulse also may be assessed by palpating the carotid, brachial, femoral, temporal, popliteal, posterior tibial, and dorsalis pedis pulses. The more centrally located pulses (e.g., the carotid and femoral) should be used when the blood pressure is abnormally low. If the carotid site is used, great care must be taken to avoid the carotid sinus area. Pressure on the carotid sinus area may cause strong parasympathetic stimulation resulting in bradycardia.

Respiratory Rate

The normal resting adult rate of breathing is 12 to 18 breaths/min. **Tachypnea** is defined as a respiratory rate greater than 20 breaths/min. Rapid respiratory rates are associated with exertion, fever, hypoxemia, hypercarbia, metabolic acidosis, anxiety, pulmonary edema, lung fibrosis, and pain. A respiratory rate less than 10 breaths/min is called **bradypnea,** and may occur with traumatic brain injury, severe myocardial infarction, hypothermia, anesthetics, opiate narcotics, and recreational drug overdoses.

The respiratory rate is counted by watching the abdomen or chest wall move out and in. In some cases, the RT may need to place a hand on the patient's abdomen to confirm the breathing rate. Ideally, the patient should be unaware that the respiratory rate is being counted. One method to accomplish this is to count the respiratory rate immediately after evaluating the patient's pulse, while keeping the fingers on the patient's wrist. This gives the impression that the pulse rate is still being counted.

Blood Pressure

The arterial blood pressure is the force exerted against the wall of the arteries as the blood moves through them. Arterial **systolic pressure** is the peak force exerted in the major arteries during contraction of the left ventricle. Arterial blood pressure typically increases with age. The normal range for systolic blood pressure in an adult is 90 to 140 mm Hg. **Diastolic pressure** is the force in the major arteries remaining after relaxation of the ventricles; it is normally 60 to 90 mm Hg. **Pulse pressure** is the difference between the systolic and diastolic pressures. A normal pulse pressure is 30 to 40 mm Hg. When the pulse pressure is less than 30 mm Hg, the peripheral pulse is difficult to detect.

Blood pressure is determined by the interaction of the force of left ventricular contraction, the systemic vascular resistance, and the blood volume (see Chapter 10). The blood pressure is recorded by listing systolic pressure over diastolic pressure (e.g., 120/80 mm Hg).

Hypertension is an arterial blood pressure *persistently* greater than 140/90 mm Hg. Hypertension is a common medical problem in adults, and in approximately 90% of cases the cause is unknown (primary hypertension). There are two subcategories of hypertension.[7] *Stage I* hypertension occurs when the systolic blood pressure is 140 to 159 mm Hg or the diastolic blood pressure is 90 to 99 mm Hg. *Stage II* hypertension occurs when the systolic blood pressure is 160 mm Hg or greater or the diastolic blood pressure is 100 mm Hg or above. In addition, there is a third category known as *prehypertension,* which is a systolic blood pressure between 120 and 139 mm Hg or a diastolic blood pressure between 80 and 89 mm Hg. Prehypertension is not a disease state and does not require treatment but is used to assess the risk for eventually developing hypertension.

Mechanically, hypertension results from increased systemic vascular resistance or an increased force of ventricular contraction. Sustained hypertension can cause central nervous system abnormalities, such as headaches, blurred vision, and confusion. Other potential consequences of hypertension include uremia (renal insufficiency), CHF, and cerebral hemorrhage. Acute, severe elevation of blood pressure can cause acute neurologic, cardiac, and renal failure and is called an *acute hypertensive crisis.*

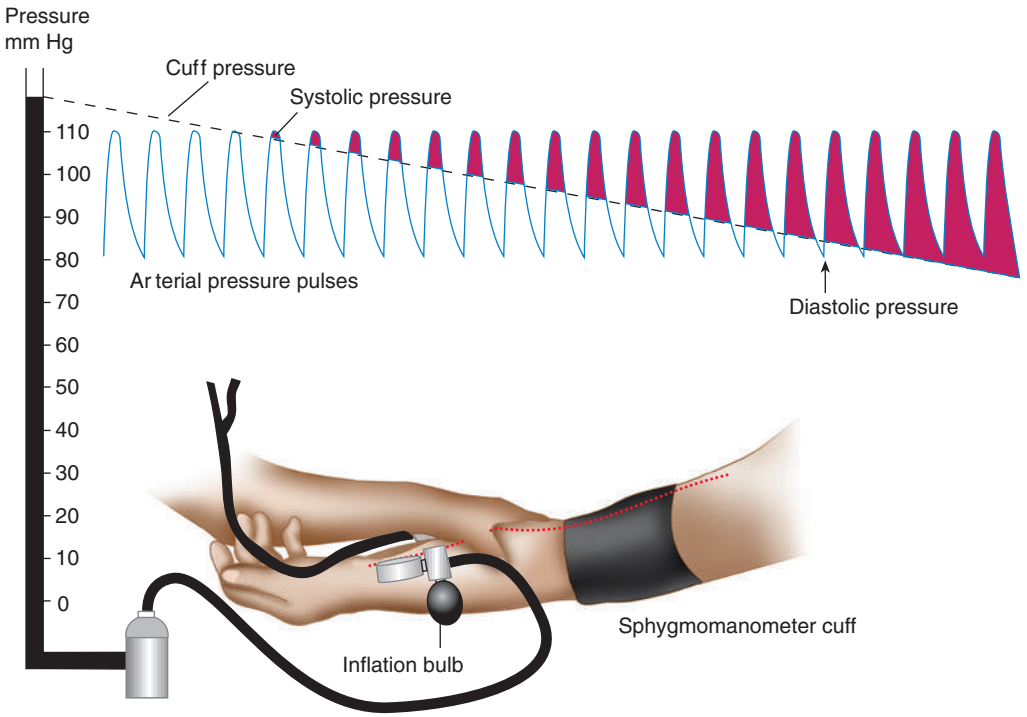

FIGURE 16-2 Auscultatory method for measuring arterial blood pressure, using a sphygmomanometer and a stethoscope. (Redrawn from Rushmer RR: Structure and functions of the cardiovascular system, ed 2, Philadelphia, 1976, WB Saunders.)

Hypotension is defined as a systolic arterial blood pressure less than 90 mm Hg or a mean arterial pressure less than 65 mm Hg.[8] Hypotension also can be defined as a decrease of more than 40 mm Hg from baseline. This expanded definition acknowledges that patients with baseline hypertension may have inadequate tissue perfusion at a blood pressure that may be considered normal for most patients.

Shock is defined precisely as the inadequate delivery of O_2 and nutrients to the vital organs relative to their metabolic demand.[9] Hypotension is not synonymous with shock. In shock, vital body organs are in imminent danger of receiving inadequate blood flow (underperfusion) and impaired O_2 delivery to the tissues (i.e., tissue hypoxia). For this reason, shock is usually treated aggressively with fluids, blood products, or vasoactive drugs, or a combination of these, depending on the cause and severity of shock.

There are two broad categories of hypotension and shock based on whether they are caused by a *hypodynamic* or *hyperdynamic* cardiovascular state.[10] Hypodynamic states include left ventricular failure *(cardiogenic)* and reduced blood volume (**hypovolemia** or *hypovolemic*) caused by either hemorrhage or severe fluid loss. Hyperdynamic states occur with profound systemic vasodilation *(peripheral vascular failure)* associated with overwhelming infection *(septic shock),* systemic allergic reaction *(anaphylaxis),* or severe liver failure.

Healthy individuals, when sitting or standing up, experience little change in blood pressure. However, similar postural changes may produce abrupt hypotension in hypovolemic patients. This condition is called **postural hypotension** and generally is treated with fluid administration. Postural hypotension is confirmed by measuring blood pressure with the patient supine and then measuring with the patient in the sitting (or standing) position. Postural hypotension may reduce cerebral blood flow and lead to **syncope** (fainting).

A common technique for measuring arterial blood pressure requires a blood pressure cuff (sphygmomanometer) and a stethoscope (Figure 16-2). When the cuff is applied to the upper arm and pressurized to exceed systolic blood pressure, the brachial artery blood flow stops. As the cuff pressure is slowly released to a point just below the systolic pressure, blood flows intermittently past the obstruction. Partial blood flow obstruction creates turbulence and vibrations called *Korotkoff sounds.* These sounds are heard with a stethoscope over the brachial artery distal to the cuff.

To measure the blood pressure, a deflated cuff is wrapped snugly around the patient's upper arm, with the lower edge of the cuff 1 inch above the antecubital fossa. While palpating the brachial pulse, the clinician inflates the cuff approximately 30 mm Hg above the point at which the pulse can no longer be felt. Then the diaphragm of the stethoscope is placed over the artery and the cuff is slowly deflated (2 to 3 mm Hg/sec) while observing the manometer.

The systolic pressure is recorded when the first Korotkoff sounds are heard. The point at which the sounds become muffled is the diastolic pressure. This muffling is the final change in the Korotkoff sounds just before they disappear. At

this point, cuff pressure equals diastolic pressure and turbulence ceases. The blood pressure is recorded as systolic over diastolic (e.g., 120/60 mm Hg).

As mentioned earlier, a paradoxical pulse is when systolic blood pressure decreases more than 10 mm Hg during a resting inhalation and can only be quantified by auscultation. To measure this, inflate the blood pressure cuff until the radial or brachial pulse can no longer be palpated. Then slowly deflate the cuff until sounds are heard only on exhalation (point 1). Next, reduce the cuff pressure until sounds are heard throughout respiration (point 2). The difference between points 1 and 2 indicates the degree of paradoxical pulse.

Most hospitals and clinics now use digital blood pressure measuring devices that do not require clinicians to listen for the Korotkoff sounds. These devices are very accurate and eliminate variances in recorded blood pressures based on human perception. The clinician need only to apply the blood pressure cuff correctly and press the start button. The device inflates and deflates the cuff automatically and displays the blood pressure and pulse rate on a digital screen.

Examination of the Head and Neck

Head

The patient's face is inspected for abnormal signs that indicate respiratory problems. The most common facial signs are nasal flaring, cyanosis, and pursed-lip breathing. Nasal flaring occurs when the external nares flare outward during inhalation. This flaring is prevalent in respiratory distress and indicates an increased work of breathing.

Cyanosis is a bluish discoloration of the skin or tissues as a result of respiratory or cardiac disease. Cyanosis is discussed in more detail later in this chapter. Patients with chronic obstructive pulmonary disease (COPD) may use pursed-lip breathing during exhalation. Breathing through pursed lips during exhalation creates resistance to flow. The increased resistance creates a slight back pressure in the small airways during exhalation. This back-pressure prevents premature airway collapse and allows more complete emptying of the lung.

Neck

Inspection and palpation of the neck help determine the position of the trachea and the jugular venous pressure (JVP). Normally, when the patient faces forward, the trachea is located in the middle of the neck. The midline of the neck can be identified by palpating the suprasternal notch. The midline of the trachea should be directly below the center of the suprasternal notch.

The trachea can shift away from the midline in certain thoracic disorders. Generally, the trachea shifts *toward* an area of collapsed lung and shifts *away* from areas with increased air or fluid (e.g., tension pneumothorax or large pleural effusion).

JVP is estimated by determining how high the jugular vein extends above the level of the sternal angle. JVP reflects the volume and pressure of venous blood in the right heart. Typically, the internal vein is assessed because it is more reliable. Individuals with obese necks may not have visible neck veins, even when the veins are distended.

When lying in a supine position, a healthy individual has neck veins that are full. When the head of the bed is elevated gradually to a 45-degree angle, the level of the blood column descends to a point no more than a few centimeters above the clavicle. With elevated venous pressure, the neck veins may be distended as high as the angle of the jaw, even when the patient is sitting upright.

JVP may vary with breathing. Under normal circumstances, the blood column descends toward the thorax during inhalation and ascends with exhalation. For this reason, JVP should always be estimated at the end of exhalation. Under abnormal conditions (e.g., cardiac tamponade), the JVP may increase during inhalation and is called **Kussmaul sign.**

Jugular venous distention (JVD) is present when the jugular vein is enlarged and can be seen more than 4 cm above the sternal angle. The most common cause of JVD is right heart failure (cor pulmonale). This occurs frequently in patients with chronic hypoxemia that causes chronic pulmonary vasoconstriction and pulmonary hypertension. Over time this leads to right heart failure from the excessive workload. Other conditions associated with JVD include left heart failure, cardiac tamponade, tension pneumothoraces, and mediastinal tumors.

The neck is a common place for the physician to palpate for enlarged lymph nodes, which is known as **lymphadenopathy.** Lymphadenopathy occurs with various medical disorders, including infection, malignancy, and sarcoidosis. Tender lymph nodes in the neck suggest a nearby infection. The lymph nodes are not tender when malignancy is the cause.

Examination of the Thorax and Lungs

Inspection

The chest should be inspected visually to assess the thoracic configuration, expansion, and the pattern and effort of breathing. For adequate inspection, the room must be well lit and the patient should be sitting upright. When the patient is too ill to sit up, the clinician should carefully roll the patient to one side to examine the posterior chest. Inspection, palpation, percussion, and auscultation of the patient's chest require that the patient be disrobed. Consequently, the clinician should make every effort to respect the patient's modesty (especially for female patients) and drape the chest whenever possible.

Thoracic Configuration. The anteroposterior (AP) diameter of the average adult thorax is less than the transverse diameter. Normally, the AP diameter increases gradually with age but may prematurely increase in patients with COPD. This abnormal increase in AP diameter is called **barrel chest** and is associated with emphysema. When the AP diameter increases, the normal 45-degree angle of articulation between the ribs and spine is increased, becoming more horizontal (Figure 16-3). Other abnormalities of the thoracic configuration are listed in Table 16-1.

Thoracic Expansion. The diaphragm is the primary muscle of (and power source for) breathing. As the diaphragm contracts it pushes the ribs outward and upward. The diaphragm

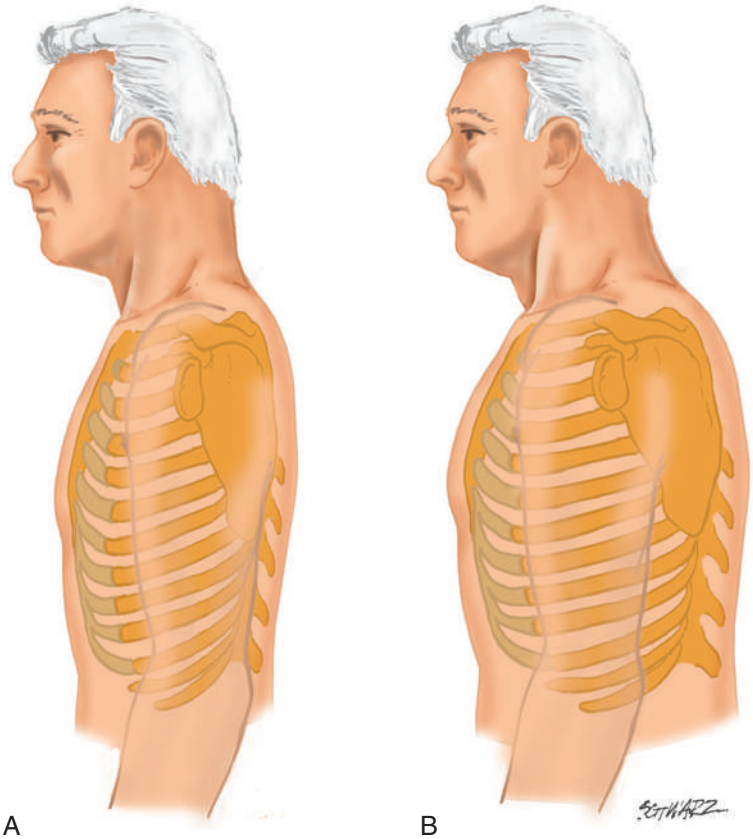

FIGURE 16-3 **A,** Patient with normal thoracic configuration. **B,** Patient with increased anteroposterior diameter. Note contrasts in the angle of slope of the ribs and development of accessory muscles.

TABLE 16-1

Abnormalities of Thoracic Configuration

Name	Condition
Pectus carinatum	Abnormal protrusion of sternum
Pectus excavatum	Depression of part or entire sternum, which can produce a restrictive lung defect
Kyphosis	Spinal deformity in which the spine has an abnormal anteroposterior curvature
Scoliosis	Spinal deformity in which the spine has a lateral curvature
Kyphoscoliosis	Combination of kyphosis and scoliosis, which may produce a severe restrictive lung defect as a result of poor lung expansion

also pushes downward on the abdominal organs, causing the abdominal wall to protrude. Therefore, when palpating the chest wall, both the chest and abdomen should expand synchronously during inspiration. However, the relative expansion of the chest and abdominal compartments depend on body position. In the supine position, the primary motion during *normal tidal breathing* is outward abdominal expansion with little noticeable chest excursion. In the upright position rib cage motion becomes more pronounced.[10]

The normal chest wall expands symmetrically and can be evaluated on the anterior and posterior chest. Anterior expansion is evaluated by placing the hands over the anterolateral chest; with the thumbs extended along the costal margin toward the xiphoid process. To evaluate posteriorly, position the hands over the posterolateral chest with the thumbs meeting at the T8 vertebra (Figure 16-4). Instruct the patient to exhale slowly and completely. When the patient has exhaled maximally, gently secure the fingertips against the sides of the patient's chest and extends the thumbs toward the midline until the tip of each thumb meets at the midline. Next instruct the patient to take a full, deep breath and note the distance the tip of each of the thumbs moves from midline. Normally, each thumb moves an equal distance of approximately 3 to 5 cm.

Diseases that affect the expansion of both lungs cause a bilateral reduction in chest expansion. Reduced expansion commonly is seen in neuromuscular disorders and COPD. Unilateral reduction in chest expansion occurs with respiratory diseases that reduce the expansion of one lung or a major part of one lung. This condition can occur with lobar consolidation, atelectasis, pleural effusion, or pneumothorax.

Breathing Pattern and Effort. At rest, a healthy adult has a consistent rate and rhythm of breathing. Breathing effort is minimal on inhalation and passive on exhalation. Abnormal breathing patterns can be broken down into two broad

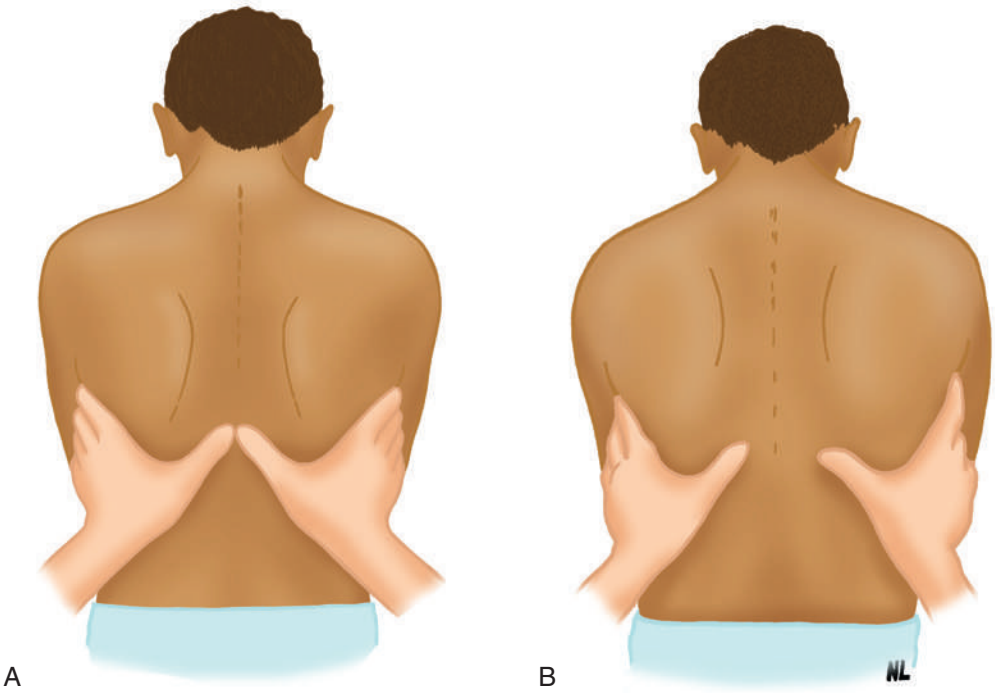

FIGURE 16-4 Estimation of thoracic expansion. **A,** Exhalation. **B,** Maximal inhalation.

TABLE 16-2

Abnormal Breathing Patterns

Breathing Pattern	Characteristics	Causes
Apnea	No breathing	Cardiac arrest, narcotic overdose, severe brain trauma
Apneustic breathing	Deep, gasping inspiration with brief, partial expiration	Damage to upper medulla or pons caused by stroke or trauma; sometimes observed with hypoglycemic coma or profound hypoxemia
Ataxic breathing	Completely irregular breathing pattern with variable periods of apnea	Damage to medulla
Asthmatic breathing	Prolonged exhalation with recruitment of abdominal muscles	Obstruction to airflow out of the lungs
Biot respiration	Clustering of rapid, shallow breaths coupled with regular or irregular periods of apnea	Damage to medulla or pons caused by stroke or trauma; severe intracranial hypertension
Cheyne-Stokes respiration	Irregular type of breathing; breaths increase and decrease in depth and rate with periods of apnea; variant of "periodic breathing"	Most often caused by severe damage to bilateral cerebral hemispheres and basal ganglia (usually infarction); also seen in patients with CHF owing to increased circulation time and in various forms of encephalopathy
Kussmaul breathing	Deep and fast respirations	Metabolic acidosis
Paradoxical breathing	*Abdominal paradox:* Abdominal wall moves inward on inspiration and outward on expiration	*Abdominal paradox:* Diaphragmatic fatigue or paralysis
	Chest paradox: Part or all of the chest wall moves in with inhalation and out with exhalation	*Chest paradox:* Typically observed in chest trauma with multiple rib or sternal fractures Also found in patients with high spinal cord injury with paralysis of intercostal muscles
Periodic breathing	Breathing oscillates between periods of rapid, deep breathing and slow, shallow breathing *without* periods of apnea	Same causes as Cheyne-Stokes respiration

categories: (1) those directly associated with cardiopulmonary or chest wall diseases that increase work of breathing and (2) those associated with neurologic disease (see Chapter 15). Table 16-2 describes common abnormal patterns of breathing.

Increased work of breathing causes accessory muscle recruitment to maintain ventilation. Common causes of an increase in the work of breathing include narrowed airways (e.g., COPD, asthma), "stiff lungs" (e.g., acute respiratory distress syndrome [ARDS], cardiogenic pulmonary edema), or a stiff chest wall (e.g., ascites, anasarca, pleural effusions). One sign of severely increased work of breathing is visable distortions in chest wall called *retractions*.

Retractions are an inward sinking of the chest wall during inspiration. This occurs when inspiratory muscle contractions generate very large negative intrathoracic pressures. The respiratory muscles can generate negative inspiratory pressures of approximately 150 cm H_2O (112 mm Hg) at maximal effort.[11] Retractions may be seen between the ribs, above the clavicles, or below the rib cage. These are called *intercostal, supraclavicular,* or *subcostal retractions*. Retractions are difficult to see in obese patients. Another form of retraction is **tracheal tugging**, which is the downward movement of the thyroid cartilage toward the chest during inspiration. Typically, this movement occurs in concert with recruitment of the accessory muscles of inspiration, primarily the sternocleidomastoid muscles of the neck.

Generally, two archetypal abnormal breathing patterns exist that provide clues about the underlying pulmonary problem. These are characterized by (1) a rapid, shallow breathing pattern and (2) a relatively brief inspiratory phase with an abnormally prolonged exhalation characterized by pronounced, sustained abdominal muscular contraction.

Rapid, shallow breathing typically occurs in patients with increased lung stiffness (e.g., ARDS, pulmonary fibrosis). Intrathoracic airways obstruction slows lung emptying and prolongs the expiratory phase as patients attempt to minimize gas trapping inside the lungs. The inspiratory-to-expiratory time ratio decreases from a normal value of 1:2 to 1:4 or greater. In contrast, extrathoracic upper airway obstruction (e.g., epiglottitis or croup) results in a prolonged inspiratory time because airways outside the thorax tend to narrow more on inhalation. Patients with severe metabolic acidosis exhibit a deep, rapid pattern called **Kussmaul breathing.**

RULE OF THUMB

Lung diseases that cause loss of lung volume (e.g., pulmonary fibrosis, ARDS) cause the patient to take rapid, shallow breaths.

RULE OF THUMB

Lung diseases that cause intrathoracic airways to narrow (e.g., asthma, bronchitis) also cause the patient to breathe with a prolonged expiratory phase.

RULE OF THUMB

Lung diseases that cause the upper airway to narrow (e.g., croup, epiglottitis) also cause the patient to breathe with a prolonged inspiratory phase.

The diaphragm may be nonfunctional in patients with spinal injuries or neuromuscular disease and may be severely limited in patients with COPD. When the diaphragm is nonfunctional or limited, the accessory muscles of ventilation become active to maintain adequate gas exchange. Heavy use of accessory muscles is reliable evidence of significant cardiopulmonary disease.

In patients with emphysema, the lungs lose their elastic recoil and become hyperinflated. Over time, hyperinflation forces the diaphragm into a low, flat position. Contraction of a flat diaphragm tends to draw in the lateral costal margins (**Hoover sign**) instead of normal expansion and greatly limits its effectiveness in moving air. Eventually, the accessory muscles assist ventilation by raising the anterior chest in an effort to increase thoracic volume. The severity of emphysema is often reflected by the magnitude of accessory muscle activity.

Diaphragmatic fatigue is found in many types of chronic and acute pulmonary diseases. Fatigue is the inability of a contracting muscle(s) to achieve a target pressure. This is distinguished from muscle weakness, the inability to achieve a target pressure in a rested muscle. For the respiratory muscles, the target pressure is that needed to maintain normal ventilation as assessed by the arterial CO_2 partial pressure ($PaCO_2$).

Acute diaphragmatic fatigue often manifests with distinctive breathing patterns; the first sign is tachypnea.[9] Sometimes tachypnea is followed by a breathing pattern in which the diaphragm and rib cage muscles alternately power breathing in an attempt to rest each muscle group (**respiratory alternans**). This pattern is noted by the upward motion of the diaphragm during inspiration on a *series of breaths,* followed by diaphragmatic contractions and outward movement of the abdominal wall on the following series of breaths. When the diaphragm is relaxed, contraction of the rib cage muscles sucks the diaphragm upward and the abdomen inward during inspiration. The opposite phenomenon occurs on breaths when the diaphragm is active. When the rib cage muscles are relaxed, the chest wall may appear to sink in as the abdomen protrudes during diaphragmatic contraction; this often gives the impression that the chest has a rocking motion. **Abdominal paradox** occurs with complete diaphragmatic fatigue, as the diaphragm is drawn upward into the thoracic cavity with *each* inspiratory effort of the rib cage muscles.

These patterns are not always associated with impending muscle fatigue. Rather, they may be adaptations to high workloads when the respiratory muscle strength is normal.[12] Also, patients with respiratory distress often have tachypnea, along with recruitment of the expiratory muscles. This situation can make it difficult to discern accurately the presence and type of abnormal breathing pattern. The RT must be careful about offering definitive therapeutic suggestions (e.g., absolute need for mechanical ventilation) based solely on his or her perception of an abnormal breathing pattern.

Palpation

Palpation is the art of touching the chest wall to evaluate underlying structure and function. It is used in selected patients to confirm or rule out suspected problems suggested by the history and initial examination findings. Palpation is performed to

evaluate vocal fremitus, estimate thoracic expansion, and assess the skin and subcutaneous tissues of the chest.

Vocal and Tactile Fremitus. *Vocal fremitus* refers to vibrations created by the vocal cords during speech. These vibrations are transmitted down the tracheobronchial tree and through the lung to the chest wall. When these vibrations are felt on the chest wall, it is called *tactile fremitus.* Assessing vocal fremitus requires a conscious, cooperative patient.

Increase intensity of vocal and tactile fremitus occurs when the lung becomes consolidated (e.g., filled with inflammatory exudate) as in pneumonia. However, if the consolidated area is not in communication with an open airway, speech cannot be transmitted and fremitus is absent or decreased. In addition, fremitus is reduced in patients who are obese or overly muscular.

Decreased intensity of vocal and tactile fremitus occurs when fluid or air collects in the pleural space (e.g., pleural effusion or pneumothoraces). Similarly, lung tissue density is reduced with hyperinflation (e.g., asthma, emphysema) that decreases transmission of speech vibrations through the lung and thereby reduces fremitus.

Tactile fremitus is assessed by asking the patient to repeat the word "ninety-nine" while the RT systematically palpates the thorax. The palmar aspect of the fingers or the ulnar aspect of the hand can be used for palpation. If one hand is used, it should be moved from one side of the chest to the corresponding area on the other side. The anterior, lateral, and posterior portions of the chest wall are evaluated.

Skin and Subcutaneous Tissues. When the lung ruptures, air frequently leaks out and collects in the subcutaneous tissues of the chest and neck. These fine air bubbles within the subcutaneous tissues produce a crackling sound and sensation when palpated. This condition is referred to as **subcutaneous emphysema**, and the sensation it produces on palpation is called *crepitus.* Crepitus is a classic sign of barotrauma. It can be felt over the chest of a patient who develops this condition as a result of receiving mechanical ventilation with high airway pressures and end-inspiratory volumes. It is also found in patients with blunt or penetrating chest trauma.

Percussion of the Chest

Percussion is the art of tapping on a surface to evaluate the underlying structure. Percussion of the chest wall produces a sound and a palpable vibration useful in evaluating underlying lung tissue. The vibration created by percussion penetrates the lung to a depth of 5 to 7 cm below the chest wall. This assessment technique is not performed routinely on all patients but is reserved for patients with suspected pneumothorax or lung consolidation.

The technique most often used in percussing the chest wall is called *mediate,* or *indirect,* percussion and can be broken down into two steps. First, place the middle finger of the nondominant hand firmly against the patient's chest wall, parallel to the ribs, with the palm and other fingers held off the chest. Second, the tips of middle and index fingers of the dominant hand are then used to strike the finger pressed against the chest. Alternatively, the lateral aspect of the thumb can be used. A quick, sharp blow should be placed near the base of the terminal phalanx. Movement of the hand striking the chest is generated at the wrist, not at the elbow or shoulder.

Percussion Over Lung Fields. Percussion of the lung fields is performed systematically by consecutively testing comparable areas on both sides of the chest. Percussion over the bony structures and over the breasts of female patients has no diagnostic value and should not be performed. Asking patients to raise their arms above their shoulders helps move the scapulae laterally and minimize their interference with percussion on the posterior chest wall.

The sounds generated during chest percussion are evaluated for intensity (loudness). Percussion over normal lung fields produces an easily heard, moderately low-pitched, resonate sound described as *tympanic.* When the percussion note is louder, deeper, and more resonate, it is said to be *hypertympanic.* Percussion may also produce a *damped,* or *dull* noise resembling the sound of a heavily muffled drum. Unilateral problems are easier to detect than bilateral problems because the normal side provides a normal standard for immediate comparison.

Clinical Implications. In modern practice, chest percussion enables rapid bedside assessment of chest abnormalities and may aid in deciding whether to obtain a chest radiograph. Any abnormality that either increases lung tissue density (e.g., pneumonia, tumor, or atelectasis) or increases the density of the pleural space (e.g., pleural effusion, empyema) results in *decreased resonance* or a *dull note* to percussion over the affected area. In contrast, *increased resonance* or a *hyperresonate note* is detected when the lungs are either hyperinflated (e.g., asthma or emphysema) or when the pleural space contains large amounts of air (**pneumothorax**). Percussion of the chest has important limitations. Abnormalities that are small or deep below the surface are not likely to be detected during percussion of the chest.

Auscultation of the Lungs

Auscultation is the process of listening for bodily sounds. Auscultation over the thorax is performed to identify normal and abnormal lung sounds and to evaluate the effects of therapy. Because auscultation can be performed quickly and is noninvasive, it is a particularly useful clinical tool. Auscultation is performed with a stethoscope to enhance sound transmission from the patient's lungs to the examiner's ears. The clinician always must ensure that the room is as quiet as possible whenever performing auscultation.

Stethoscope. A stethoscope has the following four basic parts: (1) a bell, (2) a diaphragm, (3) tubing, and (4) earpieces (Figure 16-5). The bell detects a broad spectrum of sounds and is very useful for listening to low-pitched sounds (e.g., heart sounds). Proper technique for listening to heart sounds is to place the bell lightly against the chest. This avoids stretching the skin, which inadvertently makes auscultating heart sounds more difficult because it filters out low-frequency sounds.

The diaphragm is preferred for auscultation of the lungs because most lung sounds are high frequency. The ideal tubing

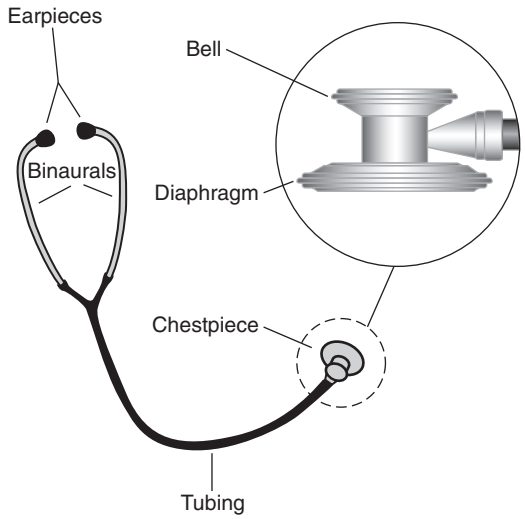

FIGURE 16-5 Acoustic stethoscope.

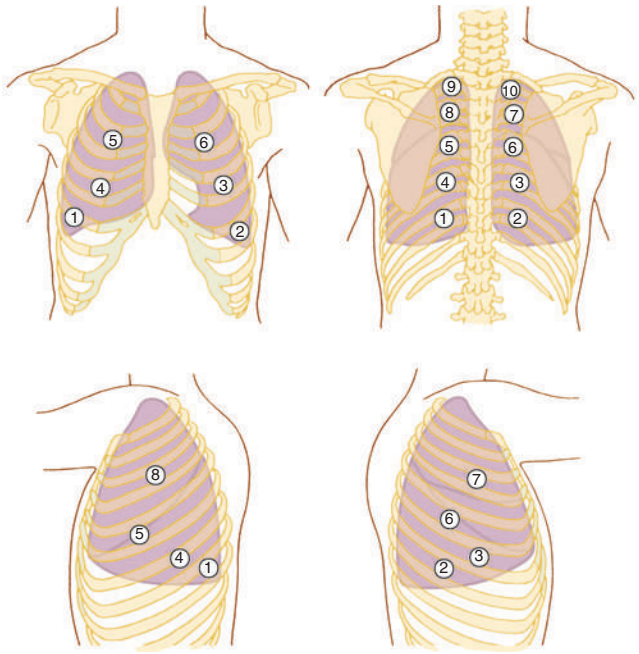

FIGURE 16-6 Sequencing for auscultation technique. (Modified from Wilkins RL, Dexter JR, editors: Respiratory diseases: a case study approach to patient care, ed 3, Philadelphia, 2007, FA Davis.)

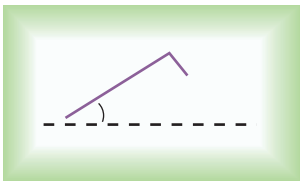

FIGURE 16-7 Diagram of normal breath sound. Upstroke represents inhalation, and downstroke represents exhalation; length of upstroke represents duration; thickness of stroke represents intensity; angle between upstroke and horizontal line represents pitch.

should be thick enough to exclude external noises and approximately 25 to 35 cm (11 to 16 inches) in length. Longer tubing may impair sound transmission.

The stethoscope should be examined regularly for cracks in the diaphragm, wax or dirt in the earpieces, and other defects that may interfere with sound transmission. A hospital-approved disinfectant should be used to clean the stethoscope *after every patient contact* to minimize contamination with microorganisms.[13] Patients who are placed in contact isolation and patients who are in protective isolation because of immunosuppression should have a dedicated stethoscope in the room to prevent cross infection.

Technique. When possible, the patient should be sitting upright in a relaxed position. The patient should be instructed to breathe a little more deeply than normal through an open mouth. Exhalation should be passive. Whenever possible, place the bell or diaphragm directly against the chest wall because clothing may produce distortion. The tubing must not be allowed to rub against any objects because this may produce extraneous sounds, which could be mistaken for adventitious lung sounds (discussed later).

Auscultation of the lungs should be systematic and include all lobes on the anterior, lateral, and posterior chest. Auscultation should begin at the lung bases with comparison of breath sounds side to side, working upward toward the lung apexes (Figure 16-6). It is important to begin at the bases because certain abnormal sounds that occur only in the lower lobes may be altered by several deep breaths. At least one full ventilatory cycle should be evaluated at each stethoscope position. If abnormal sounds are present, the clinician should listen to several breaths to clarify the characteristics.

The clinician should listen for, and distinguish among, the key features of breath sounds. The clinician should identify the pitch (vibration frequency), intensity (loudness), and duration of the inspiratory and expiratory phases. The acoustic characteristics of breath sounds can be illustrated in breath sound diagrams (Figure 16-7). The features of normal breath sounds are described in Table 16-3. One must be familiar with normal breath sounds before one can expect to identify the subtle changes that may signify respiratory disease.

Terminology. The sounds normally heard over the trachea have a loud, tubular quality and are referred to as *tracheal breath sounds.* They are also characterized by an expiratory component of equal length or slightly longer than the inspiratory component. A variation of the tracheal breath sounds can be heard both around the upper half of the sternum and between the scapulae. These are referred to as *bronchovesicular breath sounds* and are slightly lower in pitch and have equal inspiratory and expiratory components compared to tracheal breath sounds.

When auscultating over the lung parenchyma of a healthy individual, soft, muffled sounds are heard. These normal breath sounds, or *vesicular breath sounds,* are lower in pitch and intensity than bronchovesicular breath sounds. Vesicular sounds are heard primarily during inhalation, with an exhalation

TABLE 16-3

Characteristics of Normal Breath Sounds

Breath Sound	Pitch	Intensity	Location	Diagram
Vesicular	Low	Soft	Peripheral lung areas	
Bronchovesicular	Moderate	Moderate	Around upper part of sternum, between the scapulae	
Tracheal	High	Loud	Over the trachea	

component approximately one-third the duration of inhalation (see Table 16-3).

Lung Sounds in Pulmonary Disease

Respiratory disease may alter the intensity of normal breath sounds heard over the lung fields. Breath sounds are described as *diminished* when the intensity decreases and as *absent* in extreme cases. They are described as *harsh* when the intensity increases. When the expiratory component of harsh breath sounds equals the inspiratory component, they are described as *bronchial breath sounds.*

Adventitious lung sounds are added sounds or vibrations produced by the movement of air through abnormal airways. Adventitious lung sounds are classified as either *discontinuous* or *continuous.* Discontinuous adventitious lung sounds are intermittent, crackling, or bubbling sounds of short duration. Discontinuous adventitious lung sounds are referred to as either **crackles** or **rales** (from the French word for "rattle"), whereas continuous adventitious lung sounds are described with the term **wheezes;** a wheeze is a quasi-musical sound. However, the RT often will encounter the term **rhonchi** (from the Latin word for "wheezing"). It is a term no longer favored, but widely used among older clinicians to describe a low-pitched, continuous sound (vaguely resembling snoring) that is associated with secretions in the larger airways; thus it is synonymous with coarse crackles.[14]

Another continuous type of adventitious lung sound, heard primarily over the larynx and trachea during inhalation, is **stridor.** Stridor is usually a loud, high-pitched sound that sometimes can be heard without a stethoscope. Most common in infants and small children, stridor is a sign of obstruction in the trachea or larynx. Stridor is most often heard during inspiration.

When abnormal lung sounds are heard, their location and specific features should be documented. Abnormal lung sounds may be high-pitched or low-pitched, loud or faint, scattered or diffuse, and inspiratory or expiratory (or both). Faint or low-intensity crackles are often referred to as *fine crackles;* more pronounced or more intense crackles are referred to as *coarse crackles.*

Mechanisms and Significance of Lung Sounds. The exact mechanisms that produce normal and abnormal lung sounds are not fully known. However, there is sufficient agreement to allow a general description.

Normal Breath Sounds. Lung sounds are audible vibrations primarily generated by turbulent airflow in the larger airways. These sounds are altered as they travel through the lung periphery and chest wall. Normal lung tissue acts as a low-pass filter, which means it preferentially passes low-frequency sounds. This filtering effect explains the characteristic differences between tracheal breath sounds, heard directly over the trachea, and vesicular sounds, heard over the lung periphery. Normal vesicular lung sounds essentially are attenuated tracheal breath sounds.

Bronchial Breath Sounds. Bronchial breath sounds are considered abnormal when they are heard over peripheral lung regions. Normal vesicular sounds are replaced with bronchial sounds when lung tissue density increases, and attenuation is reduced. When normal air-filled lung tissue becomes atelectatic or consolidated (e.g., pneumonia), the resulting breath sounds are similar to the sounds normally heard over large upper airways.

Diminished Breath Sounds. Diminished breath sounds occur when the sound intensity at the site of generation (larger airways) is reduced, or when the sound transmission through the lung or chest wall is decreased. Shallow or slow breathing patterns both reduce sound intensity because they create less turbulent flow in the larger airways. Reduced sound transmission also occurs for a variety of other reasons, including (1) when airways are plugged with mucus, (2) the lung tissue is hyperinflated (e.g., COPD, asthma), (3) air or fluid collects in the pleural space (e.g., pneumothorax, hemothorax, pleural effusion), (4) anasarca (generalized body edema), and (5) obesity or when chest muscles are highly developed.

Wheezes and Stridor. Wheezes and stridor represent vibrations of airway wall caused when air flows at a high velocity through a narrowed airway. Airway diameter can be reduced by bronchospasm, mucosal edema, inflammation, tumors, foreign bodies, and pulmonary edema.

This narrowing initially causes an increase in the velocity of airflow, which causes the lateral wall pressure to decrease. This decrease in pressure causes the lateral walls of the narrowed airway to pull closer together, and airflow stops. When airflow stops, the lateral wall pressure increases, and the airway opens back to the previous position. This cycle repeats many times per second and causes the airway walls to vibrate and make a musical type of adventitious lung sound similar to a reed instrument.

RULE OF THUMB

Generally, expiratory wheezes indicate obstruction of intrathoracic airways such as occurs with lung diseases (e.g., bronchitis, asthma). Wheezing may be monophonic (single note) or polyphonic (multiple notes). A monophonic wheeze indicates that a single airway is partially obstructed. Monophonic wheezing may be heard during inhalation and exhalation or during exhalation only. Polyphonic wheezing suggests that many airways are obstructed, such as with asthma, and is heard only during exhalation. Bronchitis and CHF with pulmonary edema also can cause polyphonic wheezing.

It is useful to monitor the pitch and duration of wheezing. Improved expiratory flow is associated with a decrease in the pitch and length of the wheezing. If high-pitched wheezing is present during the entire expiratory time before treatment but becomes lower pitched and occurs only late in exhalation after therapy, the pitch and duration of the wheeze have diminished. This change suggests that the degree of airway obstruction has decreased.

Stridor is a serious adventitious lung sound indicating that the upper airway is compromised. It may occur in patients of any age but most often occurs in children. In children, laryngomalacia is the most common cause of chronic stridor, whereas croup is the most common cause of acute stridor. Generally, inspiratory stridor is consistent with narrowing above the glottis, whereas expiratory stridor indicates narrowing of the lower trachea. In adults, stridor most often occurs from laryngeal or subglottic edema secondary to airway trauma after prolonged intubation.

Crackles. Crackles occur when airflow moves secretions or fluid in the airways. Coarse crackles usually are heard during both inspiration and expiration and often clear when the patient coughs or when the upper airway is suctioned. Crackles also may be heard in patients without excess secretions. These crackles occur when collapsed airways pop open during inspiration. Airway collapse or closure can occur in peripheral bronchioles or in larger, more proximal bronchi.

Larger, more proximal bronchi may close during expiration when there is an abnormal increase in bronchial compliance or when the retractile pressures around the bronchi are low. In this situation, crackles usually occur early in the inspiratory phase and are referred to as *early inspiratory crackles* (Figure 16-8). Early inspiratory crackles may be loud or faint and are not silenced by a cough or a change in position. They frequently occur in patients with COPD (chronic bronchitis, emphysema, or asthma) and usually indicate severe airway obstruction.

Peripheral airways may close during exhalation when the surrounding intrathoracic pressure increases or when surfactant levels are diminished. *Fine, late inspiratory crackles* are produced by the sudden opening of peripheral airways, usually late in the inspiratory phase. They are more common in the dependent lung regions, where the peripheral airways are most prone to collapse during exhalation. They may clear with changes in posture or if the patient performs several deep inspirations. Late inspiratory crackles are most common in patients with respiratory disorders that reduce gas volume of the lung, such as atelectasis, pneumonia, pulmonary edema, and pulmonary fibrosis (Table 16-4).

RULE OF THUMB

Fine, late inspiratory crackles suggest either restrictive lung diseases such as pulmonary fibrosis or the opening of collapsed (atelectatic) alveoli.

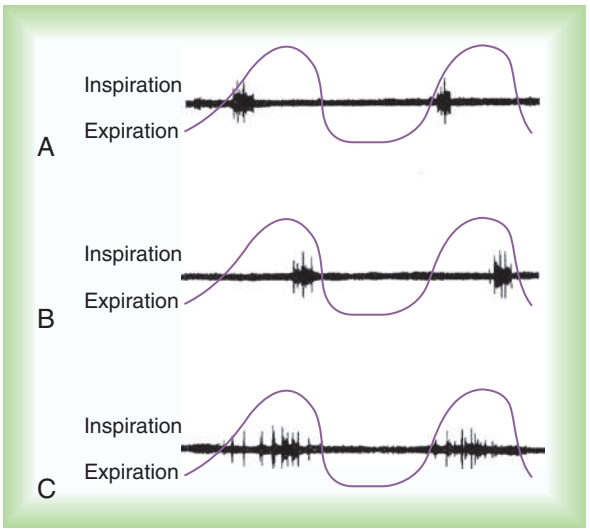

FIGURE 16-8 Timing of inspiratory crackles. **A,** Early inspiratory crackles. **B,** Late inspiratory crackles. **C,** Pan-inspiratory crackles.

TABLE 16-4

Application of Adventitious Lung Sounds

Lung Sound	Possible Mechanism	Characteristics	Causes
Wheezes	Rapid airflow through obstructed airways	High-pitched, usually expiratory	Asthma, congestive heart
Stridor	Rapid airflow through obstructed upper airway	High-pitched, monophonic	Croup, epiglottitis, postextubation laryngeal edema
Coarse crackles	Excess airway secretions moving through airways	Coarse, inspiratory and expiratory	Severe pneumonia, bronchitis
Fine crackles	Sudden opening of peripheral airways	Fine, late inspiratory	Atelectasis, fibrosis, pulmonary edema

Pleural Friction Rub. A pleural friction rub is a creaking or grating sound that occurs when the pleural surfaces become inflamed and rub together during breathing, as in pleurisy. It may be heard only during inhalation but often is identified during both phases of breathing. The rub usually is localized to a certain site on the chest wall. It sounds similar to coarse crackles but is not affected by coughing. The intensity of pleural rubs may increase with deep breathing.

Voice Sounds. Vocal resonance is produced by the same mechanism as vocal fremitus. Normal, air-filled lung tissue filters vocal sounds and reduces the intensity and clarity of spoken words. **Egophony,** or **bronchophony,** is an increased intensity and clarity of vocal resonance produced by enhanced transmission of vocal vibrations through consolidated lung tissue. The patient is instructed to repeat the words "one," "two," "three," or "ninety-nine" while the clinician listens over the chest wall with a stethoscope, comparing one side with the other. When listening over consolidation lung tissue, the words will be transmitted louder, clearer, and with a distinctive *nasal bleating quality*. Alternatively, by having the patient repeatedly pronounce a long A sound, consolidated lung will transmit the sound as an E. This is referred to as *E to A egophony*. Bronchophony often accompanies bronchial breath sounds, a dull percussion note, and increased vocal fremitus.

Cardiac Examination

Because of the close relationship between the heart and lungs, chronic lung diseases often cause cardiac problems. The techniques for physical examination of the chest wall overlying the heart (precordium) include inspection, palpation, and auscultation. Most clinicians examine the precordium at the same time they assess the lungs.

Inspection and Palpation

Inspection and palpation of the precordium help identify normal or abnormal pulsations. Pulsations on the precordium are created by ventricular contraction. Detection of pulsations depends on the force of ventricular contraction and the thickness of the chest wall through which the vibrations travel.

Normally, left ventricular contraction is the most forceful and generates a visible, palpable pulsation during systole. This pulsation is called the *point of maximal impulse* (PMI). To identify the PMI, place the palm of the right hand over the lower left sternal border.

The PMI shifts laterally with left ventricular hypertrophy. Right ventricular hypertrophy produces a systolic **heave** (or thrust) felt near the lower left sternal border. This is a common finding in patients with chronic hypoxemia, pulmonary valvular disease, or primary pulmonary hypertension The PMI may be difficult to locate in patients with severe emphysema, because systolic vibrations are not well transmitted across hyperinflated lungs.

The PMI also may shift with deviations in the mediastinum caused by pneumothorax or lobar collapse. Typically, the PMI shifts *toward* lobar collapse but *away* from a tension pneumothorax. With severe pulmonary hyperinflation the PMI shifts centrally to the epigastric area.

The second left intercostal space near the sternal border is referred to as the *pulmonic area* and is palpated to identify accentuated pulmonary valve closure. Strong vibrations may be felt in this area with the presence of pulmonary hypertension or valvular abnormalities (Figure 16-9). Valvular abnormalities may produce palpable vibrations or **thrills** that often are accompanied by a murmur (see later).

Auscultation of Heart Sounds

Heart sounds are auscultated using either the bell or diaphragm of the stethoscope. Optimal auscultation occurs when the patient leans forward or lies on the left side, as this moves the heart closer to the chest wall.

Normal heart sounds are created by closure of the heart valves (see Chapter 10). The first heart sound (S_1) is produced by closure of the mitral and tricuspid (atrioventricular [AV]) valves during ventricular contraction. When systole ends and the ventricles relax, the pulmonic and aortic (semilunar) valves close, creating the second heart sound (S_2). If either the AV valves or the semilunar valves do not close together, a *pronounced* split heart sound is heard. A third, low-pitched, heart sound (S_3) is heard over the apex of the heart that, in adults, may signify CHF. A fourth heart sound (S_4) occurs later and may be a sign of heart disease. A patient with heart disease who has S_3 and S_4 is said to have a **gallop rhythm.**

Abnormal Heart Sounds

Reduced intensity of heart sounds may result from cardiac or extracardiac abnormalities. Pulmonary hyperinflation, pleural effusion, pneumothorax, and obesity make it difficult to identify S_1 and S_2. Poor ventricular contraction resulting from heart failure or valvular disease also decreases S_1 and S_2. In contrast, an intense S_2 (**loud P2**) occurs in pulmonary hypertension due to forceful closure of the pulmonic valve.

Cardiac **murmurs** are created by (1) a backflow of blood through an incompetent valve, (2) a forward flow of blood through a stenotic ("narrowed") valve, and (3) rapid blood flow through a normal valve (as occurs with heavy exertion). Cardiac murmurs caused by incompetent or stenotic heart valves are classified as systolic or diastolic.

Systolic murmurs from an incompetent AV valve typically produce a high-pitched "whooshing" noise during S_1. In contrast, obstructed blood flow through a stenotic semilunar valve produces a crescendo-decrescendo sound. A *diastolic murmur* occurs with S_2 and is created by the backflow of blood across an incompetent semilunar valve. A *turbulent diastolic murmur* is caused by obstructed blood flow across a stenotic AV valve during diastole.

Abdominal Examination

The abdomen should be inspected and palpated for evidence of distention and tenderness. Abdominal distention and pain impair diaphragmatic movement and may contribute to or cause respiratory insufficiency. Abdominal dysfunction may

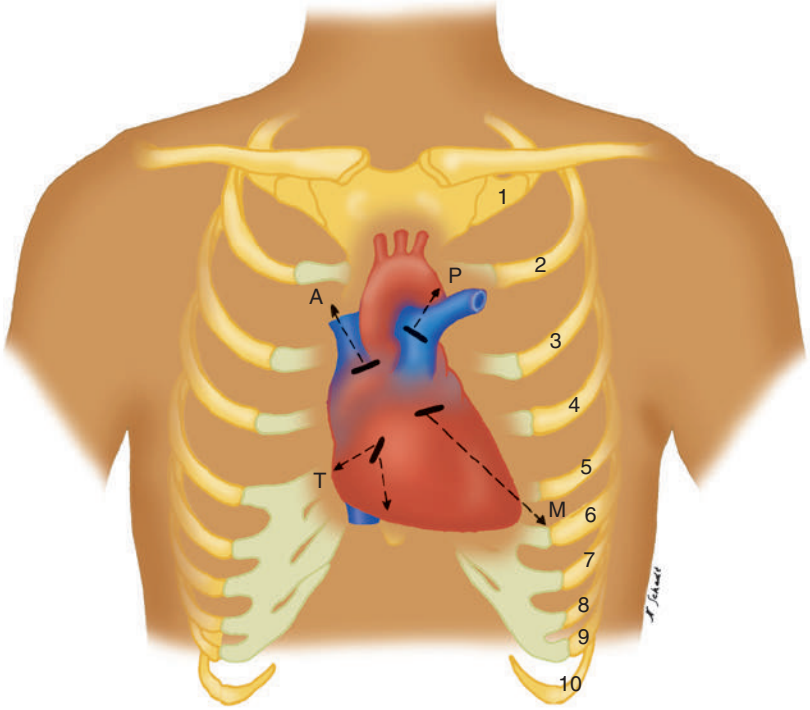

FIGURE 16-9 Anatomic and auscultatory valve area. Location of anatomic valve sites is represented by *solid bars*. *Arrows* designate transmission of valve sounds to their respective auscultatory valve areas. *A,* Aortic valve; *M,* mitral valve; *P,* pulmonic valve; *T,* tricuspid valve.

inhibit deep breathing and coughing and promote atelectasis. Of particular concern is intraabdominal hypertension, which is defined as intraabdominal pressure greater than 12 mm Hg, and is found in between 20% and 30% of critically ill patients.[15] **Abdominal compartment syndrome** occurs when intraabdominal pressures are greater than 20 mm Hg and often requires emergency decompressive surgery. This syndrome causes profound atelectasis and hypoxemia, hypotension, and renal failure.

Intraabdominal hypertension is a common finding in patients with blunt or penetrating abdominal trauma, ruptured aortic aneurysm, bowel infarction, and end-stage liver failure. It is suspected when gross examination of the abdomen reveals very pronounced abdominal distention. Intraabdominal pressure is measured by connecting an intraarterial pressure catheter to the culture port of a Foley urine catheter.

The presence of an enlarged liver (**hepatomegaly**) is a frequent cause of right lower lobe atelectasis and pleural effusion. Hepatomegaly is a common finding in patients with liver disease and patients with cor pulmonale.

Examination of the Extremities

Respiratory disease may cause several abnormalities of the extremities, including digital clubbing, cyanosis, and pedal edema.

Clubbing

Clubbing of the digits is a significant manifestation of cardiopulmonary disease. **Clubbing** is a painless enlargement of the terminal phalanges of the fingers and toes that develops over time. As the process advances, the angle of the fingernail to the nail base increases, and the base of the nail feels "spongy." The profile view of the digits allows easier recognition of clubbing (Figure 16-10), but sponginess of the nail bed is the most important sign. Causes of clubbing include infiltrative or interstitial lung disease, bronchiectasis, various cancers (particularly lung cancer),[16] congenital heart disease, chronic liver disease, and inflammatory bowel disease. COPD alone, even when hypoxemia is present, does not lead to clubbing. Clubbing of the digits in a patient with COPD indicates that something other than obstructive lung disease is occurring.

Cyanosis

Examination of the digits for cyanosis is part of the initial assessment and is done whenever hypoxemia is suspected. Cyanosis is detectable because of the transparency of the fingernails and skin. Cyanosis becomes visible when the amount of unsaturated hemoglobin in the capillary blood exceeds 5 to 6 g/dl; this may be caused by a reduction in arterial or venous O_2 content, or both.

Cyanosis of the digits is referred to as ***peripheral cyanosis*** or *acrocyanosis* and may involve extensive portions of limbs. This condition is mainly the result of poor perfusion, especially in the extremities. When capillary blood flow is poor, the tissues extract more O_2. This reduces the venous O_2 content and therefore increases the amount of reduced hemoglobin. The extremities are usually cool to the touch when peripheral cyanosis is a sign of poor peripheral perfusion. ***Central cyanosis*** on the other hand can be seen in the patient's mucosa or trunk and may

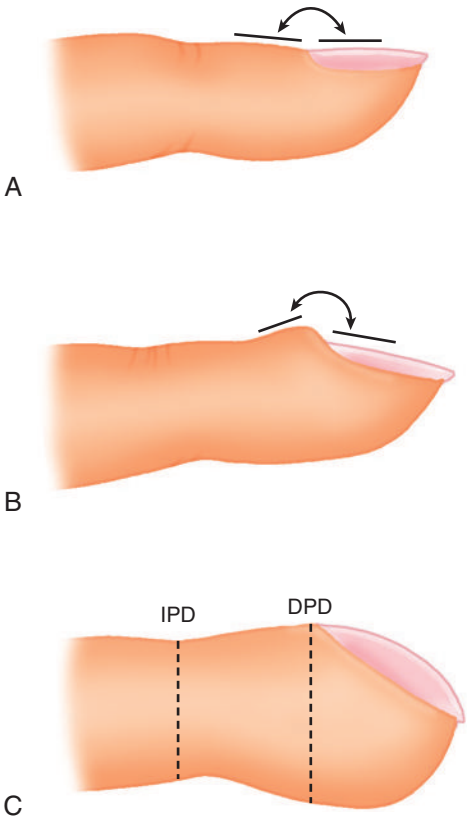

FIGURE 16-10 **A,** Normal digit configuration. **B,** Mild digital clubbing with increased hyponychial angle. **C,** Severe digital clubbing; the depth of the finger at the base of the nail *(DPD)* is greater than the depth of the interphalangeal joint *(IPD)* with clubbing.

signal severe lung disease or when venous blood is shunting as a result of congenital heart disease. However, cyanosis may be masked by room lighting and in people of color, as well as those with severe anemia.

Pedal Edema

See discussions of common cardiopulmonary symptoms.

Capillary Refill

Capillary refill is assessed by pressing briefly and firmly on the patient's fingernail until the nail bed is blanched. When pressure is released, the speed at which the blood flow and color return is noted. When cardiac output is reduced and the digital perfusion is poor, capillary refill is slow, taking several seconds to complete. In healthy individuals with good cardiac output and digital perfusion, capillary refill time is 2 seconds or less. Capillary refill time should be assessed in the context of whether or not the skin is mottled (i.e., blotched skin shade) and skin temperature.

Peripheral Skin Temperature

When systemic perfusion is poor (as in heart failure or shock), there is a compensatory vasoconstriction in the extremities that diverts blood to the vital organs. This reduction in peripheral perfusion causes the extremities to become cool to the touch. The extent to which coolness extends back toward the torso indicates the degree of circulatory failure. In contrast, patients with high cardiac output and peripheral vascular failure (as occurs in septic shock) may have warm, dry skin.

MINI CLINI

Evaluation of Acute-Onset Respiratory Distress

PROBLEM: The RT is called to evaluate a 55-year-old woman with acute respiratory distress and worsening hypoxemia. The patient is 3 days post-admission for right-sided rib fractures. This resulted from falling down a flight of stairs, secondary to alcohol intoxication with brief loss of consciousness. Since admission she had maintained adequate oxygenation with pulse oximetry (SpO_2) of 95% on 3 L/min of nasal O_2. Over the past hour she has become febrile (maximum temperature 39.5° C), tachycardic (heart rate 130 beats/min), and hypotensive (blood pressure 88/50 mm Hg; mean, 63 mm Hg), with new-onset altered mental status. Her SpO_2 is now 87% on 6 L/min nasal O_2 with a respiratory rate of 32 breaths/min. Her medical history is significant for alcoholism and a 30 pack-year smoking history. What can the physical examination and history tell us about the potential source of respiratory distress?

SOLUTION: The signs, symptoms and history suggest bacterial pneumonia possibly from aspiration during her initial loss of consciousness or from a pulmonary contusion. Bacterial pneumonia has an incubation period of 1 to 3 days. The associated high fever, tachycardia, hypotension, and altered mental status also suggest that pneumonia has resulted in sepsis (systemic inflammation). Pulmonary contusion also can result in pneumonia and ARDS (see Chapter 29), with a peak occurrence at approximately 72 hours.[17]

Rib fractures are painful and limit deep breathing and effective coughing, leading to atelectasis and retained secretions that increase the risk for pneumonia. When extensive, rib fractures also cause chest wall instability that limits effective ventilation and heightens the risk for respiratory failure. Both alcoholism and cigarette smoking further increases the susceptibility to pneumonia.[18,19] Also, a history of alcohol abuse may be a contributory factor because the onset of acute alcohol withdrawal typically occurs in this time frame.[20]

The first priority is to increase O_2 therapy to achieve adequate oxygenation ($Sp_{O2} \geq 90\%$) while conducting an examination. Worsening oxygenation, despite doubling O_2 therapy, suggests refractory hypoxemia, which is a hallmark of ARDS. This situation indicates the need for high-concentration O_2 therapy, continuous pulse oximetry and close hemodynamic monitoring.

The RT should be alert for signs suggestive for heightened work of breathing (rapid-shallow breathing, accessory inspiratory muscle use, along with tracheal or intercostal retractions and expiratory muscle recruitment), chest wall instability (paradoxical chest motion), and diminished ventilation (global decrease in breath sound intensity). Breath sounds should be evaluated for evidence suggesting the presence of secretions (coarse, bubbling crackles) or pulmonary edema (fine inspiratory crackles). Another possibility is acute pulmonary embolism, which would become a more prominent consideration if the patient had also suffered pelvic or leg fractures and was immobilized or has redness and swelling of the lower extremities. Although a pneumothorax is unlikely in this situation, the chest should be inspected for signs (e.g., subcutaneous emphysema, JVD, unilateral chest excursion).

Further work-up would include a chest radiograph to confirm the suspicion of pneumonia or chest contusion (and to rule out a pneumothorax), an arterial blood gas to evaluate the severity of hypoxemia and the adequacy of ventilation, and blood samples to evaluate the presence of infection (see Chapter 17). The results of these tests and the patient's response to therapeutic interventions would determine where the patient can be safely and optimally managed.

SUMMARY CHECKLIST

- The interview is used to obtain important diagnostic information and build a rapport between with the patient.
- Dyspnea is the sensation that occurs when breathing effort is excessive relative to the tidal volume achieved and increases with reduced lung compliance and narrowed airways. Breathlessness is the unpleasant sensation associated with a heightened drive to breathe.
- Cough is one of the most common symptoms of lung disease and occurs when the cough receptors in the airways are stimulated by foreign material, mucus, noxious gases, or inflammation.
- Chronic cough is most often caused by upper airway cough syndrome, asthma, chronic bronchitis from cigarette smoking, and gastroesophageal reflux disease.
- The most common cause of hemoptysis (spitting up blood from the lung) is infection.
- Vital signs provide reliable assessment information about the general condition of the patient and the patient's response to therapy.
- Rapid, shallow breathing indicates pathologic changes in the lung consistent with a reduction in the gas volume of the lungs.
- A prolonged expiratory phase suggests that the intrathoracic airways are narrowed.
- Normal breath sounds are generated by turbulent airflow in the larger airways.
- Crackles are generated by the sudden opening of closed airways or by the movement of excessive airway secretions with breathing.
- Wheezes are produced by the rapid vibration of narrow airways as gas passes through at high velocity.
- Cor pulmonale causes JVD, hepatomegaly, a loud P_2, and pedal edema.
- Central cyanosis is a sign of hypoxemia caused by respiratory failure, whereas peripheral cyanosis suggests circulatory failure.

CHAPTER 17

Interpreting Clinical and Laboratory Data

RICHARD H. KALLET

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe a critical value and its importance in clinical practice.
- Define leukocytosis, leukopenia, anemia, polycythemia, and thrombocytopenia.
- Identify which electrolyte disturbances interfere with normal respiratory function.
- Describe clinical tests used to identify cardiac stress and myocardial infarction.
- Identify the three main tests used to diagnose coagulation disorders.
- Describe how the sputum Gram stain and culture are used to diagnose pulmonary infections.

CHAPTER OUTLINE

KEY TERMS

acid-fast bacterium
anemia
bands
basic chemistry panel
complete blood count
critical test value
erythrocytes
hematology
hematocrit
homeostasis
hyperglycemia
hyperkalemia
hypernatremia
hypoglycemia
hypokalemia
lactate
leukocytes
leukocytosis
leukopenia
neutropenia
polycythemia
reference range
segs
thrombocytes
thrombocytopenia
troponin
troponin I

INTERPRETING CLINICAL LABORATORY TESTS

This chapter discusses common blood tests performed on patients admitted to the hospital. These tests are done to evaluate the general health and baseline status of the patient, identify organ system dysfunction, detect the presence of infection, and determine the effects of therapy. Hence, the respiratory therapist (RT) must be familiar with these tests and their value in helping diagnose respiratory dysfunction.

This chapter also presents a brief review of fundamental physiologic concepts related to these tests, contains comprehensive with reference-range values, and explains the significance of these tests in patient assessment.

Introduction to Laboratory Medicine

Laboratory medicine involves the study of patient tissue and fluid specimens and consists of five disciplines. *Clinical biochemistry* involves the analysis of blood, urine, and other bodily fluids for electrolytes and proteins; **hematology** analyzes the cellular components of blood. *Clinical microbiology* tests blood and other bodily fluids for infectious agents and includes the subspecialties that identify bacteria *(bacteriology),* viruses *(virology),* fungi *(mycology),* and parasites *(parasitology)*. *Immunology* is a closely related discipline focusing on autoimmune and immunodeficiency diseases. Finally, the *anatomic pathology* service assists with diagnosing diseases by analyzing tissue samples.

Reference Range

Laboratory tests help determine a patient's health status and aid medical decisions. Therefore it is important to determine whether a specific test result falls within an expected range of values considered to be "normal." However, the notion of "normal" can be problematic. In the early history of laboratory medicine, determining the normal range for blood chemistry and hematology tests was primitive and not representative of the larger population in terms of age, gender, race, and ethnicity. In addition, the term *normal* is not synonymous with *healthy*. For example, the normal range for cholesterol found in most Americans puts them at risk for cardiovascular disease and therefore cannot be considered healthy.

Beginning in the 1970s,[1] the term *normal ranges* was replaced with more appropriate terms such as *reference ranges, biologic reference intervals,* and *expected value*.[2] This change in terminology acknowledged that what we consider normal must take into account variations related to age, gender, race, and ethnicity, which change over time as the demographic composition of society changes. A **reference range** sets the boundaries for, and expected variability of, any analyte (e.g., electrolyte, blood cell, protein, enzyme) that would likely be encountered in healthy subjects.

Reference ranges differ from laboratory to laboratory for various reasons. These include differences in measurement techniques, the populations of healthy individuals used to establish the reference intervals, and analytic imprecision. Most differences in reference ranges between laboratories are small.[2] Reference ranges and critical values displayed in this chapter serve as representative examples; however, RTs must become familiar with the reference ranges used at their institutions.

Critical Test Value

A **critical test value** is a result *significantly* outside the reference range and represents a pathophysiologic condition. A critical value may be *potentially* life-threatening, and immediate corrective action is often warranted. Critical values are reported in the hospital to alert caregivers, decrease medical errors, and protect patients.

Typically, critical values are communicated by telephone from the clinical laboratory to the unit where the patient is situated. The nurse or RT receiving these results must read back the critical value to the clinical laboratory to ensure accuracy. The nurse or RT then must communicate the critical value in a timely fashion to the physician. The same read-back procedure is used. All communication of critical test values is documented in the medical record.

In this chapter, critical values are listed along with common pathophysiologic states with which they commonly occur. Not all clinical analytes have an associated critical value because sometimes there is no agreement on what constitutes a critical value. Others have only a one-sided value that exists below or above a critical threshold. This is true particularly for substances that do not normally appear in the blood. For example, certain enzymes and proteins are released only after extensive cellular damage following injury (see later section on enzyme tests). Under normal circumstances, these proteins or enzymes may be virtually undetectable in the serum or plasma.

When interpreting derangements for *any* test result, clinicians must consider the *context* of the change. In a patient with chronic renal disease, a serum creatinine of 3.0 mg/dl (approximately twice the upper limit of normal) is not considered urgent. But, in a patient with a bloodstream infection (i.e., sepsis) and hypotension, a sudden increase in serum creatinine to 3.0 mg/dl is considered critical because it indicates acute kidney dysfunction and possibly septic shock.

Complete Blood Count

The **complete blood count** (CBC) describes the number of circulating white blood cells (WBCs), called **leukocytes;** red blood cells (RBCs), called **erythrocytes;** and platelets, called **thrombocytes.** The WBC count is made up of five different types of cells and is reported under the *differential*. RBCs are evaluated for size and hemoglobin (Hb) content. Platelets are evaluated by the number present. Table 17-1 lists the normal CBC results for adults.

An elevated WBC count is termed **leukocytosis** and has multiple causes, including stress, infection, and trauma. The degree of leukocytosis reflects the severity of infection. A significantly elevated WBC count (>20 × 10^3/mcl) suggests the presence of a serious infection and that the patient's immune system is generating a strong response. In contrast, **leukopenia** (or leukocytopenia) is a WBC count below normal that often occurs when the immune system is overwhelmed by infection. Other causes include bone marrow diseases (e.g., leukemia, lymphoma), influenza, systemic lupus erythematosus, tuberculosis, acquired immunodeficiency syndrome (AIDS), and chemotherapy or radiation therapy given to cancer patients.

RULE OF THUMB

Leukocytosis usually represents a vigorous immune response to either infection or trauma.

RULE OF THUMB

Leukocytopenia often signifies that either the immune system has been overwhelmed by infection or there is presence of immunosuppression.

White Blood Cell Count

The WBC differential count determines the number of each type of WBC present in the blood (Table 17-2). Most circulating WBCs are either neutrophils or lymphocytes. Leukocytosis is a significant elevation in the WBC count (>15 × 10^3/mcl) that occurs when either neutrophils or lymphocytes are responding to an abnormality. Basophils, eosinophils, and monocytes make up a small proportion of the circulating WBCs and rarely cause a major increase in the WBC count.

TABLE 17-1

Reference Range Values for Complete Blood Count in an Adult

Test	Reference Range
Red blood cell count	
Men	4.4-5.9 × 10^6/mcl
Women	3.8-5.2 × 10^6/mcl
Hemoglobin	
Men	13.3-17.7 g/dl
Women	11.7-15.7 g/dl
Hematocrit	
Men	40%-52%
Women	35%-47%
White blood cell count	3.9-11.7 × 10^3/mcl
White blood cell differential	
Segmented neutrophils	40%-75%
Bands	0%-6%
Eosinophils	0%-6%
Basophils	0%-1%
Lymphocytes	20%-45%
Monocytes	2%-10%
Platelet count	150-400 × 10^3/mcl

Values for reference ranges and critical test results are from the University of California–San Francisco Moffit-Long Hospital and San Francisco General Hospital.

The WBC count differential is calculated by multiplying the percentage of each WBC subtype by the total WBC count. This prevents misinterpreting the WBC count differential when one cell type changes, causing a *relative change* (percentage) in the other four cell types. For example, if the neutrophil count doubles because of infection, the relative percentage of the other four cells types would decrease, although their absolute number would not change.

The sub-analysis of lymphocytes is important for identifying infection with human immunodeficiency virus (HIV), the causative agent of AIDS. HIV targets and destroys CD4 T lymphocytes. Opportunistic infections such as *Pneumocystis jiroveci* pneumonia generally occur when lymphocytes decrease to less than 200 × 10^6/L, and this information is used in making the diagnosis of AIDS.

Elevation of the absolute value of neutrophils is termed *neutrophilia*. Immature neutrophils are known as **bands** because of the banded shape of the nucleus. Most bands are located in the bone marrow, where they continue to mature. Mature neutrophils are known as **segs** because of the segmented shape of their nucleus. Severe infection causes the bone marrow to release stores of any available neutrophils, and both bands and segs enter the circulating blood volume. When bands and segs are elevated in the CBC, the patient is likely experiencing a more severe bacterial infection.

A reduced number of circulating neutrophils is termed **neutropenia** and is observed in patients with bone marrow disease (e.g., lymphoma, leukemia), autoimmune disorders, HIV infection, and those undergoing chemotherapy or radiation treatment for cancer. Neutropenia increases risk for the developing opportunistic infections.

RULE OF THUMB

Elevation of the WBC count usually is caused by an increase in either neutrophils or lymphocytes in response to infection.

TABLE 17-2

Reference Range Values for White Blood Cell Count Differential and Common Causes for Abnormalities

Cell Type	Relative Value (%)	Absolute Value	Causes for Abnormalities
Neutrophils	40-75	1.8-6.8 × 10^9/L	Increased with bacterial infection and trauma; reduced with bone marrow diseases (critical value <1.0)
Lymphocytes	20-45	1.0-3.4 × 10^9/L	Increased with viral and other infections; reduced with immunodeficiency problems
CD4 T lymphocytes	31-60*	410-1590 × 10^6/L	HIV disease; diagnostic threshold <200
Eosinophils	0-6	0-0.4 × 10^6/L	Increased with allergic reactions and parasitic infections
Basophils	0-1	0-0.1 × 10^6/L	Increased with allergic reactions
Monocytes	2-10	0.2-0.8 × 10^6/L	Increased with invasion of foreign material

Values for reference ranges and critical test results are from the University of California–San Francisco Moffit-Long Hospital and San Francisco General Hospital.
*Percentage of lymphocyte.

RULE OF THUMB

When bands and segs are elevated in the CBC, the patient is likely experiencing a more severe bacterial infection.

Red Blood Cell Count

The primary function of RBCs or erythrocytes is to supply oxygen to the tissues. The RBC count helps determine the ability of the blood to carry O_2. An abnormally low RBC count is referred to as **anemia** and suggests that either bone marrow production of RBCs is inadequate or excessive blood loss has occurred. Regardless, the O_2-carrying capacity of blood is reduced, and the patient is at increased risk for tissue hypoxia. Anemia has different causes: some are related to dietary deficiencies in iron or vitamins (e.g., vitamin B_{12} and folate); others are related to chronic inflammatory diseases, such as Crohn disease, HIV/AIDS, lymphoma, and autoimmune diseases that destroy erythrocytes (hemolytic and aplastic anemia). A hereditary cause is sickle cell anemia, which is common in African-Americans. For most forms of anemia, a blood transfusion may be needed if the RBC count is too low, as discussed later in this chapter.

MINI CLINI

White Blood Cell Count Differential

PROBLEM: A patient admitted to the hospital for acute shortness of breath and fever has a chest radiograph revealing pneumonia. The CBC shows an increased WBC count of 15×10^3/mcl with 75% neutrophils but only 10% lymphocytes. Given that the normal lymphocyte differential is 20% to 45%, does the value of 10% suggest a problem with lymphocyte production by the immune system? What type of pneumonia is probably present in this case?

SOLUTION: The 10% differential for the lymphocytes represents a *relative value*. Because the total WBC count is markedly elevated, the 10% in relative terms represents 1500 lymphocytes in absolute value, which is within normal range. If the total WBC count was reduced to less than normal and the differential showed a lymphocyte count of 10%, an abnormal absolute value would be present and would suggest an immunologic problem. This patient probably has bacterial pneumonia, given the elevated number of neutrophils.

Polycythemia is an abnormally elevated RBC count. It often occurs when the bone marrow is stimulated to produce extra RBCs in response to chronic hypoxemia (secondary polycythemia). Polycythemia counteracts reduced PO_2 by increasing the O_2-carrying capacity of the blood. Patients living at high altitudes and those with chronic lung disease are most likely to experience chronic hypoxia and develop secondary polycythemia.

In addition to the RBC count, the clinical laboratory reports Hb and hematocrit (Hct) levels. Hb is a protein substance with the unique ability to bind with O_2. Each healthy RBC contains 200 million to 300 million molecules of Hb, for an Hb level of 12 to 17 g/dl in a healthy adult. Patients with an inadequate Hb concentration have reduced O_2-carrying capacity. In this condition, the RBCs are smaller than normal *(microcytic anemia)* and lack normal color *(hypochromic anemia)*. The necessity for RBC transfusion depends on the cause of anemia and the patient's overall condition. Transfusions generally are indicated only when the Hb concentration falls to 7.0 g/dl (an Hct of approximately 21%), because this conservative practice actually improves patient outcomes.[3]

The Hct level is the ratio of RBC volume to whole blood. It is determined by spinning a blood sample in a centrifuge to separate the blood cells from the plasma. The proportion of the sample represented by the packed cells is the **hematocrit.** A low Hct occurs with anemia and a high Hct with polycythemia. The Hct also reflects the patient's hydration status. Dehydration causes the Hct to increase (hemoconcentration), whereas overhydration causes it to decrease via hemodilution.

RULE OF THUMB

The recommended threshold for blood transfusion is Hb of 7.0 g/dl or Hct of 21%.

Electrolyte Tests

Basic Concepts for Understanding Electrolyte Balance

Normal cellular function depends on homeostasis of fluids, electrolytes, and acid-base balance. **Homeostasis** is the ability of complex organisms to maintain a *dynamic balance* or *equilibrium* in their internal environments by making constant adjustments. The guiding principle is that the total amount of water, electrolytes, acid, and base gained each day must be balanced by the total amount lost.

Electrolytes are positively or negatively charged ions that influence the functioning of enzymes. The concentration of any electrolyte is determined by the amount of water in which it is suspended. Electrolytes always must be interpreted within the context of fluid balance. Enzymes are proteins that regulate all chemical reactions occurring within cells, such as metabolism and protein synthesis. All cellular functions operate within very narrow parameters of electrolyte concentrations. Disturbances in electrolyte balance disrupt normal cellular functioning.

Two important points must be kept in mind when interpreting blood tests. First, blood samples provide a one-time "snapshot" of processes that are constantly in flux. These "snapshots" provide the clinician with valuable but time-limited insight. Often, the most important information comes from serial measurements, whereby the degree of abnormalities and directional changes can be assessed. Changes over time provide vital

information about the severity and progression of disease as well as judging the effectiveness of therapy.

Second, the intravascular blood compartment is remote from the intracellular environment. Serum electrolyte levels provide only a hint of what might be occurring inside the cells of the body. This is because the intracellular fluid compartment represents approximately two-thirds of total body fluid. By comparison, the extracellular fluid compartment represents approximately one-third and the blood plasma is just a small fraction of the extracellular environment. Therefore monitoring blood plasma abnormalities provides important but limited indirect information about the intracellular environment.

Basic Chemistry Panel

The **basic chemistry panel** (BCP) or *basic metabolic panel* includes the predominant electrolytes sodium (Na^+), potassium (K^+), chloride (Cl^-), total carbon dioxide/bicarbonate (CO_2), and glucose. Because the body's electrolyte balance is controlled by the kidneys, excretion of renal-mediated waste products is included: creatinine and blood urea nitrogen. A comprehensive metabolic panel includes electrolytes, such as magnesium (Mg^{++}), phosphorus (PO_4^-), and calcium (Ca^{++}). Each electrolyte plays a crucial role in maintaining normal cellular function. Specific information on the reference range and physiologic significance of each electrolyte and waste product can be found in Table 17-3. Information regarding the terminology used to describe abnormal test values for electrolytes, diseases associated with these disturbances, and sample critical test results are provided in Table 17-4.

There are subtle differences in how electrolytes are reported, and this may cause confusion. The concentration of electrolytes in solution is reported by either the *number of molecules* (millimoles [mmol]) or their associated valence or *electrical charge* (milliequivalents [mEq]). Although customary practice has been to report electrolytes as mEq/L, many laboratories report electrolytes as mmol/L. In an electrolyte solution, milliequivalents are simply millimoles per liter multiplied by the valence. For example, Na^+ possesses a valence of 1, so that the expression as either mmol/L or mEq/L is the same. For Ca^{++} and Mg^{++}, which both possess a valence of 2, then the mEq value is twice the mmol value.

Glucose

Carbohydrate degradation produces serum glucose that is metabolized by cells for energy. Insulin, which comes from the pancreas, is necessary for cells to use glucose circulating in the blood. **Hyperglycemia** is an abnormally elevated blood glucose level most often resulting from either diabetes or severe sepsis. **Hypoglycemia** is an abnormally reduced serum glucose level associated with digestive problems, inadequate dietary intake of carbohydrates, or overtreatment of diabetes with insulin or drug-induced.

TABLE 17-3

Components of Basic Metabolic Panel and Common Electrolyte Tests With Sample Reference Ranges and Physiologic Significance

Test	Reference Range*	Physiologic Importance
Sodium (Na^+)	136-145 mEq/L	Primary extracellular cation; crucial for maintaining fluid balance and nerve impulse conduction
Potassium (K^+)	3.5-5.0 mEq/L	Primary intracellular cation; crucial for maintaining normal heart and kidney function and acid-base balance
Chloride (Cl^-)	98-106 mEq/L	Primary extracellular anion; crucial for maintaining serum osmolarity and acid-base balance
Total carbon dioxide (CO_2)	22-29 mEq/L	Primary metabolic end product of aerobic metabolism; crucial for maintaining acid-base balance
Calcium (Ca)	4.5-5.25 mEq/L	Most abundant mineral in the body; essential for bone strength, muscular contraction, nerve impulse conduction, and coagulation
Ionized calcium (Ca^{++})	2.2-2.7 mEq/L	The approximately 50% of calcium not bound to circulating proteins; represents the biologically active portion
Glucose (Glu)	70-139 mg/dl	Primary cellular energy source
Creatinine (Cr)	0.7-1.3 mg/dl	Waste product from muscle catabolism excreted by the kidneys; one of the key markers of kidney function because it provides a gross estimation of glomerular filtration rate
Blood urea nitrogen (BUN)	8-23 mg/dl	Waste product from metabolism of amino acids; a key marker of kidney function
Magnesium (Mg^{++})	1.7-2.1 mEq/L	Essential for regulation of most biochemical processes; important for normal muscle and neuronal functioning, regulating heart rate and blood pressure, glucose levels, bone strength, and immune function
Phosphorus (PO_4^-)	1.2-2.3 mEq/L	Main intracellular anion (phosphate), exists as PO_4^- in serum; combined with Ca in teeth and bones; serum levels inversely related to serum Ca
Lactate	0.7-2.1 mEq/L	End product of glucose metabolism under anaerobic conditions; clinically significant levels coincide with regional or systemic tissue hypoxia
Osmolarity	275-295 mOsm/kg	Tonicity or ability to attract water molecules; indicates overall ionic concentration in the serum

Values for reference ranges and critical test results are from the University of California–San Francisco Moffit-Long Hospital and San Francisco General Hospital.

*Reference ranges vary among clinical laboratories. See text for explanation.

TABLE 17-4

Sample Critical Test Results Reflecting Abnormalities in Electrolyte and Other Common Laboratory Tests

Test	Sample Critical Test Result*	Common Pathologic Conditions Associated With *Abnormally High Levels*	Common Pathologic Conditions Associated With *Abnormally Low Levels*
Sodium (Na^+)	>155 mEq/L; <125 mEq/L	*Hypernatremia:* Dehydration from excessive water loss or fluid restriction; excessive administration of saline fluids or diuretics (usually ≥180 mmol)	*Hyponatremia:* Overhydration or abnormal secretion of antidiuretic hormone; severe vomiting or diarrhea; congestive heart failure, renal or hepatic failure, Addison disease
Potassium (K^+)	>6.0 mEq/L; <3.0 mEq/L	*Hyperkalemia:* Acute or chronic kidney disease, Addison disease, severe alcoholism, rhabdomyolysis; values ≥6 mmol are life-threatening	*Hypokalemia:* Severe vomiting or diarrhea; chronic renal disease; high-dose beta-agonist therapy
Chloride (Cl^-)	>120 mEq/L; <70 mEq/L	*Hyperchloremia:* Excessive Cl^- administration (usually saline resuscitation during shock); metabolic acidosis, diabetes insipidus	*Hypochloremia:* Severe vomiting or diarrhea; metabolic alkalosis, adrenal insufficiency, severe burns, excessive intravenous dextrose administration
Total carbon dioxide (CO_2)	>40 mEq/L; <15 mEq/L	Ventilatory failure	Metabolic acidosis; hyperventilation syndrome; severe diarrhea
Calcium (Ca)	>13.5 mEq/L; <6.5 mEq/L	*Hypercalcemia:* Hyperparathyroidism, lithium or thiazide diuretic therapy, metastatic cancer, multiple myeloma	*Hypocalcemia:* Hypoparathyroidism, blood transfusions, acute pancreatitis, vitamin D deficiency
Ionized calcium (Ca^{++})	>1.5 mEq/L; <0.8 mEq/L	See above	See above
Glucose (Glu)	>500 mg/dl; <50 mg/dl	*Hyperglycemia:* Diabetes mellitus, severe sepsis	*Hypoglycemia:* Excessive insulin administration, inadequate dietary intake of carbohydrates
Creatinine (Cr)	>10 mg/dl	Acute kidney injury, chronic renal failure	Protein starvation, liver disease
Blood urea nitrogen (BUN)	>100 mg/dl	Acute kidney injury, chronic renal failure, dehydration	Liver disease, malnutrition
Magnesium (Mg^{++})	>3.7 mEq/L; <0.8 mEq/L	*Hypermagnesemia:* Chronic renal failure, Addison disease, diabetic ketoacidosis, dehydration	*Hypomagnesemia:* Cirrhosis, pancreatitis, severe alcoholism, hemodialysis, toxemia of pregnancy, ulcerative colitis
Phosphorus (PO_4^-)	<1.0 mEq/L; >2.5 mEq/L	*Hyperphosphatemia:* Commonly found in patients with renal failure, hepatic failure, bone metastasis, hypocalcemia, hypoparathyroidism	*Hypophosphatemia:* Most often seen in chronic hyperventilation syndrome; also caused by hypercalcemia, hyperparathyroidism, and malnutrition
Lactate	>4 mEq/L		Primarily causes anaerobic metabolism; frequently found in patients with hemorrhagic or septic shock; may also be due to reduced hepatic clearance, dehydration, or trauma
Osmolarity	>320 mOsm/kg; <240 mOsm/kg		

Values for reference ranges and critical test results are from the University of California–San Francisco Moffit-Long Hospital and San Francisco General Hospital.
*Reference ranges and critical test results vary among clinical laboratories. See text for explanation.

Diabetes is diagnosed by measuring fasting blood glucose levels (i.e., a glucose measurement taken after 12 hours without food). A blood glucose level greater than 140 mg/dl on two occasions usually indicates diabetes. Severe hyperglycemia occurring with metabolic acidosis is consistent with *diabetic ketoacidosis* and represents a potentially life-threatening condition if not treated immediately.

In critically ill patients, insulin resistance and severe hyperglycemia (glucose levels >200 mg/dl) are common and are associated with higher incidences of organ failure and mortality. Insulin therapy is used in critically ill surgical and medical patients to control blood sugar. The practice of maintaining tightly controlled glucose levels (80 to 110 mg/dl) in these patients has been controversial. It now appears that the association between hyperglycemia and mortality is limited to critically ill patients who are *not* diabetic at hospital admission, so that less stringent parameters (glucose levels 110 to 150 mg/dl) are probably acceptable.[4]

Anion Gap

As discussed in Chapter 14, metabolic acidosis is caused by either the addition of nonvolatile acids or a primary loss of

HCO_3^-. The anion gap provides a quick method for determining whether a decrease in HCO_3^- is caused by a disruption of normal anion balance or the presence of an abnormal acid anion. A balance normally exists between cations (+ charge) and anions (− charge) in the serum. The normal anion gap occurs because sulfate, phosphate, and organic anions such as lactate are not routinely measured, whereas most cations are measured. The anion gap is calculated by adding the CO_2 and Cl^- values and then subtracting this total from the serum Na^+. The normal anion gap is approximately 8 to 14 mEq/L, and *gap acidosis* usually coincides with an anion gap of 16 mmol/L or greater. However, serum proteins are an important determinant of the anion gap. *Hypoalbuminemia* (decreased serum albumin) is common in critically ill patients and significantly reduces the anion gap. As a rule, for every 1-g reduction in serum albumin below 4 g/dl, the anion gap is corrected upward by 3 mEq/L.

RULE OF THUMB

An anion gap greater than 16 is consistent with the presence of metabolic acidosis.

Lactate

Lactate is the end product of anaerobic glucose metabolism. Blood lactate concentration depends on lactate production in muscle cells and erythrocytes and the rate of lactate metabolism by the liver. Therefore lactic acidosis results either from overproduction of lactate or insufficient metabolism of lactate. Abnormal lactate levels can be found in diverse conditions, such as liver disease, diabetes mellitus, thiamine deficiency, malignancies, and toxic ingestion of ethanol, methanol, or salicylates. However, the most common cause of lactic acidosis is anaerobic metabolism from tissue hypoxia associated with shock. Initial lactate levels greater than 4 mEq/L signifies the inability to rapidly clear high lactate levels and is associated with higher mortality in patients with septic, traumatic, or cardiogenic shock.[5]

RULE OF THUMB

In patients with many forms of shock, a serum lactate level greater than 4 mEq/L is associated with higher mortality.

MINI CLINI

Anion Gap

PROBLEM 1: A patient in the intensive care unit is being treated for shock and acute renal failure. No arterial blood gas (ABG) samples have been drawn yet, but the RT suspects the respiratory system is involved because the patient has been breathing more rapidly over the past 12 hours. The electrolyte panel reveals a serum Na^+ of 146 mEq/L, a total CO_2 of 20 mEq/L, and a serum Cl^- of 100 mEq/L. Does the electrolyte panel suggest any problems, and what should be done if there are any?

SOLUTION: The electrolytes are normal except for a decrease in the serum CO_2. The anion gap is calculated by subtracting the sum of CO_2 and Cl^- from Na^+ (146 − [100 + 20]). In this case, the anion gap is elevated (26 mEq/L) and is consistent with a metabolic acidosis. An ABG analysis is needed to evaluate the acid-base status of the patient further. The patient's rapid breathing probably is related to the metabolic acidosis because hyperventilation decreases CO_2 levels and promotes acid-base compensation.

PROBLEM 2: A patient in the trauma intensive care unit is undergoing large fluid resuscitation with normal saline solution. The patient is in hemorrhagic shock after a motor vehicle accident. An initial ABG measurement reveals a pH of 7.25, PCO_2 of 25 mm Hg, and HCO_3^- of 10.6 with a base deficit of −14.9 mEq/L. The trauma surgeons are debating increasing the amount of normal saline solution infused. They suspect their resuscitation efforts are inadequate, and metabolic acidosis is worsening from continued lactate accumulation. What additional information can be provided by obtaining a BCP to help guide therapy?

SOLUTION: If the BCP reveals Na^+ of 140 mEq/L, Cl^- of 95 mEq/L, and CO_2 of 20 mEq/L (anion gap of 25 mEq/L), the surgeons would be correct in assuming that their resuscitation efforts were inadequate. The anion gap of 25 likely represents a worsening lactic acidosis. However, if the BCP reveals Na^+ of 150 mEq/L, CO_2 of 20 mEq/L, and Cl^- of 122 mEq/L, the anion gap would be normal (8 mEq/L). The metabolic acidosis would be caused by an abnormally high serum Cl^- concentration from excessive normal saline administration. This example represents a common problem in emergency and critical care practice: the overresuscitation of trauma patients from severe shock.

Enzyme Tests

Liver Function Tests

The liver is primarily responsible for converting food into substrates essential for cellular metabolism, protein synthesis, and detoxifying substances in the body. Liver damage is assessed by abnormal increases in the hepatic enzymes *alanine aminotransferase, aspartate aminotransferase*, and *alkaline phosphatase*. *Total bilirubin* is produced by the liver from the breakdown of destroyed RBCs. It is a crucial component of the liver panel test because it assesses one of the primary functions of the liver. Protein synthesis, another vital aspect of liver function, is assessed by measuring concentrations of total protein and albumin. Liver disease is characterized by the inability to remove toxins from the bloodstream. One of the primary toxins associated with altered mental function in patients with liver disease is the accumulation of *ammonia,* which forms from the breakdown of proteins.

Pancreatic and Muscle Enzyme Tests

Other diseases also produce abnormal amounts of enzymes in the serum. Patients with pancreatitis have abnormal levels of

the pancreatic enzymes *lipase* and *amylase*. *Creatine phosphokinase* (CPK) or *creatinine kinase* is an enzyme found mainly in heart, brain, and skeletal muscle tissue. Patients who have sustained ischemic damage to these tissues have elevated CPK levels. Three types of CPK are associated with each tissue. CPK-1 (CPK-BB) is released primarily from the lungs or brain after injury. Patients with extensive crush injuries involving the skeletal muscles and those with myositis have elevated levels of CPK-3 (CPK-MM). The third type of CPK is associated with cardiac injury and is discussed subsequently.

Lactate dehydrogenase is the enzyme that catalyzes the conversion of pyruvate into lactate. Elevated serum levels of lactate dehydrogenase are associated with tissue breakdown. This breakdown occurs with many conditions, such as rhabdomyolysis (e.g., skeletal muscle breakdown typically from traumatic crush injuries releases myoglobin into the blood), cancer, meningitis, hemolytic anemia, acute pancreatitis, acute myocardial infarction, and HIV disease. Moderate increases in lactate dehydrogenase are associated with myocardial infarction or hemolytic anemia (880 units/L), whereas large increases are seen in extensive cancers, rhabdomyolysis, severe shock, and anoxia (8800 units/L).

Cardiac Enzyme and Protein Tests

The most common CPK test is CPK-2 (CPK-MB), an enzyme released from the heart after myocardial infarction. Levels notably increase 4 to 6 hours and peak 12 to 24 hours after injury. Serial CPK-2 measurements are monitored in patients with suspected myocardial infarction, cardiac contusion from chest trauma, open heart surgery, or myocarditis. **Troponin** is a complex protein that helps regulate skeletal and cardiac muscle contractility. The protein fragment **troponin I** is associated with cardiac muscle damage. Similar to CPK-2, troponin I levels peak 12 to 16 hours after myocardial infarction. Reference values for these enzyme tests are presented in Table 17-5.

B-type natriuretic peptide (BNP) is secreted by the heart in response to increased cardiac muscle stretch. The BNP test primarily is used to evaluate patients for heart failure, particularly those presenting to the emergency department with dyspnea and pulmonary edema.[6] Values greater than 300 pg/ml indicate mild heart failure, above 600 pg/ml moderate heart failure, and greater than 900 pg/ml severe heart failure. Other conditions such as acute respiratory distress syndrome (ARDS) and severe sepsis also cause increased cardiac muscle stretch, resulting in BNP levels in the range of 300 to 500 pg/ml.[6]

TABLE 17-5

Liver Function and Other Enzymatic Tests

Test	Reference Range	Sample Critical Test Result*
Total bilirubin (T Bil)	0.1-1.1 mg/dl	≥15 mg/dl
Alanine aminotransferase (ALT)	7-56 units/L	†
Aspartate aminotransferase (AST)	10-50 units/L	†
Alkaline phosphatase (ALK)	40-125 units/L	†
Total protein (TP)	15-45 mg/dl	†
Albumin (ALB)	3.3-5.2 g/dl	†
Ammonia	18-54 μmol/L	≥500 mcg/dl
Amylase (serum)	20-110 units/L	>330 units/L
Lipase	10-140 units/L	>420 units/L
Creatinine phosphokinase (CPK)	20-220 units/L	>10,000 units/L
Troponin I	0 ng/ml	>0.05 ng/ml
B-type natriuretic peptide	<100 pg/ml	†
Lactate dehydrogenase (LDH)	110-220 units/L	>880 (moderate); >8800 (severe)

Values for reference ranges and critical test results from the University of California–San Francisco Moffit-Long Hospital/San Francisco General Hospital.
*Critical test results vary among clinical laboratories based on instrumentation and calibration procedures. Not all tests have an associated critical result that can be reported.
†No critical value established.

Coagulation Studies

Coagulation is the process by which the blood and vascular tree form clots to stop bleeding and repair damage to the injured blood vessels. In brief, damage to the internal vascular wall (endothelium) exposes the blood to tissue factors (i.e., proteins) that attract and activate platelets, which stimulates clotting. **Thrombocytopenia** (low platelets) and *thrombasthenia* (abnormal platelet functioning) lead to excessive bleeding, whereas *thrombocytosis* (excessive platelets) causes excessive clotting. In addition to direct platelet measurement, the functionality of the entire process of coagulation is measured by the *prothrombin time* (PT) and *partial thromboplastin time* (PTT). These tests assess two different pathways by which fibrin clots are formed.

PT is the time in seconds required by plasma to form a fibrin clot after exposure to tissue factors. It assesses the *extrinsic coagulation pathway* and reflects the function of clotting factors I, II, V, VII, and X. In contrast, PTT primarily assesses the *intrinsic coagulation pathway*. It is used to evaluate abnormalities in blood clotting and monitor the effects of anticoagulation therapy. Abnormalities in PTT are associated with clotting factors I through VI and factors VIII through XII. Clinically, abnormal increases in PT and PTT are found in patients with vitamin K deficiencies and patients receiving anticoagulation therapy such as warfarin or heparin. Increased PT and PTT also occur in patients with *disseminated intravascular coagulation* (DIC) and patients with end-stage liver disease.

Because PT test results (Table 17-6) depend on manufactured animal tissue factors, which have unavoidable variability, PT is accompanied by an additional measurement known as the *international normalized ratio* (INR). The INR expresses PT relative to an established sample value. The reference range for INR is 0.9 to 1.3. INR values of approximately 5.0 indicate a high likelihood for bleeding. Values of 0.5 are associated with a tendency toward increased clotting.

D-dimer is a small protein fragment found in the blood when fibrin clots are dissolving. It belongs to a larger group of substances referred to as *fibrin degradation products*. D-dimer levels are measured to help diagnose deep vein thrombosis,

TABLE 17-6

Coagulation Studies

Test	Reference Range	Critical Test Result
Prothrombin time (PT)	12-15 sec	>30 sec
Partial thromboplastin time (PTT)	25-39 sec	>50 sec
International normalized ratio (INR)	0.8-1.2	>5 sec
Fibrin D-dimer	<200 ng/ml	*
Platelet count	150,000-400,000/mm^3	<25,000/mm^3

Values for reference ranges and critical test results are from the University of California–San Francisco Moffit-Long Hospital and San Francisco General Hospital.
*No critical value established.

pulmonary embolism, or DIC. Unless significant clotting has occurred in the body, the D-dimer test is normal.

Protein C has an integral role in regulating coagulation. In its activated state (activated protein C), it inhibits coagulation and promotes clot degradation. Protein C levels are reduced in patients with severe sepsis and acute respiratory distress syndrome.[7] Low protein C promotes abnormal clot formation and damages blood vessels in the microcirculation throughout the body (DIC). Significant deficiencies in protein C levels (<40% of normal) are associated with increased risk for death in patients with severe sepsis. Protein C levels are sometimes used to assess the severity of inflammation and coagulation disorders in patients with severe sepsis.

Infection Monitoring

Procalcitonin (PCT) is an inactive protein of the hormone calcitonin that is released in response to bacterial infections (particularly sepsis). PCT levels are directly related to the severity of infection. Because PCT does not increase in response to viral infections, it is a unique marker for bacterial infections. PCT levels typically increase within 2 to 4 hours of sepsis with peak levels occurring 24 to 48 hours later. Once infection is controlled with appropriate antibiotic therapy, PCT levels promptly decrease. Therefore measuring PCT increasingly is used to titrate antibiotic therapy. In healthy individuals PCT levels are less than 0.1 ng/ml. A diagnosis of sepsis is confirmed when PCT levels are greater than 0.5 ng/ml and excluded when PCT levels are 0.2 ng/ml or less.[8] Antibiotic therapy often is initiated when PCT levels reach 0.25 to 0.50 ng/ml. Measurements of PCT are repeated every 1 to 2 days to evaluate antibiotic therapy. When PCT decreases by approximately 90% from peak values, antibiotic therapy is usually terminated.

C-reactive protein (CRP) is a plasma protein expressed by the liver in response to infection (particularly sepsis) or trauma. The primary role of CRP is activating the complement system that assists antibodies in destroying bacteria. CRP levels begin to increase 6 to 8 hours after the onset of infection or injury and peak at approximately 36 to 50 hours.[9] Normal CRP levels are approximately 0.8 mg/L with cutoff values of 80 to 100 mg/L indicative of infection and levels of approximately 130 mg/L associated with severe sepsis.

MICROBIOLOGY TESTS

Sputum Gram Stain

Patients suspected of having a serious lung infection require a sputum sample to identify the microorganism causing the infection, thereby facilitating appropriate antibiotic selection. The Gram stain is the first test used in evaluating sputum samples. A laboratory technician smears the sputum sample onto a glass slide, applies a staining solution, and examines it through a microscope.

The Gram stain determines the quality of the sputum sample. Some patients have difficulty producing an adequate sputum sample and may expectorate only saliva into the sputum cup. In such cases, the Gram stain shows few (<25 per low-power field) or no pus cells and numerous epithelial cells, and the sample must be discarded. A sample with numerous pus cells and few epithelial cells is most likely a true lung sample and likely reflects the infection source.

RULE OF THUMB

A legitimate sputum sample has few epithelial cells and many pus cells (leukocytes).

After the sample is verified, the laboratory technician identifies the Gram stain reaction (either positive or negative) and the shape of any bacteria present (rods vs. cocci). For example, *Streptococcus pneumoniae,* a common bacterium associated with pneumonia, is characterized as lancet-shaped, gram-positive diplococci. Although a Gram stain can be helpful in identifying an invading organism so antibiotics can be more quickly started, a definitive diagnosis is made only by culture of the specific organism over several days.

Sputum Culture

If the Gram stain reveals an adequate sample, the technician prepares a portion of the sputum for culture. The sputum sample is placed in a medium permitting growth of the organism. When the organism has matured, it is examined microscopically to determine its exact type and sensitivity to antibiotic therapy. This information allows the physician to initiate appropriate antibiotic therapy. Gram staining and culturing are also applied to samples of blood, pleural fluid, or any other body fluid involved in an infection.

Acid-Fast Testing

Pulmonary tuberculosis is caused by a mycobacterium *(Mycobacterium tuberculosis)*. The rapid identification and isolation of patients with suspected tuberculosis infection is an extremely important infection control measure. A rapid and effective method for detecting tuberculosis infection is to perform a Gram stain of a slide containing a sample of sputum followed

by an acid wash. A characteristic of all mycobacteria is that after staining, the subsequent acid wash does not weaken the cell wall sufficiently to remove the color dye. This resistance to decolorization classifies the organism as an **acid-fast bacterium.**

Sweat Chloride

Patients with cystic fibrosis have increased levels of Cl^- in their sweat because of an inability to reabsorb it. These patients typically have sweat Cl^- levels greater than 60 mmol/L, whereas values of 40 to 60 mmol/L are considered borderline for cystic fibrosis. Sweat Cl^- levels less than 40 mmol/L are considered unlikely to confirm the diagnosis. Although the sweat electrolyte test is an important tool for diagnosing cystic fibrosis, it must be combined with other tests.

CLINICAL APPLICATION OF LABORATORY DATA

RTs are focused primarily on the pulmonary system and not as much on other organ systems. However, many of the laboratory tests previously discussed in this chapter are relevant to the RT's implementation of various aspects of the plan of care.

Coagulation Disorders

In patients requiring arterial blood gas (ABG) testing or nasotracheal suctioning, the RT must evaluate the clotting characteristics of the blood. For ABG testing, patients with an abnormally low platelet count or an elevated PT and INR need to have the puncture site compressed for a longer time after the arterial sample is obtained to prevent bleeding and hematoma development. Patients with an extremely low platelet count should have an arterial puncture performed (or undergo nasotracheal suctioning) *only* when it is essential because of the extremely high risk for bleeding.

In addition, RTs are intimately involved in assessing patients with suspected pulmonary embolism. Patients with pulmonary embolism present with some of the same symptoms as patients with myocardial infarction (e.g., dyspnea and chest pain), and it is important for the RT to be familiar with tests such as D-dimer, troponin I, CPK-1, and CPK-2, which help make the differential diagnosis.

Electrolyte Disorders

Severe electrolyte disorders have a profound impact on pulmonary function. The primary concern of the RT is the effect of electrolyte disorders on respiratory muscle function. Many electrolyte disorders cause generalized skeletal muscle weakness. This weakness may limit ambulation and increases the risk for patients developing pneumonia and venous thromboembolism that can lead to pulmonary embolism. In a patient with pulmonary disease, respiratory muscle weakness impairs the ability to sustain spontaneous ventilation and the ability to maintain pulmonary hygiene through deep breathing and adequate cough.

Primary electrolyte disorders causing respiratory muscle weakness include low serum levels of Ca^{++}, Mg^{++} and phosphate.[10,11] A patient with hypoglycemia often complains of weakness, so that weaning from a ventilator is unlikely to be successful in the patient with hypoglycemia. In addition, abnormally high serum K^+ levels, or **hyperkalemia** (>8.0 mmol/L), and abnormally low serum K^+, or **hypokalemia** (<2.0 mmol/L), or phosphorus, or hypophosphatemia (<1.0 mg/dl) can lead to respiratory muscle weakness. In addition, severe hyperkalemia (>6.0 mmol/L) increases the likelihood of cardiac arrhythmias. Severe hypocalcemia (<6.5 mmol/L) sometimes leads to laryngeal stridor and dyspnea.

Electrolyte disorders and other toxins in the bloodstream can depress neurologic function. Pulmonary function is profoundly affected because decreased mental functioning may depress respiratory drive, prevent patients from cooperating with therapy, and suppress the ability of patients to protect their airway and clear secretions by depressing the cough mechanism. In severe cases, **hypernatremia** is a major cause of central nervous system depression, which can lead to lethargy, coma, and respiratory arrest.[12] In patients with severe liver disease, elevated ammonia levels also depress neurologic function.

Finally, laboratory tests are used by physicians to assess the overall likelihood of survival of a critically ill patient. For patients with primary pulmonary failure, survival is related to the prevention of secondary multiple organ system failure. As a result, following trends in creatinine, total bilirubin, and platelets is crucial in monitoring the development or progression of renal, hepatic, and hematologic failure.

SUMMARY CHECKLIST

- The three formed elements of the blood are the WBCs (leukocytes), RBCs (erythrocytes), and platelets (thrombocytes).
- Elevation of the WBC count is known as *leukocytosis*. It often occurs with infection, stress, or trauma.
- A reduced WBC count is known as *leukopenia*. It puts the patient at risk for serious infection.
- Abnormal elevation of the RBC count is known as *polycythemia,* and an abnormal reduction in the RBC count is known as *anemia*.
- Anemia reduces the O_2-carrying capacity of the blood and increases the risk for tissue hypoxia. Severe electrolyte abnormalities, including low Ca^{++}, Mg^{++}, and PO_4^-, cause respiratory muscle weakness.
- Weakness from anemia and electrolyte abnormalities can inhibit a patient from participating in their care plan and slow their recovery.
- Severe hyperkalemia (>6 mmol/L) greatly increases the risk for cardiac arrhythmias.
- Troponin I and CPK-MM tests are used to help diagnose myocardial infarction.
- To minimize bleeding risk in arterial punctures and nasotracheal suctioning, extreme caution should be used in patients with thrombocytopenia and elevated PT or INR.
- A sputum Gram stain is useful for determining the quality of the sample and the type of organism present. Samples with many epithelial cells and few pus cells suggest oral and not pulmonary secretions.

CHAPTER 18

Interpreting the Electrocardiogram

ALBERT J. HEUER

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the value and limitations of the electrocardiogram.
- Review the electrocardiogram equipment set-up.
- Describe the electrophysiology of cardiac cells.
- Describe how the cardiac impulse is conducted.
- Recognize various abnormal electrocardiographic recordings and major treatment alternatives.

CHAPTER OUTLINE

KEY TERMS

atrial kick
automaticity
depolarization
ectopic beat
ectopic foci
impulse-conducting system
repolarization

The electrocardiogram (ECG) is an important diagnostic tool that in some settings is obtained by the respiratory therapist (RT). As a result, this can place the RT in a prime position to recognize and respond to life-threatening arrhythmias. This chapter emphasizes the basics of cardiac physiology, lead placement, ECG interpretation, and the identification and key points in the treatment of dysrhythmias. More details of the cardiopulmonary anatomy and emergency cardiovascular life support are presented in Chapters 10 and 37.

An ECG can be done using either a 12-lead system, which provides more diagnostic value than the alternative approach, or a 3-lead system, which is commonly used for telemetry. A 12-lead ECG provides a more complete assessment of the electrical activity of the heart by viewing it from 12 different angles and is the focus of this chapter.

The ECG is a popular evaluation tool because it is inexpensive, noninvasive, and easy to obtain. It is used primarily to help evaluate a patient with signs and/or symptoms of myocardial disease. A physician would order an ECG for most adult patients complaining of certain types of chest pain, shortness of breath, dyspnea with palpitations, weakness, lethargy, or syncope; these are the classic clinical symptoms associated with heart disease. In addition, the ECG is routinely used to detect abnormalities that are occurring or have already occurred, such as a myocardial infarction (MI), the general health status of middle-aged or older patients or for preoperative screening. However, ECGs done at rest have little or no value as a predictor of future heart

problems and they cannot directly identify certain abnormalities, such as valvular defects.[1]

MINI CLINI

Acute Chest Pain in the Emergency Room

PROBLEM: A 52-year-old man presents with severe chest pain that radiates to his left shoulder and shortness of breath. The newly graduated resident physician is obtaining a comprehensive history and performing a physical examination; the RT assisting with the evaluation notes that the man is diaphoretic and tachycardic, with pale skin color. After giving an order for O_2, the physician resumes taking the history and performing the physical. What additional tests should the RT recommend be obtained at this time?

SOLUTION: A STAT ECG should be ordered to help differentiate among chest pain associated with an MI or other cardiac abnormality such as angina and other causes such as orthopedic injury. As discussed later in this chapter, T wave inversion and ST segment elevation suggest cardiac ischemia and perhaps an MI, which would warrant immediate treatment.

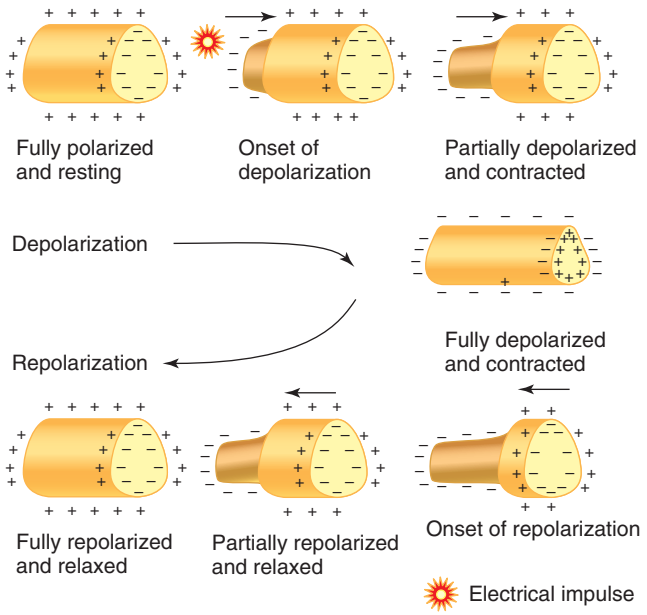

FIGURE 18-1 Depolarization and repolarization of a cardiac cell. (Modified from Wesley K: Huszar's basic dysrhythmias and acute coronary syndromes: interpretation and management, ed 4, St Louis, 2014, Elsevier.)

BASIC PRINCIPLES OF ELECTROPHYSIOLOGY

The muscle cells of the heart normally are stimulated and paced by the electrical activity of the cardiac **impulse-conducting system.** The impulse-conducting system cells have the ability to stimulate the heart without the influence of the nervous system. However, the autonomic nervous system normally plays a major role in controlling heart function.[1]

Cardiac muscle cells normally generate an electrical imbalance across the cell membrane, with a positive charge on the outside and a negative charge on the inside. This is the resting or polarized state in which there is no electrical activity. Stimulation of the "polarized" cells causes an influx of Na^+ into the interior portion of the cell; this is called **depolarization** (Figure 18-1). Depolarization causes the cardiac muscle cells to contract momentarily. Depolarization is immediately followed by **repolarization,** which is a rapid return of the cell to the "polarized" position in which the electrical imbalance across the membrane is reestablished.

The impulse-conducting system has three types of cardiac cells capable of electrical excitation: pacemaker cells (e.g., sinoatrial [SA] node, atrioventricular [AV] node), specialized rapidly conducting tissue (e.g., Purkinje fibers), and atrial and ventricular muscle cells. The ability of these cells to depolarize without stimulation is known as **automaticity.** Each of these cardiac cell groups varies in degree of automaticity.[1-3]

Impulse-Conducting System

The impulse-conducting system is responsible for initiating the heartbeat and controlling the heart rate. It also coordinates the contraction of the heart chambers, which is essential to move blood effectively. A defect in the impulse-conducting system may lead to inadequate cardiac output and decreased tissue perfusion. Normally, the SA node, which is located in the upper portion of the right atrium, has the greatest degree of automaticity and paces the heart (Figure 18-2). Any heartbeat originating outside the SA node is considered an **ectopic beat.**[2] The SA node is innervated by the autonomic nervous system, which allows the sympathetic and parasympathetic nervous systems to influence heart rate. Stimulation of the sympathetic nervous system, such as occurs with the administration of certain medications (e.g., adrenergic bronchodilators), increases the heart rate, whereas activation of the parasympathetic nervous system slows the heart rate by influencing the degree of automaticity within the SA node.

The electrical impulse generated by the SA node travels rapidly across the right atrium, through intraatrial pathways, to the left atrium by way of the Bachmann bundle; this causes a wave of depolarization to occur over the atria, producing atrial contraction. Next, the impulse moves to the AV node, located in the intraventricular septum in the inferior aspect of the right atrium (see Figure 18-2). The AV node is the "backup" pacemaker because it has the second greatest degree of automaticity in the healthy heart. In most cases, if the SA node fails to function properly, the AV node paces ventricular activity at a lower heart rate of 40 to 60 beats/min, which is generally sufficient to maintain adequate cardiac output.[2]

The electrical impulse is temporarily delayed at the AV node to allow the ventricles time to fill with blood. That brief delay also limits the rate of the ventricular stimulation during excessively fast atrial rhythms that, if passed to the ventricles, would lead to inadequate cardiac output.[3,4]

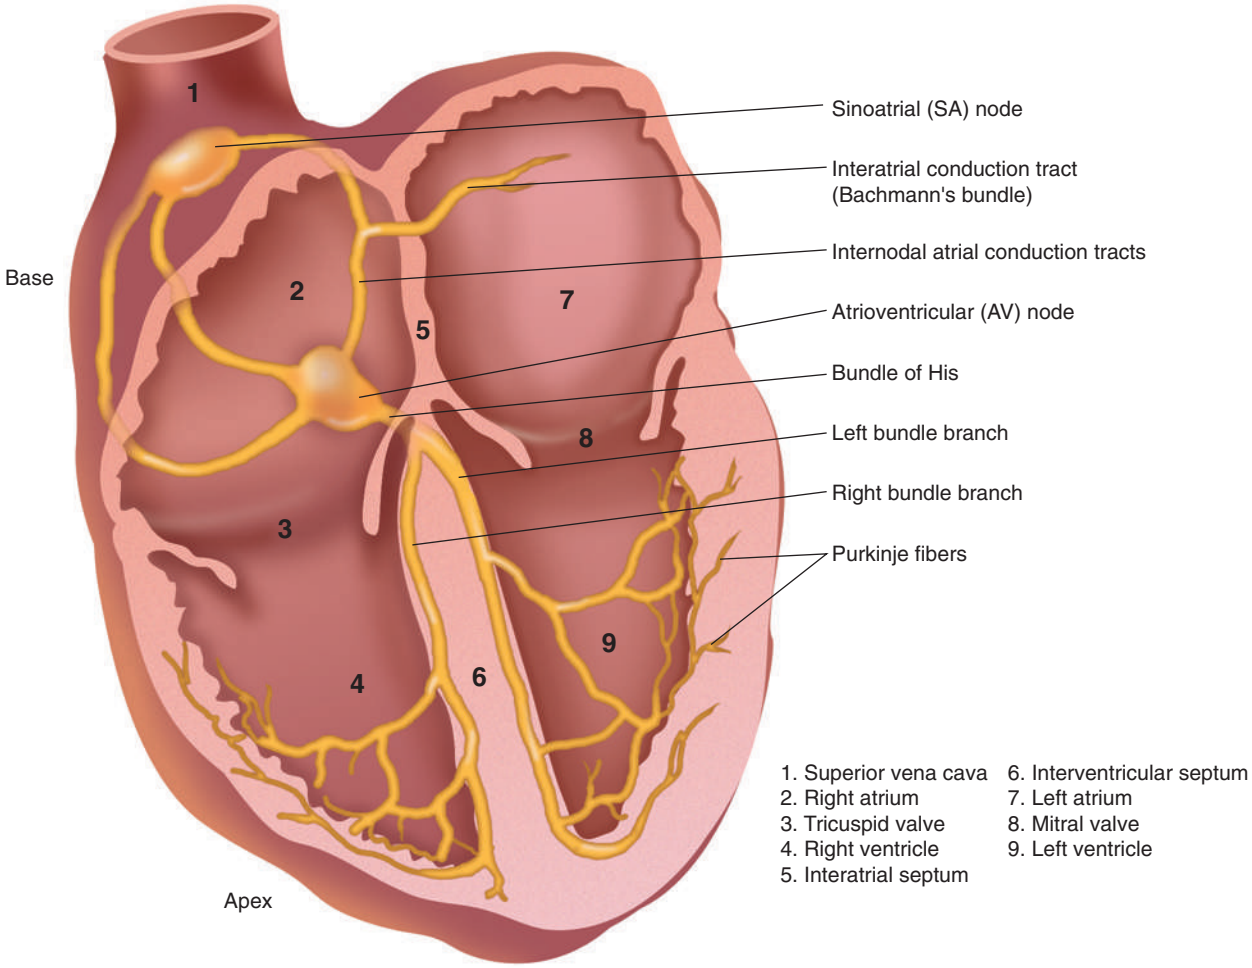

FIGURE 18-2 Anatomy of the impulse-conducting system of the human heart.

The impulse exits the AV node, enters the bundle of His, and rapidly moves to the bundle branches. The bundle branches carry the impulse rapidly into the right and left ventricles. The bundle branches terminate in the Purkinje fibers, which are small, finger-like projections that penetrate the myocardium (see Figure 18-2). These fibers stimulate contraction of the myocardium from the apex of the heart upward toward the base of the heart, causing a coordinated contraction of the ventricles, which normally is effective in moving blood. The impulse travels most rapidly in the Purkinje fibers, which is essential if contraction of the ventricles is to occur in a coordinated fashion. Immediately after depolarization of the ventricles, repolarization occurs in preparation for the next impulse.[3,4]

ELECTROCARDIOGRAM PROCEDURAL SUMMARY

Once the physician orders a 12-lead ECG, the equipment is gathered, which includes the portable ECG unit, lead wires, and electrodes.

The lead wires permit the connection between the ECG unit and the electrodes, which have adhesive permitting temporary attachment to the skin. Generally, the lead wires should be attached to the electrodes before being placed on the skin, to avoid unnecessary pressure to the skin's surface. The lead wires are often marked to help ensure proper placement on the patient's body.

The 12 leads can be subdivided into two groups: 6 extremity (limb) leads and 6 chest (precordial) leads. For the six limb leads, four electrodes are placed on the extremities, one on each wrist and one on each ankle. These leads are bipolar, which permits the measurement of electrical activity in two different directions. Additionally, the ECG unit can vary the orientation of these four electrodes to create six different views. Any electrical activity of the heart that is directed up, down, left, or right is recorded by the limb leads. The limb leads are called leads *I, II, III,* aV_R, aV_L, and aV_F (Table 18-1).

The six chest or precordial leads are called leads V_1, V_2, V_3, V_4, V_5, and V_6. These leads are unipolar, which means that they measure electrical activity in only one direction. These leads are placed in a horizontal plane across the chest, starting with V_1 in the fourth intercostal space to the right of the sternum. The rest of the chest leads are on the left side, starting with V_2, which is placed in the fourth intercostal space just to the left of the

TABLE 18-1

The 12 Leads of an Electrocardiograph and the Myocardial Wall That Each Set Views

Facing Lead*	View
I, aV_L, V_5, V_6	Lateral
II, III, aV_F	Inferior
V_1, V_2	Septal
V_3, V_4	Anterior
Cells and Function	
Pacemaker cells	Specialized cells that have a high degree of automaticity and provide electrical power for the heart
Conducting cells	Cells that conduct the electrical impulse throughout the heart
Myocardial cells	Cells that contract in response to electrical stimuli and pump blood

*Excludes aV_R, which faces the interior, endocardial surface of the ventricles.

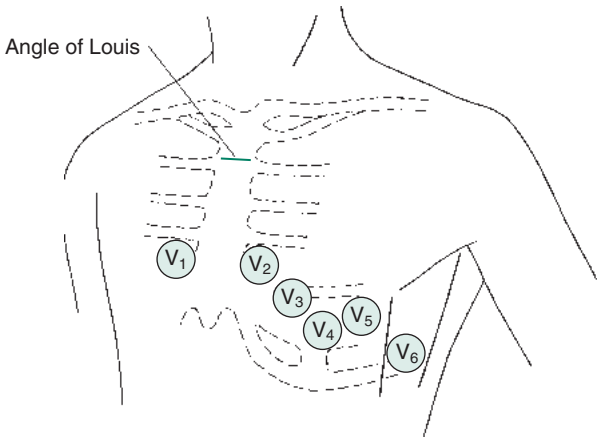

FIGURE 18-3 Proper precordial lead placement. (From Heuer AJ, Scanlan CL: Clinical assessment in respiratory care, ed 7, St Louis, 2013, Elsevier.)

sternum, and ending with V_6, which is placed at the fifth intercostal space at the left midaxillary line (V_6). Figure 18-3 illustrates proper placement of ECG leads. The view from each chest lead provides its own angle of orientation to measure cardiac electrical activity moving anteriorly or posteriorly.[2,4]

After all leads are properly placed and the ECG unit is activated, all 12 leads together provide a comprehensive view of the electrical activity of the heart. Given that an array of conditions, including cardiac ischemia and acute MI can alter electrical conduction through the heart, the ECG has considerable diagnostic value. The balance of this chapter focuses mainly on how electrocardiographic waves are generated, interpreting ECGs, identifying abnormal rhythms, and some treatment considerations.

Basic Electrocardiographic Waves

The wave of depolarization occurring in the atria is seen as the P wave on the ECG (Figure 18-4). The normal P wave is no

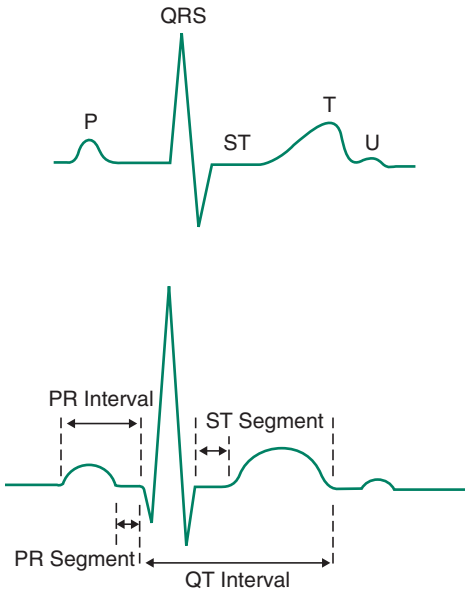

FIGURE 18-4 Normal configuration of electrocardiographic waves, segments, and intervals. (From Heuer AJ, Scanlan CL: Clinical assessment in respiratory care, ed 7, St Louis, 2013, Elsevier.)

more than 2.5 mm high and 3 mm long. Atrial hypertrophy may cause the P wave to enlarge to a larger height and length. Atrial repolarization is not seen on the electrocardiographic tracing because it is obscured by the electrical activity occurring in the ventricles at the same time.

The wave of depolarization occurring over the ventricles is seen as the QRS complex on the electrocardiographic tracing. The QRS complex is normally larger than the P wave because the muscle mass of the ventricles is much greater than that of the atria. The normal QRS complex is not wider than 3 mm (0.12 second) because of the rapid movement of the impulse through the ventricles by the bundle branches and Purkinje fibers. Abnormalities in the ventricular conduction system may lead to irregular QRS complexes that are wider than normal.

The QRS complex usually consists of several distinct waves, each of which has a letter assigned to it as a label. If the first wave of the complex is negative (downward), it is labeled the *Q wave*. The initial positive (upward) deflection is electrocardiographically referred to as the *R wave,* and the next negative deflection after the R wave is labeled the *S wave*. Not all QRS complexes have all three components present, but the waves making up ventricular depolarization are electrocardiographically referred to as the *QRS complex,* regardless of its exact makeup. The wave of repolarization occurring in the ventricles immediately after depolarization is the *T wave* (see Figure 18-4).

Two important segments of the electrocardiographic pattern must be observed and measured. The first is the *PR interval,* which refers to the distance (time) between the start of atrial depolarization and the start of ventricular depolarization. The PR interval represents the time in which the impulse begins in the SA node and travels across the atria to the AV node, where it is held briefly before passing on to the ventricles. Normally,

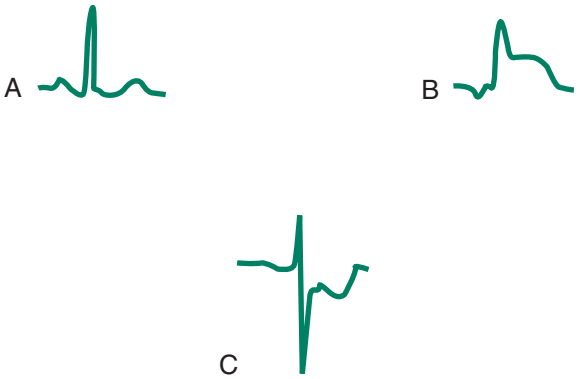

FIGURE 18-5 ST segments. **A,** Normal. **B,** Abnormal elevation. **C,** Abnormal depression. (From Heuer AJ, Scanlan CL: Clinical assessment in respiratory care, ed 7, St Louis, 2013, Elsevier.)

the PR interval represents a period no longer than 0.20 second. PR intervals longer than 0.20 second suggest that the impulse is abnormally delayed at the AV node and a "block" is present, often as a result of a serious defect in the impulse-conducting system.

The next important part of the ECG to evaluate is the *ST segment,* which represents the time from the end of ventricular depolarization to the start of ventricular repolarization. The normal ST segment is isoelectric and is seen as a flat line that is not above or below the neutral baseline. Certain pathologic abnormalities in the myocardium cause the ST segment configuration to become abnormal; this is seen as an elevated or depressed ST segment and is common in cardiac ischemia and MI (Figure 18-5). Because this configuration represents a potentially life-threatening arrhythmia, abnormal ST segments must be identified as soon as possible.[3-5]

RULE OF THUMB

A negative QRS complex in lead I is consistent with right-axis deviation, which is often caused by cor pulmonale.

Electrocardiographic Paper and Measurements

Electrocardiographic paper is made up of gridlike boxes that define time on the horizontal axis and voltage on the vertical axis. Dark lines circumscribe larger boxes that are 5 × 5 mm, and lighter lines define smaller boxes that are 1 × 1 mm (Figure 18-6). Because the paper passes through the electrocardiograph at a set speed of 25 mm/sec, each large box represents 0.20 second, and each small box represents 0.04 second on the horizontal axis. The standard ECG is calibrated so that 1 mV causes an upward deflection of 10 small boxes or 2 large boxes on the vertical axis; this allows measurement of the exact voltage occurring during depolarization of the cardiac muscle fibers.[1,4,6]

Interpreting the Electrocardiogram

The following steps should be followed in interpreting the ECG.

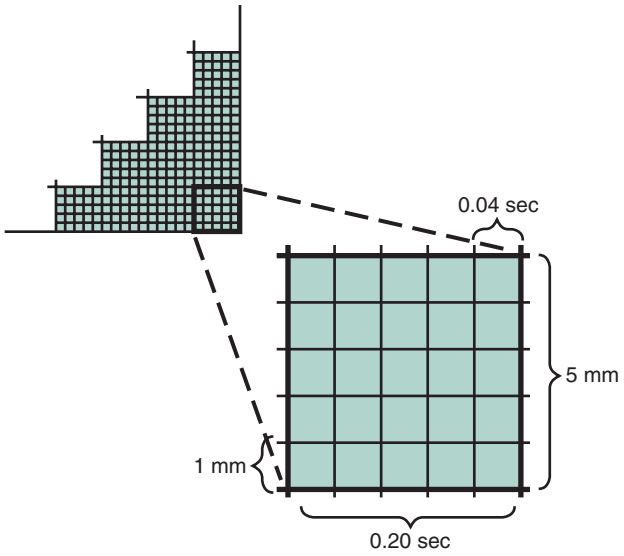

FIGURE 18-6 Gridlike boxes of electrocardiographic paper illustrating the 1 × 1 mm and 5 × 5 mm boxes. (From Heuer AJ, Scanlan CL: Clinical assessment in respiratory care, ed 7, St Louis, 2013, Elsevier.)

MINI CLINI

Weaning Complications

PROBLEM: The clinician is in the intensive care unit (ICU) attending to a 65-year-old woman who is being weaned from the ventilator after 2 weeks of mechanical ventilation. After 15 minutes of T-piece weaning, the patient complains of mild shortness of breath and the bedside ECG shows an increase in heart rate, inverted T waves, and acute elevation of the ST segment. What do the inverted T waves and ST segment elevation indicate? What should be done?

SOLUTION: The inverted T waves and elevated ST segment suggest that the heart is experiencing acute hypoxia, probably caused by the stress of weaning. T wave inversion and ST segment elevation are serious signs indicating that the patient is not tolerating the weaning. She should be put back on full ventilatory support at an elevated FiO_2 and monitored closely. Weaning should not be attempted again until the patient's clinical condition improves significantly. The attending physician should be notified.

Steps to Follow

Step 1. *Identify the atrial and ventricular rates.* Normally, the rate of the atria and ventricles is the same, but rates may differ when a defect in the conduction system is present. The clinician can identify the heart rate by counting the number of QRS complexes (for the ventricular rate) or the number of P waves (for the atrial rate) in 6 seconds (30 large boxes) and multiplying this number by 10. When the rate is regular, the clinician also can count the number of large boxes between two successive complexes and divide this number into 300 to obtain the heart rate.

Step 2. *Measure the PR interval.* This is done by determining the number of small boxes between the start of the P wave and the start of the QRS complex. Normally, this interval is less than 0.20 second (five small boxes) and is consistently the same for each complex. PR intervals that are longer than 0.20 second or vary from one complex to the next indicate an abnormality in the impulse-conducting system.

Step 3. *Evaluate the QRS complex.* Normally, the QRS complex is shorter than 0.12 second. If it is longer, there is an abnormality in the impulse-conducting system within the ventricles, which often leads to a decrease in cardiac output and blood pressure.

Step 4. *Evaluate the T wave.* Normally, the T wave is upright and rounded. Inverted T waves suggest ischemia of the heart muscle, and abnormal configuration of the T wave occurs with electrolyte abnormalities such as hyperkalemia.

Step 5. *Evaluate the ST segment.* The ST segment should be flat or at least no more than 1 mm above or below baseline. As stated earlier, significant elevation or depression of the ST segment indicates serious problems with oxygenation of the myocardium and must be recognized as soon as possible.

Step 6. *Identify the R-R interval.* The R-R interval is identified to assess regularity of the rhythm. The distance, in millimeters or time, is measured between the R waves of several successive QRS complexes. Normally, there is little variance in the R-R interval between QRS complexes, but if the variance between the different R-R intervals exceeds 0.12 second, an abnormal rhythm exists.

Step 7. *Identify the mean QRS axis.* The limb lead exhibiting the largest amount of voltage is identified. If the lead shows a positive QRS complex, the axis is very close to the position on the hexaxial reference circle where that limb lead is labeled. If the QRS complex with the most voltage is negative, the mean axis is moving in the opposite direction from where that lead is labeled on the hexaxial reference circle.[1-3]

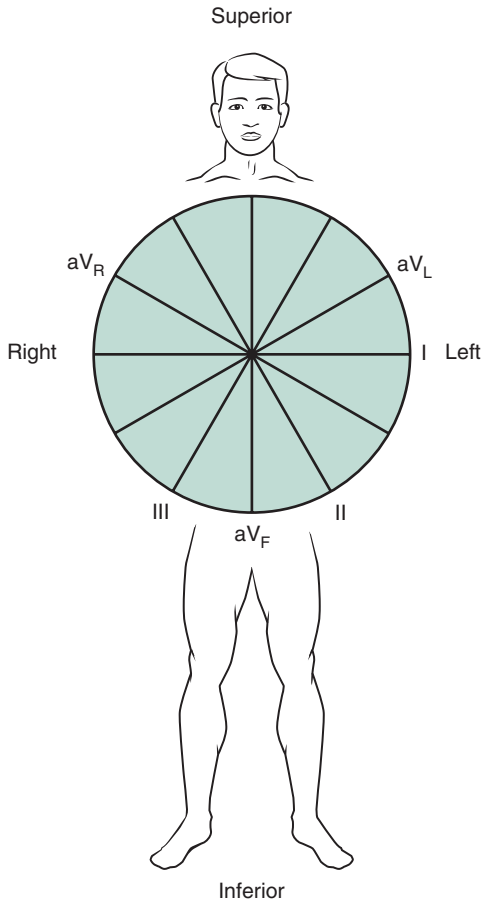

FIGURE 18-7 Hexaxial reference circle used for axis evaluation. (From Heuer AJ, Scanlan CL: Clinical assessment in respiratory care, ed 7, St Louis, 2013, Elsevier.)

Axis Evaluation

A less understood area of ECG interpretation for RTs is the axis evaluation and the identification of related deviations from normal. Axis evaluation is used to determine the general direction of current flow during ventricular depolarization; this is helpful to know when hypertrophy of one of the ventricles is suspected, which would cause the direction of current flow to deviate from normal. Normally, the mean QRS axis (vector) points leftward (patient's left) and downward, between 0 and +90 degrees in the frontal plane (Figure 18-7). The normal position of the QRS axis results from the slight tilt of the heart to the left and from the large muscle mass of the left ventricle compared with the right ventricle.

The mean QRS axis is identified by using the hexaxial reference circle (see Figure 18-7) with the position of each limb lead labeled on the circle. Next, the clinician identifies the limb lead with the most voltage (either positive or negative) from the ECG being evaluated. If the lead with the most voltage is positive (upright), the clinician locates the position of that lead on the hexaxial reference circle. The mean axis must be very close to that position on the circle. If the lead with the most voltage is negative (downward), the mean axis points in the opposite direction from that lead. If the lead with the most voltage is lead II and it is positive, the mean QRS axis must be approximately +60 degrees because this is where lead II is located on the hexaxial reference circle (see Figure 18-7). This is considered a normal axis because it falls between 0 and +90 degrees.[5,6]

In some situations, the most voltage may be equally present in two leads. The mean axis must fall equally between the two leads if they are both upright QRS complexes. If the QRS complexes in leads II and aV_F are equally positive in voltage, the mean axis must be at approximately +75 degrees and is considered normal. This is a common situation. If the mean QRS axis is between +90 degrees and +180 degrees, the patient has right-axis deviation; this is quickly identified by looking at lead I. If lead I is negative, right-axis deviation is present; this is commonly seen in patients with chronic obstructive pulmonary disease with cor pulmonale. Left-axis deviation is present when the mean axis is between +90 degrees and −90 degrees on the hexaxial reference circle. This is common in patients with left ventricular hypertrophy.

MINI CLINI

Right-Axis Deviation on Electrocardiogram

PROBLEM: A 54-year-old man with chronic obstructive pulmonary disease (COPD) has been admitted to the hospital for abdominal surgery. His routine laboratory data are normal, but his heart (cardiac silhouette) appears somewhat enlarged. The ECG shows a normal sinus rhythm with a right-axis deviation. How is the right-axis deviation detected and what does the right-axis deviation suggest?

SOLUTION: Normally, the mean axis (summary of electrical activity) of the heart travels from top to bottom and from right to left. This results in the mean axis of 0 to +90 degrees in the healthy heart. The slight leftward shift of the normal axis results from the angle at which the heart is situated in the chest and the fact that the left ventricle is normally larger than the right one. Right-axis deviation indicates that the electrical activity of the heart has been abnormally shifted to the patient's right side, between +90 degrees and +180 degrees. In this case, right-axis deviation is detected by noting a negative deflection of the QRS in lead I. This is most commonly the result of right ventricle enlargement, such as occurs with cor pulmonale (right heart failure caused by chronic hypoxic lung disease).

Recognizing Arrhythmias

Normal Sinus Rhythm. Recognizing abnormal ECGs results is easier if you have an appreciation for the normal tracing. The normal sinus rhythm begins with an upright P wave that is identical from one complex to the next. The PR interval is consistent throughout the rhythm strip and is 0.12 to 0.20 second. The QRS complexes are identical and no longer than 0.12 second. The ST segment is flat. The R-R interval is regular and does not vary more than 0.12 second between QRS complexes. The heart rate is between 60 and 100 beats/min (Figure 18-8).[2,3]

Sinus Tachycardia. Heart rates exceeding 100 beats/min are abnormal in resting adult patients and are electrocardiographically referred to as *sinus tachycardia* when a P wave is appropriately present before each QRS complex (Figure 18-9). Other than the rate exceeding 100 beats/min, sinus tachycardia does not differ from a normal sinus rhythm. This abnormality is common and can be caused by numerous problems. Most often, sinus tachycardia is caused by anxiety, pain, fever, hypovolemia, or hypoxemia. It also may be a side effect of certain medications, such as adrenergic bronchodilators. Treatment typically involves eliminating the underlying cause.[5,6]

Sinus Bradycardia. A heart rate of less than 60 beats/min that is otherwise normal is electrocardiographically referred to

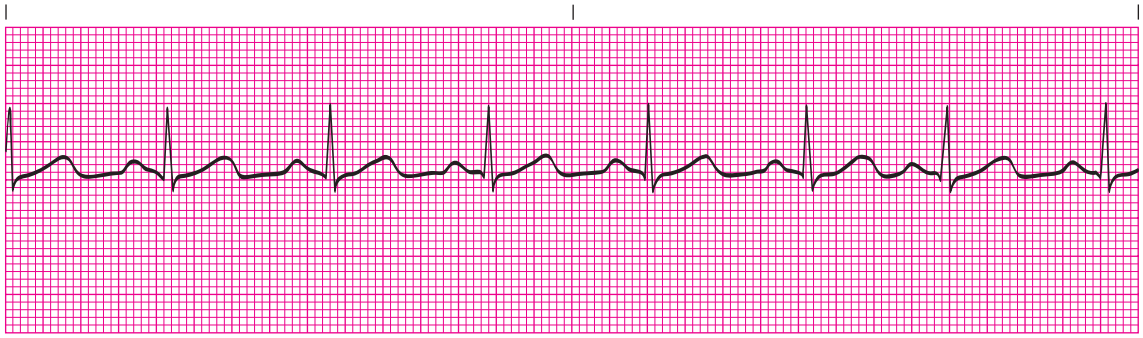

FIGURE 18-8 Electrocardiographic tracing showing a **normal sinus rhythm**. (Modified from Atwood S, Stanton C, Storey Davenport J: Introduction to basic cardiac dysrhythmias, ed 4, St Louis, 2009, Mosby/JEMS.)

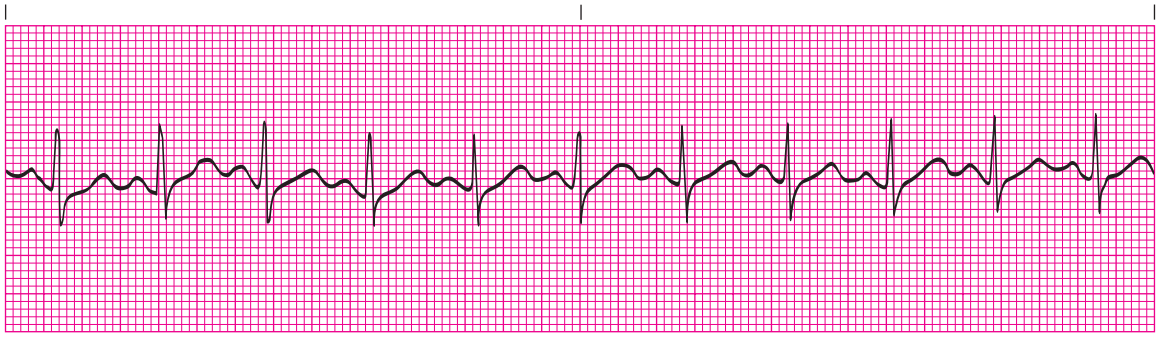

FIGURE 18-9 Electrocardiographic tracing showing **sinus tachycardia**. (Modified from Atwood S, Stanton C, Storey Davenport J: Introduction to basic cardiac dysrhythmias, ed 4, St Louis, 2009, Mosby/JEMS.)

as *sinus bradycardia*. Other than the rate being too slow, sinus bradycardia does not differ from a normal sinus rhythm (Figure 18-10). This abnormal rhythm is not as common as sinus tachycardia, but it represents a significant clinical problem if it causes the patient's blood pressure to decrease significantly or impairs tissue perfusion, causing symptoms such as fatigue, lightheadedness, or syncope. It is most often caused by hypothermia, abnormalities in the SA node, or intense athletic conditioning. Numerous medications, such as atropine, are available to stimulate the heart rate when clinical bradycardic symptoms occur.[5,6]

Sinus Arrhythmia. Sinus arrhythmia is a common arrhythmia and is recognized by the irregular spacing between QRS complexes. The spacing is measured by identifying the intervals between the R waves of successive QRS complexes, which are normally consistent. When the R-R interval varies more than 0.12 second throughout the rhythm strip, sinus arrhythmia is present (Figure 18-11). This arrhythmia may occur with the effects of breathing on the heart or as a side effect of medications such as digoxin. Most cases of sinus arrhythmia are benign and do not need treatment.[5,6]

First-Degree Heart Block. In first-degree heart block, the PR interval is longer than 0.20 second. In addition, there is one P wave before each QRS complex (Figure 18-12). This tracing indicates that the impulse from the SA node is getting through to the ventricles but is abnormally delayed in passing through the AV node or bundle of His. Typically, the QRS complex has

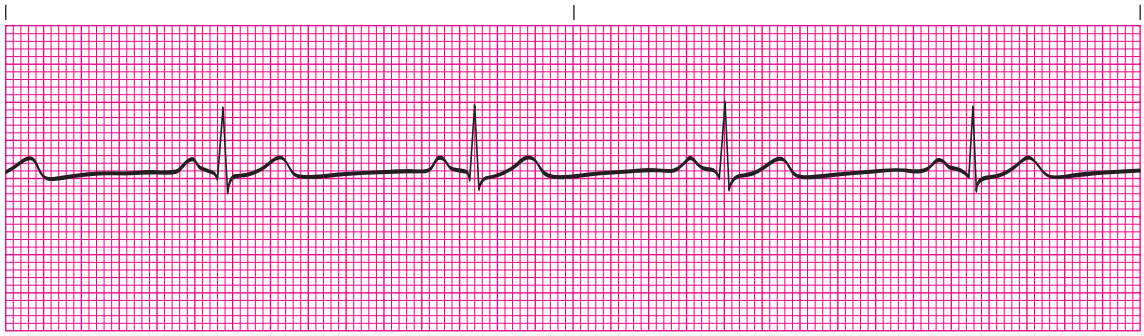

FIGURE 18-10 Electrocardiographic tracing showing **sinus bradycardia** with first-degree heart block. (Modified from Atwood S, Stanton C, Storey Davenport J: Introduction to basic cardiac dysrhythmias, ed 4, St Louis, 2009, Mosby/JEMS.)

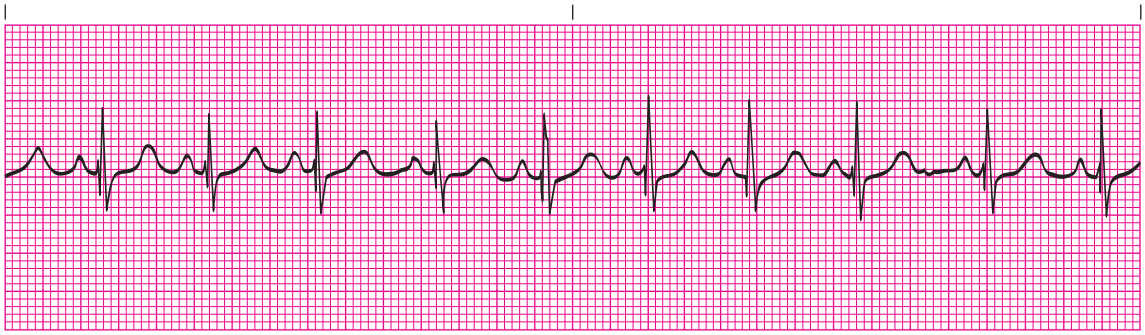

FIGURE 18-11 Electrocardiographic tracing showing **sinus arrhythmia**. (Modified from Atwood S, Stanton C, Storey Davenport J: Introduction to basic cardiac dysrhythmias, ed 4, St Louis, 2009, Mosby/JEMS.)

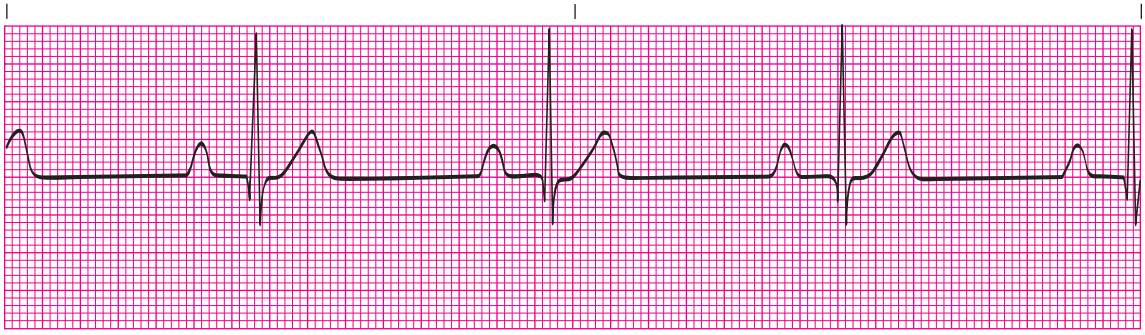

FIGURE 18-12 Electrocardiographic tracing showing **first-degree heart block**. (Modified from Atwood S, Stanton C, Storey Davenport J: Introduction to basic cardiac dysrhythmias, ed 4, St Louis, 2009, Mosby/JEMS.)

a normal configuration, and the R-R intervals are regular. First-degree heart block is common after an MI that damages the AV node, or it may be a complication of certain medications, such as digoxin or beta blockers. Treatment usually is not needed for first-degree heart block if the patient is able to maintain an adequate blood pressure.[6,7]

Second-Degree Heart Block. Second-degree heart block comes in two different types. Type I (Wenckebach or Mobitz type I) block is a relatively benign and often transient arrhythmia. It occurs when an abnormality in the AV junction delays or blocks conduction of some of the impulses through the AV node. It can be recognized by progressive prolongation of the PR interval until one impulse does not pass on to the ventricles at all (seen as a P wave not followed by a QRS complex). The cycle then repeats itself.

Second-degree heart block type II (Mobitz type II) is less common and is more often the result of serious problems such as MI or ischemia. Type II heart block is seen as a series of nonconducted P waves followed by a P wave that is conducted to the ventricles (Figure 18-13). Sometimes the ratio of nonconducted to conducted P waves is fixed at 3:1 or 4:1. The PR interval for the conducted impulses is consistent.[6,7]

Treatment for type I second-degree heart block is not needed because it usually does not impair cardiac output or cause symptoms. Type II second-degree heart block requires treatment in most cases because the resulting reduction in ventricular rate causes a decrease in blood pressure. Medications such as atropine provide a better cardiac output until a pacemaker can be inserted. Because type II block may progress to third-degree heart block without warning, a pacemaker is indicated even if the patient is asymptomatic.[8,9]

Third-Degree Heart Block. Third-degree heart block is the most serious of the different types of heart block. It indicates that the conduction system between the atria and ventricles is completely blocked, and impulses generated in the SA node are not conducted to the ventricles. The atria and ventricles are paced by independent sources. Most commonly, the atria are paced by the SA node, and the ventricles are paced by the AV node. This arrhythmia can be recognized when it is established that there is no relationship between the P waves and the QRS complexes. The P-P intervals are regular and the R-R intervals are regular, but they have no correlation with one another. In addition, the QRS complexes are normal in configuration if the ventricles are paced by the AV node (Figure 18-14). If the ventricles are paced by an ectopic site in the myocardium, the QRS complexes may be abnormally wide. Typically, the ventricular rate is slower than the atrial rate.[6,7]

Third-degree heart block is a serious arrhythmia because it often is caused by MI or drug toxicity (especially digitalis), and it may render the heart unable to meet the normal metabolic demands of the body. In almost all cases, treatment usually includes medication to speed up the ventricles and a temporary external pacemaker until a permanent one can be placed.[8,9]

Atrial Flutter. Atrial flutter is the rapid depolarization of the atria resulting from an ectopic focus that depolarizes at a rate of 250 to 350 times per minute. Typically, only one ectopic

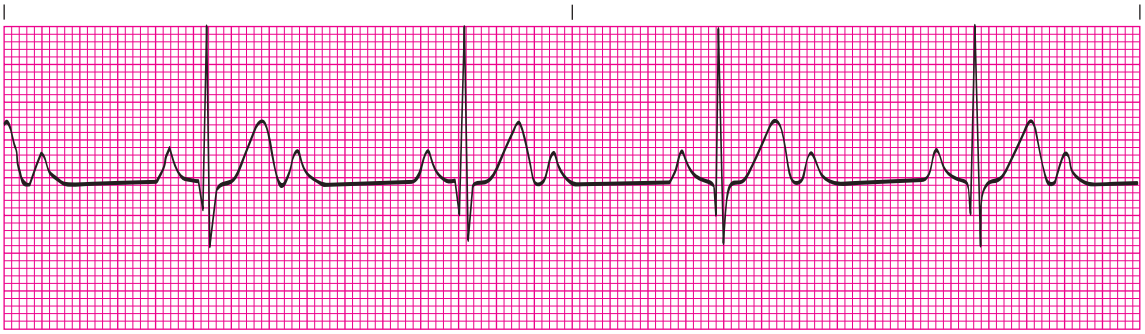

FIGURE 18-13 Electrocardiographic tracing showing **second-degree heart block type II**. (Modified from Atwood S, Stanton C, Storey Davenport J: Introduction to basic cardiac dysrhythmias, ed 4, St Louis, 2009, Mosby/JEMS.)

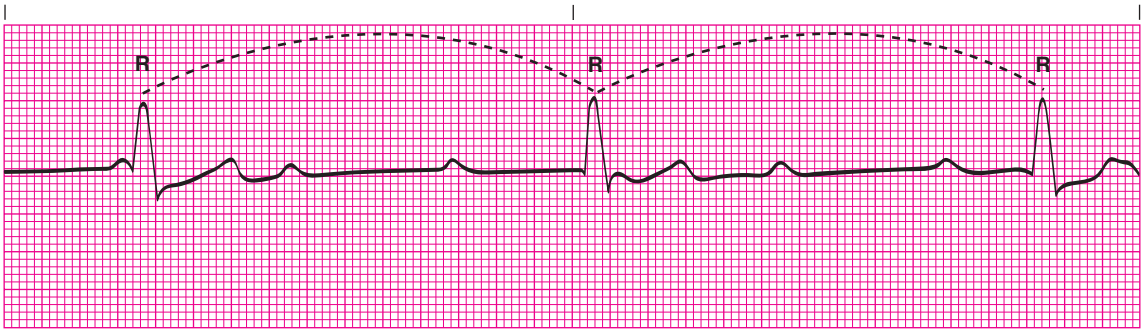

FIGURE 18-14 Electrocardiographic tracing showing **third-degree heart block**. (Modified from Atwood S, Stanton C, Storey Davenport J: Introduction to basic cardiac dysrhythmias, ed 4, St Louis, 2009, Mosby/JEMS.)

focus is causing the arrhythmia, which results in each P wave appearing similar. The result is a characteristic saw-toothed baseline pattern (Figure 18-15). Numerous P waves are present for every QRS complex, and the QRS complexes are normal in configuration. The R-R interval may be regular or it may vary, depending on the ability of the atrial impulse to pass through the AV node.[1,3,4]

Various conditions can produce atrial flutter, including rheumatic heart disease, coronary heart disease, stress, renal failure, and hypoxemia. This arrhythmia is not considered life-threatening, but it may lead to atrial fibrillation if untreated. Treatment usually includes medications such as digoxin, beta blockers, or calcium channel blockers. Once the rate is significantly slowed, cardioversion is attempted to return the heart rhythm back to a normal sinus rhythm.[8,9]

Atrial Fibrillation. Atrial fibrillation is present when the atrial muscle quivers in an irregular pattern that does not result in a coordinated contraction. The baseline electrical activity appears erratic, and no true P waves are seen in atrial fibrillation (Figure 18-16). The AV node determines the ventricular response to the atrial activity by controlling which impulses pass through and which do not. The ventricular rate is often very irregular and results in an abnormal R-R interval.[1,3,4]

The causes of atrial fibrillation are similar to the causes of atrial flutter. However, atrial fibrillation is a more serious arrhythmia because it can lead to a significant reduction in cardiac output resulting from the loss of the **atrial kick** that helps fill the ventricles before systole. The resulting stagnation of blood in the atria can lead to formation of blood clots, which can lead to pulmonary emboli or an embolic stroke. Treatment for atrial fibrillation is similar to the treatment for atrial flutter. However, patients with sustained atrial fibrillation are often treated with anticoagulants or antithrombolytic medications to treat potential blood clot formation, medications to slow the heart rate and cardioversion. [8,9]

RULE OF THUMB

Atrial fibrillation generally results in a reduction in cardiac output due to what is known as a loss of *atrial kick* resulting from a lack of coordination between the atria and ventricles. However, an even bigger problem is the potential for blood clot formation from stagnation of blood in the atria. These blood clots can easily travel to the pulmonary artery, causing a pulmonary embolism, or to the aorta, leading to an embolic stroke. As a result, most patients with atrial fibrillation should receive anticoagulant therapy.

Premature Ventricular Contractions. Premature beats can occur when a portion of the impulse-conducting system or myocardium other than the SA node becomes diseased and triggers depolarization of the surrounding cardiac cells. Sources for the impulse outside the SA node are called **ectopic foci.** Ectopic foci occur when hypoxia, acid-base imbalances, or electrolyte abnormalities are present and cause the cardiac cells in the ventricles to become abnormally excited. PVCs are easy to

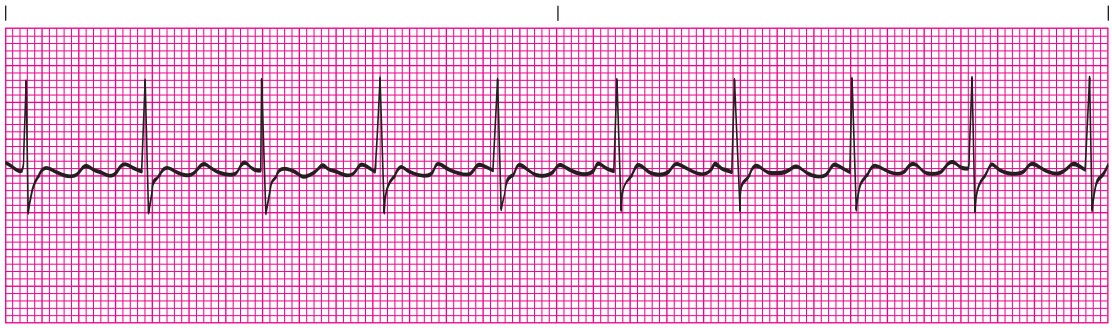

FIGURE 18-15 Electrocardiographic tracing showing **atrial flutter**. (Modified from Atwood S, Stanton C, Storey Davenport J: Introduction to basic cardiac dysrhythmias, ed 4, St Louis, 2009, Mosby/JEMS.)

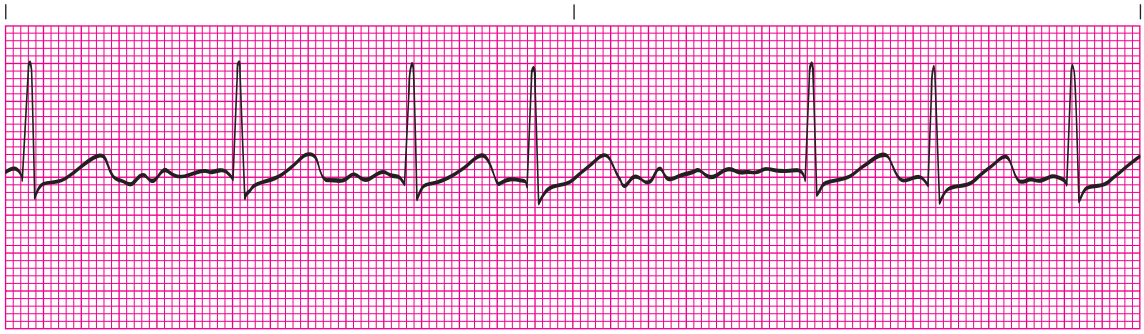

FIGURE 18-16 Electrocardiographic tracing showing **atrial fibrillation**. (Modified from Atwood S, Stanton C, Storey Davenport J: Introduction to basic cardiac dysrhythmias, ed 4, St Louis, 2009, Mosby/JEMS.)

recognize because they cause a unique and bizarre QRS complex that is much wider than normal (Figure 18-17). The QRS complex of a PVC is wider than normal because the ectopic focus is using channels outside the normal conduction system to move the impulse throughout the myocardium. PVCs have no P wave preceding them and may occur as a singular event or, more commonly, as a temporary run of PVCs. They also may occur at every other beat (bigeminy) or every third beat (trigeminy).[1,3,4]

An occasional PVC is not of major concern and may occur as a result of stress, caffeine intake, nicotine use, or electrolyte imbalance. However, frequent PVCs are more serious and most often occur in response to ischemia of the myocardium. They also are commonly seen as a side effect of some medications. Treatment is based on the frequency and cause of the PVCs and is needed when the PVCs are frequent (more than six per minute), paired together, or multifocal (appear differently because they come from more than one ectopic focus) or when they land directly on the T wave *(R on T phenomenon)*. In such cases, treatment must be prompt because the problem may progress rapidly to ventricular tachycardia (VT) and ventricular fibrillation (VF) (see subsequent discussion). Antiarrhythmic medications (e.g., lidocaine) may offer a temporary solution until the underlying cause can be addressed.[8,9]

Ventricular Tachycardia. VT is a run of three or more PVCs. It usually is easy to recognize as a series of wide, bizarre QRS complexes that have no preceding P wave. The ventricular rate is usually 100 to 250 beats/min (Figure 18-18). It is considered sustained VT if it lasts longer than 30 seconds.

Sustained or symptomatic VT is a serious arrhythmia because it indicates that an ectopic focus is rapidly firing from the ventricles, which results from increased automaticity. It suggests a significant pathologic defect in the myocardium and often leads to VF if untreated. MI, coronary artery disease, and hypertensive heart disease are the most common causes.[1,3,4]

Treatment must be prompt and specific and usually consists of cardioversion followed by long-term antiarrhythmic drugs for long-term suppression. Patients at high risk for recurrent VT may have an internal cardioverter-defibrillator (ICD) placed so that if VT occurs it can be treated automatically and promptly. Asymptomatic patients with recurrent nonsustained VT and ventricular ectopic beats may be treated with beta blockers to reduce symptoms of non–life-threatening ventricular arrhythmias. Symptomatic or sustained VT is considered a medical emergency, and the patient must be treated and monitored continuously in the ICU until his or her condition is stabilized.[8-12]

RULE OF THUMB

VT causes the cardiac output to decrease significantly because the ventricles do not have time to fill between contractions. This places the patient in danger of cardiac arrest and death.

Ventricular Fibrillation. VF is the most life-threatening arrhythmia and is defined as erratic quivering of the ventricular muscle mass. It causes the cardiac output to drop to zero; the patient becomes unconscious and represents a true medical

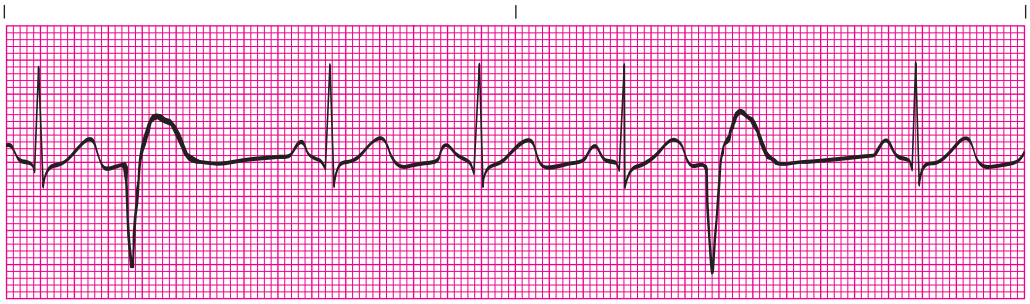

FIGURE 18-17 Electrocardiographic tracing showing **PVCs**. (Modified from Atwood S, Stanton C, Storey Davenport J: Introduction to basic cardiac dysrhythmias, ed 4, St Louis, 2009, Mosby/JEMS.)

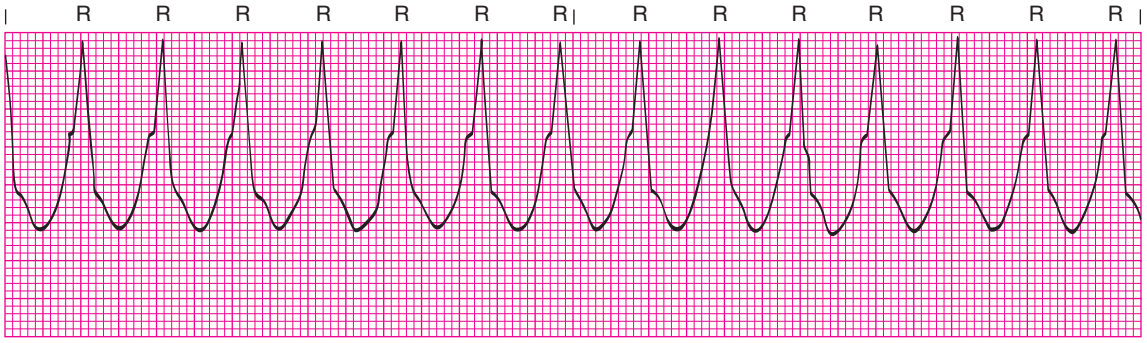

FIGURE 18-18 Electrocardiographic tracing showing **ventricular tachycardia**. (Modified from Atwood S, Stanton C, Storey Davenport J: Introduction to basic cardiac dysrhythmias, ed 4, St Louis, 2009, Mosby/JEMS.)

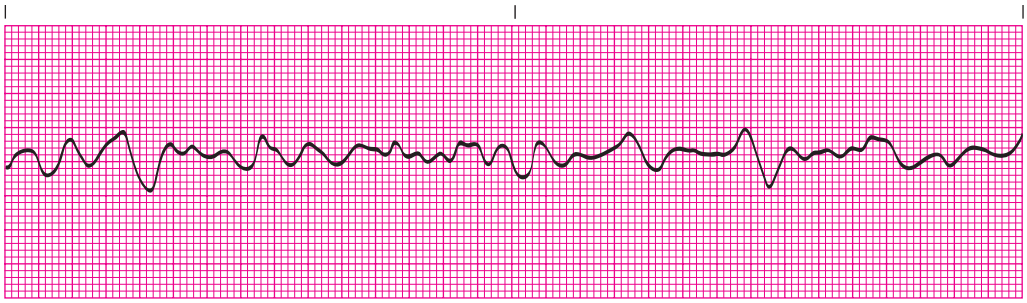

FIGURE 18-19 Electrocardiographic tracing showing **ventricular fibrillation**. (Modified from Atwood S, Stanton C, Storey Davenport J: Introduction to basic cardiac dysrhythmias, ed 4, St Louis, 2009, Mosby/JEMS.)

emergency. The electrocardiographic tracing of VF shows grossly irregular fluctuations with a zigzag pattern (Figure 18-19). This pattern is caused by the same problems associated with VT.

Treatment calls for rapid defibrillation, cardiopulmonary resuscitation, and administration of O_2 and antiarrhythmic medications; treatment of the underlying cause of the ischemia **is also warranted (see Chapter 37).** Survivors of VF usually receive an internal cardioverter-defibrillator.[8-12]

Pulseless Electrical Activity

In addition to the arrhythmias noted throughout this chapter, pulseless electrical activity (PEA) is a serious condition characterized by a disassociation between the electrical and mechanical activity of the heart. In essence, the ECG pattern on the monitor does not generate a pulse. PEA is relatively rare and generally does not occur without a precipitating event, such as a tension pneumothorax, MI, drug overdose, or severe electrolyte or acid-base disturbances.

Treatment involves emergency life support and the immediate reversal of the cause. PEA also illustrates why RTs and other clinicians should never "treat the monitor" and underscores the importance of using ECGs as just one of several clinical indicators in assessing patients.[10-12] The prompt recognition and response to VT, VF, and PEA are discussed in detail in Chapter 37, which covers the broader topic of emergency cardiovascular life support.

MINI CLINI

Pulseless Electrical Activity

PROBLEM: A 68-year-old man with a recent complaint of radiating chest pain is being placed on O_2 therapy with a nasal cannula at 2 L/min. Immediately after being set up on a 12-lead ECG, the patient loses consciousness. The ECG continues to show an apparent sinus bradycardia, but assessment reveals that the patient is pulseless.

SOLUTION: This is an apparent case of PEA, which should be treated as a potentially life-threatening emergency. A "code blue" should be initiated, cardiopulmonary resuscitation should be started immediately, and potential causes, including in this instance MI, should be considered and treated.

SUMMARY CHECKLIST

- The ECG is an inexpensive, noninvasive, and easy way to evaluate patients, but it does not predict future heart problems nor identify all abnormalities (i.e., valvular defects).
- The impulse-conducting system has three types of cardiac muscle cells capable of electrical excitation: pacemaker cells (e.g., SA node, AV node), specialized rapid conducting tissue (e.g., Purkinje fibers), and atrial and ventricular muscle cells. Each of these vary in their degree of automaticity.
- An elevated or depressed ST segment is common in MI and is a potentially life-threatening arrhythmia.
- Axis evaluation is used to determine the general direction of current flow during ventricular depolarization and is helpful in identifying hypertrophy of one of the ventricles.
- Sinus bradycardia is a significant clinical problem only if it causes the patient's blood pressure to decrease significantly or the patient becomes symptomatic.
- Frequent, paired together, multifocal PVCs or the R on T phenomenon with PVCs is serious because it often is due to ischemia of the myocardium and can progress rapidly to ventricular tachycardia and fibrillation.
- Type II second-degree heart block usually causes a significant decrease in cardiac output and may also progress to third-degree heart block. Even if the patient is asymptomatic, treatment calls for medication such as atropine until a pacemaker can be placed.
- Third-degree heart block is the most serious of the different types of heart block often caused by MI or drug toxicity (especially digitalis) and may render the heart unable to meet the normal metabolic demands of the body. Treatment usually includes medication to speed up the ventricles and a pacemaker.
- Atrial fibrillation is a serious arrhythmia that can lead to a significant reduction in cardiac output. In addition, if untreated, over time it can potentially cause an embolic event. Treatment entails medications to control the rate, antithrombolytics or anticoagulants, and potential cardioversion.
- Sustained or symptomatic VT is a serious arrhythmia that often leads to VF if untreated. Prompt treatment usually consists of cardioversion, antiarrhythmic drugs, and transfer to the ICU.

- VF is the most life-threatening arrhythmia, requiring emergent treatment with rapid defibrillation, cardiopulmonary resuscitation, and administration of O_2 and antiarrhythmic medications.
- Always treat the patient, not the rhythm on the ECG monitor. Patients with PEA often have a seemingly productive rhythm on the ECG but are pulseless and require immediate emergency life support.

CHAPTER 19

Analysis and Monitoring of Gas Exchange

MICHAEL A. GENTILE, ALBERT J. HEUER, AND RICHARD H. KALLET

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the difference between monitoring and analysis.
- Describe the two types of electrochemical oxygen analyzers.
- Describe calibration and problem-solving techniques for oxygen analyzers.
- State how to obtain, process, and analyze arterial and capillary blood gas samples.
- List the quality control procedures applied to blood gas analysis.
- List the potential advantages of point-of-care testing.
- Describe how to obtain and interpret transcutaneous oxygen and carbon dioxide monitoring.
- Describe the basic principles used by an oximeter to monitor oxygen saturation.
- State how to perform and interpret pulse oximetry.
- Describe how to perform capnometry and interpret capnograms.

Many important and potentially lifesaving clinical decisions are based on a patient's gas-exchange information. Gas exchange takes place inside each of the body's cells, where complex metabolic pathways use oxygen (O_2) to create energy and produce carbon dioxide (CO_2) as a waste product. Although it is possible but clinically not practical to analyze gas exchange at the cellular level, clinical focus normally is on gas exchange between the lungs and blood or between the blood and tissues. Gas exchange between the lungs and blood is usually analyzed by measuring O_2 and CO_2 levels in the arterial blood. Clinicians, including RTs, also can measure CO_2 levels in the expired gas to monitor ventilation. The most common approach to analyzing gas exchange between the blood and tissues is to measure O_2 levels in the mixed venous blood. This chapter focuses on these important parameters related to gas exchange.

ANALYSIS VERSUS MONITORING

Although the term *analysis* is defined broadly as *study* or *interpretation,* analysis conducted in a clinical laboratory has a special meaning, as does the term *monitoring*. In clinical practice, *laboratory analysis* refers to measurements of fluids or tissue that must be removed from the body. Such measurements are made by an **analyzer.** Conversely, monitoring is an ongoing process by which clinicians obtain and evaluate dynamic physiologic processes, usually at the bedside. A **monitor** is a device that provides data to the clinician in real time, usually without removal of samples from the body.

INVASIVE VERSUS NONINVASIVE PROCEDURES

Invasive procedures require insertion of a sensor or collection device into the body, whereas **noninvasive** monitoring gathers data externally.[1] Because laboratory analysis of gas exchange requires blood samples, it is considered invasive. Monitoring can be either invasive or noninvasive. In general, invasive procedures provide more accurate data than noninvasive methods, but carry greater risk.

When both approaches are available, the need for measurement accuracy dictates which is chosen. However, clinicians sometimes combine the approaches—using the invasive approach to establish accurate baseline information and applying the noninvasive method for ongoing monitoring of a patient. After the gradient between the invasive and noninvasive method is established, trending changes by noninvasive methods can be useful in making clinical decisions.

MEASURING FRACTIONAL INSPIRED OXYGEN

Gas-exchange analysis begins with knowledge of the system inputs—the inspired O_2 and CO_2 concentrations. Healthy individuals breathe air that contains a fixed O_2 concentration (21%) and negligible amounts of CO_2 (approximately 0.2%). Hypoxemic patients are routinely given supplemental O_2. In most cases, O_2 analyzers are used to measure the fractional inspired O_2 concentration (FiO_2).

Instrumentation

Although many methods exist for measuring O_2 concentrations, most bedside systems apply electrochemical principles. There are two common types of **electrochemical** O_2 analyzers are the polarographic (Clark) electrode and the galvanic fuel cell. Under ideal conditions of temperature, pressure, and relative humidity, both types are generally accurate to within ± 2% of the actual concentration.[1]

The Clark electrode is similar to electrodes used in blood gas analyzers and transcutaneous monitors, discussed later in this chapter. This system typically consists of a platinum cathode and a silver–silver chloride anode (Figure 19-1). O_2 molecules diffuse through the sensor membrane into the electrolyte, where a polarizing voltage causes electron flow between the anode and cathode. While silver is oxidized at the anode, the flow of electrons reduces O_2 (and water) to hydroxyl ions (OH^-) at the cathode. More O_2 molecules undergoing reduction causes greater electron flow across the poles (current). The resulting current change is proportional to the PO_2, with its value displayed on a galvanometer, calibrated in $\%O_2$. Response times for O_2 analyzers range from 10 to 30 seconds.

Most galvanic fuel cells use a gold anode and a lead cathode. In contrast to the Clark electrode, current flow across these poles is generated by the chemical reaction itself.

The Clark electrode and galvanic cell are suitable for basic FiO_2 monitoring. When greater accuracy or faster response times are needed (e.g., when performing indirect calorimetry), a paramagnetic, zirconium cell, Raman scattering, or mass spectroscopy analyzer should be selected.

Procedure

To obtain accurate results with an O_2 analyzer, the clinician first must calibrate it. Although procedures differ according to the

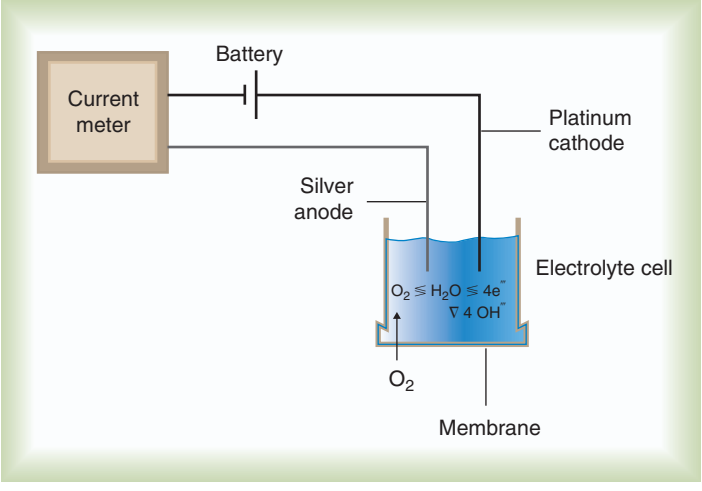

FIGURE 19-1 The basic principle underlying the Clark polarographic analyzer. (Modified from Kacmarek RM, Hess D, Stoller JK, editors: Monitoring in respiratory care, St Louis, 1993, Mosby.)

manufacturer, the basic steps are similar. This requires exposing the sensor to two gases with different O_2 concentrations, usually 100% O_2 and room air (21% O_2). In one common procedure, the sensor is first exposed to 100% O_2. If the analyzer fails to read 100%, the device's *calibration,* or balance control, must be adjusted until it reads 100%. Then the clinician exposes the sensor to room air and confirms a second reading of 21% (±2%). The clinician should use the analyzer to measure a patient's FiO_2 only after confirming both readings.

Problem-Solving and Troubleshooting

Because O_2 analyzers include replaceable components that deteriorate over time (batteries, electrodes, membranes, electrolytes), the best way to avoid problems is through preventive maintenance. This should include both scheduled parts replacement and routine operational testing.

Even with the best preventive maintenance, O_2 analyzers may malfunction. The clinician would know that an analyzer is not working if it fails to calibrate or gives an inconsistent reading during use. Common causes of analyzer malfunction are low batteries, sensor depletion, and electronic failure. Because a low battery condition is common, the first step in troubleshooting is to replace the batteries. If the analyzer still does not calibrate on fresh batteries, the problem is probably a depleted sensor. With most analyzers, a depleted sensor must be replaced. If an analyzer still fails to calibrate after battery and sensor replacement, the most likely problem is an internal failure of its electrical system. In this case, the device should be taken out of service and repaired.

Inaccurate readings also can occur with electrochemical analyzers, resulting from either condensed water vapor or pressure fluctuations. Galvanic cells are particularly sensitive to condensation. To avoid this problem during continuous use in humidified circuits, the clinician should place the analyzer sensor proximal to any humidification device.

Fuel cell and Clark electrode readings also are affected by ambient pressure changes. Under conditions of low pressure (high altitude), these devices read lower than the actual O_2 concentration. Conversely, higher pressures, such as pressures that occur during positive pressure ventilation, cause these devices to read higher than the actual FiO_2. These observations are consistent with the fact that both devices measure the PO_2 but report a percent concentration scale.

RULE OF THUMB

Three common causes of O_2 analyzer malfunction are low batteries, sensor depletion, and electronic failure.

SAMPLING AND ANALYZING BLOOD GASES

In the clinical setting, it is common for the collection of blood specimens (sampling) to be performed separately from their analysis. Each procedure involves different knowledge and skill. For these reasons, these topics are covered separately.

Sampling

Clinicians have been using blood samples to assess gas-exchange parameters for more than 50 years.[2] The definition of *respiratory failure* is based largely on blood gas measurements (i.e., PaO_2, and $PaCO_2$). Depending on the need, blood gas samples can be obtained by percutaneous puncture of a peripheral artery, from an indwelling catheter: arterial, central venous, or pulmonary artery (PA) or by capillary sampling.

Arterial Puncture and Interpretation

Results obtained from sampling arterial blood gas (ABG) are the foundation for the diagnosis and management of oxygenation and acid-base disturbances. ABGs are considered the "gold standard" of gas-exchange analysis, against which all other methods are compared.

Arterial puncture involves drawing blood from a peripheral artery (radial, brachial, femoral, or dorsalis pedis) through a single percutaneous needle puncture (Figure 19-2). The radial artery is the preferred site for arterial blood sampling for the following reasons:

- It is near the surface and relatively easy to palpate and stabilize.
- Effective **collateral circulation** normally exists in the ulnar artery.
- The artery is not near any large veins.

Other sites (brachial, femoral, and dorsalis pedis) are riskier and should be used only by clinicians specifically trained in their use. Likewise, arterial puncture in infants (through either the radial or the temporal artery) requires advanced training. Arterial cannulation sites for indwelling catheters include radial, brachial, femoral, dorsalis pedis, umbilical (in neonates), and axillary arteries. The focus here is on radial artery puncture.

To guide practitioners in providing quality care, the American Association for Respiratory Care (AARC) has published Clinical Practice Guideline: Sampling for Arterial Blood Gas Analysis.[3] Complementary recommendations have been published by the National Committee for Clinical Laboratory Standards.[4] Modified excerpts from the AARC guideline appear in Clinical Practice Guideline 19-1.

Equipment. Box 19-1 lists the equipment needed to perform an arterial puncture. Commercial vendors provide kits containing most of the equipment listed.

Procedure. Box 19-2 outlines the basic procedure for radial artery puncture of adults. Before radial artery puncture is performed, a **modified Allen test** (Figure 19-3) is recommended. The test is normal (indicating adequate collateral circulation) if the palm, fingers, and thumb flush pink within 5 to 10 seconds after pressure on the ulnar artery is released. A normal test result indicates the presence of collateral circulation in the ulnar artery, but may not predict the development of complications after radial artery puncture or cannulation.

The modified Allen test has been a widely used clinical method to assess adequacy of ulnar artery collateral blood flow

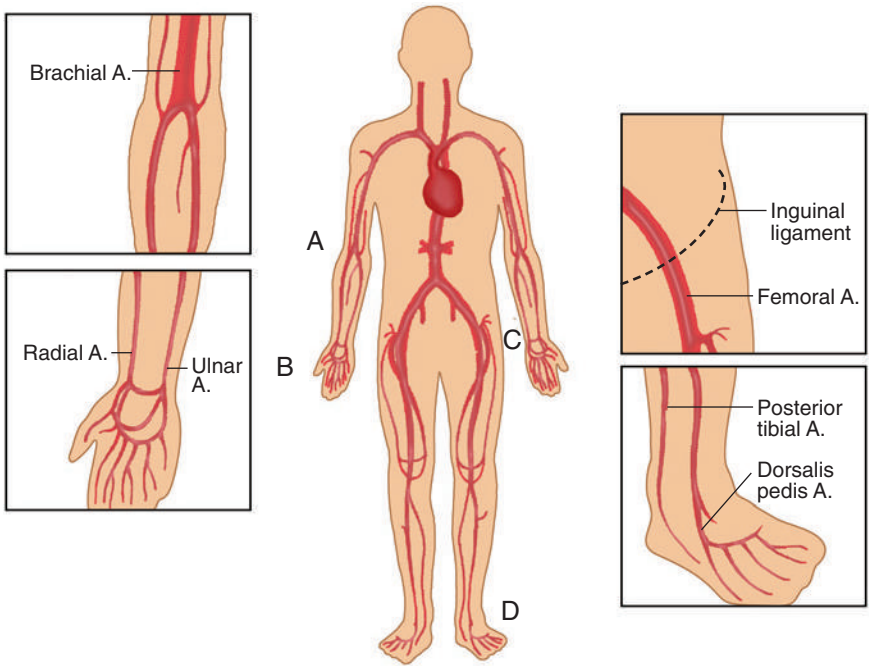

FIGURE 19-2 Arteries *(A.)* used for arterial puncture. **A,** Brachial artery. **B,** Radial artery (with collateral flow through the ulnar arteries). **C,** Femoral artery. **D,** Dorsalis pedis (with collateral flow through the posterior tibial artery). The radial artery is the preferred site.

Box 19-1 Recommended Equipment for Percutaneous Arterial Blood Sampling

- Standard precautions barrier protection (gloves, safety goggles)
- Preheparinized blood gas kit syringe (1 to 3 ml)
- Short-bevel 20- to 22-gauge needle with a clear hub (23- to 25-gauge for children and infants)
- Patient and sample label
- Isopropyl alcohol (70%), povidone-iodine (Betadine) (check patient for iodine sensitivity), or chlorhexidine swabs
- Sterile gauze squares, tape, bandages
- Puncture-resistant container
- Ice slush, depending upon the analyzer. **Note:** For most point-of-care (bedside) analyzers, samples should not be chilled and should be run within 1 to 2 minutes after being obtained.
- Towels
- Sharps container
- Local anesthetic (optional)
- Hypodermic needle (25- or 26-gauge)
- Needle capping device

despite the lack of evidence that it can predict ischemic complications in the setting of complete radial artery occlusion.[5] The criteria for an abnormal test result are not agreed on, and therefore the significance of an abnormal test is unclear. For example, test results (1) may be inaccurate in predicting post-cannulation hand ischemia, (2) may vary depending on the clinician performing the test (poor interrater reliability), and (3) are known to yield high incidences of both false normal and abnormal results. In addition, prior radial artery cannulation, severe circulatory insufficiency, wrist or hand burns, or jaundice makes interpreting the results difficult. Despite these limitations, an Allen test may reveal gross circulatory abnormalities and therefore should be performed beforehand and then documented in the patient's medical record.

In patients who have undergone previous radial artery cannulation, the modified Allen test can provide documentation of possible arterial thrombosis and should be used to direct catheter placement. In that circumstance, it is imprudent to ignore totally the utility of the modified Allen test, especially if another arterial site is available for cannulation.[6]

In most cases, a sample volume of 0.5 to 1 ml of blood is adequate. The actual sample volume needed depends on (1) the anticoagulant used, (2) the requirements of the specific analyzer used, and (3) whether other tests will be performed on the sample. It should be noted that point-of-care (bedside) analyzers tend to require less blood (≤0.5 ml) than laboratory analyzers.

The following rules for careful handling of the needle help avoid transmission of blood-borne diseases:

- Never recap a used needle without a safety device.
- Never handle a used needle using both hands.
- Never point a used needle toward any part of the body.
- Never bend, break, or remove used needles from syringes by hand.
- Always dispose of used syringes, needles, and other sharp items in appropriate puncture-resistant sharps containers.

Indications for Blood Gas Sampling. Knowing when to obtain a blood gas sample is just as important as knowing how to perform the procedure. See Clinical Practice Guideline 19-1 for the general indications for ABG sampling. Box 19-3 lists

19-1 Sampling for Arterial Blood Gas Analysis

AARC Clinical Practice Guidelines (Excerpts)*

INDICATIONS

- The need to evaluate ventilation ($PaCO_2$), acid-base balance (pH and $PaCO_2$), oxygenation status (PaO_2 and SaO_2), and oxygen-carrying capacity of blood (PaO_2, HbO_2, total Hb, and dyshemoglobins)
- The need to assess the patient's response to therapy or diagnostic tests (e.g., oxygen or exercise testing)
- The need to monitor the severity and progression of a documented disease process

CONTRAINDICATIONS

- Abnormal results of a modified Allen test (lack of collateral circulation) may be indicative of inadequate blood supply to the hand and suggest the need to select another puncture site.
- Arterial puncture should not be performed through a lesion or distal to a surgical shunt. For example, arterial puncture should not be performed on a patient undergoing dialysis. If there is evidence of infection or peripheral vascular disease involving the selected limb, an alternative site should be selected.
- Because of the need for monitoring the femoral puncture site for an extended period, femoral punctures should not be performed outside the hospital.
- Coagulopathy or medium-dose to high-dose anticoagulation therapy, such as heparin or warfarin (Coumadin), streptokinase, and tissue plasminogen activator (but not aspirin), may be a relative contraindication.

PRECAUTIONS AND POSSIBLE COMPLICATIONS

- Arteriospasm
- Hemorrhage
- Air or clotted blood emboli
- Trauma to the vessel
- Anaphylaxis from local anesthetic
- Arterial occlusion
- Patient or sampler contamination
- Vasovagal response
- Hematoma
- Pain

ASSESSMENT OF NEED

The following assessments are useful for deciding whether arterial blood sampling is needed:

- History and physical indicators, such as positive smoking history, recent onset of difficulty breathing (independent of activity level), or trauma
- Presence of other abnormal diagnostic tests or indices, such as abnormal pulse oximetry reading or chest x-ray examination
- Initiation, change, or discontinuation of therapy (e.g., oxygen therapy or mechanical ventilation)
- Projected enrollment in a pulmonary rehabilitation program

FREQUENCY

The frequency with which sampling is repeated should depend on the clinical status of the patient and the indication for performing the procedure. Because repeated punctures at a single site can cause injury, clinicians should consider either finding alternative sites or using an indwelling catheter.

MONITORING

The following should be monitored as part of arterial blood sampling:

- FiO_2 (analyzed) or prescribed flow
- Patient's respiratory rate
- Proper application of oxygen device
- Patient's temperature
- Mode of ventilatory support and settings
- Appearance of the puncture site (for hematoma) after application of pressure and before dressing

**For the complete guideline, see American Association for Respiratory Care: Clinical practice guideline: sampling for arterial blood gas analysis. Respir Care 37:891, 1992.*

common clinical situations associated with the need for ABG analysis.

Problem-Solving and Troubleshooting. There are two major problem areas associated with arterial puncture. The first problem involves difficulties in getting a good sample. The second problem involves pre-analytic error.

Getting a Good Sample. Problems with getting a good sample include an inaccessible artery, absent pulse, deficient sample return, and alteration of test results caused by the patient's response. If the selected artery cannot be located, another site should be considered. Likewise, if an adequate pulse cannot be palpated at the chosen site, another site should be selected or an acceptable noninvasive approach should be considered as an alternative (e.g., pulse oximetry). Ultrasound guidance may useful in artery identification and sampling success.[7]

If the clinician gets only a small spurt of blood, the needle has probably passed through the artery. In this situation, the needle is slowly withdrawn until a pulsatile flow fills the syringe. The tip of the needle is never redirected without it first being withdrawn to the subcutaneous tissue. If the needle must be withdrawn completely and the clinician does not have an adequate sample, the procedure is repeated with a fresh blood gas kit.

Small sample volumes or the need to apply syringe suction also may indicate that venous blood has been obtained. However,

Box 19-2 Procedure for Radial Artery Puncture

- Check the medical record to (1) confirm the order and indications and (2) determine the patient's primary diagnosis, history (especially bleeding disorders or blood-borne infections), current status, respiratory care orders (especially oxygen therapy or mechanical ventilation), and anticoagulant or thrombolytic therapy.
- Confirm steady-state conditions (20 to 30 minutes after changes).
- Obtain and assemble necessary equipment and supplies.
- Wash hands and don barrier protection (e.g., gloves, eyewear).
- Identify the patient using current patient safety standards.
- Explain the procedure to the patient.
- Position the patient, extending the patient's wrist to approximately 30 degrees.
- Perform a modified Allen test, and confirm collateral circulation.
- Clean site thoroughly with 70% isopropyl alcohol or an equivalent antiseptic.
- Inject a local anesthetic subcutaneously/periarterially, wait 2 minutes for effect (optional).
- Use a preheparinized blood gas kit syringe, or heparinize a syringe and expel the excess (fill dead space only).
- Palpate and secure the artery with one hand.
- Insert the needle, bevel up, through the skin at a 45-degree angle until blood pulsates into the syringe.
- Allow 1 ml of blood to fill syringe (the need to aspirate indicates a venous puncture).
- Apply firm pressure to puncture site with sterile gauze until the bleeding stops.
- Expel any air bubbles from the sample, and cap or plug the syringe.
- Mix the sample by rolling and inverting the syringe.
- Place the sample in a transport container and chilled or not, depending on analyzer manufacturer recommendation. **Note:** For most point-of-care (bedside) analyzers, samples should not be chilled and should be run within 1 to 2 minutes after being obtained.
- Dispose of waste materials and sharps properly.
- Document the procedure and patient status in the medical record and on the specimen label.
- Check the site for hematoma and adequacy of distal circulation.

From Malley WJ: Clinical blood gases: assessment and intervention. St Louis, 2005, Saunders.

Box 19-3 Clinical Indications for Arterial Blood Gas Analysis

- Sudden, unexplained dyspnea
- Cyanosis
- Abnormal breath sounds
- Severe, unexplained tachypnea
- Heavy use of accessory muscles
- Changes in ventilator settings
- Cardiopulmonary resuscitation
- New appearance of diffuse infiltrates in chest radiograph
- Sudden appearance or progression of cardiac arrhythmias
- Acute hypotension
- Acute deterioration in neurologic function

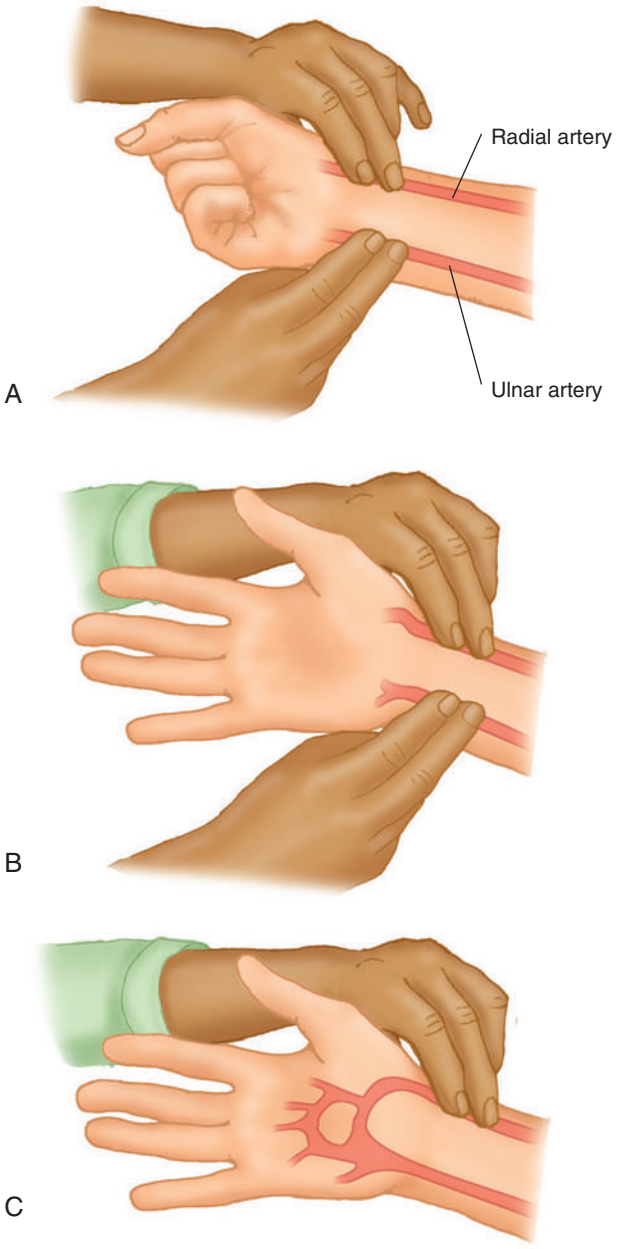

FIGURE 19-3 Modified Allen test. **A,** The hand is clenched into a tight fist, and pressure is applied to the radial and ulnar arteries. **B,** The hand is opened (but not fully extended); the palm and fingers are blanched. **C,** Removal of pressure on the ulnar artery should cause flushing of the entire hand (within 5 to 10 seconds), indicative of adequate collateral circulation or a normal modified Allen test.

when drawing arterial blood from hypotensive patients or when using small needles (<23-gauge), the clinician may need to pull gently on the syringe barrel. If clinicians suspect that pain or anxiety during the procedure may have altered the results (most typically causing hyperventilation, but sometimes breath-holding), they should consider using a local anesthetic for subsequent sampling attempts.

Pre-analytic Error. **Pre-analytic errors** are problems occurring before sample analysis that can alter the accuracy of the blood gas results. Table 19-1 summarizes the most common

TABLE 19-1

Pre-analytic Errors Associated With Arterial Blood

Error	Effect on Parameters	How to Recognize	How to Avoid
Air in sample	↓ PCO_2 ↑ pH ↑ low PO_2 ↓ high PO_2	Visible bubbles or froth Low PCO_2 inconsistent with patient status	Discard frothy samples Fully expel bubbles Mix only after air is expelled Cap syringe quickly
Venous admixture	↑ PCO_2 ↓ pH Can greatly lower PO_2	Failure of syringe to fill by pulsations Patient has no symptoms of hypoxemia	Avoid brachial and femoral sites Do not aspirate sample Use short-bevel needles Avoid artery "overshoot" Cross-check with SpO_2
Excess anticoagulant (dilution)	↓ PCO_2 ↑ pH ↑ low PO_2 ↓ high PO_2	Visible heparin remains in syringe before sampling	Use premade lyophilized (dry) heparin blood gas kits Fill dead space only Collect >2 ml (adults) and >0.6 ml (infants)
Metabolic effects	↑ PCO_2 ↓ pH ↓ PO_2	Excessive time lag since sample collection Values inconsistent with patient status	Analyze within 15 min Place sample in ice slush

errors associated with arterial blood sampling, including recommendations on how to recognize and avoid these problems. Clinicians can avoid most pre-analytic errors by ensuring that the sample is obtained anaerobically (with immediate expulsion of air bubbles), properly anticoagulated, and quickly analyzed.

The traditional method used to avoid pre-analytic errors caused by blood cell metabolism is to chill the sample quickly by placing it in ice.[3] However, some studies suggest that results may be altered if samples are stored in certain types of plastic syringes, especially if placed on ice before being analyzed. In addition, chilled samples can result in potassium transport between blood cells and plasma and can result in erroneous elevation in potassium measured from a blood gas sample. Hence, the best ways to minimize such pre-analytic errors is to use low-diffusability syringes, which minimize the risk for room-air altering the sample, and to analyze the sample as soon as possible after it has been obtained. Furthermore, samples that have been stored for an undetermined time, whether chilled or not, should be discarded.[8,9] Another consideration is that pneumatic tube transport of samples containing small air bubbles can have a noticeable effect on increasing PaO_2.[9] Finally, most point-of-care (bedside), analyzer systems (discussed later in this chapter) require that the sample not be chilled and be analyzed within 1 to 2 minutes after being obtained, depending on the manufacturer.

RULE OF THUMB

Three common methods for avoiding pre-analytic errors in ABG measurements are ensuring that the sample is obtained anaerobically (with immediate expulsion of air bubbles), the sample syringe is properly anticoagulated, and the sample is promptly analyzed.

Interpretation of Arterial Blood Gases. Because gas exchange is a dynamic process, looking at results from a single blood sample is akin to looking at a single frame of streaming video, representing a single point in time rather than an ongoing physiologic process. Blood gas results must be interpreted in light of the patient status at the time the sample was obtained.

Any major change in the patient's condition or therapy disrupts the patient's steady state. However, over time, a new steady state emerges. The time needed to restore steady-state conditions varies with the patient's pulmonary status. Patients with healthy lungs achieve a steady state in only 5 minutes after changes, whereas patients with chronic obstructive pulmonary disease (COPD) may require up to 30 minutes. For example, when FiO_2 is changed, the measured PaO_2 would accurately reflect the patient's gas-exchange status within 5 minutes in healthy individuals but may require up to 30 minutes in patients with COPD.

To document the patient's status, the following need to be recorded: (1) date, time, and site of sampling; (2) results of the modified Allen test, when performed; (3) patient's body temperature, position, activity level, and respiratory rate; and (4) FiO_2 concentration or nasal cannula flow and all applicable ventilatory support settings. Noting such information may prove useful in interpretation of the results.

RULE OF THUMB

To ensure a steady state, waiting up to 30 minutes after any major change in ventilatory support may be necessary before sampling and analyzing the blood gases of a critically ill patient.

In the first step of interpreting results, clinicians must ensure they are looking at the results for the correct patient. The name and patient identification number from the blood gas report must match the patient. Interpretation of the results can be divided into two basic steps: interpretation of the oxygenation status and interpretation of the acid-base status.

TABLE 19-2

Common Sites for Indwelling Vascular Catheters and the Information They Provide

Location	BLOOD COLLECTION		PRESSURE MONITORING	
	Sample	Reflects	Pressure	Reflects
Peripheral, umbilical artery	Arterial blood	Pulmonary gas exchange (O_2 uptake/CO_2 removal)	Systemic arterial pressure	LV afterload, vascular tone, blood volume
Central vein	Venous blood (unmixed)	Not useful for assessing gas exchange; can be used for some other laboratory tests	CVP	Fluid volume, vascular tone, RV preload
Pulmonary artery	Mixed venous blood (balloon deflated)	Gas exchange at tissues (O_2 consumption/ CO_2 production)	PAP, PCWP	RV afterload, vascular tone, blood volume, LV preload

CVP, Central venous pressure; *LV,* left ventricular; *PAP,* pulmonary artery pressure; *PCWP,* pulmonary capillary wedge pressure; *RV,* right ventricular.

The oxygenation status is determined by examining the PaO_2, arterial O_2 saturation (SaO_2), and arterial O_2 content (CaO_2). The PaO_2 represents the partial pressure of O_2 dissolved in the plasma of the arterial blood and is the result of gas exchange between the lung and blood. The PaO_2 is reduced in various settings but most often when lung disease is present. PaO_2 of less than 40 mm Hg is called *severe* hypoxemia, PaO_2 of 40 to 59 mm Hg is called *moderate* hypoxemia, and PaO_2 of 60 mm Hg to the predicted normal is called *mild* hypoxemia.

SaO_2 represents the degree to which the hemoglobin (Hb) is saturated with O_2 (see Chapter 12). Normally, the Hb saturation with O_2 is 95% to 100% with healthy lungs. When the lungs cannot transfer O_2 into the blood at normal levels, the SaO_2 usually decreases in proportion to the degree of lung disease. Blood gas analyzers report a calculated SaO_2. Measurement of SaO_2 by hemoximetry and Hb content is required for accurate determination of CaO_2.

CaO_2 represents the content of O_2 in 100 ml of arterial blood and is a function of the amount of Hb present and the degree to which it is saturated. A normal CaO_2 is 18 to 20 ml of O_2 per 100 ml of arterial blood. A reduced CaO_2 is often the result of low PaO_2 and SaO_2, reduced Hb level, or the presence of dyshemoglobins.

The acid-base status of the patient is determined by evaluating the pH, $PaCO_2$, and plasma bicarbonate (HCO_3^-). The steps for interpreting the acid-base status of the ABG results are described in Chapter 14.

RULE OF THUMB

Mild hypoxemia is defined as a PaO_2 of 60 mm Hg relative to predicted normal, whereas moderate hypoxemia is a PaO_2 between 40 and 59 mm Hg and severe hypoxemia is defined as a PaO_2 less than 40 mm Hg.

Indwelling Catheters (Arterial, and Central Venous Pressure, and Pulmonary Artery Lines)

Indwelling catheters provide ready access for blood sampling and allow continuous monitoring of vascular pressures, without the traumatic risks associated with repetitive percutaneous punctures. However, infection and thrombosis are more likely with indwelling catheters than with intermittent punctures.

The most common route for an indwelling arterial vascular line is the radial artery; less commonly used sites are the dorsalis pedis, brachial, axillary, and femoral arteries. Venous blood gases are obtained from either a central venous catheter or a PA catheter, which can access both the superior vena cava and a main branch of the PA. In neonates, the umbilical artery is cannulated for arterial blood sampling. Table 19-2 summarizes the usefulness of these various sites in providing relevant clinical information. Chapter 51 provides details on the use of these systems for hemodynamic pressure and flow monitoring.

Equipment. Figure 19-4 shows the basic setup used for an indwelling vascular line, in this case, a brachial artery catheter. The catheter connects to a disposable continuous-flush device. This device keeps the line open by providing a continuous low rate of flow (2 to 4 ml/hr) of intravenous (IV) saline solution through the system.

Heparinized saline flush solution may be used with indwelling vascular catheters. However, results of coagulation studies are affected by heparinized flush solution and unnecessary exposure to heparin may increase the risk for heparin-induced thrombocytopenia.[10] Because arterial pressures are much higher than venous pressures, the IV bag supplying these systems must be pressurized, usually by using a hand bulb pump. A strain-gauge pressure transducer connected to the flush device provides an electrical signal to an amplifier or monitor, which displays the corresponding pressure waveform.

Procedure. Access for sampling blood from most intravascular lines is provided by a three-way stopcock (Figure 19-5). Equipment and supplies are the same as specified for arterial puncture, with the addition of a second "waste" syringe. Box 19-4 outlines the proper procedure for taking an arterial blood sample from a three-way stopcock system.

The procedure is slightly different when obtaining mixed venous blood samples from PA catheters because PA catheters have separate sampling and IV infusion ports and a balloon at the tip is used to measure pulmonary capillary wedge pressure. The clinician must ensure that the balloon is deflated and withdraw the sample slowly (e.g., approximately 3 ml/min or 1 ml in 20 seconds). If the clinician fails to deflate the balloon or

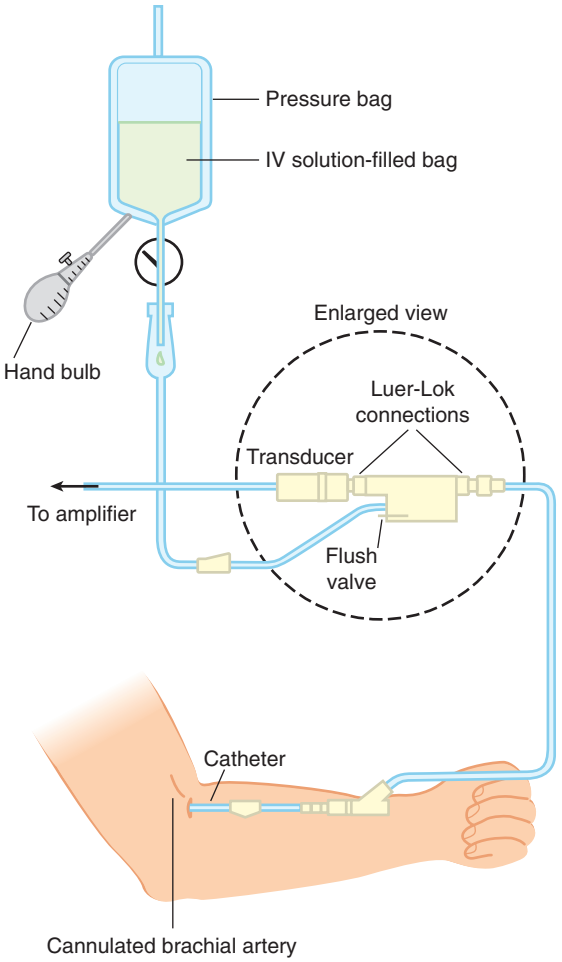

FIGURE 19-4 An indwelling vascular line (brachial artery catheter) used to monitor blood pressure and obtain a blood sample.

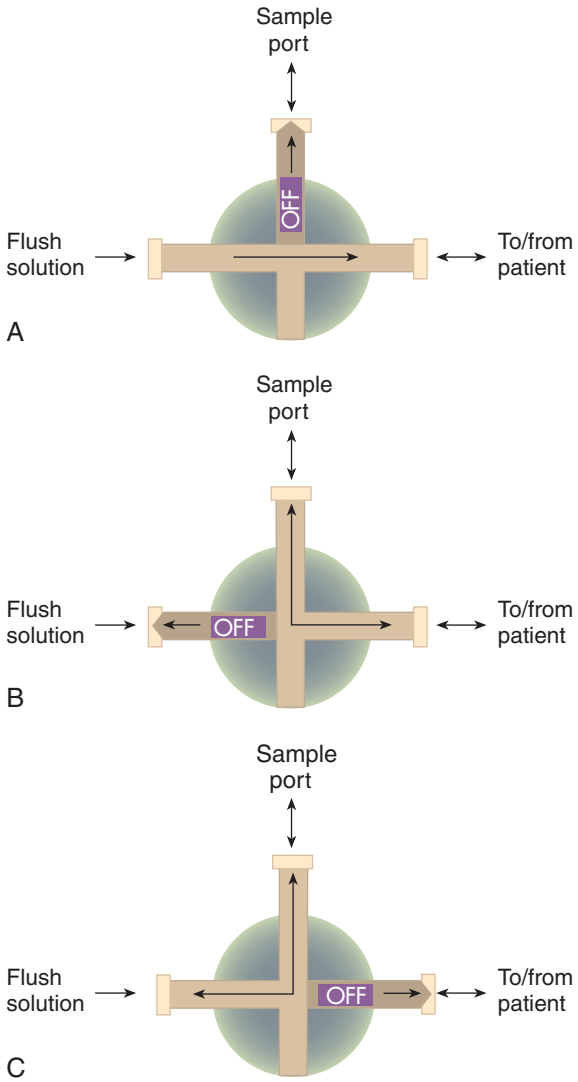

FIGURE 19-5 A three-way stopcock in a vascular line system showing the various positions used. **A,** Normal operating position, with flush solution going to the patient and the sample port closed. **B,** Position to draw a blood sample from the vascular line (closed to flush solution). **C,** Position to flush sample port (closed to patient). In any intermediary position, all ports are closed.

withdraws the sample too quickly, the venous blood may be "contaminated" with blood from the pulmonary capillaries. The result is always a falsely high O_2 level. In addition, close attention must be paid to the infusion rate through the catheter. Rapid flow of IV fluid can dilute the blood sample and affect O_2 content measurements.

Problem-Solving and Troubleshooting. With the exception of venous admixture, the pre-analytic errors that occur when sampling blood from a vascular line are the same as the errors that occur with intermittent puncture, as are the ways to avoid them. For clinicians, the challenge with vascular lines is to maintain their function properly and troubleshoot the many potential problems that can occur. Because these are key components of bedside monitoring skills, they are discussed in the section on hemodynamics in Chapter 51.

Capillary Blood Gases

Capillary blood gas sampling is used as an alternative to direct arterial access in infants and small children. Properly obtained capillary blood from a well-perfused patient can provide clinically useful estimates of arterial pH and PCO_2 levels. However, capillary PO_2 is of little value in estimating arterial oxygenation. Therefore, O_2 saturation by pulse oximetry also must be evaluated when obtaining a capillary blood gas sample. Clinicians must exercise extreme caution when using capillary blood gases to guide clinical decisions. Direct arterial access is still the preferred approach for assessing gas exchange in infants and small children.

Capillary blood values are meaningful only if the sample site is properly warmed. Warming the skin (to approximately 42° C) causes dilation of the underlying blood vessels, which increases capillary flow well above tissue needs. Blood gas values resemble the values in the arterial circulation; this is why a sample obtained from a warmed capillary site is often referred to as **arterialized blood.** It has been shown that capillary blood samples from the earlobe reflect arterial PCO_2 and PO_2 better than samples drawn from a finger stick.[11] The posterior medial or lateral curvature of the heel is the recommended site for

Box 19-4 Procedure for Sampling Arterial Blood from an Indwelling Catheter

- Check the medical record to affirm order (as per arterial puncture).
- Confirm steady-state conditions (20 to 30 minutes after changes).
- Obtain and assemble needed equipment and supplies.
- Wash hands and don barrier protection (e.g., gloves, eyewear).
- Identify the patient using current patient safety standards.
- Explain the procedure to the patient.
- Attach the waste syringe to the stopcock port.
- Position the stopcock so that blood flows into the syringe and the IV bag port is closed.
- Aspirate at least 1 to 2 ml, or five to six times the tubing volume, of fluid or blood.
- Reposition the stopcock handle to close off all ports.
- Disconnect and properly discard waste syringe.
- Attach new heparinized syringe to the sampling port.
- Position the stopcock so that blood flows into the sample syringe and the IV bag port is closed.
- Fill syringe with 1 ml of blood.
- Reposition the stopcock handle to close off the sampling port and open the IV bag port.
- Disconnect the syringe, expel air bubbles from sample, and cap or plug the syringe.
- Flush the line and stopcock with the IV solution.
- Mix the sample by rolling and inverting the syringe.
- Confirm that the stopcock port is open to the IV bag solution and catheter.
- Confirm undampened pulse pressure waveform on the monitor graphic display.
- Place the sample in a transport container (ice slush) if specimen is not to be analyzed within 10 to 30 minutes.
- Dispose of waste materials properly. **Note:** For most point-of-care (bedside) analyzers, samples should not be chilled and should be run within 1 to 2 minutes after being obtained.
- Document the procedure and patient status in the medical record and on the specimen label.

Box 19-5 Procedure for Capillary Blood Sampling

- Check the medical record (as per arterial puncture).
- Confirm steady-state conditions (20 to 30 minutes after changes).
- Obtain and assemble necessary equipment and supplies.
- Wash hands and don barrier protection (e.g., gloves, eyewear).
- Select site (e.g., heel, earlobe, great toe, finger).
- Warm site to 42°C for 10 minutes using a compress, heat lamp, or commercial hot pack.
- Clean skin with an antiseptic solution.
- Puncture the skin (<2.5 mm) with the lancet.
- Wipe away the first drop of blood and observe free flow (do not squeeze).
- Fill the sample tube from the middle of the blood drop until it is completely full (75 to 100 mcl).
- Place the metal flea in the capillary tube, and then seal the tube ends.
- Tape sterile cotton or a bandage over the puncture wound.
- Mix the sample by moving the magnet back and forth along the capillary tube.
- Sample should be immediately chilled or analyzed within 10 to 15 minutes if left at room temperature.
- Dispose of waste materials properly.
- Document the procedure and patient status in the medical record and on the specimen label.

capillary puncture specimens in infants younger than 1 month old to avoid nerve and bone damage.

To guide practitioners in providing quality care, the AARC has published Clinical Practice Guideline: Capillary Blood Gas Sampling for Neonatal and Pediatric Patients.[12] Modified excerpts from the AARC guideline appear in Clinical Practice Guideline 19-2.

Equipment. Equipment needed for capillary blood sampling includes a lancet, preheparinized capillary tubes, small metal stirrer bar (metal flea), a magnet, clay or wax sealant or caps, gauze or cotton balls, bandages, ice, gloves, skin antiseptic, warming pads (42°C), sharps container, and labeling materials.

Procedure. Box 19-5 outlines the basic procedure for capillary blood sampling. The most common site for sampling is the heel, specifically the lateral aspect of the plantar surface.

Problem-Solving and Troubleshooting. Sampling of capillary blood is useful for patient management only if the procedure is performed according to an established quality assurance program. The most common technical errors in capillary sampling are inadequate warming of the capillary bed and squeezing of the puncture site. Squeezing the puncture site may result in venous and lymphatic contamination of the sample.[13] Both errors invalidate the test results. Other pre-analytic errors are essentially the same as the errors described for arterial puncture. Because of the small sample volume (75 to 100 mcl or 0.075 to 0.1 ml) and collection tube size, the clinician must ensure an adequate sample collection while avoiding air contamination and clotting.

Analyzing

The primary **analytes** or parameters of pH, PCO_2, and PO_2 in a blood sample are measured with a blood gas analyzer. Typically, analyzers use these measures to compute several secondary values, such as plasma bicarbonate level, base excess or deficit, and Hb saturation. If actual measurement of total Hb saturation (oxyhemoglobin [HbO_2], methemoglobin [metHb], and carboxyhemoglobin [HbCO]) is required, the sample usually must be analyzed separately using hemoximetry. Some analyzers combine the blood gas and hemoximetry measurements, which may require a larger sample size (usually 100 mcl).

Blood gas analysis and hemoximetry are moderately complex laboratory procedures. Clinicians performing these tests must have documented training and must demonstrate proficiency in performing the procedures, preventive maintenance, troubleshooting, and instrument calibration. In addition, clinicians must be skilled in validating test results using rigorous **quality control** methods that ensure clinical decisions used to determine patient care are based on accurate information.[14]

To guide practitioners in providing quality care, the AARC has published Clinical Practice Guideline: Blood Gas Analysis and Hemoximetry: 2013.[15] Related recommendations have been

19-2 Capillary Blood Gas Sampling for Neonatal and Pediatric Patients

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

Capillary blood gas sampling is indicated when:

- ABG analysis is indicated, but arterial access is unavailable
- Noninvasive monitor readings (e.g., $PtcCO_2$: $PETCO_2$, SpO_2) are abnormal
- Assessment of initiation, administration, or change in therapy (e.g., mechanical ventilation) is indicated
- A change in patient status is detected by history or physical assessment
- Monitoring the severity and progression of a documented disease process is desirable

CONTRAINDICATIONS

Capillary punctures should not be performed at or through the following:

- The posterior curvature of the heel (because it can puncture the bone)
- The heel of a patient who has begun walking and has callus development
- The fingers of neonates (because it can cause nerve damage)
- Previous puncture sites
- Inflamed, swollen, or edematous tissues
- Cyanotic or poorly perfused tissues
- Localized areas of infection
- Peripheral arteries

Capillary punctures should not be performed:

- On patients less than 24 hours old (because of poor peripheral perfusion)
- When there is a need for direct analysis of oxygenation
- When there is a need for direct analysis of arterial blood

Relative contraindications include:

- Peripheral vasoconstriction
- Polycythemia (caused by shorter clotting times)
- Hypotension

PRECAUTIONS AND POSSIBLE COMPLICATIONS

- Contamination and infection of the patient, including calcaneus osteomyelitis and cellulitis
- Inappropriate patient management may result from reliance on capillary PO_2 value
- Inadvertent puncture or incision and consequent infection
- Tibial artery laceration (puncture of posterior sample of medial aspect of heel)
- Burns
- Hematoma
- Bruising
- Scarring
- Bleeding

ASSESSMENT OF NEED

Capillary blood gas sampling is an intermittent procedure and should be performed only when a documented need exists and arterial access is unavailable or contraindicated. Documented need exists in response to initiation, administration, or change in therapy and is determined by history and physical assessment or results of noninvasive respiratory monitoring.

MONITORING

The following should be monitored and documented in the medical record as part of the capillary sampling procedure:

- FiO_2 or prescribed oxygen flow
- Appearance of puncture site
- Oxygen modality or ventilator settings
- Complications or adverse reactions to the procedure
- Ease or difficulty of obtaining the sample
- Results of blood gas analysis
- Patient's temperature, respiratory rate, position or level of the foot or finger to obtain a sample of activity, and clinical appearance
- Date, time, and sampling site
- Noninvasive monitoring values (e.g., SpO_2)

**For the complete guideline, see American Association for Respiratory Care: Clinical practice guideline: capillary blood gas sampling for neonatal and pediatric patients. Respir Care 46:506, 2001.*

published by the National Committee for Clinical Laboratory Standards.[9] Modified excerpts from the AARC guideline appear in Clinical Practice Guideline 19-3.

Instrumentation

Many instrumentation companies manufacture laboratory blood gas analyzers. Although available in a range of designs, these devices typically share the following key components:

- Operator interface (e.g., operating controls, display screen, touch screen keypads, software)
- Measuring chamber incorporating the typical three-electrode system
- Calibrating gas tanks
- Reagent containers (buffers used for calibration, rinse solutions)
- Waste container
- Results display, storage, and transmittal system (e.g., screen, printer, disk storage device, network interface)

Measurement of the three primary parameters—pH, PCO_2, and PO_2—is accomplished using three separate electrodes. To measure PO_2, blood gas analyzers use the Clark polarographic electrode (see Figure 19-1).

The pH electrode consists of two electrodes or half cells (Figure 19-6). The measuring half cell contains a silver–silver

19-3 Blood Gas Analysis and Hemoximetry

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

- The need to evaluate the adequacy of a patient's ventilatory ($PaCO_2$), oxygenation (PaO_2 and HbO_2), or acid-base balance (pH, $PaCO_2$, HCO_3^-)
- The need to quantify the response to therapeutic intervention (e.g., oxygen therapy, mechanical ventilation) or diagnostic evaluation (e.g., exercise desaturation)
- The need to monitor the severity and progression of disease processes

CONTRAINDICATIONS

Contraindications to pH and blood gas analysis and hemoximetry include:

- An improperly functioning analyzer
- An analyzer for which the performance has not been validated by quality control or proficiency testing procedures
- Any specimen gathered with *known* or suspected preanalytic errors (e.g., aircontamination, improper anticoagulation, improper storage or handling)
- An incomplete requisition that precludes adequate interpretation and documentation of results
- An inadequately labeled specimen lacking the patient's full name or other unique identifier, such as the medical record number, date, and time of sampling

HAZARDS AND POSSIBLE COMPLICATIONS

- Infection of specimen handler from blood (human immunodeficiency virus, hepatitis C, other blood-borne pathogens)
- Inappropriate patient medical treatment based on an improperly analyzed blood specimen, on analysis of an unacceptable specimen, or on incorrect reporting of results

ASSESSMENT OF NEED

Presence of the listed indications in a patient to be tested supports the need for sampling and analysis.

MONITORING

- Monitoring of personnel, sample handling, and analyzer performance to ensure proper handling, analysis, and reporting should be ongoing during the process.
- There must be documented evidence of active review of quality control; proficiency testing; and physician alert, or "panic values" on a level commensurate with the number of tests performed

**For the complete guideline, see American Association for Respiratory Care: Clinical practice guideline: Blood gas analysis and hemoximetry: 2013. Respir Care 58:1694, 2013.*

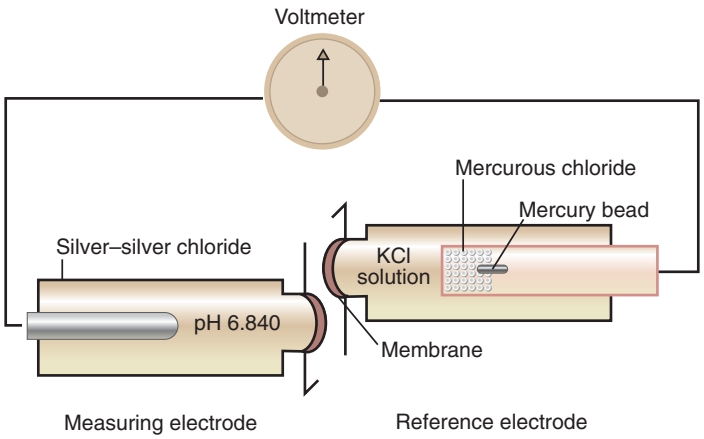

FIGURE 19-6 Blood gas analyzer pH electrode system, consisting of both a measurement and a reference electrode. (Modified from Shapiro BA, Peruzzi WT, Kozelowski-Templin R: Clinical application of blood gases, ed 5, St Louis, 1994, Mosby.)

chloride rod surrounded by a solution of constant pH and enclosed by a pH-sensitive glass membrane. As the sample passes this membrane, the difference in H^+ concentration on either side of the glass changes the potential of the measuring electrode. The reference half cell (mercury–mercurous chloride) produces a constant potential, regardless of sample pH. The difference in potential between the two electrodes is proportional to the H^+ concentration of the sample, which is displayed on a voltmeter calibrated in pH units.

To measure PCO_2, blood gas analyzers use the Severinghaus electrode, which is essentially a pH electrode exposed to an electrolyte solution in equilibrium with the sample through a CO_2-permeable membrane. As CO_2 diffuses through this membrane into the electrolyte solution, it undergoes the following hydration reaction:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

The greater the partial pressure of CO_2, the more H^+ that is produced by this reaction and the more the pH of the electrolyte solution changes. The measuring electrode detects the pH change as a change in electrical potential, which is proportional to the PCO_2 of the sample.

Procedure

To provide accurate and clinically useful data, blood gas analysis must be performed as follows:

- On a sample free of pre-analytic errors
- With a properly functioning analyzer (validated by quality control procedures)
- Using a procedure that follows the manufacturer's recommendations

Box 19-6 Basic Procedure for Analyzing a Blood Gas Sample

- Apply standard precautions.
- Confirm that the instrument and its electrodes are operating properly.
- Identify the specimen, and confirm all relevant information provided.
- Note the time at which the sample was obtained (discard sample if >60 minutes has passed).
- Inspect the sample for obvious signs of preanalytic error (e.g., air bubbles, gross dilution, clotting, air exposure).
- Mix the sample (critical for hemoglobin and hematocrit measurements).
- Uncap the syringe, and expel and discard a drop or two of blood from the syringe tip.
- Introduce the sample (manually or by automatic aspiration).
- Confirm the readings.
- Remove the syringe and clear the system.
- Dispose of waste materials properly.
- Transmit the results.
- Contact the responsible clinician if the results warrant.

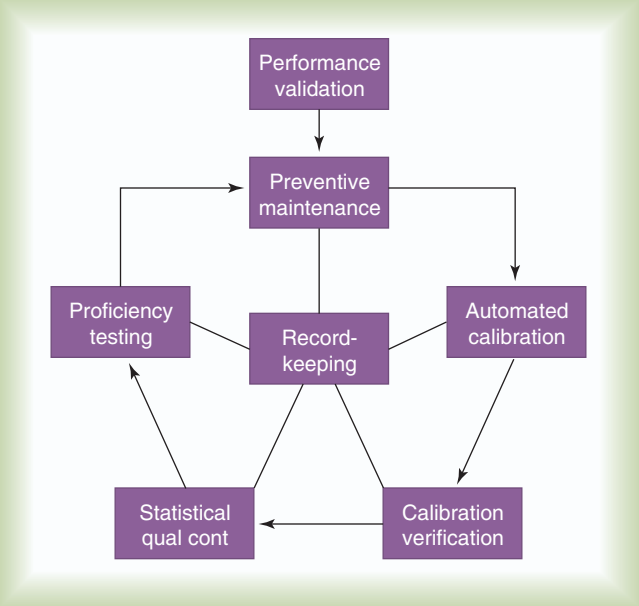

FIGURE 19-7 Blood gas analysis quality control program. (Data from Kozelowski-Templin R: Blood gas analyzers. Respir Care Clin North Am 1:35–46, 1995.)

Prior discussion addressed how to avoid pre-analytic errors. Subsequent discussion focuses on blood gas quality control and key elements involved in the analysis procedure.

Box 19-6 outlines the steps commonly used in most established procedures for laboratory blood gas analysis. One should always refer to the manufacturer's literature for the particular steps to use with a specific analyzer.

Rigorous application of the U.S. Centers for Disease Control and Prevention (CDC) standard precautions is essential. In addition, the Occupational Safety and Health Administration requires personnel to wear personal protective equipment when handling all laboratory specimens. Waste fluids are potentially infectious and should be handled as if they were blood samples. In addition, the National Committee for Clinical Laboratory Standards recommends adding a strong disinfectant, such as 2% glutaraldehyde or a 1:4 solution of sodium hypochlorite, to the waste container of the instrument either during use or before disposal.

Quality Assurance

High-quality patient care depends on consistently accurate blood gas results. Modern laboratory analyzers are often automated, computer-controlled, self-calibrating systems. Likewise, most point-of-care (bedside), analyzer systems are self-calibrating. This sophistication has led to the false assumption that accurate results are "automatic," with clinicians needing only to input the sample properly and record the results. Nothing could be further from the truth. As with all diagnostic laboratory procedures, the accuracy of blood gas testing depends on rigorous quality control.

The Clinical Laboratory Standards Institute (CLSI) established guidelines and standards for blood gas analysis and quality assurance. Government regulatory agencies collaborate to update the Clinical Laboratory Improvement Amendments (CLIA) that establish proficiency testing requirements.[16] Although an in-depth review of laboratory quality control is beyond the scope of this text, all clinicians must understand the key elements.[17]

Figure 19-7 depicts the key components of laboratory quality control. A brief description of each element follows.

Recordkeeping. Meticulous recordkeeping and clearly written, comprehensive policies and procedures are the hallmark of a quality control program. Both statutory law and professional accreditation requirements emphasize this component as the basis for demonstrating and ensuring quality.

Performance Validation. Performance validation is the process of testing a new instrument to confirm accurate measurement. Typically, this process involves using samples with known values to assess both the accuracy (comparing the value from the tested instrument with a known value) and the **precision** (examining the repeatability of results) of the instrument.

Preventive Maintenance and Function Checks. Many blood gas analyzer components (e.g., filters, membranes, electrolyte solution, and single-test and multitest cartridges) have a limited life and deteriorate or fail over time, resulting in faulty analysis. The best way to avoid these problems is to schedule regular preventive maintenance. This should include scheduled parts replacement and routine function tests, as recommended by the manufacturer.

Automated Calibration. Calibration is the only fully automated element of blood gas quality control for laboratory analyzers. Blood gas analyzers regularly calibrate themselves by adjusting the output signal of each electrode when exposed to media having known values. In most units, the media used to calibrate the gas electrodes are precision mixtures of O_2 and CO_2. For the pH electrode, standard pH buffer solutions are

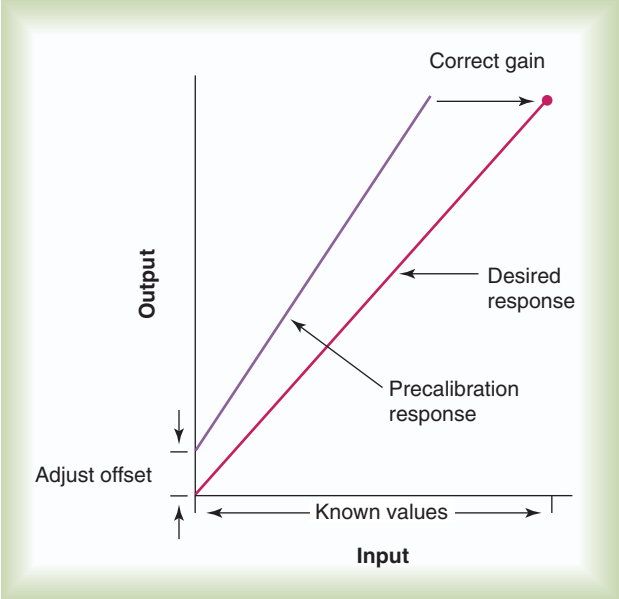

FIGURE 19-8 Two-point calibration procedure. (Modified from Chatburn RL: Fundamentals of metrology: evaluation of instrument error and method agreement. In Kacmarek RM, Hess D, Stoller JK, editors: Monitoring in respiratory care, St Louis, 1993, Mosby.)

used. **Calibration media** must meet the requirements set by nationally recognized standards organizations. Users are responsible for ensuring that calibration media are properly stored and that in-use life and expiration dates are strictly enforced.

Calibration is performed to ensure that the analyzer output is both accurate and linear across the range of measured values. Parameters must be measured with known input values representing at least two points, usually a low and a high value. Figure 19-8 shows a typical two-point calibration procedure. In this example, the instrument's initial precalibration response indicates that the output readings are consistently higher than the actual input, with this positive **bias** worsening at higher levels. Calibration is performed first by adjusting the offset (or balance) of the instrument so that the low output equals the low input (in this case zero). Next, the gain (or slope) of the device is adjusted to ensure that the high output equals the high input. When both offset and gain are adjusted against known inputs, the instrument is properly calibrated and can undergo calibration verification with control samples.

Internal Statistical Quality Control. Internal quality control takes calibration verification a step further by applying statistical and rule-based procedures (Westgard rules)[18,19] to help detect, respond to, and correct instrument error. In one common approach, the results of control media analyses are plotted on a graph and compared with statistically derived limits, usually ± 2 standard deviation (SD) ranges (Figure 19-9). Control results that fall outside these limits indicate analytic error.

There are two categories of analytic error: (1) **random error** and (2) **systematic error.** Random error is observed when sporadic, out-of-range data points occur (see Figure 19-9, point *A*). Random errors are errors of precision or, more precisely, **imprecision.** Conversely, either a trending or an abrupt shift in data points outside the statistical limits (see Figure 19-9, point *B*) is sometimes observed. This phenomenon is called *systematic error* or sometimes *bias.* Bias plus imprecision equals total instrument error, or *inaccuracy.* Table 19-3 outlines the major factors causing these two types of error and suggests some common corrective actions.

TABLE 19-3
Correction of Analytic Errors

Error Type	Common Contributing Factors	Common Corrective Actions
Imprecision (random) errors	Statistical probability Sample contamination Sample mishandling	Rerun control Repeat analysis on different instrument
Bias (systematic) errors	Contaminated buffers Incorrect gas concentrations Incorrect procedures Component failure	Perform function check of suspected problem area Repair or replace failed components

MINI CLINI

Blood Gas Quality Control

PROBLEM: Using control media for calibration verification, the RT responsible for the quality control of a blood gas analyzer in the intensive care unit (ICU) notes that the "high PCO_2" control readings have increased progressively over the last four quality control analyses from 60 ± 1 mm Hg to 66 ± 1 mm Hg. What is the likely cause and what actions should the RT take?

SOLUTION: The observed problem indicates a trending, or systematic, error (bias). If the analyzer solutions and calibrating gases have not been changed during the error period, the likely problem is component failure—probably the PCO_2 electrode. The electrode should be checked, and any faulty components should be replaced.

External Quality Control (Proficiency Testing). The federal government mandated a rigorous program of external quality control for analytic laboratories. CLIA standards were established in 1988. To meet these standards, analytic laboratories must undergo regular proficiency testing designed to evaluate their operating procedures and the competence of their personnel.[20] **Proficiency testing** requires analysis and reporting on externally provided control media with unknown values, usually three times per year, with five samples per test. There are many CLIA-approved proficiency testing providers. A commonly used provider is the College of American Pathologists (CAP) proficiency testing survey. Proficiency testing survey

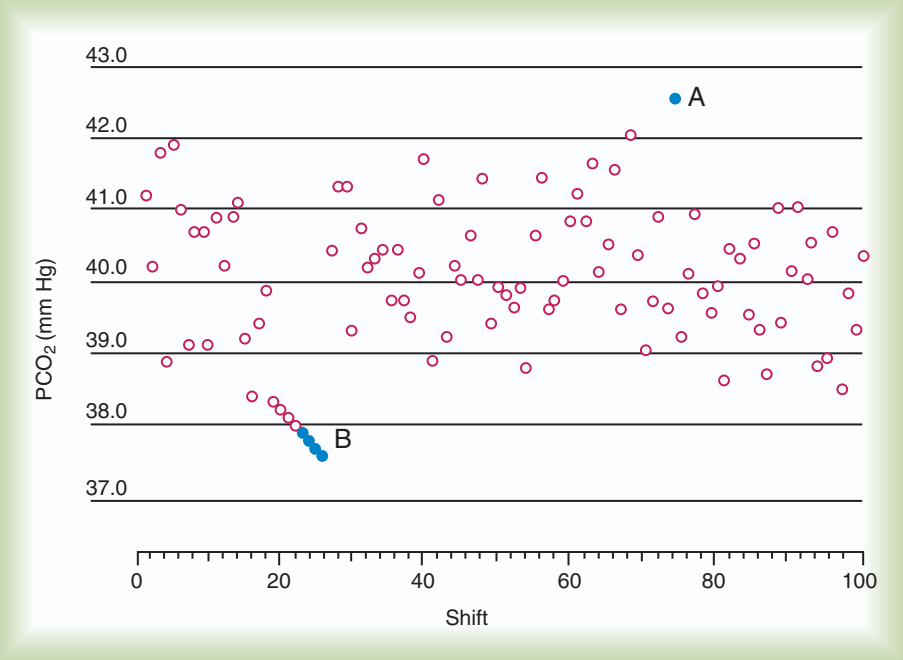

FIGURE 19-9 Schematic representation of a quality control plot for PCO_2. The horizontal axis depicts time. *White circles* represent values within 2 standard deviations of the mean; *blue circles* represent values outside 2 standard deviations of the mean. Point *A* represents a random error; point *B* represents systematic errors. (Modified from Shapiro BA, Peruzzi WT, Kozelowski-Templin R: Clinical application of blood gases, ed 5, St Louis, 1994, Mosby.)

analyses must be performed along with the regular workload by the personnel routinely responsible for testing, following the laboratory's standard testing practices.[21]

Criteria for acceptable performance specify a range around a target value, such as ± 0.04 for pH. A single incidence of unsatisfactory performance requires documentation of remedial action. Multiple or recurring incidences of poor performance can result in severe sanctions, including suspension of Medicare and Medicaid reimbursement or the loss of the laboratory's operating license and accreditation.

Remedial Action. Remedial action is the ongoing process of applying appropriate measures to correct errors identified through the quality assurance cycle. Analytic errors include calibration and internal quality control failures, actual sample errors, and unsatisfactory proficiency test results. A comprehensive quality assurance program also tries to identify and correct both pre-analytic and post-analytic errors, such as clerical misreporting.

Examples of remedial action include procedural changes, staff training and retraining, closer supervision, and more frequent preventive maintenance checks. The remedial action chosen should be appropriate for the identified problem. As with all other components of the process, meticulous documentation is necessary.

Point-of-Care Testing

Point-of-care testing takes blood gas analysis from the specialized laboratory to the patient's bedside.[22] Point-of-care testing reduces turnaround time, which may lead to quicker diagnosis and treatment. Theoretically, cost savings can be accrued by eliminating delays in therapy, decreasing patient length of stay in the hospital and emergency department (ED).[23] Point-of-care testing is used increasingly in the hospital and physician office settings.[24]

Instrumentation. Figure 19-10 shows a typical point-of-care blood gas analyzer (GEM 4000; Instrumentation Laboratory, Bedford, MA). Smaller point-of-care analyzers using similar technology, such as the i-STAT point-of-care system (Abbott Laboratories, Abbott Park, IL), are also gaining popularity. In addition to blood gas analysis, such devices can be used to measure several chemistry and hematology parameters, including serum electrolytes, blood glucose levels, blood urea nitrogen, hematocrit, hemoximetry, lactate, bilirubin, and prothrombin and partial thromboplastin times. It should be noted that unlike conventional analyzers, blood samples for most point-of-care analyzers should not be chilled and should be run within 1 to 2 minutes after being obtained.

These devices are portable, and some can perform 900 tests using a disposable cartridge. They typically include a display screen for accessing menu functions and viewing results. Most devices include a simple keypad or touch screen for data and command entry. Analysis occurs using disposable cartridges or inside a chamber in the body of the unit.

Some devices employ single-use sample cartridges that differ according to the array of tests being performed. Each cartridge contains the necessary calibration solution, a sample handling system, a waste chamber, and miniaturized electrochemical or photochemical sensors. The cartridge system requires no operator oversight because it is self-calibrating and disposable after a single use. After self-calibration and introduction of the sample

FIGURE 19-10 GEM Premier 4000 critical care analyzer for blood gas, electrolyte, metabolite, and integrated cooximetry testing; the device also performs continuous automated quality assurance. (Courtesy Instrumentation Laboratory, Bedford, MA.)

into the cartridge, the sensors measure the concentration of the analytes and conduct their output signal through conductive contact pads to the analyzer microprocessor. Test results usually are ready within 60 seconds. Waste management involves simple removal and proper disposal of the analysis cartridge.

Other devices use self-contained multiuse cartridge packs that include all testing components, are maintenance-free, and incorporate automated quality control management systems. Multiuse cartridges are typically replaced every 30 days or when testing components are used up.

Clinical Performance. More recent method comparisons indicate that portable point-of-care blood gas analyzers can achieve accuracy and precision levels comparable to those with laboratory-based analyzers.[14,25] Such findings have resulted in the widespread use of these systems.

Clinical laboratories have expanded point-of-care testing solutions to improve operational costs, streamline workflow in the clinical laboratory and critical care setting, and provide blood analysis results more quickly.[26,27] Guidelines for providers who are considering adoption of this new technology have been published in the clinical laboratory literature.[28]

BLOOD GAS MONITORING

A blood gas monitor is a bedside tool (usually dedicated to a single patient) that can provide measurements either continuously or at appropriate intervals without permanently removing blood from the patient. Of the systems which are currently in use, two of the most common ones are transcutaneous blood gas monitoring and tissue oxygen monitoring.

TABLE 19-4

Ratios Correlating $PtcO_2$ With PaO_2

Age Group	$PtcO_2/PaO_2$ Ratio	Perfusion Status	$PtcO_2/PaO_2$
Premature infants	1.14:1	Stable	0.79:1
Neonates	1.00:1	Moderate shock	0.48:1
Children	0.84:1	Severe shock	0.12:1
Adults	0.79:1		
Older adults	0.68:1		

From Tobin MJ: Respiratory monitoring. JAMA 264:244–251, 1990.

Transcutaneous Blood Gas Monitoring

Transcutaneous blood gas monitoring provides continuous, noninvasive estimates of arterial PO_2 and PCO_2 through a surface skin sensor. Transcutaneous blood gas monitoring has been used for many decades in infants and now is available for use in adults because of advances in technology. As with capillary sampling, the device arterializes the underlying blood by heating the skin. Warming also increases the permeability of the skin to O_2 and CO_2, which enhances diffusion from the capillaries to the sensor, where they are measured as transcutaneous partial pressures ($PtcO_2$ and $PtcCO_2$).

Numerous factors influence the agreement between arterial blood and transcutaneous gas measurements, with O_2 levels being affected most. The two most important factors are age and perfusion status (Table 19-4). With regard to perfusion status, PaO_2 and $PtcO_2$ are similar only in patients with normal cardiac output and fluid balance, because accurate transcutaneous measures require adequate skin perfusion. Peripheral vasoconstriction and impaired capillary flow decrease the $PtcO_2$; common causes include low cardiac output, shock, and dehydration. Some clinicians use $PtcO_2$ not to monitor oxygenation as a surrogate for PaO_2 but to assess blood flow changes during procedures such as vascular surgery and resuscitation. Agreement between $PaCO_2$ and $PtcCO_2$ is better because CO_2 is more diffusible. $PaCO_2$ changes of 5 mm Hg can be monitored or "trended" by transcutaneous blood gas analysis. Based on these factors, $PtcCO_2$ monitoring is a reasonable choice when there is a need for continuous, noninvasive analysis of trends in ventilation and $PaCO_2$. In hemodynamically stable infants and children, PaO_2 can be "correlated" with $PtcO_2$, thus decreasing the need for repeated arterial samples. Because pulse oximetry cannot provide accurate estimates of excessive blood O_2, the transcutaneous monitor may be useful for monitoring hyperoxia in neonates. However, prevention of hyperoxia in premature neonates is more often achieved by maintaining pulse oximetry saturation between 85% and 93%.[29]

Transcutaneous blood gas monitoring of $PtcCO_2$ can be useful in adult patients during deep sedation and mechanical ventilation in the ED, in the ICU, and during surgery.[30-35] $PtcCO_2$

19-4 Transcutaneous Monitoring of Carbon Dioxide and Oxygen: 2012

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS
- The need to monitor continuously the adequacy of arterial oxygenation or ventilation
- The need to quantify the real-time responses to diagnostic and therapeutic interventions, as evidenced by $PtcO_2$ or $PtcCO_2$ values

CONTRAINDICATIONS
There are no absolute contraindications. In patients with poor skin integrity or adhesive allergy, alternative devices should be considered.

HAZARDS AND POSSIBLE COMPLICATIONS
- False-negative or false-positive results may lead to inappropriate treatment.
- Tissue injury (e.g., erythema, blisters, burns, skin tears) may occur at the measuring site.

ASSESSMENT OF NEED
- When direct measurement of arterial blood is unavailable or not readily accessible, $PtcO_2$ or $PtcCO_2$ measurements may suffice temporarily if the limitations of the data are appreciated.
- Transcutaneous blood gas monitoring is appropriate for continuous and prolonged monitoring (e.g., during mechanical ventilation, continuous positive airway pressure [CPAP], and supplemental oxygen administration).
- $PtcO_2$ values can be used for diagnostic purposes, such as in the assessment of functional shunts or in determining the response to oxygen challenge in the assessment of congenital heart disease.

ASSESSMENT OF OUTCOME
- Results should reflect the patient's clinical condition (i.e., they should validate the basis for ordering the monitoring).
- Results of therapeutic interventions and clinical decisions based on the transcutaneous measurements should be noted in the medical record.

MONITORING
The schedule for patient assessment during transcutaneous monitoring should be integrated into the patient assessment as part of vital signs monitoring. Results should be documented in the patient's medical record and should detail the following conditions:
- Date and time of measurement, transcutaneous reading, patient's position, respiratory rate, and activity level
- Inspired oxygen concentration or supplemental oxygen flow, specifying the type of oxygen delivery device
- Mode of ventilatory support, and ventilator, or CPAP settings
- Electrode placement site, electrode temperature, and time of placement
- Results of simultaneously obtained PaO_2, $PaCO_2$, and pH, when available
- Clinical appearance of the patient and subjective assessment of perfusion, pallor, and skin temperature

**For the complete guideline, see American Association for Respiratory Care: Clinical practice guideline: Transcutaneous monitoring of Carbon Dioxide and Oxygen: 2012s. Respir Care 57:1955, 2012.*

is a more accurate reflection of $PaCO_2$ than both $PETCO_2$ and nasal $ETCO_2$ in intubated and spontaneously breathing adult patients. The use of $PtcCO_2$ in conjunction with pulse oximetry reduces the need for repeated ABG sampling.[36]

To guide practitioners in providing high-quality care, the AARC has published Clinical Practice Guideline: Transcutaneous Blood Monitoring of Carbon Dioxide and Oxygen: 2012.[37] Modified excerpts from the AARC guideline appear in Clinical Practice Guidelines 19-4.

Instrumentation

Figure 19-11 shows a simplified diagram of a transcutaneous blood gas monitor sensor. Included are a heating element and two electrodes, one each for O_2 and CO_2. These electrodes are similar in design to the electrodes found in bench-top analyzers. However, instead of measuring gas tensions in a blood sample, transcutaneous electrodes measure PO_2 and PCO_2 in an

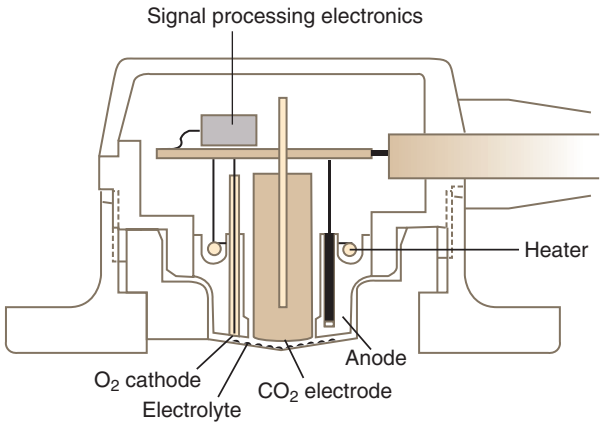

FIGURE 19-11 Schematic diagram of transcutaneous O_2-CO_2 sensor. (Modified from Mahutte CK, Michiels TM, Hassell KT, et al: Evaluation of a single transcutaneous PO_2-PCO_2 sensor in adult patients. Crit Care Med 12:1063–1066, 1984.)

FIGURE 19-12 SenTec Digital Monitoring System, combined $PtcCO_2$ and SpO_2 sensor suitable for neonatal, pediatric, and adult patients. (Courtesy SenTec AG, Therwil, Switzerland.)

Box 19-7 Procedure for Using a Transcutaneous Monitor

- Place the unit at bedside, and provide manufacturer-specified warm-up time.
- Check the membrane to ensure that it is free of bubbles or scratches, and change it if necessary.
- Select the monitoring site by evaluating perfusion, skin thickness, and absence of bones.
- Prepare the sensor with an adhesive ring and electrolyte gel.
- Set the appropriate probe temperature (per the manufacturer's recommendations).
- Prepare the site by removing excess hair and cleaning the skin.
- Securely attach probe to the patient.
- Schedule site change time (2 to 12 hours, depending on patient/device).
- Set the high and low alarms.
- Monitor and document the results per institutional protocol.
- Change site at appropriate intervals.
- Validate the reading against arterial blood gas values.

From Koff PB, Hess D: Transcutaneous oxygen and carbon dioxide measurements. In Kacmarek RM, Hess D, Stoller JK, editors: Monitoring in respiratory care, St Louis, 1993, Mosby.

electrolyte gel between the sensor and the skin. When properly set up, the response time for these electrodes is 20 to 30 seconds, a bit slower than the response time for pulse oximetry.

Figure 19-12 shows a transcutaneous monitor with digital signal processing. A Severinghaus-type $PtcCO_2$ electrode and two-wavelength reflectance SpO_2 are combined into a single sensor. The sensor can be applied to the skin surface in neonates and infants or to the earlobe of pediatric and adult patients for combined noninvasive monitoring of ventilation and oxygenation.

Procedure

Box 19-7 outlines the basic procedure for setting up a transcutaneous blood gas monitor. Once the electrodes are properly set up, the clinician should compare the monitor readings with a concurrent ABG. Consistency between values validates monitor performance under the existing conditions. This validation should be repeated any time the patient's status undergoes a major change. During validation studies of patients with anatomic shunts, the electrode site and arterial sampling site should be on the same "side" of the shunt.

MINI CLINI

Selecting a Monitoring System

PROBLEM: Concerned about retinopathy of prematurity, the RT sets up a noninvasive system to monitor a preterm infant for hyperoxia. What type of system should the RT choose and why?

SOLUTION: Because the infant should be monitored for hyperoxia, a system that provides continuous data would be the best choice. Because hyperoxia is best assessed using PO_2 (as opposed to Hb saturation), the RT needs to use a PO_2 electrode system. A transcutaneous PO_2 electrode system would provide the needed measurement noninvasively.

Problem-Solving and Troubleshooting

Monitoring requires setup and calibration. In terms of technical limitations, transcutaneous blood gas sensors must be calibrated and maintained using methods similar to those described for bench-top analyzers. Improper calibration yields erroneous patient information. Meticulous care of the sensor membranes is also essential for proper maintenance.

Because the sensor is heated, clinicians must take care to avoid thermal injury to the patient's skin. Thermal injury can be avoided by careful monitoring of sensor temperature (the safe upper limit is approximately 42° C) and regularly rotating the sensor site. Proper sensor-electrolyte contact is essential, as is proper application to the skin surface.

When arterial and transcutaneous blood gas values are inconsistent with each other or with the clinical status of the patient, the clinician should explore possible causes before reporting any results. Often, discrepancies can be reduced by switching the monitoring site or recalibrating the instrument. If these steps fail to resolve the inconsistencies, the clinician should recommend an alternative method for assessing gas exchange, such as pulse oximetry or more frequent ABG analysis.

Tissue Oxygen

Tissue O_2 (PtO_2) can be measured by probes inserted directly into organs, tissue, and body fluids. Ease of probe placement and the sensitivity of PtO_2 as an indicator of tissue perfusion make tissue O_2 monitoring attractive for clinical research applications. Clinical indications for measuring PtO_2 include monitoring brain tissue O_2 as an early sign of ischemia, assessing brain blood flow autoregulation, and monitoring the adequacy of brain perfusion in patients with traumatic brain injury.[38] In patients with traumatic brain injury, brain PtO_2 values are between 25 and 30 mm Hg when intracranial pressure and cerebral perfusion are normal. The critical threshold for ischemic brain damage and poor outcome is suspected to be at a brain PtO_2 of approximately 10 to 15 mm Hg.[38]

Instrumentation

Both electrochemical and **optical fluorescence tissue** O_2 probes have been developed for clinical use and research applications.

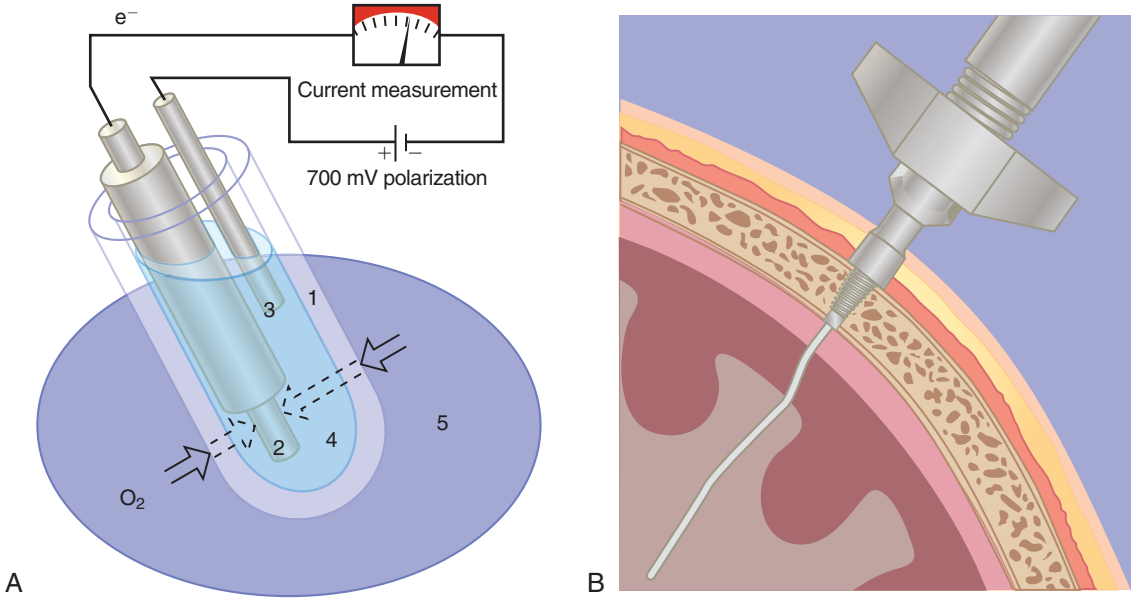

FIGURE 19-13 **A,** Schematic of Clark-type polarographic tissue oxygen probe. Polyethylene membrane *(1)*, gold cathode *(2)*, silver anode *(3)*, electrolyte solution *(4)*, cerebral tissue *(5)*. **B,** Insertion into cerebral tissue. (From Mulvey JM, Dorsch NW, Mudaliar Y, et al: Multimodality monitoring in severe traumatic brain injury: the role of brain tissue oxygenation monitoring. Neurocrit Care 1:391–402, 2004.)

Figure 19-13 shows a Clarke-type polarographic sensor and its insertion into brain tissue through an intracranial bolt. **Optode** probes capable of monitoring tissue pH, CO_2, and O_2 have also been developed.[39]

OXIMETRY

Oximetry is the measurement of blood Hb saturations using **spectrophotometry.** According to the principles of spectrophotometry, every substance has a unique pattern of light absorption, similar to a fingerprint. The pattern of light absorption of a substance varies predictably with the amount present; this is known as the *Lambert-Beer law*. By measuring the light absorbed and transmitted by a substance, scientists can identify its presence and determine its concentration.

The particular pattern of light absorption exhibited by a substance at different wavelengths is called its *absorption spectrum*. As shown in Figure 19-14, each form of Hb (i.e., reduced Hb, HbO_2, HbCO, metHb) has its own unique pattern. By comparing the amount of light transmitted through (or reflected from) a blood sample at two or more specific wavelengths, the relative concentrations of Hb forms can be measured. For example, oxygenated Hb absorbs less red light (600 to 750 nm) and more infrared light (850 to 1000 nm) than deoxygenated or reduced Hb. Comparing a blood sample's light absorption with red and infrared light yields the $\%HbO_2$ and %Hb. When measuring additional forms of Hb, additional (more than two) wavelengths of light must be used.

Several types of oximetry are used in clinical practice, including hemoximetry (also called *cooximetry*), pulse oximetry, venous oximetry, and tissue oximetry. Hemoximetry is a laboratory analytic procedure requiring invasive sampling of arterial blood. Pulse oximetry is a noninvasive monitoring technique performed at the bedside. Venous oximetry requires invasive monitoring through a fiberoptic catheter placed in the vena cava or PA. Tissue oximetry is a noninvasive method of measuring the saturation of Hb at the tissue level.

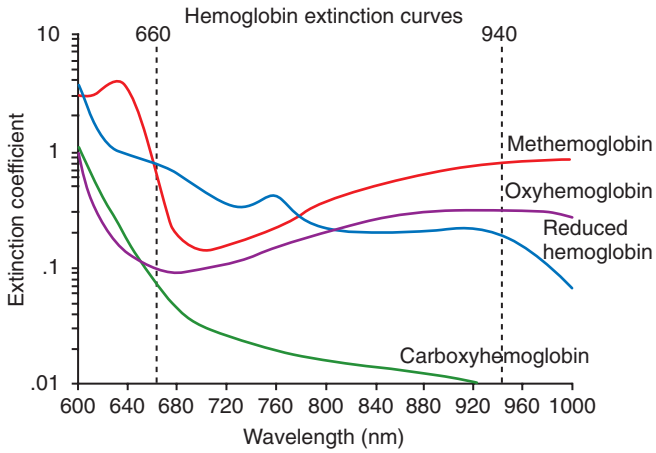

FIGURE 19-14 Principle of spectrophotometric oximetry. Different forms of hemoglobin (e.g., reduced Hb, HbO_2, HbCO, metHb) absorb light differently at different wavelengths. By comparing points of equal absorbance (isobestic points) between pairs of Hb forms (e.g., Hb vs. HbO_2, Hb vs. HbCO), the relative proportion of each can be measured.

Hemoximetry

Hemoximetry (known in some settings as *cooximetry*) is an analytic method of oximetry and is covered in the AARC Clinical Practice Guideline: Blood Gas Analysis and Hemoximetry[15]

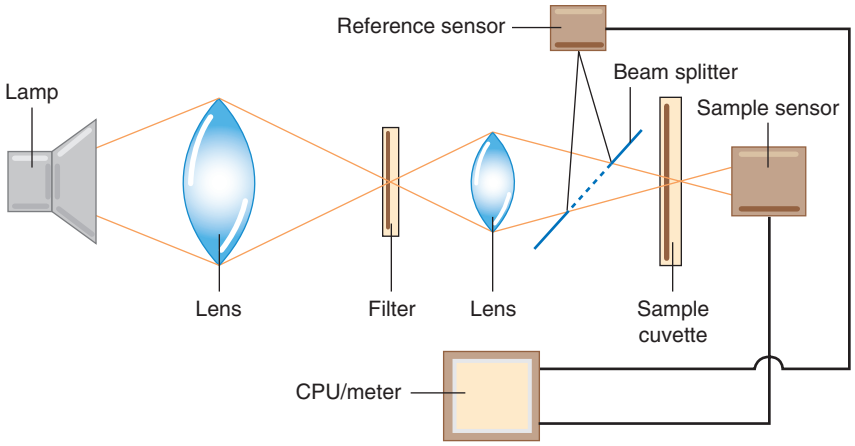

FIGURE 19-15 Simplified diagram showing key components of a laboratory hemoximeter. (Modified from Lane EE: Clinical arterial blood gas analysis, St Louis, 1987, Mosby.)

(see Clinical Practice Guideline 19-3). Related recommendations have been published by CLSI.[9]

Instrumentation

Figure 19-15 is a simplified diagram showing the key components of a laboratory hemoximeter. Light generated by a thallium cathode lamp passes through a series of lenses and filters, yielding the specific wavelengths needed for analysis. A beam splitter divides the light into two portions, directing one through a reference solution and the other through a sample chamber, or **cuvette.** Photodetection sensors measure the amount of light transmitted through these two sources. By comparing the difference in light transmission through the reference and sample solutions, a microprocessor computes the relative amount of Hb present, with its output sent to the calibrated device meter or display. Because a laboratory hemoximeter uses four or more different wavelengths of light, it can simultaneously compute the relative concentrations of multiple forms of Hb, such as reduced Hb, HbO_2, HbCO, and metHb.

Procedure and Quality Assurance

Similar to modern blood gas analyzers, laboratory hemoximeters are highly automated and simple to use. Some devices now combine both technologies into a single instrument. However, the caveats remain the same. Accurate and clinically useful hemoximetry results can be expected only if an error-free sample is assessed on a calibrated analyzer, using the manufacturer's protocol.

Although variations exist among devices, the basic procedure is similar. First, the blood is introduced into the sampling port of the analyzer, usually by either aspiration or injection. Required sample sizes vary from approximately 200 mcl to 40 mcl (microanalysis). Once introduced, erythrocyte Hb is released into the solution by hemolysis. After hemolysis, the sample is transported to the cuvette for analysis. On completion of the analysis, the sampling system (cuvette and tubing) is flushed and cleaned. As with blood gas analysis, operators must follow CDC standard precautions and ensure proper disposal of syringes and waste materials.

TABLE 19-5

Problems Causing Measurement Errors With Hemoximeters

Problem	Potential Error
Incomplete hemolysis	Falsely low total Hb, HbO_2
Sickle cell anemia (caused by incomplete hemolysis)	Falsely low HbO_2
Presence of vascular dyes (e.g., methylene blue)	Falsely low total Hb, HbO_2
High lipid levels (e.g., from parenteral nutrition)	Falsely low total Hb, HbO_2
Presence of high levels of fetal hemoglobin	Falsely high HbCO
Elevated bilirubin levels (>20 mg/dl)	Falsely high total Hb, HbO_2, metHb
Dirty cuvette chamber	Falsely high total Hb, HbO_2

Quality assurance procedures for hemoximetry are essentially the same as the procedures used for blood gas analysis, differing only with regard to the control materials used. In addition, careful cleaning and maintenance of the cuvette chamber is essential because clouding of its walls decreases absorbance and can cause falsely elevated values.[40]

Problem-Solving and Troubleshooting

A major assumption underlying hemoximetry is that the measured changes in light absorbance result only from variations in the relative concentrations of various Hbs. In practice, this assumption does not always hold true. Table 19-5 outlines some of the potential problems and resulting errors that can occur with hemoximetry.

Pulse Oximetry

Pulse oximeters are portable noninvasive monitors that estimate arterial blood oxyhemoglobin saturation levels. So as not to confuse these estimates with actual SaO_2 measures obtained by hemoximetry, the abbreviation SpO_2 is used to refer to pulse oximetry readings. No other device in recent medical history has been so widely and quickly adopted into clinical practice.

19-5 Pulse Oximetry

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS
- To monitor the adequacy of arterial oxyhemoglobin saturation
- To quantify the response of arterial oxyhemoglobin saturation to therapeutic intervention or to diagnostic procedures, such as bronchoscopy
- To comply with mandated regulations or recommendations by authoritative groups

CONTRAINDICATIONS
The ongoing need for actual measurements of pH, $PaCO_2$, total Hb, and abnormal Hb may be a relative contraindication to pulse oximetry.

PRECAUTIONS
- Device limitations causing false-negative results for hypoxemia or false-positive results for normoxemia or hyperoxemia may lead to inappropriate treatment of patients.
- Factors affecting SpO_2 accuracy include motion artifact, abnormal Hbs, intravascular dyes, low perfusion states, skin pigmentation, and nail polish.

ASSESSMENT OF NEED
- When direct measurement of SaO_2 is unavailable or not readily accessible, a pulse oximetry measurement may temporarily suffice if the limitations of the data are appreciated.
- SpO_2 is appropriate for continuous and prolonged monitoring (e.g., during sleep, exercise, or bronchoscopy).
- SpO_2 may be adequate when assessment of acid-base status or PaO_2 is not required.

ASSESSMENT OF OUTCOME
The following should be used to evaluate the benefits of pulse oximetry:
- SpO_2 results should reflect the patient's clinical condition.
- Documenting the results of therapeutic interventions, and clinical decisions based on the SpO_2 measurements should be noted in the medical record.

FREQUENCY
After initially establishing agreement between SaO_2 and SpO_2, the frequency of SpO_2 monitoring (i.e., continuous vs. spot check) depends on the clinical status of the patient, the indications for performing the procedure, and recommended guidelines. For example, continuous SpO_2 monitoring is indicated throughout a bronchoscopy to detect desaturation, whereas a spot check may suffice for evaluating oxygen therapy in a stable postoperative patient. Direct measurement of SaO_2 is needed whenever SpO_2 does not confirm or verify suspicions about the patient's clinical state.

MONITORING
Continuous pulse oximetry monitoring, should be incorporated into the bedside assessment of a patient's vital signs.

**For the complete guideline, see American Association for Respiratory Care: Clinical practice guideline: sampling for arterial blood gas analysis. Respir Care 37:891, 1992.*

However, its rapid embracement has been accompanied by equally sweeping misconceptions regarding the appropriate applications and technologic limitations.[41] Moreover, the true impact of pulse oximetry on patient outcomes is unknown.[42] To guide practitioners in providing quality care, the AARC has published Clinical Practice Guideline: Pulse Oximetry.[43] Modified excerpts from the AARC guideline appear in Clinical Practice Guideline 19-5.

Instrumentation

The pulse oximeter combines the principle of spectrophotometry, as used by hemoximeters, with **photoplethysmography.** Photoplethysmography uses light to detect the tiny volume changes that occur in living tissue during pulsatile blood flow. However, compared with a hemoximeter, the pulse oximeter usually uses only two wavelengths of light, one red (approximately 660 nm) and one infrared (approximately 940 nm) (see Figure 19-14). In addition, rather than measuring light transmission through a blood sample in a glass cuvette, the pulse oximeter measures transmission through living tissue, such as a finger or earlobe, or reflectance through the skin surface.

Figure 19-16, *A* provides a schematic block diagram of a pulse oximeter, consisting of a transmission sensor, processor, and display unit. The sensor has two sides. From one side, separate red and infrared light-emitting diodes (LEDs) alternately transmit light through the tissue. The transmitted light intensity is measured by a photodetector on the other side. The resulting output signal is filtered and amplified by instrument electronics, with processing and display functions controlled by a microprocessor.

Figure 19-16, *B* shows a schematic of a reflectance pulse oximeter sensor. This type of sensor has only one side, which contains both the LED light sources and the photodetector. The principle of operation is identical to a transmission sensor except that the sensor is placed on the skin surface, usually the forehead, and reflected light from the tissue back to the sensor is used to calculate SpO_2.

Figure 19-17 shows a typical output signal generated by the photodetector (the pulsatile component can be observed on

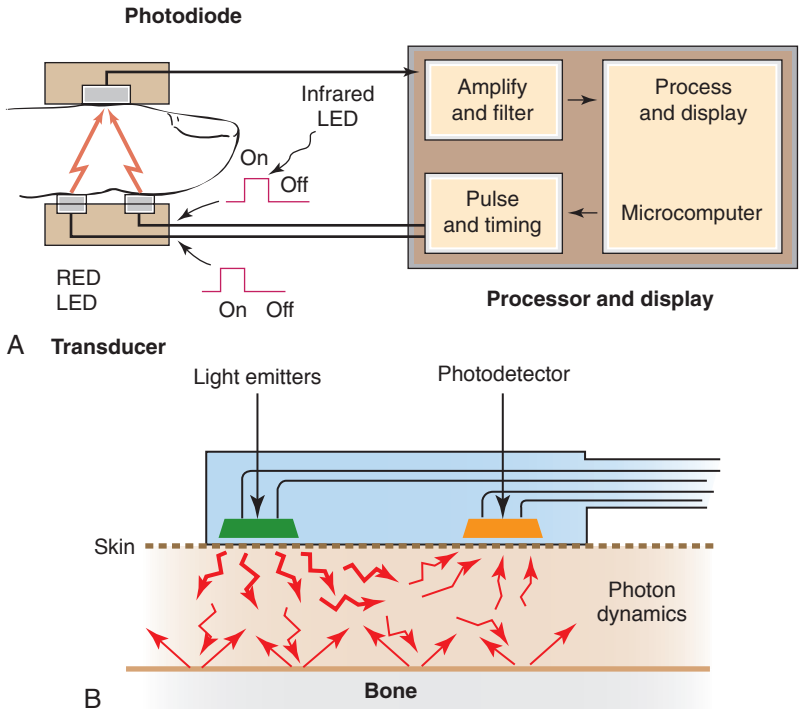

FIGURE 19-16 **A,** Schematic block diagram of a transmission pulse oximeter sensor and monitor. **B,** Schematic of a reflectance pulse oximeter sensor. *LED,* Light-emitting diode. (**A,** Modified from Gardner R: Pulse oximetry: is it monitoring's "silver bullet"? J Cardiovasc Nurs 1:79–83, 1987; **B,** from Keogh BF, Kopotic RJ: Recent findings in the use of reflectance oximetry: a critical review. Curr Opin Anaesthesiol 18:649–654, 2005.)

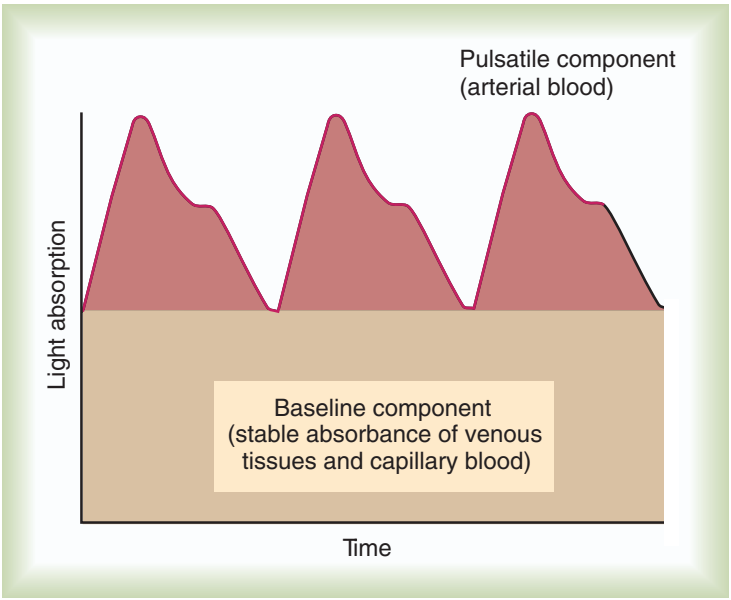

FIGURE 19-17 Output signal generated by pulse oximeter. Saturation is based on the ratio of light absorption between two or more wavelengths during pulsatile and baseline phases.

instruments that have a plethysmographic display). A baseline component represents the stable absorbance of the tissue bed, which mainly represents venous and capillary blood. At the top is the pulsatile component, caused by intermittent arterial flow through the tissues. By comparing light absorbance during the pulsatile phase with the baseline value at each wavelength, a pulse-added measure is obtained. Arterial oxyhemoglobin saturation is computed as the ratio of the pulse-added absorbances at the two different wavelengths.

The accuracy of pulse oximetry readings is usually within ± 3% to 5% of invasive hemoximetry readings.[43,44] Generally, the lower the actual SaO_2, the less accurate and reliable is the SpO_2 measurement. Most clinicians consider pulse oximeter readings unreliable at saturations less than 80%. Instrument response

Box 19-8 Key Points for Performing Pulse Oximetry

- Always follow manufacturer's recommended protocol.
- Never mix sensors among different devices.
- Ensure the sensor is the correct size for the site chosen.
- Ensure the sensor is properly applied (not too tight or loose).
- Before taking or recording a reading, confirm the adequacy and accuracy of the pulse signal.
- When doing spot checks, allow sufficient response time before taking a reading because response times vary greatly.
- For continuous monitoring of adults and children, set the low alarm at 88% to 92%.
- Whenever possible, validate the initial SpO_2 reading against the actual SaO_2.
- Clean multiuse sensors and disinfect the instrument housing between patients.
- Inspect the sensor site frequently throughout the duration of continuous monitoring and change it as needed.
- Never act on SpO_2 readings alone.
- Avoid using pulse oximetry to monitor hyperoxia in neonates.

times vary by manufacturer, sensor location, and the patient's hemodynamic status from 10 seconds to 1 minute or longer.

Procedure

The actual procedure used to measure SpO_2 varies according to the device used, sensor site selected, and whether a spot check or continuous monitoring is required. Box 19-8 lists key points to be considered when performing pulse oximetry.

Given the limits of this technology, meticulous documentation is important. Specifically, all SpO_2 results should be recorded in the patient's medical record. The following details should be documented:

- Date, time of measurement, and reading
- Patient's position, activity level, and location during monitoring
- FiO_2 or O_2 flow and O_2 delivery device
- Probe type and placement site
- Model of device (if more than one device is available for use)
- Results of simultaneously obtained ABGs and hemoximetry (if available)
- Stability of readings (length of observation time and range of fluctuation)
- Patient's clinical appearance, including assessment of perfusion at the measuring site (e.g., cyanosis, skin temperature)
- Agreement between oximeter and actual patient heart rate, as determined by palpation or electrocardiogram

RULE OF THUMB

When using a pulse oximeter to detect hypoxemia in an otherwise healthy adult, never set the low alarm below 92%. Generally, this level ensures that the alarm is activated before true arterial saturation drops below that critical.

MINI CLINI

Troubleshooting Pulse Oximetry

PROBLEM: The RT draws an ABG sample from a conscious and alert patient in a postsurgical unit who also is being monitored with a pulse oximeter, which reads 80% saturation. The patient is breathing 35% O_2 through an air-entrainment mask. The patient's extremities are pink and warm. After running the blood sample through a calibrated ABG analyzer with a hemoximeter, the RT obtains the following values:

PaO_2 = 90 mm Hg
Hb = 12 g/dl
SaO_2 = 98%
metHb = 0.5%
HbCO = 1%

Explain the difference between the pulse oximeter and hemoximeter readings of this patient's blood O_2 levels and what action the RT should take.

SOLUTION: Given that a calibrated hemoximeter provides more accurate results than a pulse oximeter and that the patient exhibits no signs of hypoxemia, it is likely that the pulse oximeter reading is falsely low. Because the total Hb and metHb levels are not grossly abnormal, potential problems include motion artifact, poor sensor placement, and device malfunction. The oximeter and sensor should be rechecked, and, if found to be malfunctioning, they should be replaced.

Problem-Solving and Troubleshooting

Problems with pulse oximetry fall into two categories: (1) inherent technology problems and (2) problems associated with clinical interpretation of the data. Dozens of technical factors may affect the readings, limit the precision, or alter the performance of pulse oximeters. Table 19-6 summarizes the most important of these factors and the types of errors they cause.

Motion artifact probably is the most common source of error and false alarms. Although new technologies promise to reduce motion artifact, relocation of the sensor to the earlobe, toe, or forehead can minimize the problem. Falsely elevated readings can occur with dark skin pigmentation at low saturation levels; this can be compensated for by setting oximeter low alarms 3% to 5% higher in applicable cases.

Early studies on the effects of nail polish found significant differences in lowering SpO_2 readings. More recent studies have found either no effect or small differences that are considered clinically irrelevant; this may be due to improvements in LED light sources.[45,46] The effect of nail polish may be minimized by using a different site or by rotating the sensor so that the light path does not cross the fingernails.

If ambient light interference is creating problems, the sensor can be loosely covered with an opaque towel or cloth. Problems that occur during procedures producing electromagnetic interference (e.g., electrocautery, magnetic resonance imaging) need only be recognized. Careful monitoring of the patient during episodes of false low alarms is essential.

TABLE 19-6

Factors Affecting Accuracy or Precision of Pulse Oximeters

Factor	Potential Error
Presence of HbCO	Falsely high $\%HbO_2$
Presence of high levels of metHb	Falsely low $\%HbO_2$ if SaO_2 >85% Falsely high $\%HbO_2$ if SaO_2 <85%
Presence of fetal hemoglobin	No effect
Anemia (very low hematocrit, <10%)	Falsely low CaO_2 and high $\%HbO_2$
Vascular dyes (e.g., methylene blue)	Falsely low $\%HbO_2$
Elevated bilirubin levels	No effect
Dark skin pigmentation	Falsely high $\%HbO_2$ (3%-5%)
Nail polish (especially black)	Falsely high $\%HbO_2$
Ambient light	Varies (e.g., falsely high $\%HbO_2$ in sunlight); also may cause falsely high pulse reading
Poor perfusion (vasoconstriction)	Inadequate signal; unpredictable results
Motion artifact	Unpredictable, spurious readings
Electrocautery	Falsely low HbO_2
Magnetic resonance imaging	Falsely low HbO_2

RULE OF THUMB

If the pulse oximeter is reading a critically low value (<90%) but the patient appears in no distress, then it is likely that there is an erroneous pulse oximeter reading. In such situations is best to further assess the patient's clinical status and troubleshoot the pulse oximetry equipment setup. If further examination suggests that the patient is stable, it is likely that the problem is the is equipment related and the setup, including the sensor, should be checked.

Regarding problems with interpreting pulse oximetry data, rule number one is to treat the patient, not the monitor. The clinician should never interpret or act on monitoring data without first assessing the patient and verifying proper sensor placement and signal quality. A related problem is simple confusion over the relationship between oxyhemoglobin saturation and PO_2. Many clinicians rely solely on PaO_2 readings to assess oxygenation and do not understand oxyhemoglobin saturation. To these clinicians, an SpO_2 reading of 80% might be confused easily with PaO_2 of 80 mm Hg. The latter measure of partial pressure is normal, whereas a saturation of 80% indicates moderate to severe hypoxemia, equivalent to PaO_2 of approximately 50 mm Hg.

A similar interpretation error (PaO_2 vs. SpO_2) occurs because of the limited accuracy of most pulse oximeters. It is common practice to set the low alarm of a monitoring oximeter to 90%. In theory, this practice makes sense because an SaO_2 reading of 90% normally corresponds to a PO_2 reading of approximately 60 mm Hg (the lower limit of clinically acceptable oxygenation). However, with the accuracy of some oximeters being only ± 4%, an SpO_2 reading of 90% could mean an actual SaO_2 reading of 86%, corresponding to a PO_2 level of 55 mm Hg or less.

At the high end, oximetry data can be even less meaningful. Because of the characteristics of the oxyhemoglobin dissociation curve (see Chapter 12), a patient with an SpO_2 reading of 100% could represent a PaO_2 level between 100 and 600 mm Hg. Therefore pulse oximetry should not be used for monitoring hyperoxia (as is important for neonates).

It is also important to remember that a pulse oximeter does not measure PCO_2. A patient breathing an elevated FiO_2 can have normal SpO_2 readings despite severe hypercarbia. ABG analysis is needed when acute ventilatory failure may be present.

SpO_2 can read falsely high when carbon monoxide poisoning or methemoglobinemia is present. This false reading is due to the fact that the two-wavelength pulse oximeter measures only saturation of the Hb and not specifically saturation with O_2. HbCO and metHb cannot be distinguished from HbO_2 with a pulse oximeter. A falsely high SpO_2 reading occurs when significant HbCO is present. When metHb is elevated, the SpO_2 reading is higher than the actual measured SaO_2. As metHb level increases, SpO_2 decreases and plateaus at approximately 85% when the metHb level reaches 30%.[47]

To address these limitations, pulse oximeters using seven or more wavelengths of light have been developed. Use of multiwavelength pulse oximeters capable of measuring reduced Hb, HbO_2, HbCO, and metHb has been referred to as **pulse cooximetry.** The accuracy of these measurements does not equal that of conventional hemoximetry (cooximetry), but pulse cooximetry may be useful for trend monitoring in some clinical situations (e.g., monitoring therapy for acute carbon monoxide poisoning in the emergency department).[48]

As with transcutaneous monitoring, if pulse oximetry and blood gas values are inconsistent with each other, or the clinical status of the patient, the RT should explore possible causes before reporting, interpreting, or acting on results. Often, discrepancies can be reduced by switching sites or replacing the sensor probe. If these steps fail to resolve the inconsistencies, the RT should document the problem and recommend obtaining an ABG measurement with hemoximetry if indicated.

Venous Oximetry

Continuous central venous (vena cava) and mixed venous (PA) O_2 saturation monitoring ($S\bar{v}O_2$) is performed to assess the balance between O_2 delivery and use as an indirect index of global tissue oxygenation and perfusion. Decreased $S\bar{v}O_2$ is indicative of cardiac failure in patients with myocardial infarction and after cardiovascular surgery, as well as in patients with severe cardiopulmonary disease, including those in septic or cardiogenicshock.[49] Regional and organ-specific $S\bar{v}O_2$ monitoring has been performed via catheters placed in the coronary sinus, hepatic vein, and cranial jugular venous bulb for cerebral perfusion monitoring. Normal values for $S\bar{v}O_2$ range from 60% to 80%.

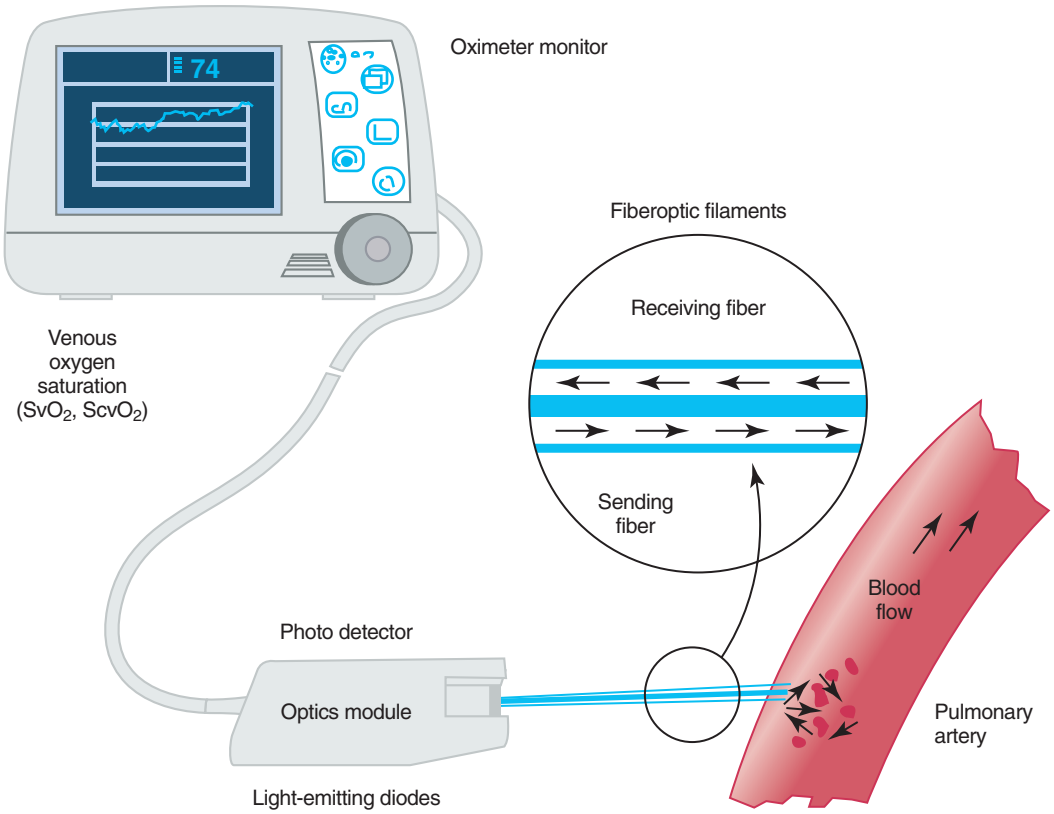

FIGURE 19-18 Diagram of a venous oximetry monitoring system using reflectance oximetry. (Courtesy Edwards Life Science, Irvine, CA.)

Instrumentation

Figure 19-18 shows a diagram of an $S\bar{v}O_2$ monitoring system. Venous oximetry is measured through a fiberoptic catheter by reflectance spectrophotometry. Two or three wavelengths of light are emitted from LEDs through fiberoptic filaments into the venous blood. Some of this light is reflected back and received through another fiberoptic channel, which is read by a photodetector. The amount of light that is absorbed by the venous blood and reflected back is determined by the amount of O_2 that is saturated or bound to Hb. This information is processed by the monitor, updated, and displayed as $S\bar{v}O_2$.

Clinical Usefulness

Continuous $S\bar{v}O_2$ can be monitored through an $S\bar{v}O_2$-equipped PA catheter or venous catheter. Mixed venous oximetry from the PA is an indication of global O_2 use. Central venous oximetry is nearly interchangeable with mixed venous oximetry. Both correlate with mixed venous saturation measured by hemoximetry with an accuracy of ± 3% to 5%. Accuracy of venous oximetry monitoring depends on several factors, including the frequency of calibration with measured $S\bar{v}O_2$ and Hb, the position of the catheter free floating in the vein, the absence of wall artifact, damage to the fiberoptic filaments, and clot formation at the catheter tip.[50,51]

Tissue Oximetry

Tissue level O_2 saturation (StO_2) assesses the adequacy of circulation and O_2 delivery. Low StO_2 can be used for early detection of tissue hypoperfusion in patients with traumatic injuries.[52] Cerebral StO_2 monitoring also can be used to monitor brain oxygenation and detect cerebral ischemia during neurosurgical or cardiovascular procedures.[53]

Instrumentation

Tissue oximetry is essentially a reflectance oximeter that uses near-infrared spectroscopy to measure StO_2. Multi-wavelengths of light in the near-infrared spectrum transilluminate muscle tissue in the hand or brain through the forehead. Because biologic tissue, including the skull, is relatively transparent in the near-infrared range, the absorbance and reflectance characteristics of HbO_2 and reduced Hb concentrations in the tissue being monitored is used to calculate StO_2. To date, StO_2 monitoring is used primarily for research purposes but may eventually be used for clinical practice.

CAPNOMETRY AND CAPNOGRAPHY

Capnometry is the measurement of CO_2 in respiratory gases. A capnometer is the device that measures CO_2. **Capnography** is the graphic display of CO_2 levels versus time (scalar display) as they change during breathing. **Volumetric capnography** is the graphic displaying of CO_2 versus expired tidal volume that allows for the measurement of physiologic dead-space fraction and volumetric CO_2 excretion.[54]

Although capnography can be applied to any patient, its primary clinical use is for monitoring during either general

anesthesia (where it is a standard of care) or mechanical ventilation. Other common indications include use during a cardiopulmonary resuscitation to both identify the proper placement of an artificial airway and to assess the effectiveness in restoring adequate perfusion pressures, which are discussed elsewhere in this text. However, the following section of this chapter focuses mainly on the application of capnography and capnometry during mechanical ventilation. To guide practitioners in providing quality care, the AARC has published Clinical Practice Guideline: Capnography/Capnometry During Mechanical Ventilation: 2011.[55] Modified excerpts from the AARC guideline appear in Clinical Practice Guidelines 19-6.

Instrumentation

The key component in a capnograph is a rapid-responding CO_2 analyzer. Rapid CO_2 analysis can be achieved using infrared absorption, Raman scattering, mass spectroscopy, or photoacoustic technology, with the infrared capnometer being the most common.

Figure 19-19 provides a simple schematic of a double-beam infrared capnometer. A filtered infrared light source passes through a sample chamber. (Because glass absorbs infrared radiation, the chamber "windows" usually are constructed with sodium chloride or sodium bromide.) After the infrared light

19-6 Capnography and Capnometry During Mechanical Ventilation: 2011

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

There are three broad categories of indications for capnography/capnometry:

- Verification of artificial airway placement (determining that tracheal, rather than esophageal, intubation has been accomplished)
- Assessment of pulmonary circulation and respiratory status
- Improve the matching of $\dot{V}/\dot{Q}$
- Measurement of the volume of CO_2 elimination to assess metabolic rate or alveolar ventilation
- Optimization of mechanical ventilation
- Improve the V_D/V_T ratio
- Continued monitoring of the integrity of the ventilatory circuit, including the artificial airway
- Evaluation of the efficiency of mechanical ventilatory support (by [PaCO2 – $PETCO_2$])

CONTRAINDICATIONS

There are no absolute contraindications to capnography in mechanically ventilated patients, provided that the data obtained are evaluated with consideration given to the patient's clinical condition.

HAZARDS AND POSSIBLE COMPLICATIONS

- Misunderstanding of the data provided may lead to inappropriate treatment of the patient.
- With mainstream analyzers, too large a sampling window can excessively increase the circuit mechanical dead space.
- The sampling window or the sampling lines can place additional weight on the circuit and increase traction on the patient's artificial airway (primarily a concern in young pediatric patients).
- With sidestream analyzers, the sampling rate may cause auto-triggering of mechanical ventilators.

ASSESSMENT OF NEED

- Capnography is a standard of care during general anesthesia. The American Society of Anesthesiologists has suggested that capnography be available for patients with acute ventilatory failure on mechanical ventilatory support.[56] The American College of Emergency Physicians recommends capnography as an adjunctive method to ensure proper endotracheal tube position.[57] The 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care recommend capnography to verify endotracheal tube placement in all age groups.[58]
- Assessing the need for capnography in a specific patient is guided by the clinical situation; in particular both the primary cause and the severity of respiratory failure should be considered.

ASSESSMENT OF OUTCOME

Results should reflect the patient's condition. Documentation of results (along with all ventilatory and hemodynamic variables available), therapeutic interventions, and clinical decisions made based on the capnogram should be included in the patient's medical record.

MONITORING

During capnography, the following should be considered and monitored:

- *Ventilatory variables:* Tidal volume, respiratory rate, minute ventilation, peak airway pressure, plateau pressure, positive end expiratory pressure, inspiratory/expiratory time ratio, and concentrations of respiratory gas mixture
- *Hemodynamic variables:* Systemic and pulmonary blood pressures, cardiac output, and intrapulmonary shunt

**For the complete guideline, see American Association for Respiratory Care: Clinical Practice Guideline: Capnography/Capnometry During Mechanical Ventilation. Respir Care 56:503, 2011.*

passes through the sample chamber, a lens focuses the remaining, unabsorbed radiation onto an electrical photodetector. Because CO_2 absorbs infrared radiation, the greater the concentration of CO_2 in the sample, the less is the infrared light that arrives at the detector. Variations in the concentration of CO_2 alter the electrical output signal of the detector. This signal is used either to display the CO_2 concentration with LEDs (capnometer) or to generate a real-time graphic display (capnogram).

Capnometers use two different methods to sample the respiratory gases: mainstream sampling and sidestream sampling (Figure 19-20). The mainstream analyzer places an in-line analysis chamber between the patient's airway and the ventilator circuit. The sidestream analyzer uses a sampling tube to pump a small volume of gas continually from the ventilator circuit into the analysis chamber within the device. Box 19-9 lists the

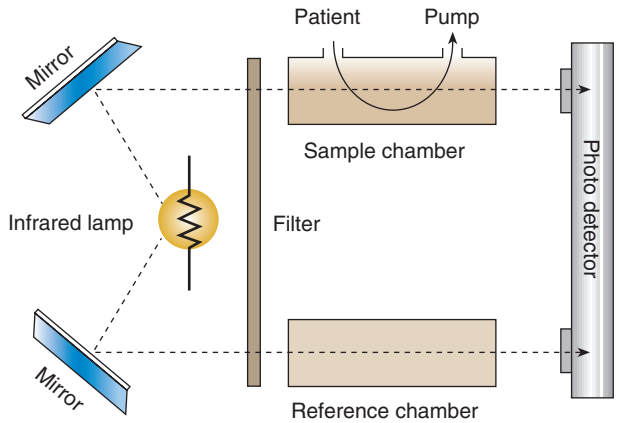

FIGURE 19-19 Schematic representation of infrared capnometer.

Box 19-9 Advantages and Disadvantages of Mainstream and Sidestream Capnometers

MAINSTREAM

Advantages

- Sensor at patient airway
- Fast response (crisp waveform)
- Short lag time (real-time readings)
- No sample flow to reduce tidal volume

Disadvantages

- Secretions and humidity can block sensor window
- Sensor requires heating to prevent condensation
- Requires frequent calibration
- Bulky sensor at patient airway
- Does not measure N_2O
- Difficult to use with nonintubated patients
- Reusable adapters require cleaning and sterilization

SIDESTREAM

Advantages

- No bulky sensors or heaters at airway
- Ability to measure N_2O
- Disposable sample line
- Ability to use with nonintubated patients

Disadvantages

- Secretions block sample tubing
- Trap required to remove water from sample
- Frequent calibration required
- Slow response to CO_2 changes
- Lag time between CO_2 change and measurement
- Sample flow may decrease tidal volume

From Kacmarek RM, Hess D, Stoller J, editors: Monitoring in respiratory care, St Louis, 1993, Mosby.

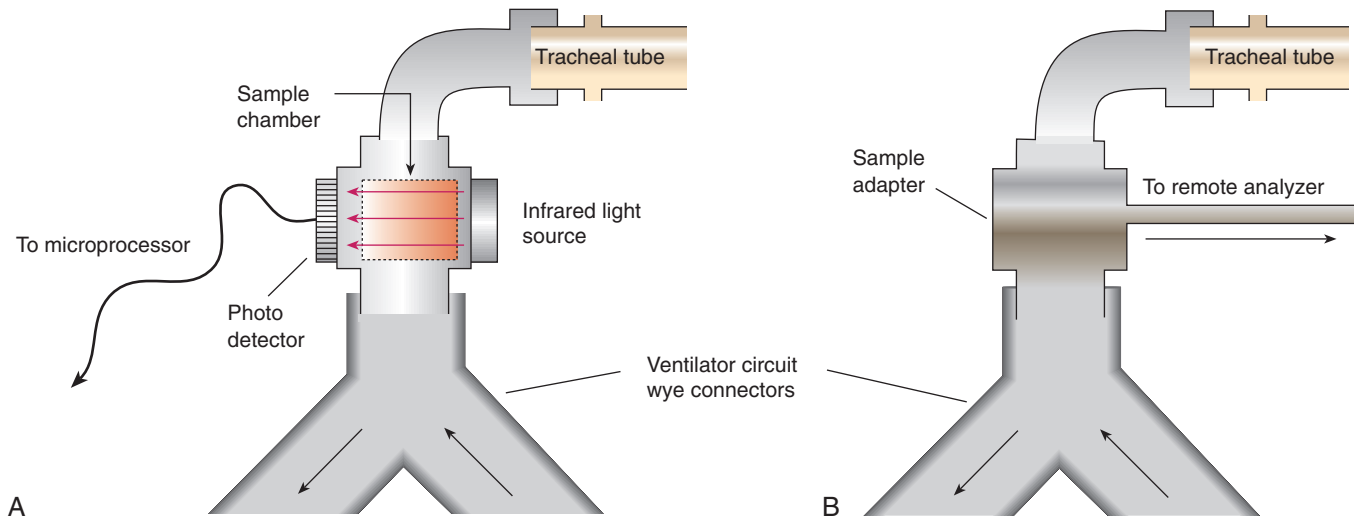

FIGURE 19-20 **A,** Mainstream CO_2 sampling. The sample chamber, light source, and photodetector are attached to the breathing circuit, with the output signal sent to a microprocessor for analysis and display. **B,** Sidestream CO_2 sampling through an in-line sampling adapter with a small-bore connector. A small sample of expired gas is drawn continuously through the tubing and analyzed inside a remote capnometer.

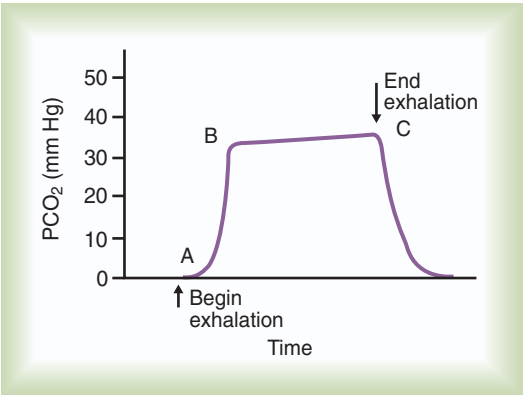

FIGURE 19-21 Normal single-breath capnograph tracing.

advantages and disadvantages of these two approaches. Differences notwithstanding, clinicians should use the method best suited to the patient's needs.

Interpretation

Interpretation of the capnogram can be useful in assessing trends in alveolar ventilation and detecting ventilation/perfusion ratio ($\dot{V}/\dot{Q}$) imbalance caused by either pulmonary disease or cardiovascular disorders. Capnometry also is used to measure physiologic dead space, detect esophageal intubation, assess blood flow during cardiac arrest, and guide setting positive end-expiratory pressure levels. To interpret abnormal events, clinicians first must understand the normal capnogram.

Normal Capnogram

Figure 19-21 shows a typical normal single-breath capnogram. Initially, the expired PCO_2 is 0 mm Hg, indicating exhalation of pure dead space gas from the airways (*A*, phase I). Soon after, alveolar gas begins mixing with dead space gas in the airways, causing a rapid increase in expired PCO_2 (*A* to *B*, phase II). The CO_2 concentration then reaches a plateau indicates exhalation of alveolar gas (*B* to *C*, phase III). Gas sampled at the end of exhalation is called *end-tidal gas,* with its partial pressure of CO_2 abbreviated as $PETCO_2$. In healthy individuals, $PETCO_2$ averages 3 to 5 mm Hg less than $PaCO_2$, or 35 to 43 mm Hg (approximately 5% to 6% CO_2). The sharp downstroke and return to baseline that normally occurs after the end-tidal point indicates inhalation of fresh gas with zero CO_2.

The same phases are also captured during volumetric capnography. The difference is that the area within the V_T-CO_2 curve with each breath is used to calculate the mean expired PCO_2, which in turn is used to calculate physiologic dead-space according to the Bohr-Enghoff equation ($V_D/V_T = [PaCO_2 - PECO_2]/PaCO_2$).[54] The area within the V_T-CO_2 curve (when multiplied by the respiratory rate) calculates CO_2 excretion per minute, which under normal physiologic conditions equals CO_2 production.[54]

Abnormal Capnogram

The first step in assessing the capnogram is to determine the actual $PETCO_2$ and whether it has changed over time. Table 19-7 differentiates between the causes of high and low $PETCO_2$ readings by the suddenness of the change. A $PETCO_2$ of zero usually indicates a system leak, endotracheal tube displacement out of the airway, esophageal intubation, or cardiac arrest.

TABLE 19-7
Conditions Associated With Changes in $PETCO_2$

Change	High $PETCO_2$	Low $PETCO_2$
Sudden	Sudden increase in cardiac output	Sudden hyperventilation
	Sudden release of a tourniquet	Sudden decrease in cardiac output
	Injection of sodium bicarbonate	Massive pulmonary embolism
		Air embolism
		Disconnection of ventilator
		Obstruction of endotracheal tube
		Leakage in the circuit
Gradual	Hypoventilation	Hyperventilation
	Increase in CO_2 production	Decrease in oxygen consumption
		Decreased pulmonary perfusion

NOTE: An absent $PETCO_2$ means that a system leak, esophageal intubation, or cardiac arrest has occurred.

MINI CLINI

Interpreting Capnometry Data

PROBLEM: The RT is monitoring an intubated, mechanically ventilated patient in the ICU with a capnograph. She notices the expired CO_2 level suddenly drop to near zero. On auscultation, the patient exhibits good bilateral breath sounds, and all connections between the airway and capnograph are tight. What is the likely problem?

SOLUTION: The most common causes of a zero $PETCO_2$ are extubation and ventilator or monitoring system disconnection. However, a $PETCO_2$ of zero also can occur with shock or cardiac arrest (no CO_2 returns to the lungs for exhalation). The RT should check this patient's cardiovascular status immediately. If the patient's cardiovascular system is functioning within normal limits, the RT should check the position of the endotracheal tube.

After the capnogram has been assessed for changes in $PETCO_2$, the waveform and its pattern should be analyzed. A normal capnogram starts with a sharp upstroke, followed by a plateau and then a rapid downstroke. As indicated in Figure 19-22, changes in this normal contour may indicate a $\dot{V}/\dot{Q}$ abnormality. Such patterns, although not diagnostic, can indicate the severity of the $\dot{V}/\dot{Q}$ disturbance and warn of developing problems, such as acute pulmonary emboli.

Waveform changes also may occur with equipment malfunction. Because the normal inspired CO_2 level is zero, the capnogram baseline should also be at zero. An elevated baseline (>0 mm Hg) indicates rebreathing. However, an expired CO_2

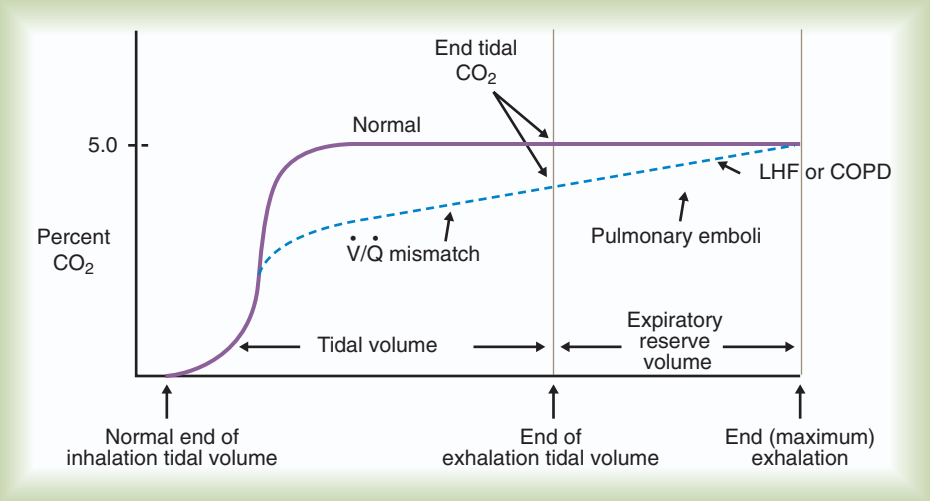

FIGURE 19-22 Normal and abnormal capnogram waveforms. For a healthy individual *(solid line),* the end-tidal CO_2 ($ETCO_2$) at the completion of normal tidal exhalation is equal to end-tidal CO_2 at maximum exhalation. With shock caused by left ventricular heart failure *(LHF)* or chronic obstructive pulmonary disease *(COPD)*, the CO_2 level increases more slowly and does not reach a true end-tidal plateau. The $ETCO_2$ is less than normal at the completion of a normal exhalation (but may increase slightly with a maximum exhalation). Similar findings can be noted with a pulmonary embolus except that the low $ETCO_2$ does not increase with a maximum exhalation. (Modified from Darin J: Capnography. Curr Rev Resp Ther 3:146, 1981; Erickson L, Wollmer P, Olsson CG, et al: Diagnosis of pulmonary embolism based upon alveolar dead space analysis. Chest 96:357–362, 1989; Hatte CJ, Rokseth R: The arterial to end-expiratory carbon dioxide tension gradient in acute pulmonary embolism and other cardiopulmonary diseases. Chest 66:352–357, 1974. In: Pilbeam SP, Cairo JM: Mechanical ventilation, ed 4, St Louis, 2006, Mosby.)

level of zero might indicate patient disconnect. (For more information on the use of capnography during mechanical ventilation, see Chapter 51.)

Procedure

Bedside capnography procedures vary according to the type of equipment used and the manufacturer's recommended protocol. Generally, a capnograph should be calibrated as recommended by its manufacturer, using precision CO_2 mixtures in the clinical range of measurement.

In terms of infection control, nondisposable components that contact the patient's airway or ventilator circuit should undergo high-level disinfection between patients. The monitor should be cleaned as needed, according to the manufacturer's recommendations.

Problem-Solving and Troubleshooting

Monitoring a patient with a capnograph that is properly calibrated and operating according to the manufacturer's specifications presents few major problems. The most significant error is assuming that the end-expired CO_2 levels can substitute for actual $PaCO_2$ measurements. The most common problem is contamination or obstruction of the sampling system or monitor by secretions or condensate.[57] Proper use of water traps and regular changing of sample tubing or chambers can help prevent this problem. Other potential problems include the following:

- False reading caused by the presence of gases with infrared absorption spectra similar to CO_2 (e.g., nitrous oxide)
- Inaccurate readings with high frequencies of breathing (this is more of a problem with sidestream systems)
- Misinterpreting low or absent cardiac output as a disconnect or possible esophageal intubation (all three can result in a $PETCO_2$ of zero)

SUMMARY CHECKLIST

- To measure the inspired O_2 concentration, a properly calibrated electrochemical O_2 analyzer should be used.
- The most common causes of O_2 analyzer malfunction are low batteries, sensor depletion, and electronic failure.
- As the "gold standard" of gas-exchange analysis, ABG results help the clinician assess ventilation, acid-base balance, oxygenation, and the O_2-carrying capacity of blood.
- The radial artery is the preferred site for adult arterial blood sampling. Before radial puncture, a modified Allen test to confirm collateral circulation is performed.
- For critically ill patients, the clinician waits 20 to 30 minutes after a change in treatment before sampling arterial blood.
- Most pre-analytic blood gas errors can be avoided by ensuring that the sample was obtained anaerobically, is properly anticoagulated, and is promptly analyzed.
- Indwelling peripheral artery, central venous, and PA catheters give ready access for blood sampling and allow continuous pressure monitoring but with increased risk for infection and thrombosis.

- Capillary blood pH and PCO_2 are sometimes used to assess acid-base status in infants and children. Capillary PO_2 is of little value in estimating arterial oxygenation.
- To perform blood gas analysis and hemoximetry, the clinician must be proficient in performing procedures, preventive maintenance, troubleshooting, instrument calibration, and quality control.
- A blood gas analyzer measures pH, PCO_2, and PO_2 using three separate electrodes.
- To obtain accurate blood gas results, the clinician ensures that the sample is free of pre-analytic error and follows the manufacturer's recommended analysis protocol.
- Blood gas analysis quality control involves a cycle of performance validation for new instruments, preventive maintenance and function checks, automated calibration, calibration verification with control media, internal statistical quality control, external proficiency testing, and thorough recordkeeping of all processes.
- Portable point-of-care blood gas analyzers can achieve accuracy and precision levels comparable with laboratory-based analyzers.
- Transcutaneous blood gas monitoring provides continuous noninvasive analysis of gas exchange.
- Oximetry is the measurement of blood Hb saturations using spectrophotometry. Hemoximetry is a laboratory procedure that requires an arterial blood sample. Pulse oximetry combines spectrophotometry with photoplethysmography to obtain a noninvasive measure of blood Hb saturations.
- At best, pulse oximetry readings fall within ± 3% to 5% of readings obtained by hemoximetry (cooximetry).
- Technical factors may affect the readings, limit the precision, or alter the performance of pulse oximeters. To interpret test results properly, clinicians must have in-depth knowledge of these factors.
- Capnometry is the measurement of CO_2 in respiratory gases. A capnometer is the device that measures the CO_2. Capnography is the graphic display of CO_2 levels as they change during breathing.
- A capnogram may be used to assess trends in alveolar ventilation, to identify $\dot{V}/\dot{Q}$ imbalance caused by cardiopulmonary disorders, to estimate physiologic dead space, to detect esophageal intubation, and to determine the amount of blood flow during cardiac arrest.

CHAPTER 20

Pulmonary Function Testing

ZAZA COHEN

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- List the three categories of pulmonary function tests.
- State the primary purposes of pulmonary function testing.
- Describe the pathophysiologic patterns associated with obstructive and restrictive lung disease.
- State what is meant by the term *spirometer,* and list the parameters that can be measured by it.
- List and describe the four general principles that should be considered for pulmonary function tests.
- List and describe the measurements that indicate pulmonary mechanics.
- Describe the purpose and technique for the bronchoprovocation test.
- List and describe the four volumes and four capacities that can be measured with pulmonary function testing.
- Describe the purpose and techniques used to measure diffusing capacity.
- Interpret pulmonary function reports.

CHAPTER OUTLINE

KEY TERMS

compliance
diffusing capacity of the lung
diffusing capacity of the lung for carbon monoxide
diffusing capacity of the lung-to–effective total lung capacity ratio
effective total lung capacity
expiratory reserve volume
forced expiratory flow between 25% and 75% of forced vital capacity ($FEF_{25\%-75\%}$)
forced expiratory flow between 75% and 85% of forced vital capacity ($FEF_{75\%-85\%}$)
forced expiratory flow between 200 ml and 1200 ml of FVC ($FEF_{200-1200}$)
forced expiratory volume in 1 second (FEV_1)
forced expiratory volume in 1 second-to-vital capacity ratio (FEV_1/FVC)
forced expiratory volume in half of a second ($FEV_{0.5}$)
forced vital capacity
functional residual capacity
inspiratory capacity
inspiratory reserve volume
maximal voluntary ventilation
minute ventilation
obstructive pulmonary disease
peak expiratory flow rate
residual volume
restrictive pulmonary disease
thoracic gas volume
tidal volume
total lung capacity
vital capacity

The most important function of the lungs is gas exchange. As mixed venous blood passes through the pulmonary circulation, the lungs add oxygen and remove excess carbon dioxide. The ability of the lungs to perform gas exchange depends on the following four general physiologic functions:

1. The diaphragm and thoracic muscles must be capable of expanding the thorax and lungs to produce a subatmospheric pressure.
2. The airways must be unobstructed to allow gas to flow into the lungs and reach the alveoli.
3. O_2 and CO_2 must be able to diffuse through the alveolar-capillary membrane.
4. The cardiovascular system must circulate blood through the lungs and ventilated alveoli.

Pulmonary function tests can provide valuable information about these important individual processes that support gas exchange. Various measurements are available to aid in the diagnosis and assessment of pulmonary diseases, to determine the need for therapy, and to evaluate the effectiveness of respiratory care. For respiratory therapists (RTs), knowledge of these tests and the ability to interpret the measurements are essential for assessing patients objectively and for planning and implementing effective patient care. The key terms used in this chapter are terms adopted and defined by the pulmonary medical community and should become the standard vocabulary of all RTs.[1]

PULMONARY FUNCTION TESTING

A complete evaluation of the respiratory system includes a patient history, physical examination, radiographic imaging, arterial blood gas analysis, and tests of pulmonary function. Test results become most meaningful when considered in the context of a complete clinical evaluation. Although diagnostic pulmonary function testing is performed in a laboratory setting and usually only on patients in a stable condition, RTs also perform many of these tests at the bedside on patients who are acutely ill or being evaluated for surgical readiness. There are three categories of pulmonary function tests, measuring (1) dynamic flow rates of gases through the airways, (2) lung volumes and capacities, and (3) the ability of the lungs to diffuse gases. A combination of these measurements provides a quantitative picture of lung function. Although pulmonary function tests do not diagnose specific pulmonary diseases, these tests identify the presence and type of pulmonary impairments and the degree of pulmonary disease present. Some basic tests of pulmonary function are often performed at the bedside to provide immediate information about the need for respiratory therapy and its effectiveness.

Purposes

Generally, the primary purposes of pulmonary function testing are to identify pulmonary impairment and quantify the severity of pulmonary impairment if present.[2] Pulmonary function testing has diagnostic and therapeutic roles and helps clinicians answer some general questions about patients with lung disease (Box 20-1).

Box 20-1 Basic Diagnostic and Therapeutic Questions for Clinical Pulmonary Function Testing

DIAGNOSTIC
- Is lung disease present?
- What type of lung impairment is present?
- What is the degree of lung impairment?
  - Is more than one type of lung impairment present?
  - Can multiple lung diseases be separated?

THERAPEUTIC
- Is therapy indicated?
- What treatments are most effective?
- To what degree is the disease reversible?
- Can treatments be evaluated?
- Is rehabilitation feasible?

The indications for pulmonary function testing are as follows[2-5]:

- *To identify and quantify changes in pulmonary function*. The most common purposes of pulmonary function testing are to detect the presence or absence of pulmonary disease, to classify the type of disease as either obstructive, restrictive, or both (mixed), and to quantify the severity of pulmonary impairment as mild, moderate, severe, or very severe. Over time, pulmonary function tests help quantify the progression or the reversibility of the disease.
- *To evaluate need and quantify therapeutic effectiveness*. Pulmonary function tests may aid clinicians in selecting or modifying a specific therapeutic regimen or technique (e.g., bronchodilator medication, airway clearance therapy, rehabilitation exercise protocol). Clinicians and researchers use pulmonary function tests to measure changes in lung function objectively before and after treatment.
- *To perform epidemiologic surveillance for pulmonary disease*. Screening programs may detect pulmonary abnormalities caused by disease or environmental factors in general populations, in people in occupational settings, in smokers, or in other high-risk groups. In addition, researchers have determined what normal pulmonary function is by measuring the pulmonary function of healthy people.
- *To assess patients for risk for postoperative pulmonary complications*. Preoperative testing can identify patients who may have an increased risk for pulmonary complications after surgery. Sometimes the risk for complications can be reduced by preoperative respiratory care, or in some cases, the risk may be significant enough to rule out surgery.
- *To determine pulmonary disability*. Pulmonary function tests can also determine the degree of disability caused by lung diseases, such as occupational asthma or coal workers' pneumoconiosis. Some federal entitlement programs and insurance policies rely on pulmonary function tests to confirm claims for financial compensation.

There are also contraindications to pulmonary function testing.[2,6] Patients with acute, unstable cardiopulmonary problems, such as hemoptysis, pneumothorax, myocardial infarction, pulmonary embolism, and patients with acute chest or abdominal pain should not be tested. Patients who have nausea and who have recently vomited should not be tested because there is a risk of aspiration. Testing for patients who have had recent cataract removal surgery should be delayed because changes in ocular pressure may be harmful to the eye. Pulmonary function testing requires patient effort and cooperation. Patients with dementia or confusion may not achieve optimal or repeatable results. Pulmonary function testing should not be performed if valid and reliable results cannot be predicted. In patients who are acutely ill or who have recently smoked a cigarette, the test validity of measuring the **forced vital capacity** (FVC) may be hindered.

Pathophysiologic Patterns

Pulmonary function testing provides the basis for classifying pulmonary diseases into two major categories, **obstructive pulmonary disease** and **restrictive pulmonary disease**. These two types of lung diseases sometimes occur together as a mixed impairment. Obstructive and restrictive types of lung diseases differ in several important ways. Figure 20-1 shows normal lungs with the pathophysiologic aspects of obstructive lung diseases and restrictive lung diseases, and the differences are summarized in Table 20-1. The primary problem in obstructive pulmonary disease is an increased airway resistance (R_{aw}). R_{aw} is the difference in pressure between the ends of the airways divided by the flow rate of gas moving through the airway, according to the following formula:

$$R_{aw} = \frac{\Delta P}{\dot{V}}$$

There is an inverse relationship between R_{aw} and flow rate $\dot{V}$. If the pressure difference is constant, a reduced flow rate indicates an increase in R_{aw}. Because the radius of the airways normally lessens slightly during expiration, flow rates are usually measured during expiration. According to Poiseuille's law (see Chapter 6), R_{aw} is inversely related to the radius (r) of the airways:

$$R_{aw} = \frac{8\eta l}{r^4}$$

The most important point of this formula is that a small decrease in airway radius (or diameter) leads to exponential increase in the airway resistance. Airway radius can be reduced by excessive contraction of the bronchial and bronchiolar muscles (bronchospasm), excessive secretions in the airways, swelling of the airway mucosa, airway tumors, collapse of the bronchioles, and other causes. By measuring flow rates, pulmonary function tests measure R_{aw}, estimate the size of the airways, and indicate the presence of obstructive disease.

The primary problem in restrictive lung disease is reduced lung compliance, thoracic compliance, or both. **Compliance** is the volume of gas inspired per the amount of inspiratory effort;

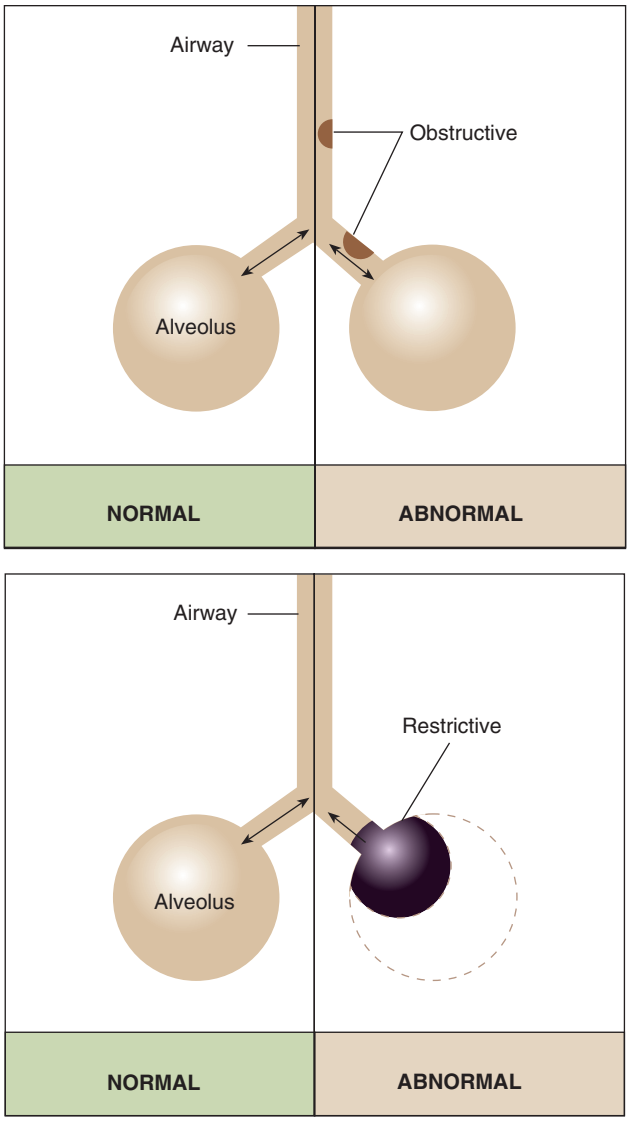

FIGURE 20-1 Pathophysiologic aspects of lung disease.

TABLE 20-1

Comparison of Obstructive and Restrictive Types of Pulmonary Diseases

Characteristic	Obstructive Disease	Restrictive Disease
Anatomy affected	Airways	Lung parenchyma, thoracic pump
Breathing phase difficulty	Expiration	Inspiration
Pathophysiology	Increased airway resistance	Decreased lung or thoracic compliance
Useful measurements	Flow rates	Volumes or capacities

effort is measured as the amount of pressure created in the lung or in the pleural space when the inspiratory muscles contract. Compliance is calculated according to the following formula:

$$C = \frac{\Delta V}{\Delta P}$$

There is a direct relationship between compliance (C) and volume (V). If the pressure difference is constant, a reduced inspiratory volume indicates a reduction in compliance. Reduced lung compliance is usually the result of alveolar inflammation (pneumonia), swelling (pulmonary edema), or scarring (pulmonary fibrosis); a reduced thoracic compliance may be the result of thoracic wall abnormalities, such as kyphoscoliosis, or exogenous pressure exerted on the thoracic cavity, such as ascites or pregnancy. Neuromuscular diseases also can result in reduced lung volumes and restrictive-type pulmonary impairments, mainly by affecting the function of the inspiratory muscles. In these circumstances, lung compliance and thoracic compliance may be normal, but the patient is unable to generate enough sub-atmospheric pressure to take a full, deep breath.

Some obstructive diseases and some restrictive diseases also may affect the ability of the lung to diffuse gases. In some diseases, there is damage to the alveolar-capillary membrane, or less alveolar surface area is accessible for diffusion. Measuring the **diffusing capacity of the lung for carbon monoxide** (DLCO) can identify the destruction of alveolar tissue or the loss of functioning alveolar surface area.

For each measurement of pulmonary function, there is a predicted value and upper and lower limit of normal (ULN, and LLN, respectively). It is expected that most healthy individuals would fall between the values of LLN and ULN. Measurements outside that range often indicates the presence of an abnormality. The severity of pulmonary impairment is based on a comparison of each patient's measurement with the predicted normal value for the patient. Several methods are used for comparison with the normal value. A common method of comparison is to compute a percentage of the predicted normal value according to the following equation:

$$\%\ \text{Predicted} = \frac{\text{Measured value}}{\text{Predicted normal value}} \times 100$$

The percent predicted value can be used to quantify severity of impairment. Typical degrees of severity are listed in Table 20-2.

Infection Control

Pulmonary function testing is generally regarded as a very low-risk procedure. However, there is potential to transmit infective microorganisms to patients and technologists.[2] Transmission can occur by direct or indirect contact. Standard precautions should be applied because of the potential exposure to saliva, mucus, or blood, which can harbor potentially hazardous microorganisms. Patients with oral lesions or active respiratory infections pose the greatest potential hazard, and patients with compromised immune systems are at the greatest risk. Practitioners should wear gloves when handling potentially contaminated mouthpieces, valves, tubing, and equipment surfaces. When performing procedures on patients with potentially infectious airborne diseases, practitioners should wear a personal respirator or a close-fitting surgical mask, especially if the testing induces coughing. Practitioners should always wash their hands between testing patients and after contact with testing equipment. Although it is unnecessary to clean the interior surfaces of the testing instruments routinely between patients,[2] the mouthpiece, nose clips, tubing, and any parts of the instrument that come into direct contact with a patient should be disposed, sterilized, or disinfected between patients. Any equipment surface showing visible condensation from exhaled air should be discarded, disinfected, or sterilized before reuse. When testing instruments are disassembled for cleaning and disinfecting, manufacturer recommendations should be considered and recalibration may be necessary before testing resumes. The routine use of low-resistance, in-line barrier filters is controversial.[2] Filters may be appropriate when internal surfaces of manifolds and valves proximal to mouthpieces are inaccessible or difficult to disassemble for cleaning and disinfecting. Filters provide visible evidence to reassure patients that their protection has been considered.

TABLE 20-2

Severity of Pulmonary Impairments Based on a Percentage of Predicted Normal Values

Degree of Impairment	Obstruction Based on FEV_1 (%)	Gas Exchange Based on DLCO (%)
Normal	80-120	80-120
Mild	70-79	61-79
Moderate	60-69	40-60
Moderately severe	50-59	
Severe	35-49	<40
Very severe	<35	

DLCO, Diffusing capacity of the lung for carbon monoxide.

Equipment

Pulmonary function testing requires measurement of gas volume or flow, and various instruments and measurement principles are used to make these measurements. There are two general types of measuring instruments: instruments that measure gas volume and instruments that measure gas flow. Both types of instruments simultaneously measure time, and both compute various volumes and flow rates used in pulmonary function testing. The term *spirometer* is sometimes used as a generic term for all volume-measuring and flow-measuring devices.

Volume-measuring devices are specifically called *spirometers* and include water-sealed, bellows, and dry rolling seal types. These devices expand as they collect gas volumes. The magnitude of the expansion is the *volume* measured, and the speed of expansion represents the *flow rate*. In the absence of leaks and with low-momentum forces, volume-measuring devices can be extremely accurate for measuring volumes, and with low inertia and friction forces, volume-measuring devices can be extremely accurate when computing flow rates.

Flow-measuring devices are commonly called *pneumotachometers,* although some practitioners reserve this term for only the device originally designed by Fleisch. These devices measure flow using a variety of unique principles. The Fleisch-type pneumotachometer measures the change in pressure as gas flows through it. Known as *thermistors* or *mass flowmeters,*

another type of flow-measuring device measures the temperature change created by gas flowing through it. There are also *tubinometers,* which use rotation of a fan or blades similar to a windmill. Detailed descriptions and examples of each type of device are beyond the scope of this chapter.[7]

Regardless of the type of device or the principle of measurement used, several important characteristics are common to all measuring devices. Having an understanding of these common characteristics provides RTs the ability to select and use these devices properly. Every measuring instrument has capacity, accuracy, error, resolution, precision, linearity, and output. The ideal instrument would have unlimited capacity to measure every pulmonary parameter, and it would have perfect accuracy and precision over its entire measurement range. However, in real practice, there are no ideal instruments.

The *capacity* of an instrument refers to the range or limits of how much it can measure. Most instruments are designed with capacities to measure volumes and flow rates of all adults. The *accuracy* of a measuring instrument is how well it measures a known reference value. For volume measurements, standard reference values are provided by a graduated 3.0-L calibration syringe. No measuring instrument is perfect, and there usually is an arithmetic difference between reference values and measured values. This difference is called the *error. Accuracy* and *error* are opposing terms; the greater the accuracy, the smaller is the error. Accuracy and error are commonly expressed as percentages, with their sum always equaling 100%. To determine percent accuracy and percent error, several reference values are measured, and the mean of the measured values is computed and compared with the reference values. *Resolution* is the smallest detectable measurement; instruments with high resolution can measure the smallest volumes, flows, and times. *Precision* is synonymous with reliability (repeatability) of measurements and the opposite of variability. When multiple values are measured for a given test, the standard deviation of these values indicates the extent to which these values vary from the mean, and are therefore an indication of the precision of an instrument. A small standard deviation indicates low variability and high precision. *Linearity* refers to the accuracy of the instrument over its entire range of measurement, or its *capacity.* Some devices may accurately measure large volumes or high flow rates but may be less accurate when measuring small volumes or low flow rates. To determine linearity, accuracy and precision are calculated at different points over the range (capacity) of the device. *Output* includes the specific measurements made or computed by the instrument.

Most volume-measuring and flow-measuring devices measure the FVC and **forced expiratory volume in 1 second (FEV1).** Others calculate various forced expiratory flow (FEF) rates, and some measure tidal volume (V_T) and **minute ventilation** ($\dot{V}_E$). Diagnostic spirometers usually measure and calculate **vital capacity** (VC), FVC, FEV_1, **peak expiratory flow rate** (PEF), and FEF rates. Some measure and calculate **maximal voluntary ventilation** (MVV). Some of these instruments may be a component of a laboratory system providing the volume-measuring or flow-measuring capability for other diagnostic tests of pulmonary function. For example, they may be used with gas analyzers to measure **functional residual capacity** (FRC) and **total lung capacity** (TLC) or the inspiratory VC during *single-breath diffusing capacity (DLCO-SB).* Whether a spirometer or pneumotachometer is used in a diagnostic laboratory, a physician's office, or at the bedside in a hospital, it should meet or exceed the national performance standards for volume-measuring and flow-measuring devices.

In 1978, the American Thoracic Society (ATS) adopted the initial standards for diagnostic spirometers. These standards were most recently updated in 2005 in collaboration with the European Respiratory Society (ERS), are now recognized internationally as the standards for the industry,[2-4] and have been adopted by other medical organizations and government agencies. In clinical practice, RTs should use only devices that meet or exceed current ATS/ERS performance standards. The standards are summarized in Table 20-3. In addition, the spirometer standards also require spirometers to have a thermometer or to produce values corrected for body temperature, ambient pressure, and fully saturated with water vapor (BTPS). For quality control, the standards include verifying volume accuracy at least daily, although best practice in many laboratories is to verify accuracy before each test subject.

Most modern pulmonary function laboratories use computers for data acquisition and reproduction. Computer-assisted testing decreases the time necessary to complete the tests and enhances the effectiveness of pulmonary function testing by increasing accuracy, increasing patient acceptance, and

TABLE 20-3

2005 Spirometer Performance Standards of the American Thoracic Society/European Respiratory Society (ATS/ERS) Task Force

Test	Volume (L)	Flow (L/sec)	Accuracy	Time (sec)	Back Pressure (cm H_2O/L/sec)
VC	0.5-8 L	0-14	≤3% or 0.05 L*	30	
FVC	0.5-8 L	0-14	≤3% or 0.05 L*	15	<1.5%scm H_2O/L/sec at 14 L/sec
FEV_1	0.5-8 L	0-14	≤3% or 0.05 L*	1	<1.5%scm H_2O/L/sec at 14 L/sec
PEF		0-14	≤10% or 0.3 L/sec*		<1.5%scm H_2O/L/sec at 14 L/sec
FEF		±14	≤5% or 0.2 L/sec*		<1.5%scm H_2O/L/sec at 14 L/sec
MVV	250 L/min at 2 L/breath		±10% or 15 L/min*	12-15	<1.5%scm H_2O/L/sec at 14 L/sec

*Whichever is greater.

monitoring patient performance. Although computer-assisted testing and interpretations of test results are often applied by a computer, pulmonary function testing always requires a trained and competent RT to administer the tests, and computer analysis should not replace human analysis.

PRINCIPLES OF MEASUREMENT AND SIGNIFICANCE

For tests of pulmonary function, these general principles should be considered: test sensitivity and specificity, validity, and reliability.

Sensitivity and specificity address the test's ability to detect disease, or absence of it, respectively. Some tests are extremely *sensitive,* and apparently healthy individuals may have an abnormal test result. However, some tests are not sensitive; individuals must be extremely sick to have an abnormal test result. Most tests of pulmonary function are not *specific* because several different diseases may cause the test result to be abnormal. This limitation of many pulmonary function tests explains why these tests identify a pattern of impairment rather than diagnose specific diseases.

Validity of the test relates to its meaningfulness or the ability to measure what it is intended to measure. When performing pulmonary function testing, strictly following testing procedures, ensuring patient effort and performance, and ensuring equipment accuracy and calibration establish test validity.

Reliability of the test is its consistency. A reliable test produces consistent test results with minimal variability. To be reliable, each test must be performed more than once. Ensuring test validity and reliability is the most important role of the RT. Test results that are invalid or unreliable can lead to misdiagnosis, mistreatment, and poor outcomes.

RULE OF THUMB

Never report test results that are invalid or unreliable.

There are three basic tests of pulmonary function: spirometry, lung volumes, and diffusing capacity. When the purpose of the testing is to identify the presence and the degree of pulmonary impairment and the type of pulmonary disease, all three testing components are required. When the purpose of the testing is more limited, such as to assess postoperative pulmonary risk or to evaluate and quantify therapeutic effectiveness, the scope of measurement also is limited.

General indications, contraindications, and potential complications of pulmonary function testing were briefly discussed at the beginning of this chapter. A complete listing of all indications, contraindications (absolute and relative), hazards, and complications, assessment of need and test quality, techniques and different types of equipment that make the measurements, and quality control measures is outside of the scope of this chapter. They are summarized in the corresponding American Association for Respiratory Care (AARC) Clinical Practice Guidelines and ATS/ERS included in the references for this chapter. Many pulmonary function laboratories also perform arterial blood gas analysis (see Chapter 19), and some laboratories provide more specialized and advanced tests, such as bronchial challenge tests and exercise stress tests.

Spirometry

Spirometry—the measurement of air entering and leaving the lungs—includes measurement of several values of forced airflow and volume during inspiration and expiration. For the most part, the purpose of spirometry is to assess the ability of the lungs to move large volumes of air quickly through the airways to identify airway obstruction. Some measurements are aimed at large intrathoracic airways, some are aimed at small airways, and some assess obstruction throughout the lungs. Measuring flow rates is a surrogate for measuring airways resistance, as discussed earlier in the chapter. To a lesser extent, spirometry can also identify and quantify a restrictive pattern of pulmonary disease. The major values measured during spirometry are discussed below.

Spirometry is an effort-dependent test that requires careful patient instruction, understanding, coordination, and cooperation. Spirometry standards for FVC specify that patients must be instructed in the FVC maneuver, that the appropriate technique be demonstrated, and that enthusiastic coaching occur.[3] When measuring FVC, the RT needs to coach the preceding **inspiratory capacity** (IC) as enthusiastically as the FVC. According to the standards, nose clips are encouraged, but not required and patients may be tested in the sitting or standing position. Although standing usually produces a larger FVC compared with sitting, sitting is considered safer in case of lightheadedness. It is recommended that the position be consistent for repeat testing of the same patient. FVC should be converted to body temperature conditions and reported as liters under BTPS conditions.

Except for PEF rate, all other measurements that originate from FVC come from the "best curve"—these include **forced expiratory flow between 200 ml and 1200 ml of FVC (FEF200-1200); forced expiratory flow between 25% and 75% of FVC ($FEF_{25\%-75\%}$); forced expiratory flow between 75% and 85% of FVC ($FEF_{75\%-85\%}$);** and instantaneous $FEF_{25\%}$, $FEF_{50\%}$, and $FEF_{75\%}$. The *best test curve* is defined as the trial that meets the acceptability criteria and gives the largest sum of FVC plus FEV_1. The validity and reliability of these other measurements of pulmonary mechanics are based on their origin from a valid and reliable FVC. (See AARC Clinical Practice Guideline 20-1.)

Forced Vital Capacity

FVC is the most commonly performed test of pulmonary mechanics, and many measurements are made while the patient is performing the FVC maneuver (Figure 20-2). Measuring FVC often occurs under baseline or untreated conditions. For baseline testing, patients should temporarily abstain from bronchodilator medications. Short-acting bronchodilators (e.g., beta agonist: albuterol; anticholinergic agent: ipratropium bromide)

20-1 Spirometry

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

The indications for spirometry include the need to do the following:

Detect the presence or absence of lung dysfunction suggested by history or physical signs and symptoms or the presence of other abnormal diagnostic tests (e.g., chest radiograph, arterial blood gases).

- Quantify the severity of known lung disease.
- Assess the change in lung function over time or after administration of or change in therapy.
- Assess the potential effects or response to environmental or occupational exposure.
- Assess the risk for surgical procedures known to affect lung function.
- Assess impairment or disability (e.g., for rehabilitation, legal reasons, military).

CONTRAINDICATIONS

Circumstances listed here could affect the reliability of spirometry measurements. In addition, forced expiratory maneuvers may aggravate these conditions, which may make test postponement necessary until the medical condition resolves. The following are some relative contraindications to performing spirometry:

- Hemoptysis of unknown origin (forced expiratory maneuver may aggravate the underlying condition)
- Pneumothorax
- Unstable cardiovascular status (forced expiratory maneuver may worsen angina or cause changes in blood pressure) or recent myocardial infarction or pulmonary embolus
- Thoracic, abdominal, or cerebral aneurysms (danger of rupture resulting from increased thoracic pressure)
- Recent eye surgery (e.g., cataract)
- Presence of an acute disease process that might interfere with test performance (e.g., nausea, vomiting)
- Recent surgery of thorax or abdomen

HAZARDS AND COMPLICATIONS

Although spirometry is a safe procedure, untoward reactions may occur, and the value of the test data should be weighed against potential hazards. The following have been reported anecdotally:

Pneumothorax

- Paroxysmal coughing
- Increased intracranial pressure
- Contraction of nosocomial infections
- Syncope, dizziness, lightheadedness
- O_2 desaturation resulting from interruption of O_2 therapy
- Chest pain
- Bronchospasm

ASSESSMENT OF NEED

Need is assessed by determining that valid indications are present.

ASSESSMENT OF TEST QUALITY

Spirometry performed for the listed indications is valid only if the spirometer functions acceptably and the subject is able to perform the maneuvers in an acceptable and reproducible fashion. All reports should contain a statement about the technician's assessment of test quality and specify which acceptability criteria were not met.

QUALITY CONTROL

Volume verification (i.e., calibration): At least daily before testing, use a calibrated known-volume syringe with a volume of at least 3 L to ascertain that the spirometer reads a known volume accurately. The known volume should be injected or withdrawn at least three times, at flows that vary between 2 L/sec and 12 L/sec (3-L injection times of approximately 1 second, 6 seconds, and between 1 second and 6 seconds). The tolerance limits for an acceptable calibration are ±3% of the known volume. For a 3-L calibration syringe, the acceptable recovered range is 2.91 to 3.09 L. The practitioner is encouraged to exceed this guideline whenever possible (i.e., reduce the tolerance limits to less than ±3%).

- Leak test: Volume-displacement spirometers must be evaluated for leaks daily. One recommendation is that any volume change of more than 10 ml/min while the spirometer is under at least 3 cm H_2O pressure be considered excessive.
- A spirometry procedure manual should be maintained.
- A log that documents daily instrument calibration, problems encountered, corrective action required, and system hardware or software changes should be maintained.
- Computer software for measurement and computer calculations should be checked against manual calculations, if possible. In addition, biologic laboratory standards (i.e., healthy, nonsmoking individuals) can be tested periodically to ensure historic reproducibility, to verify software upgrades, and to evaluate new or replacement spirometers.
- The known-volume syringe should be checked for accuracy at least quarterly using a second known-volume syringe, with the spirometer in the patient-test mode; this validates the calibration and ensures that the patient-test mode operates properly.
- For water-seal spirometers, water level and paper tracing speed should be checked daily. The entire range of volume displacement should be checked quarterly.

QUALITY ASSURANCE

Each laboratory or testing site should develop, establish, and implement quality assurance indicators for equipment calibration and maintenance and patient preparation.

Methods should be devised and implemented to monitor technician performance (with appropriate feedback) while obtaining, recognizing, and documenting acceptability criteria.

MONITORING

The following should be evaluated during the performance of spirometric measurements to ascertain the validity of the results:

- Acceptability of maneuver and reproducibility of FVC and FEV_1
- Level of effort and cooperation by the subject
- Equipment function or malfunction (e.g., calibration)
- The final report should contain a statement about test quality.
- Spirometry results should be subject to ongoing review by a supervisor, with feedback to the technologist.
- Quality assurance or quality improvement programs should be designed to monitor technician competency initially and in an ongoing fashion.

**For the complete guideline, see American Association for Respiratory Care: Clinical practice guideline: spirometry. 1996 update.*

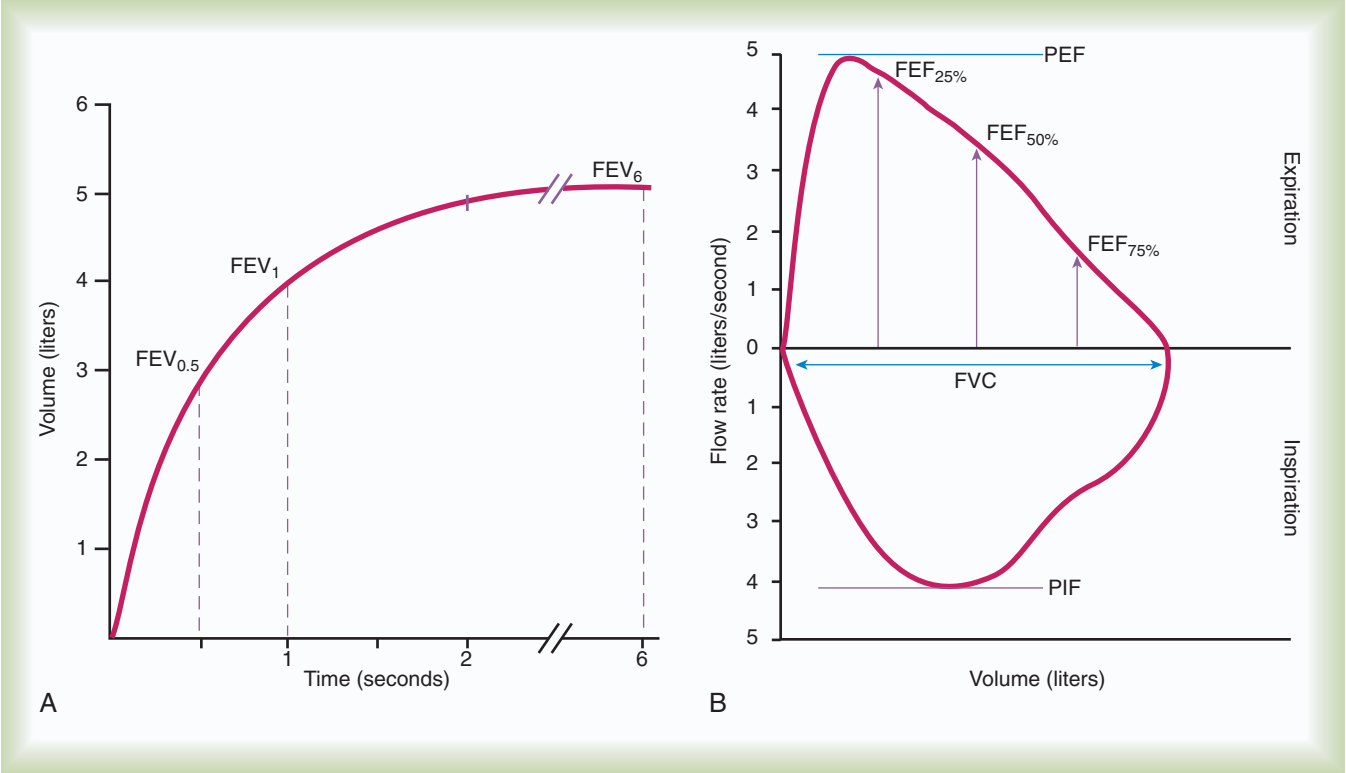

FIGURE 20-2 Forced vital capacity, forced expiratory volumes, and flow rates. **A,** Forced vital capacity on a volume-time graph. **B,** Forced vital capacity on a flow-volume graph. *PEF,* Peak expiratory flow; *PIF,* peak inspiratory flow.

should not be used for 4 hours before baseline spirometry, whereas long-acting beta-agonist bronchodilators and oral therapy with aminophylline should be stopped for 12 hours. When a patient's baseline results show airway obstruction, performing FVC after treatment (e.g., albuterol bronchodilator aerosol or metered dose inhaler) can help determine if the treatment is effective. The FVC maneuver is also performed repeatedly during bronchial provocation testing.

FVC may be measured on a spirometer that reveals volumes or flows, that presents a graph of volume and time or flow and volume, that is mechanical or electronic, and that has a calculator or computer. The forced expiratory VC sometimes is followed by a forced inspiratory VC to produce a complete image of forced breathing called a *flow-volume loop* (see Figure 20-2, *B*).

RULE OF THUMB

If you do not inhale it, you cannot exhale it. So, coach the preceding IC as enthusiastically as the FVC.

To ensure validity, each patient must perform a minimum of three acceptable FVC maneuvers. To ensure reliability, the largest FVC and second largest FVC from the acceptable trials should not vary by more than 0.15 L. To perform an FVC trial, the patient should inhale rapidly and completely to TLC from the resting FRC level. The forced exhalation of an acceptable FVC trial should begin abruptly and without hesitation. A satisfactory start of expiration is defined as an extrapolated volume at the zero time point less than 5% of FVC or 0.15 L, whichever is greater (Figure 20-3). The volume exhaled before the zero time point is called the *extrapolated volume.* To be valid, no more than 5% of the VC or 0.15 L is allowed to be exhaled before the zero time point. An acceptable FVC trial also is smooth, continuous, and complete. A cough, an inspiration, a Valsalva maneuver, a leak, or an obstructed mouthpiece while an FVC maneuver is being performed disqualifies the trial. FVC must be completely exhaled or an exhalation time of at least 6 seconds must occur for adults and children older than 10 years (longer times are commonly needed for patients with airway obstruction). A 3-second exhalation is acceptable for children younger than 10 years old. An end-expiratory plateau must be obvious in the volume-time curve (see Figure 20-3); the objective standard is less than 0.025 L exhaled during the final second of exhalation. Consistent with its definition, the largest acceptable FVC (BTPS) measured from the set of three acceptable trials is the patient's FVC.

Forced Expiratory Volume in 1 Second

During FVC testing, several other measurements are also made. FEV_1 is a measurement of the volume exhaled in the first second of FVC (see Figure 20-2, *A*). To ensure validity of FEV_1, the measurement must originate from a set of three acceptable FVC trials. The first second of forced exhalation begins at the zero time point (see Figure 20-3). To ensure reliability of FEV_1, the largest FEV_1 and second largest FEV_1 from the acceptable trials

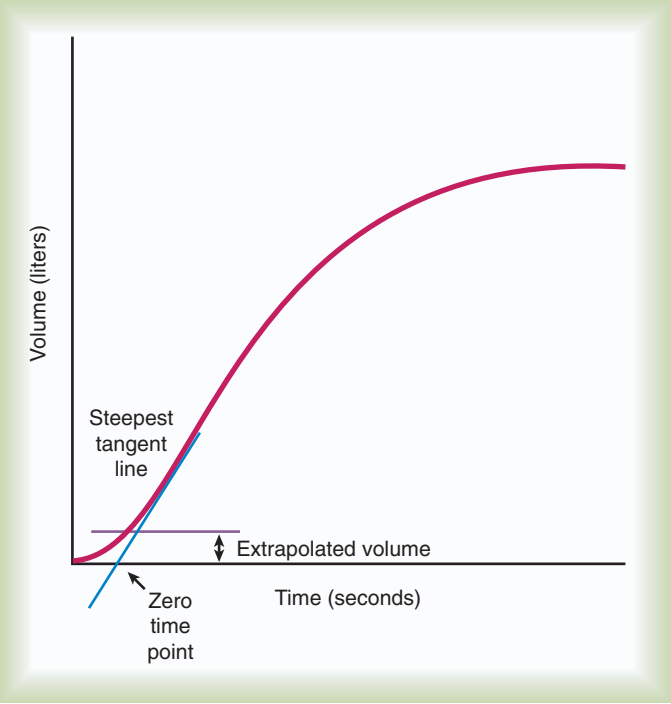

FIGURE 20-3 Extrapolated volume and zero time point determination.

should not vary by more than 0.15 L. Consistent with its definition, the largest FEV_1 (BTPS) measured is the patient's FEV_1. The largest FEV_1 sometimes comes from a different trial than the largest FVC.

The **forced expiratory volume in 1 second-to-vital capacity ratio (FEV1/FVC),** is calculated by dividing the patient's largest FEV_1 by the patient's largest VC and converting it to a percentage (by multiplying by 100). The two values do not have to come from the same trial; the VC should be the largest one measured, even if measured as a slow VC or during inspiration.

Forced Expiratory Flow Between 200 ml and 1200 ml of Forced Vital Capacity and Forced Expiratory Flow Between 25% and 75% of Forced Vital Capacity

$FEF_{200\text{-}1200}$ and $FEF_{25\%\text{-}75\%}$ represent average flow rates that occur during specific intervals of FVC. Both measurements can be made on a volume-time spirogram as the slope of a line connecting the two points in their subscripts. For $FEF_{200\text{-}1200}$, the 200-ml point and the 1200-ml point are identified. A straight line is drawn connecting these points, and the line is extended to intersect two vertical time lines 1 second apart on the graph (Figure 20-4). The volume of air measured between the two time lines is $FEF_{200\text{-}1200}$ in liters per second. The volume measured must be corrected to BTPS.

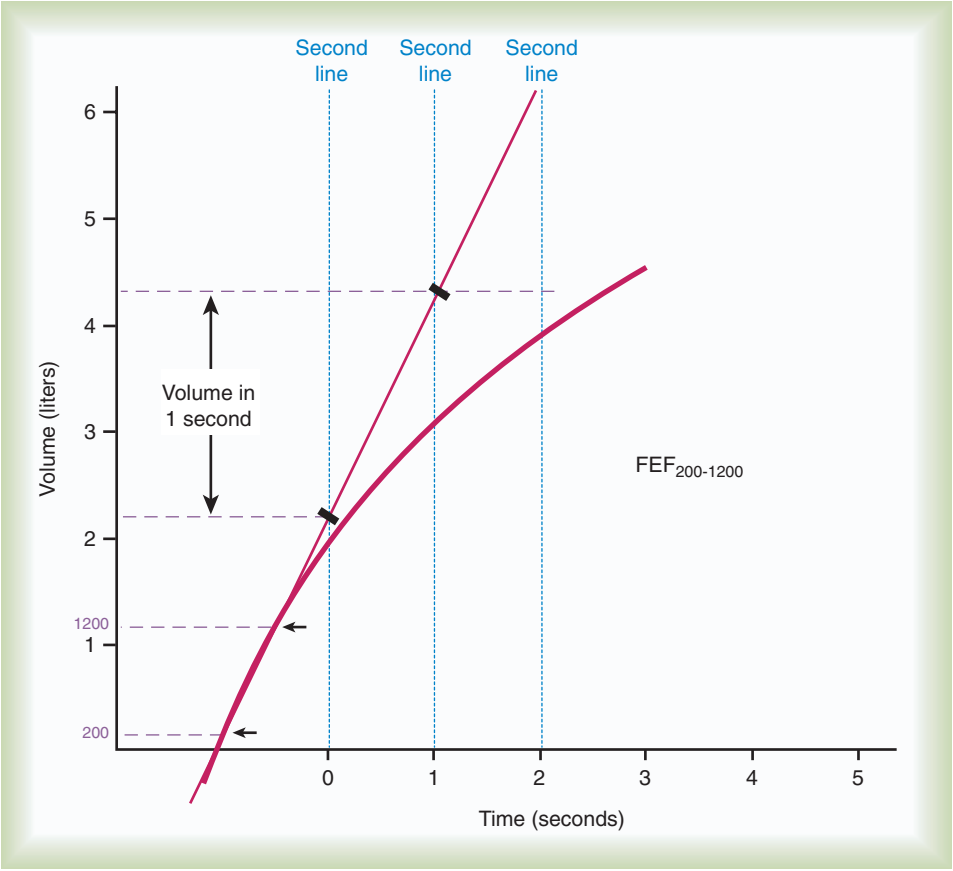

FIGURE 20-4 Forced expiratory flow rate 200 to 1200 ml.

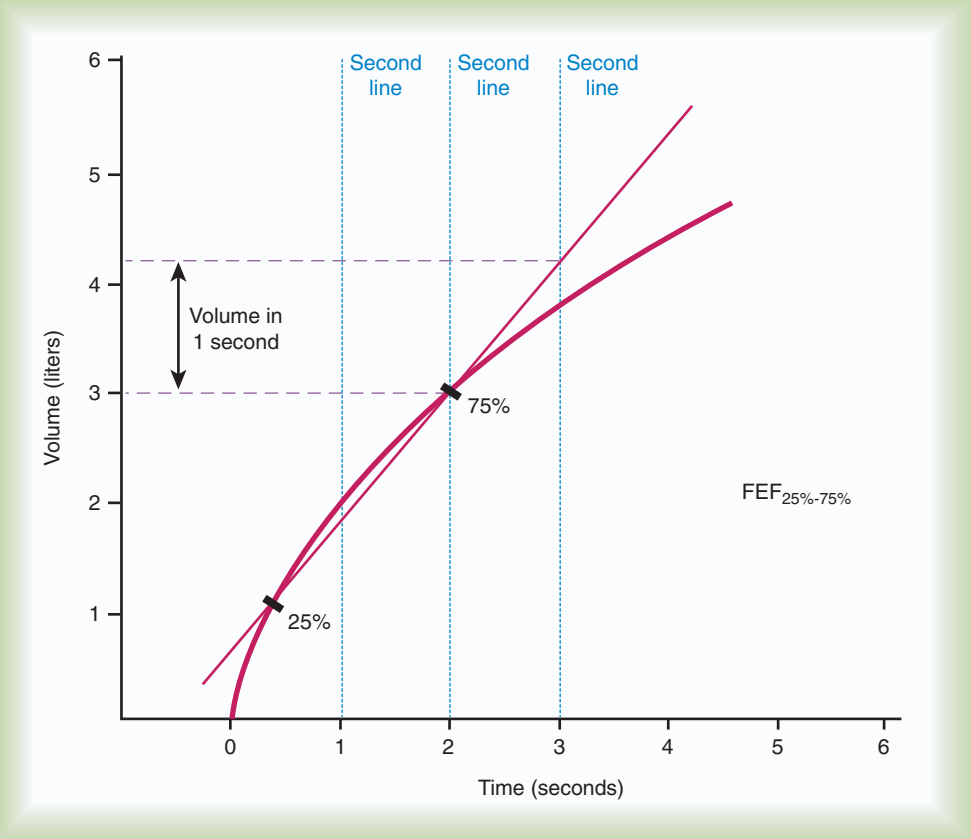

FIGURE 20-5 Forced expiratory flow (FEF) rate 25% to 75% of the forced vital capacity.

$FEF_{25\%-75\%}$ is a measure of the flow during the middle portion of FVC, or the time necessary to exhale the middle 50%. For $FEF_{25\%-75\%}$, the VC of the best curve is multiplied by 25% and 75%, and the points are identified on the tracing. A straight line is drawn connecting these points, and the line is extended to intersect two vertical time lines 1 second apart on the graph. The volume of air measured between the two time lines is $FEF_{25\%-75\%}$ in liters per second. The volume measured must be corrected to BTPS (Figure 20-5).

Peak Expiratory Flow

PEF is difficult to identify on a volume-time graph of FVC. The peak flow is the slope of the tangent to the steepest portion of the FVC curve. PEF is easy to identify on a flow-volume graph as the highest point on the graph (see Figure 20-2, *B*). PEF is sometimes measured independently of FVC with a peak flow meter. These devices are designed to indicate only the greatest expiratory flow rate. The validity of PEF rate is based on a preceding inspiration to TLC and a maximal effort. The FVC principles of ensuring reliability should apply to measurements of PEF rate. The two largest repeated measurements should agree within 5%.

In addition to PEF rate, the other instantaneous flow rates, such as FEF at 25% ($FEF_{25\%}$) of FVC, forced expiratory flow at 50% ($FEF_{50\%}$) of FVC, and forced expiratory flow at 75% ($FEF_{75\%}$) of FVC, during FVC are graphed on a flow-volume curve. When FVC is followed by a forced inspiratory VC, a flow-volume loop is produced (see Figure 20-2, *B*). On the flow-volume loop, the maximal forced inspiratory flow rate at 50% ($FIF_{50\%}$) of VC can be measured and compared with $FEF_{50\%}$.

Maximal Voluntary Ventilation

Another measurement of pulmonary mechanics is maximal voluntary ventilation (MVV). It is another effort-dependent test for which the patient is asked to breathe as deeply and as rapidly as possible for at least 12 seconds. MVV is a test that reflects patient cooperation and effort, the ability of the diaphragm and thoracic muscles to expand the thorax and lungs, and airway patency. Because of the potential for acute hyperventilation and fainting or coughing, the patient should be seated. Measuring systems that incorporate rebreathing may minimize the effects of hyperventilation. After a demonstration of the expected breathing pattern is performed, the patient should be instructed to breathe as rapidly and as deeply as possible for at least 12 seconds. The patient's breathing is measured on a spirogram (Figure 20-6) or electronically for the specific number of seconds (t) and the volume (V) breathed when the MVV is converted to liters per minute. As with all volumes measured on a spirometer, the recorded values should be in BTPS conditions. The validity of MVV depends on the duration of the maneuver, which should be at least 12 seconds; the breathing frequency, which should be at least 90 breaths/min;

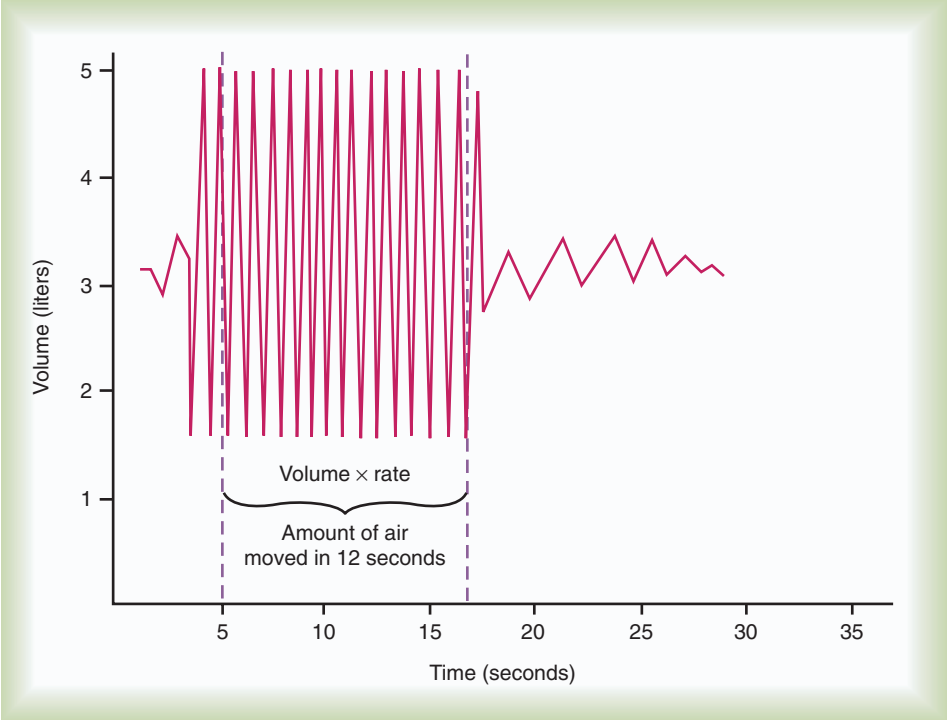

FIGURE 20-6 Maximal voluntary ventilation tracing. Actual ventilations recorded during a 12-second period.

and the average volume, which should be at least 50% of FVC. In addition, measured MVV should be compared to two other values: subject's $FEV_1 \times 40$, and predicted value for MVV. If the measured MVV is less than 80% of either of those values, a repeat test should be performed to ensure accuracy. Reliability is shown when there is less than 20% variability between the two largest trials. The largest MVV (BTPS) should be reported.

Other Values Obtained During Spirometry. During spirometry, a few additional measurements can be obtained, such as V_T, expiratory reserve volume (ERV), and IC. These values are usually interpreted in the context of other lung volumes (see later) and are discussed later in this chapter.

An important caveat during interpretation of spirometry values is the concept of "pseudorestriction." Some patients with obstructive lung disease will not be able to exhale a significant portion of their VC during forced maneuvers, leading to smaller than actual FVC measurement. These patients will have reduced FVC, will have reduced FEV_1, and may actually have normal FEV_1/FVC ratio, suggestive of restrictive physiology, hence the name *pseudorestriction*. In these patients, it is important to give them enough time to fully exhale by making sure that they reach a plateau at the end of FVC maneuver (see Figure 20-3) to allow proper measurement of FVC. Comparing FVC to slow vital capacity (SVC, see later) is another method of looking for obstructive physiology.

Interpretation

The normal values for the spirometric measurements of pulmonary mechanics are based on height, age, gender, and

MINI CLINI

Decreased Forced Vital Capacity and Forced Expiratory Volume in 1 Second: Is It Obstruction or Restriction?

PROBLEM: Both obstructive and restrictive diseases may exhibit decreased FVC and FEV_1. How can the two kinds of patterns be differentiated?

SOLUTION: FVC and FEV_1 are reduced in both obstructive and restrictive diseases for different reasons. With restrictive disease, lung expansion is reduced. If a person can inhale only a small volume, he or she can exhale only a small volume. All lung volumes are smaller than normal, including TLC, FVC, and FEV_1.

With obstructive disease, there is airway obstruction, which slows expiratory flow. FEV_1 is reduced because of the increased airway resistance, which decreases expiratory flow rates. FVC is reduced because airway obstruction in the bronchioles causes air trapping in the lung. If a person cannot exhale all of his or her air because some is trapped in the lungs, the volume the person does exhale is reduced.

To differentiate between obstructive and restrictive patterns of impairment, compare FEV_1 with FVC using the FEV_1/FVC ratio. Only individuals with airway obstruction exhale less than 70% of FVC in the first second. Individuals with restrictive disease or healthy lungs are able to exhale more than 70% of FVC during the first second. Therefore FEV_1/FVC less than 70% is often used as the sign of obstructive lung disease.

TABLE 20-4

Examples of Regression Equations for Predicted Normal Pulmonary Mechanics in White Adults

Parameters	Equations	R^2
Men ≥20 Years Old		
FVC (L)	0.00018642 (Ht)^2 + 0.00064 (A) – 0.000269 (A)^2 – 0.2033	0.8668

A, Age in years; *Ht,* height in centimeters.

ethnicity. Table 20-4 provides common regression equations to predict normal values for the measurements of pulmonary mechanics for individuals of specific height (in centimeters), age (in years), and gender.[8,9] A positive correlation exists between measurements of pulmonary mechanics and height, and a negative correlation exists between measurements of pulmonary mechanics and age for patients older than 20 years. Male values are larger than female values when height and age are equal. The populations that were studied to determine the normal values of pulmonary mechanics were predominantly white. To account for ethnic differences of nonwhites, the predicted normal values for whites commonly are reduced by 12% to 15% when applied to nonwhites. Ethnic-specific equations for special populations, such as African-Americans and Mexican-Americans, have also been developed.[8]

Although traditional textbooks suggest the typical normal VC is 4.80 L, the predicted normal FVC for a 20-year-old, 180-cm man approaches 5.60 L. A reduced FVC may occur with obstructive or restrictive impairments. Figure 20-7 shows FVC from volume-time spirometer tracings for normal, obstructive, and restrictive conditions. The FVC values in both the obstructed and the restricted curves are shown as reduced volumes compared with the normal curve. The primary difference between the curve in the restricted patient compared with the curve in the obstructed patient is the slope of the tracing; obstructive diseases produce flattened slopes and smaller FEV_1.

Figure 20-8 displays the FVC from flow-volume tracings for obstructive and restrictive conditions. The shapes of these tracings are different; obstructive diseases produce lower peaks and lower flow rates at all lung volumes. Forced inspiratory flow rates sometimes are useful for identifying extrathoracic airway obstructions. In moderate and severe obstructive lung diseases, the FVC is reduced if weakened bronchioles collapse and trap air in the lungs, creating an increase in residual volume. Some laboratories compare the volumes of SVC and FVC to identify air trapping. VC is reduced in restrictive lung diseases because the patient's inhaled volume is reduced.

Although FEV_1 is measured as a volume, it is considered a flow rate. The predicted normal FEV_1 for a 20-year-old, 180-cm man approaches 4.70 L. FEV_1 may be reduced with obstructive or restrictive impairments. For patients with airway obstruction, FEV_1 measures the general severity of airway obstruction. For patients with restrictive impairment, FEV_1 may be reduced when the patient's VC is smaller than the predicted FEV_1.

To interpret other flow rates, a generalization may be helpful. Gas exhaled during the early portion of the FVC reflects the resistance in the larger airways, and gas exhaled during the later portion of the FVC reflects the resistance in the smaller airways. As exhalation of FVC proceeds, flow decreases, and the airways reflected in the measurements get smaller. Any flow measured in the first half of the FVC reflects on the bronchi; any flow measured beyond 50% of the VC reflects on the bronchioles.

PEF, $FEF_{200-1200}$, and $FEF_{25\%}$ occur near the onset of FVC. A reduced PEF rate, $FEF_{200-1200}$, or $FEF_{25\%}$ may occur as a result of a large airway obstruction and from lack of sufficient effort to inhale maximally and exhale forcibly. $FEF_{25\%-75\%}$ and $FEF_{50\%}$

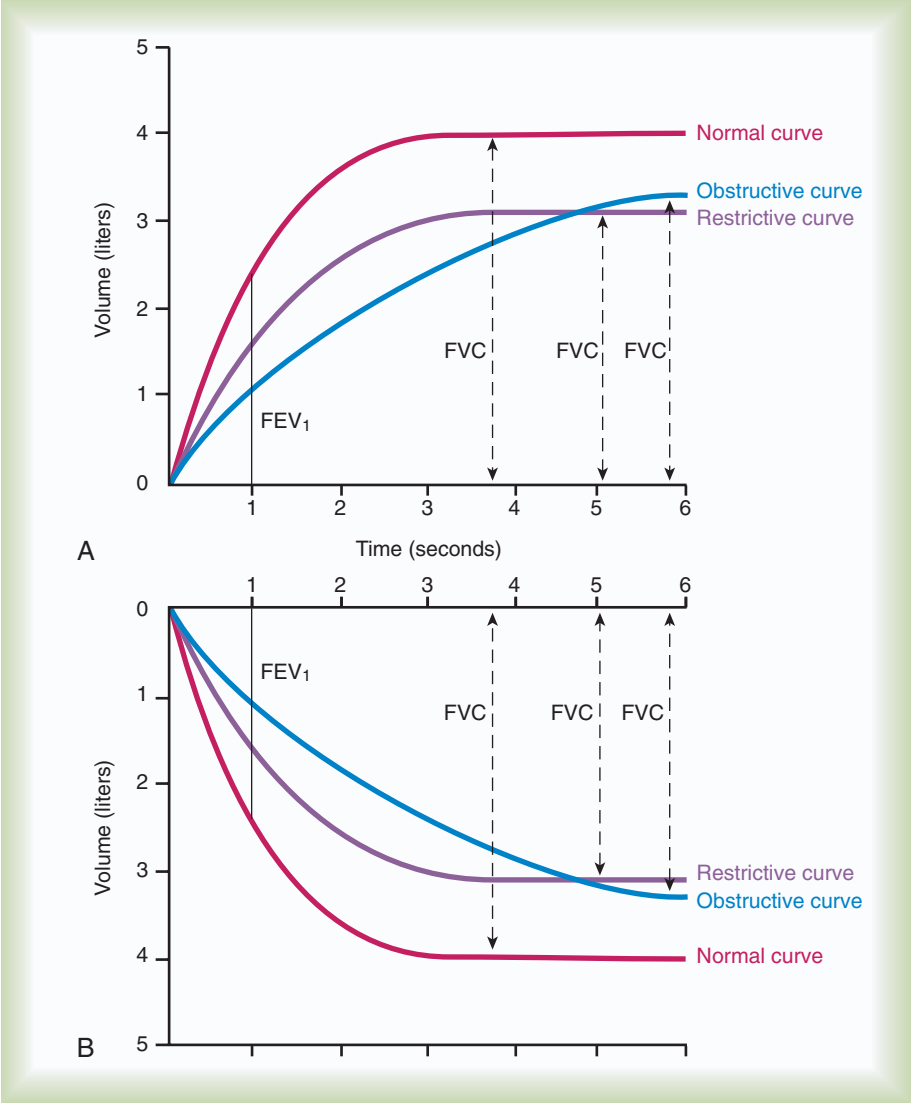

FIGURE 20-7 Forced vital capacity (FVC) curves comparing normal, obstructive, and restrictive disorders. **A,** Curves as they appear on commonly available spirometers with tracings beginning at the bottom left corner. **B,** The same curves as they appear on some spirometers with tracings beginning at upper left corner.

occur in the middle of FVC. Reduced $FEF_{25\%-75\%}$ or $FEF_{50\%}$ may occur because of small airway obstruction and from lack of effort to sustain a maximal exhalation. $FEF_{75\%}$ and $FEF_{75\%-85\%}$ occur late in FVC and reflect on the smallest airways. Experts differ on the significance of these flow rates. A singular reduction in small airway flow may indicate nothing at all or may be an early indicator of obstruction.

The shape of the flow-volume loop and the $FEF_{50\%}/FIF_{50\%}$ ratio provide additional information about upper airway obstruction. Compared with the normal flow-volume loop, a fixed upper airway obstruction produces a curve that appears box-shaped. In Figure 20-9, both expiratory and inspiratory flows are decreased and limited by the solid obstruction; the $FEF_{50\%}/FIF_{50\%}$ ratio remains normal. Variable upper airway obstructions produce two different shapes depending on the site of the obstruction. Because the intraairway pressure during a forced inspiration is less than atmospheric outside the thorax, a variable extrathoracic upper airway obstruction limits inspiratory flow, and the $FEF_{50\%}/FIF_{50\%}$ ratio is greater than 1.0. Because the intraairway pressure during a forced inspiration is greater than atmospheric pressure inside the thorax, a variable intrathoracic upper airway obstruction limits expiratory flow, and the $FEF_{50\%}/FIF_{50\%}$ ratio is less than 1.0.

Similar to other spirometric measurements of pulmonary mechanics, normal values of MVV are based on gender, age, and height. MVV is reduced in patients with moderate and severe airway obstruction. A measured value less than 75% of predicted is significant. The normal for men is approximately 160 to 180 L/min; it is slightly lower in women. In restrictive lung disease, MVV may be normal or only slightly reduced. Respiratory muscle strength is a primary determinant of MVV in patients with interstitial lung disease and an important determinant in patients with chronic obstructive pulmonary disease (COPD). Undernourished patients also may have a reduced MVV.

RULE OF THUMB

If a person cannot exhale at least 70% of his or her VC in 1 second, it is highly likely the person has an obstructive disorder.

Reversibility

Based on the initial results of baseline spirometry, additional testing of pulmonary mechanics is often desirable. If the baseline test indicates airway obstruction, determining the reversibility of the obstruction is indicated. RTs also use the concept of reversibility when evaluating routine therapy by performing spirometry before and after therapy. In the laboratory, the FVC maneuver is often repeated after the patient has received a bronchodilator administered by small volume nebulizer or metered dose inhaler. This laboratory protocol is commonly known as *spirometry before and after bronchodilator*. Reversibility of the airway obstruction indicates effective therapy. Although improvement in other measurements of pulmonary function is sometimes used, reversibility is defined as a 15% or greater improvement in FEV_1 *and* at least a 200-ml increase in FEV_1. Improvement is determined using the percent change formula:

$$\%\ \text{Improvement} = \frac{\text{Post}FEV_1 - \text{Pre}FEV_1}{\text{Pre}FEV_1} \times 100$$

Bronchoprovocation

When the patient's history suggests episodic symptoms of hyperreactive airways and airway obstruction, such as seasonal or exercise-induced wheezing, and the results of baseline spirometry are normal, performing a bronchial provocation may be indicated.[10] Bronchial provocation testing uses an agent to stimulate a hyperreactive airway response and to create airway obstruction. Although several types of provocations are

possible, such as inhaling histamine or cold air or exercising, provoking a hyperreactive airway response by inhaling methacholine is the most popular technique with the most predictable results. The procedure usually begins with the patient inhaling a normal saline aerosol and then repeating the FVC maneuver. Some very sensitive patients exhibit hyperreactive airways with saline alone; a positive response to saline is defined as a decrease in FEV_1 of 10% or greater. The methacholine provocation protocol systematically exposes the patient to increasing dosages of methacholine. Usually starting with a low dose of 0.03 mg/ml, patients inhale methacholine aerosol and then repeat the FVC maneuver. A *positive response* to methacholine is defined as a decrease in FEV_1 of 20% or greater (another example of percent change). If a positive response does not occur, the methacholine dose is doubled to 0.06 mg/ml, and the FVC maneuver is repeated. The process of "double-dosing" and performing FVC maneuvers continues until there is a positive response or until the full dose, 16 mg/ml, is given. If a positive response occurs, treatment with a fast-acting bronchodilator is indicated, and sometimes administering O_2 is helpful. The final test report should include the concentration of methacholine that caused the 20% decrease in FEV_1 in the form of $PD\%FEV_1$. For example, $PD_{22}FEV_1$ = 4 mg/ml indicates that the provocation dose of 4 mg/ml resulted in a 22% decrease in FEV_1.[10-12]

It should be noted that given the nature and goal of this test to induce bronchospasm, and in many cases do so in patients with a suspicion of preexisting lung disease, certain precautions need to be taken when performing a methacholine challenge. Most notably, it is imperative that an evidence-based protocol be in place to address patients who respond to the test adversely by developing status asthmaticus or other life-threading conditions. In general, the protocol should include the availability of fast-acting bronchodilators, a code/crash cart, and health care professionals who are trained in Advance Cardiac Life Support.

RULE OF THUMB

Normal pulmonary function values are predictably based on the subject's age, height, gender, ethnicity, and sometimes weight. Normal pulmonary function predictably declines with age older than 20 years.

Lung Volumes and Capacities

There are four lung volumes and four lung capacities. A lung capacity consists of two or more lung volumes. The lung volumes are **tidal volume** (V_T), **inspiratory reserve volume** (IRV), **expiratory reserve volume** (ERV), and **residual volume** (RV). The four lung capacities are TLC, IC, FRC, and VC. These volumes and capacities are shown in Figure 20-10. The lung volumes that can be measured directly with a spirometer or pneumotachometer include V_T, IC, IRV, ERV, and VC. Because the RV cannot be exhaled, the RV, FRC, and TLC must be measured using indirect methods.

Knowing TLC is necessary to identify patients with a restrictive pattern of pulmonary impairment. Measuring FRC is necessary to quantify hyperinflation, which may be associated with obstructive impairment. Calculating RV is necessary to gauge any air trapping present. Measurements of V_T, IC, ERV, IRV, and VC may be used in calculations of TLC or be useful to clinicians considering weaning parameters such as the rapid-shallow-breathing index (f/V_T) or inspiration goals of hyperinflation therapy. Standards for measuring lung volumes and capacities were initially published in 2005[4]; these standards focus primarily on the techniques to measure FRC. Following the measurement of FRC, measurements of ERV and VC enable calculation of TLC according to the formulas:

$$TLC = FRC + IC$$

or

$$TLC = (FRC - ERV) + VC$$

MINI CLINI

Why Are Functional Residual Capacity and Residual Volume Increased in Emphysema?

PROBLEM: In the advanced stages of pulmonary emphysema, FRC and RV are increased; in addition, VC is often decreased. Why do these changes occur?

SOLUTION: When the ventilatory muscles relax, the opposing forces of lung recoil and chest wall expansion determine the size of FRC. Emphysema is characterized by a destruction of elastic tissue in the lung, which causes a lower lung recoil force. When lung recoil forces decrease, as in emphysema, chest wall expansion forces predominate and the chest wall expands outward, pulling the lung with it. As the lung stretches to a larger volume, its recoil force increases, and eventually equilibrium is reestablished between the lung and chest wall. This new equilibrium occurs at an increased lung volume, so FRC is increased. RV is increased in emphysema because VC is decreased owing to small airway obstruction. When a person with emphysema tries to exhale completely, the bronchioles collapse, trapping air in the lungs and increasing RV. Increased FRC is called *hyperinflation,* and increased RV is called *air trapping.*

The V_T is measured directly from a spirogram (see Figure 20-10). For the purposes of ensuring test validity and standardization, the patient should be in a sitting or reclining position and wearing a nose clip. It sometimes takes the patient 1 to 2 minutes to be at rest and become accustomed to the nose clip and mouthpiece. The patient breathes through a tight-fitting mouthpiece until a normal, rhythmic breathing pattern is established. Because V_T varies normally from breath to breath, an average V_T is a more reliable measurement. In the laboratory, an average V_T sometimes is measured during 3 minutes of quiet breathing while the spirometer records volumes and graphs volume and time. At the bedside, an average V_T usually is

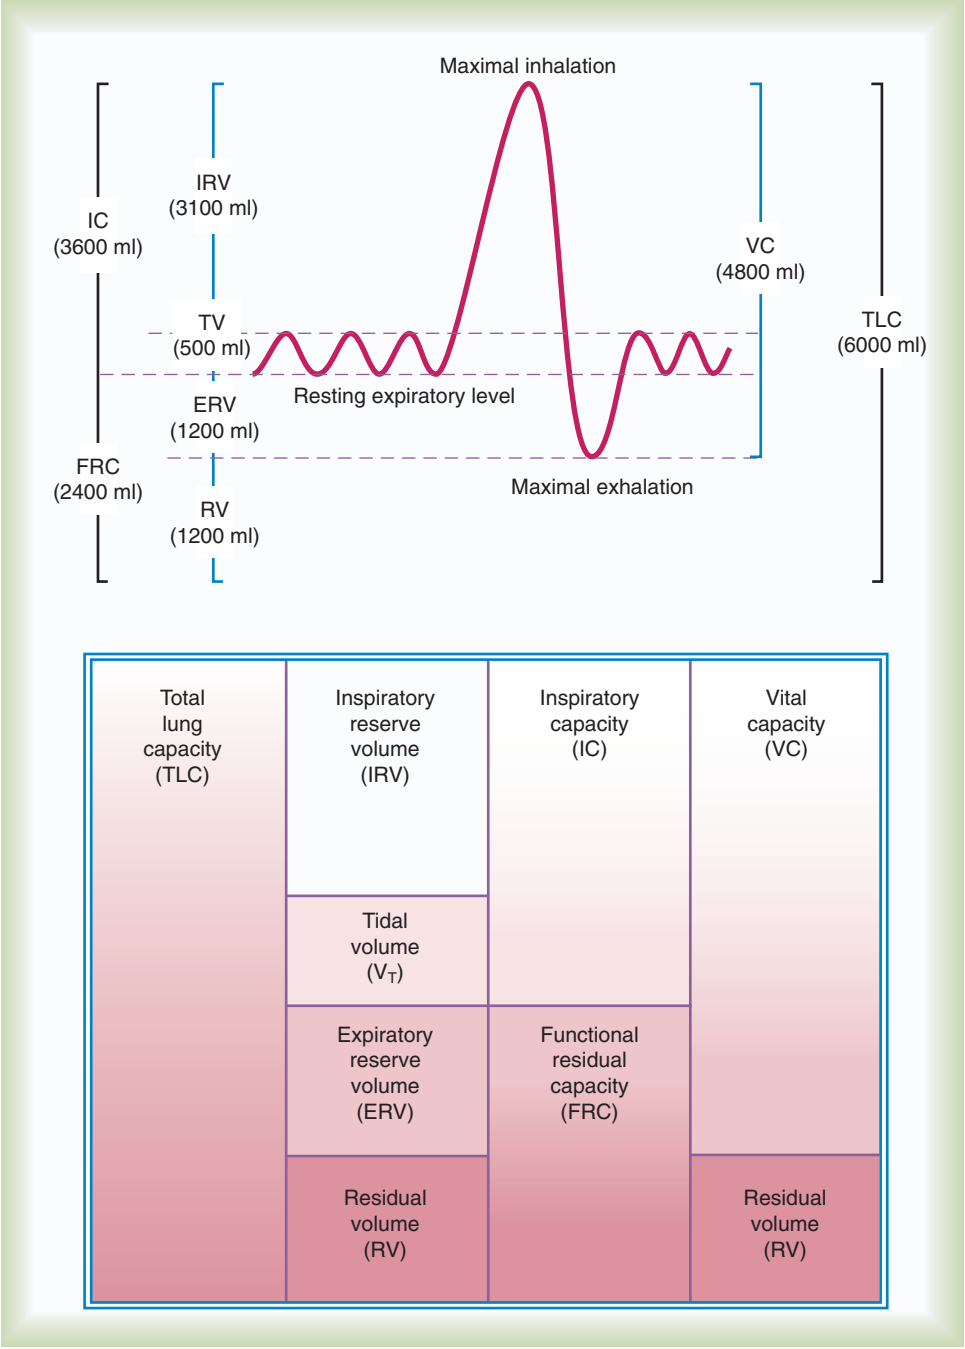

FIGURE 20-10 Lung volumes and capacities. Volumes listed are average normal values for a young, healthy adult man.

measured over 1 minute; the patient breathes normally into a spirometer that stores in memory each volume exhaled for 1 minute and computes an average. An alternative approach is to measure the total volume of air exhaled for 1 minute ($\dot{V}_E$) and divide by the breathing frequency (f) counted during the same period. The following formula can be used to calculate the V_T: $V_T = (\dot{V}_E \div f)$.

The IC is also measured directly from a spirogram. The patient is asked to inhale maximally from the resting FRC at the end of a normal effortless exhalation. To ensure validity, a consistent resting expiratory level should be obvious on the spirogram before inhaling. To ensure reliability, the IC should be measured at least twice, and the two largest measurements should agree within 5%. Because the definition of IC is the maximal volume inhaled, the largest measurement is the patient's IC. (See Clinical Practice Guideline 20-2.)

The ERV is measured directly from the spirogram (see Figure 20-10). The patient is asked to breathe normally for a few breaths and then exhale maximally. The ERV is the volume of air exhaled between the resting expiratory level and the maximal

20-2 Measurement of Static Lung Volumes

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

Indications include the need to do the following:

- Diagnose restrictive disease patterns.
- Differentiate between obstructive and restrictive disease patterns.
- Assess response to therapeutic interventions (e.g., transplantation, radiation, chemotherapy, lobectomy).
- Aid in the interpretation of other lung function tests.
- Make preoperative assessments in patients with impaired lung function that would be affected by surgery.
- Evaluate pulmonary disability.
- Quantify the amount of gas trapping by comparing results of different techniques.

CONTRAINDICATIONS

- No apparent absolute contraindications exist; relative contraindications for spirometry include hemoptysis of unknown origin, untreated pneumothorax, unstable cardiovascular status, and thoracic and abdominal or cerebral aneurysms.
- With respect to whole-body plethysmography, factors such as claustrophobia, upper body paralysis, obtrusive body casts, or other conditions that immobilize or prevent the patient from fitting into or gaining access to the "body box" are a concern. In addition, the procedure may necessitate stopping intravenous therapy or supplemental O_2.

HAZARDS AND COMPLICATIONS

- Nosocomial infection contracted from improperly cleaned tubing, mouthpieces, and pneumotachographs.
- Hypoxemia from interruption of O_2 therapy with the body box.
- Depressed ventilatory drive in susceptible subjects (i.e., CO_2 retainers) as a consequence of breathing 100% O_2 during the nitrogen washout; such patients should be carefully observed.
- Hypercapnia and hypoxemia during helium-dilution FRC determinations as a consequence of failure to remove CO_2 or add O_2 adequately.

ASSESSMENT OF NEED

Determine that valid indications are present.

ASSESSMENT OF OUTCOME AND TEST QUALITY

- Outcome and test quality are determined by ascertaining that the desired information has been generated for the specific indication and that validity and reproducibility have been ensured.
- Results are valid if the equipment functions acceptably and the subject is able to perform the maneuvers in an acceptable and reproducible fashion.
- Report of test results should contain a statement by the technician performing the test about test quality (including patient understanding of directions and effort expended) and, if appropriate, which recommendations were not met.
- Equipment calibration and quality control measures specific to measuring lung volumes should be applied and documented.

MONITORING

The following should be monitored during lung-volume determinations:

- Test data of repeated efforts (i.e., reproducibility of results) to ascertain the validity of results
- The patient for any adverse effects of testing (patients on supplemental O_2 may require periods of time to rest on O_2 between trials)

**For the complete guideline, see American Association for Respiratory Care: Clinical practice guideline: static lung volumes: 2001 revisions and updates.*

exhalation level on the spirogram. To ensure validity, a consistent resting expiratory level should be obvious on the spirogram before exhaling maximally. To ensure reliability, the ERV should be measured at least twice and the two largest measurements should agree within 5%. Because the definition of ERV is the maximal volume exhaled, the largest measurement is the patient's ERV.

The VC is the most commonly measured lung volume. There are several methods of measuring the VC. The VC can be measured during inspiration or during a slow prolonged expiration when air trapping is of concern. To measure the VC during inspiration, the patient exhales maximally and then inhales as deeply as possible. The volume of the maximal inspiration is the inspiratory VC. To measure the VC during expiration, the patient inhales maximally and then exhales maximally, taking all the time necessary to exhale completely. The exhaled volume is the slow VC. An alternative method is to measure the IC and the ERV and add these volumes together for a "combined" VC, but this method should be reserved only for patients who cannot otherwise execute the VC. The VC also is measured when it is exhaled forcefully and as rapidly as possible. This technique is called the *FVC*, and it is used to assess pulmonary mechanics under the section spirometry.

Because the RV cannot be exhaled, RV, FRC, and TLC cannot be measured directly with a spirometer or pneumotachometer. There are three indirect techniques to measure these lung volumes: helium dilution, nitrogen washout, and body plethysmography. The He dilution and N washout techniques measure whatever gas is in the lungs at the beginning of the test, if the gas is in contact with unobstructed airways. The body plethysmographic technique measures all the gas in the thorax at the resting expiratory volume. Because the plethysmographic

technique measures all gas in the thorax, including gas that is trapped distal to obstructed airways or gas in the pleural space, the lung volume measured by this technique is called the **thoracic gas volume** (TGV) (V_{TG}, or FRC_{Pleth}). In healthy individuals, TGV is identical to FRC measured by both the gas dilution and washout techniques. However, in patients with obstructive lung disease with gas trapping, TGV is often larger than FRC measured by other methods. TGV is also more complex and cumbersome to perform. Therefore, unless specifically requested by a physician, He dilution or N washout methods are routinely used. The latter two allow measurements of either FRC or TLC. Once one of them is measured, the other can be calculated using the previous formulas. For simplicity, we will only describe the maneuvers used to measure FRC below.[13] (See AARC Clinical Practice Guideline 20-2.)

Helium Dilution

The helium dilution technique for measuring lung volumes uses a closed, rebreathing circuit (Figure 20-11).[14-16] This technique is based on the assumptions that the patient has no He in his or her lungs, and that an equilibration of He can occur between the spirometer and the lungs. First, volume (V1) and concentration (C1) of He are measured at the beginning of the test. Next, the valve is turned to connect the patient to the breathing circuit, usually at the resting expiratory level of the FRC. The patient is connected to the He-air mixture, and the concentration of He is diluted slowly by the patient's lung volume. Wearing nose clips, the patient breathes normally in the closed circuit. Exhaled CO_2 is absorbed with soda lime, and O_2 is added at a rate equal to the patient's O_2 consumption. A constant volume is maintained to ensure accurate He concentration measurements. The patient rebreathes the gas in the system until equilibrium of He concentration is established. In healthy patients and patients with a small FRC, equilibration occurs in 2 to 5 minutes. Patients with obstructive lung disease may require 20 minutes to equilibrate because of slow gas mixing in the lungs. The He dilution time or the duration of the test is gives a reasonable indication of the distribution of ventilation.

For FRC to be calculated using the He dilution technique, several observations must be made: V1 and C1 (see earlier discussion), before the patient is connected to the breathing circuit; the final He concentration (C2) after He equilibrium between the spirometer and patient is established, the spirometer temperature, and the time necessary for He equilibration to occur. If there was no absorption of the He across the pulmonary capillaries,

$$V1 \times C1 = V2 \times C2$$

where V2 is the volume of the He at the end of the test. After measuring V1, C1 and C2, V2 is calculated: FRC = V2 −V1 (see Figure 20-11).

Corrections for temperature and He absorption are normally applied. All lung volumes and capacities must be reported under BTPS conditions. Volumes measured by spirometers are at ambient temperature, pressure, and saturated (ATPS) conditions and must be adjusted for the temperature difference between the spirometer and the patient's body temperature. This ATPS to BTPS adjustment can increase volumes 5% to 10%, and the difference is large enough to invalidate the test

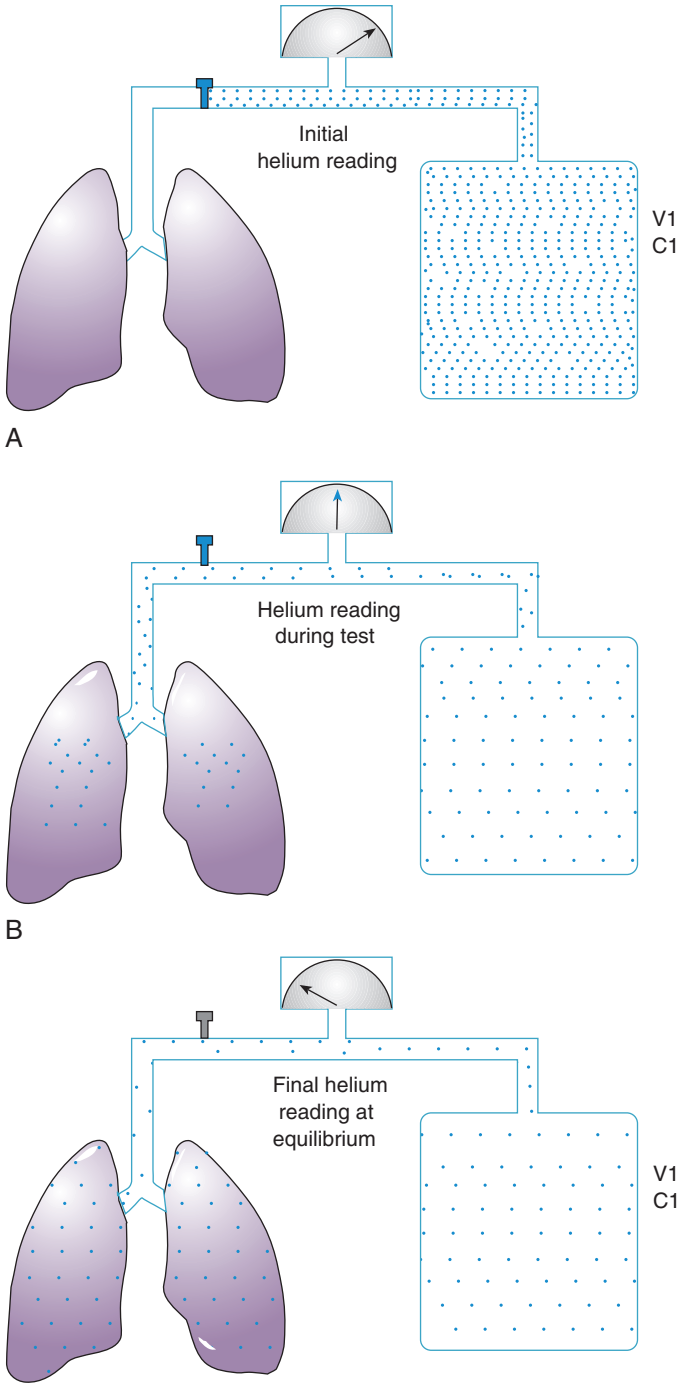

FIGURE 20-11 Helium dilution method for measuring functional residual capacity. **A,** Initial He readings, He volume (V1) and concentration (C1), lung volume is at functional residual capacity. **B,** He reading during test. **C,** Final He concentration reading (C2) at equilibrium. See text for details.

results, unless the correction is made. Although He is an inert gas with a negligible solubility in plasma, it is assumed that a small amount of He diffuses across the alveolar-capillary membrane. To account for the loss, 30 ml of BTPS-corrected volume is subtracted for each minute of He breathing, up to 200 ml for a 7-minute test. Once these corrections are made, TLC can be calculated using spirometry data.

Nitrogen Washout

The nitrogen N technique uses a nonrebreathing or open circuit (Figure 20-12).[15,16] The technique is based on the assumptions that the N concentration in the lungs is 78% and in equilibrium with the atmosphere, that the patient inhales 100% O_2, and that the O_2 replaces all of the N in the lungs. Similar to the He dilution technique, the patient is connected to the system at FRC. The patient's exhaled gas is monitored, and its volume and N percentage are measured.

Generally, two types of circuits are used to measure lung volumes with this technique. In one type of circuit, all of the exhaled gases are collected in a large container, where the volume and concentration of N are measured. In the second type of circuit, the volume and concentration of each exhaled breath are measured separately and stored in a memory; the sum of the volumes and the weighted average of the N concentration are calculated by a computer.

Wearing nose clips, the patient breathes 100% O_2 until nearly all of the N has been washed out of the lungs, leaving less than 1.5% N in the lungs. When the peak exhaled concentration of N is less than 1.5%, the patient exhales completely, and the fractional concentration of alveolar N (F_AN_2) is noted. Similar to the He technique, the time it takes to wash out the N is approximately 2 to 5 minutes in healthy individuals and longer in patients with obstructive lung disease. The test must occur in a leak-proof circuit because the presence of any air increases the measured N percentages and results in grossly elevated measurements of lung volume.

For FRC to be calculated by the N washout technique, several measurements must be made: the total volume of gas exhaled during the test (V_E), the fractional concentration of exhaled N in the total gas volume (F_EN_2), the fractional concentration of N in the alveoli at the end of the test (F_AN_2), and the spirometer temperature. FRC can be calculated with the following equation:

$$FRC = \frac{V_E \times F_EN_2}{0.78 - F_AN_2}$$

The calculated FRC must be adjusted for the temperature difference between the spirometer and the patient's body temperature using the BTPS correction factor. During the test, some N from the plasma and body tissues is usually excreted and exhaled with lung N. For this reason, another correction is needed, using duration of the test and the weight of the patient.

Plethysmography

The plethysmography technique applies Boyle's law and uses measurements of volume and pressure changes to determine lung volume, assuming temperature is constant.[15-17] The plethysmography technique measures the volume of all compressible gas in the thorax, including gas trapped behind airway obstructions or in the pleural space. Gas in the abdomen also may be included in the measurement. The whole-body plethysmograph consists of a sealed chamber in which the patient sits (Figure 20-13). Pressure transducers (electronic manometers) measure pressure at the mouth and in the chamber. An electronically controlled shutter near the mouthpiece allows the airway to be

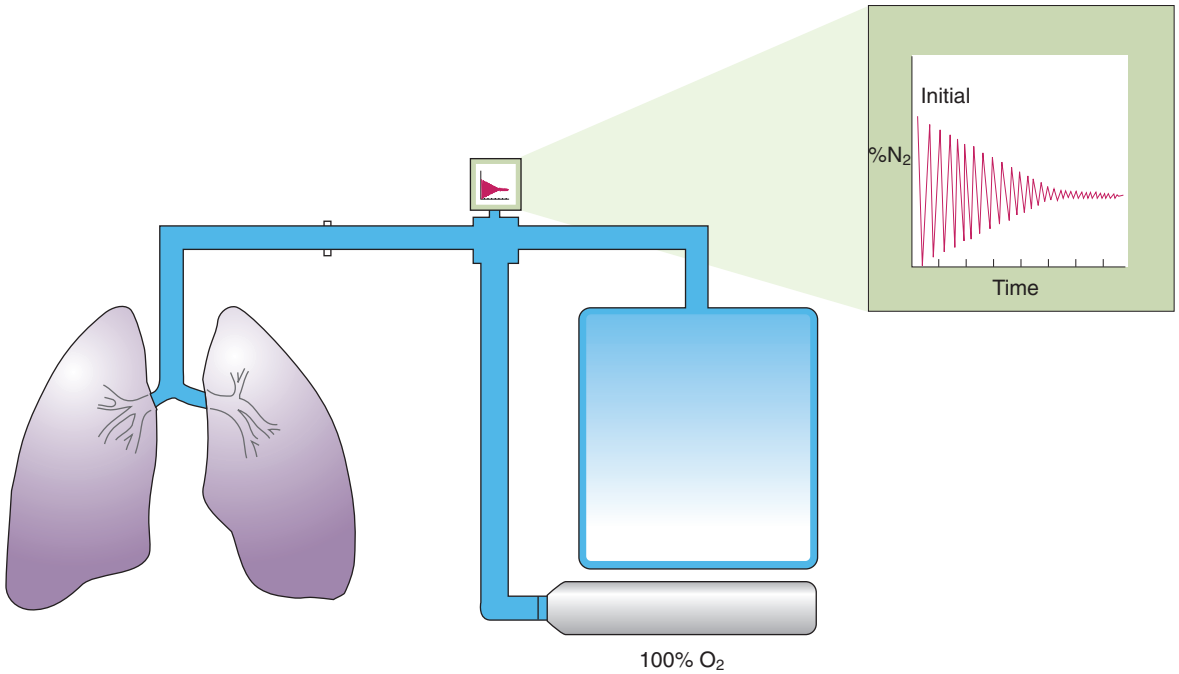

FIGURE 20-12 Nitrogen washout method for measuring functional residual capacity, residual volume, and total lung capacity.

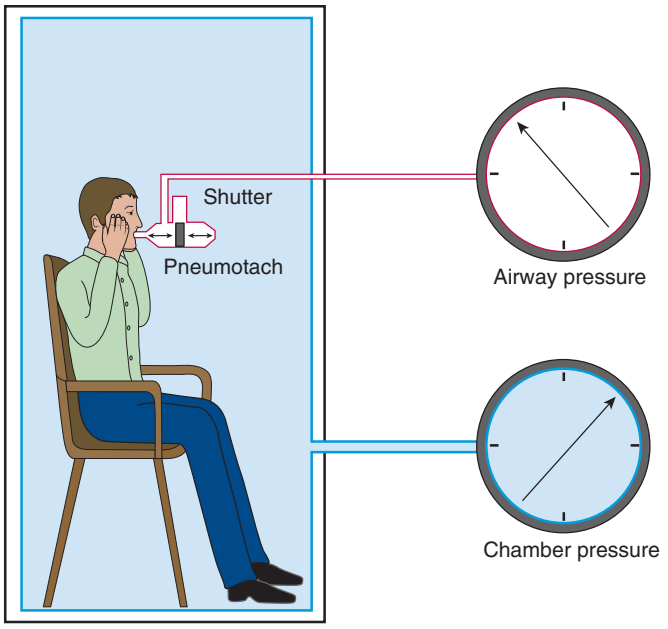

FIGURE 20-13 Body plethysmography method for measuring lung volumes. *V* is the change in gas volume in the lungs, as sensed by the chamber pressure manometer. *P* is the change in pressure produced by the respiratory efforts of breathing against the shutter, as sensed by the airway pressure manometer.

occluded periodically, measuring airway pressure changes under conditions of no airflow. Without airflow, pressure changes measured at the mouth are pressure changes in the alveoli. According to Boyle's law ($V \times P = k$), when temperature is constant, volume changes in the thorax create volume changes in the chamber, which are reflected by pressure changes in the chamber. When measurement of TGV is being done, the patient sits in the chamber and initially breathes normal tidal volumes through the mouthpiece. When the patient is near FRC, the shutter is closed at end expiration for 2 to 3 seconds. The patient holds his or her cheeks and performs gentle panting at 1 Hz or one pant per second. During panting, changes in airway pressure (ΔP) and changes in chamber volume (ΔV) are measured. Because the panting maneuver occurs with small pressure changes around barometric pressure, the simplified equation used to calculate TGV is:

$$TGV = P_B \times (\Delta V \div \Delta P)$$

where P_B is the barometric pressure in cm H_2O.

A series of three to five panting maneuvers should be performed. After panting, the patient should exhale completely to record ERV and then inhale maximally to record the inspiratory vital capacity.

Because the body plethysmographic method of measuring FRC actually measures TGV, the value obtained for some patients may be larger than values resulting from either the He dilution or N washout techniques. Such a difference occurs whenever there is gas in the thorax that is not in communication with patent airways, as might be the case in patients with pneumothorax, pneumomediastinum, or emphysema. Assuming that TGV actually represents FRC, calculations can be made for TLC and RV, similar to He dilution or N washout methods.

Interpretation

Changes in lung volumes and capacities are generally consistent with the pattern of impairment. TLC, FRC, and RV increase with obstructive lung diseases and decrease with restrictive impairment. Some lung volumes provide valuable diagnostic information. For example, TLC is always reduced in restrictive lung disease, unless obstruction and restriction occur together. When obstruction and restriction occur together, the TLC may be a less sensitive measure of the restrictive impairment. Other volumes and capacities may remain normal with mild obstructive or restrictive disease. The pattern of lung volume changes and the proportion of FRC and RV to TLC are also important.

Normal Values for Lung Volumes. The normal V_T is approximately 500 to 700 ml for an average healthy adult. In the normal population, great variation of tidal volumes and measurements beyond the normal range are not indicative of a disease process. Normal V_T is often observed in both restrictive and obstructive lung diseases. V_T alone is not a valid indicator of the type of lung disease.

The normal IC is approximately 3.6 L, with a significant variation in the normal population. IC may be normal or reduced in restrictive and obstructive lung diseases. A reduction of IC occurs in restrictive lung diseases because the patient's inhaled volume is reduced and there is a reduction in TLC. In mild obstructive lung diseases, IC is usually normal. In moderate and severe obstructive diseases, IC can be reduced because the resting expiratory level of FRC has increased owing to hyperinflation of the lungs. An increase in IC may occur when the patient inhales from below the resting expiratory level when the measurement is performed; athletes and musicians who play wind instruments may have increased inspiratory capacities. RTs use the measurement of IC in clinical protocols to decide between methods of lung expansion therapy (see Chapter 42).

IRV is not commonly measured. Similar to V_T and IC, IRV can be normal in both restrictive and obstructive diseases and is not a useful diagnostic measurement. The normal value for IRV is 3.10 L.

The normal ERV is approximately 1.2 L and represents approximately 20% to 25% of the VC. It can be either normal or reduced in obstructive and restrictive lung diseases. ERV is subtracted from FRC to calculate RV.

The normal value of the VC is 4.8 L and represents approximately 80% of TLC. Normal values for VC can vary significantly depending on age, gender, height, and ethnicity. A reduction of VC occurs in restrictive lung diseases because the patient's inhaled volume is reduced and there is a reduction in TLC. In mild obstructive lung diseases, the slow VC is usually normal if the patient exhales leisurely and has had enough time to exhale

completely or if the VC is measured during inspiration. Measurements made from FVC provide valuable data for pulmonary mechanics.

RV, FRC, and TLC are the most important measurements of lung volumes. Age, height, gender, ethnicity, and sometimes weight or body surface area correlate with normal values for these lung volumes.[18] Table 20-5 provides common regression equations to predict the lung volumes for individuals of specific height (in centimeters), age (in years), and gender. A positive correlation exists between lung volumes and height, and a negative correlation exists between lung volumes and age for patients older than 20 years. Male values are larger than female values when height and age are equal.

TABLE 20-5

Examples of Regression Equations for Predicting Normal Lung Volumes and Capacities in Adults

Lung Volumes	Equations
Men	
FRC (L)	0.0234 (Ht) + 0.01 (A) – 1.09
RV (L)	0.0131 (Ht) + 0.022 (A) – 1.23
TLC (L)	0.0799 (Ht) – 7.08
FRC/TLC%	43.8 + 0.21 (A)
RV/TLC%	14.0 + 0.39 (A)
Women	
FRC (L)	0.0224 (Ht) + 0.001 (A) – 1.00
RV (L)	0.0181 (Ht) + 0.016 (A) – 2.00
TLC (L)	0.0660 (Ht) – 5.79
FRC/TLC%	45.1 + 0.16 (A)
RV/TLC%	20.0 + 0.34 (A)

From Stocks J, Quanjer PH: Reference values for residual volume, functional residual capacity and total lung capacity. Eur Respir J 8:492–497, 1995.
A, Age in years; *Ht,* height in centimeters.

The typical normal TLC is 6.0 L. The normal RV is approximately 1.2 L and represents approximately 20% of TLC. FRC is approximately 2.4 L, which represents approximately 40% of the TLC. RV and FRC are usually enlarged in acute and chronic obstructive lung diseases because of hyperinflation and air trapping (Figure 20-14). TLC also may be enlarged in COPD. TLC is always reduced in restrictive lung diseases because of a loss of lung volume; RV and FRC are often reduced proportionately. Certain acute disorders, such as pulmonary edema, atelectasis, and consolidation, also cause a reduction of TLC and FRC.

Diffusing Capacity

The third major category of pulmonary function testing is measuring the ability of the lungs to transfer gases across the alveolar-capillary membrane. As discussed in Chapter 12, the diffusion of gases across a sheet of membrane depends on various factors.

$$V_{gas} = D_L \times (P_1 - P_2)$$

Vgas = Amount of the gas transferred into the lungs
P1 = Partial pressure of the gas in the alveolus
P2 = Partial pressure of the gas in the pulmonary capillary

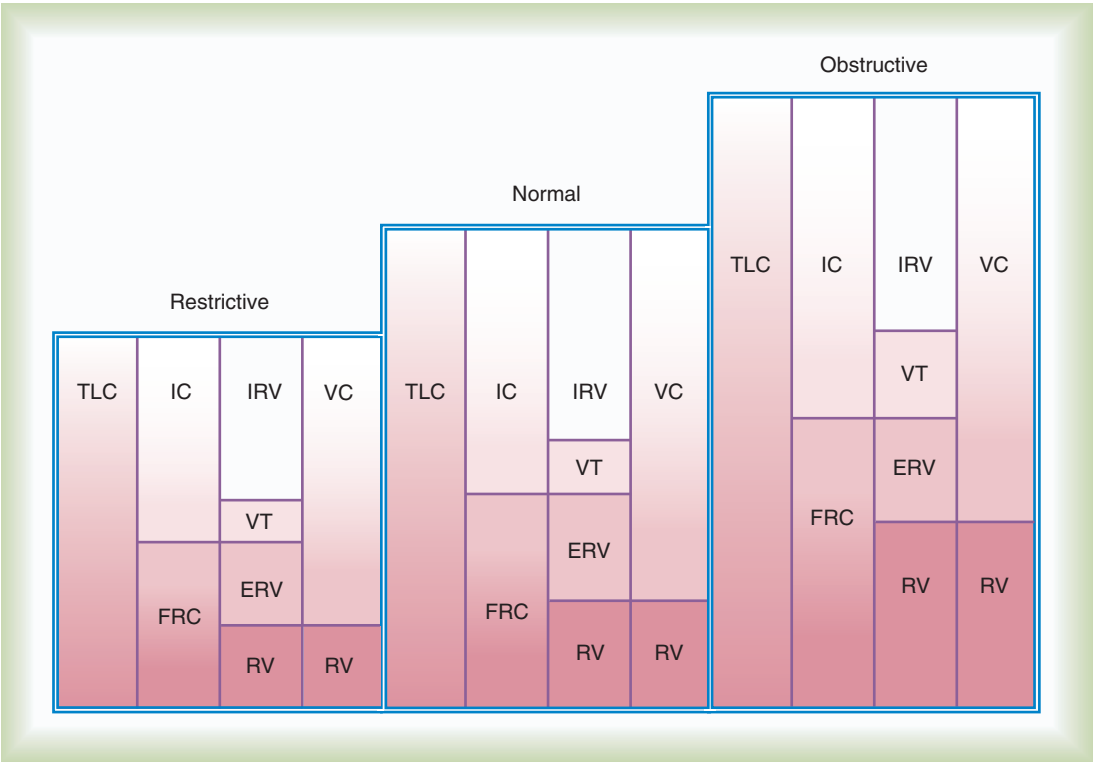

FIGURE 20-14 Changes in lung volumes and capacities with pulmonary disease. *ERV,* Expiratory reserve volume; *FRC,* functional residual capacity; *IC,* inspiratory capacity; *IRV,* inspiratory reserve volume; *TLC,* total lung capacity; *VT,* tidal volume.

Carbon monoxide (CO) is the gas normally used to measure the DL. The **diffusing capacity of the lung for carbon monoxide** (DLCO) is expressed in ml/min/mm Hg under standard temperature and pressure and dry conditions. CO is used as the transfer gas because CO is similar to O_2 in important ways. CO and O_2 have similar molecular weights and solubility coefficients. Similar to O_2, CO also chemically combines with hemoglobin (Hb). CO has a very high affinity for Hb and diffuses rapidly into the pulmonary blood, keeping the *pulmonary capillary partial pressure of CO (P_2 in the formula above)* near zero. Consequently, the formula for the DLCO calculation can be rewritten as follows:

$$DL_{CO} = \frac{\dot{V}_{CO}}{P_ACO}$$

Where $\dot{V}_{CO}$ is the amount of CO taken up by the lungs and P_ACO is the alveolar partial pressure of CO during the test.

Single-Breath Technique

There are several techniques to measure the diffusing capacity of the lung for CO, including steady-state, intrabreath, and rebreathing techniques, but the single-breath method (DLCO-SB) is the most common measurement technique because it is quick and reproducible. Standards for measuring diffusing capacity of the lung were initially published in 1995 and updated in 2005; these standards focus primarily on the DLCO-SB.[5,19] During the single-breath method, the patient exhales completely to RV, rapidly inspires to TLC a volume of air containing small concentration of CO and He, maintains breath holding for 10 seconds, and then exhales at least 1 L rapidly. He is added to the inhaled gas mixture to help with the estimation of effective lung volume, as well as alveolar CO concentration (F_ACO). Note that F_ACO is different from the inhaled CO concentration because dilution by RV and this corrected value should be used in calculation of P_ACO. The dilution of CO is proportional to the dilution of He, and can be calculated using inhaled (F_IHe) and exhaled (F_EHe) He concentrations. A sample of exhaled alveolar gas is collected and analyzed for expired CO (F_ECO). The **effective total lung capacity** (or alveolar volume, V_A) can be similarly calculated using measured VC and inhaled and exhaled He concentrations. The V_A is necessary to calculate $\dot{V}_{CO}$, and it is used in the determination of the diffusing capacity of the lung-to-alveolar volume ratio ($DLCO/V_A$, discussed later). The total time of the test (t) is recorded and used in ultimate calculation of DLCO. To regulate the breath holding period, some measuring systems close the mouthpiece with a timed shutter. The suitable breathing pattern requires patient cooperation and coordination; some patients benefit from a timer as a visual aid.

It is important to note that the rate of CO transfer across the membrane is not uniform throughout the test. When a bolus of CO gas is inhaled, the rate of gas diffusion declines logarithmically with time, meaning that the rate of gas transfer at the beginning of the test (high CO concentration) is much greater than at the end of the test (low CO concentration). The single-breath method (DLCO-SB) is based on the diffusion decay curve described by Forster and colleagues[20] (Figure 20-15). The final formula for DLCO calculation incorporates all measurements used to calculate $\dot{V}_{CO}$ and P_ACO, as well as the correction for nonlinearity of CO transfer.[5]

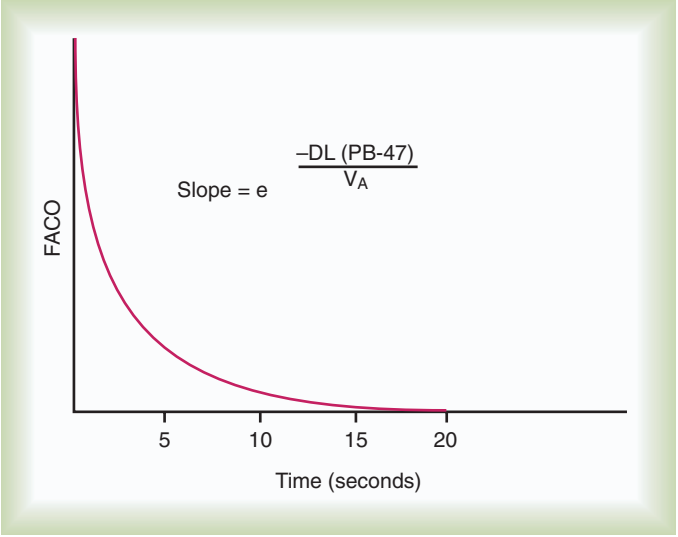

FIGURE 20-15 Concentration of alveolar carbon monoxide after a single breath to total lung capacity.

The reliability of the DLCO is based on repeatability of the test. At least 4 minutes should be allowed between tests to allow an adequate elimination of CO from the lungs. In patients with obstructive airway disease, a longer period (e.g., 10 minutes) may be necessary. The actual DLCO reported should be the mean of two acceptable tests. An acceptable test is defined as one that is reproducible to within 10% or 3 ml of the CO/min/mm Hg value, whichever is greater.[21] (See AARC Clinical Practice Guideline 20-3.)

Interpretation

Normal values for the DLCO using the single-breath technique are based primarily on a patient's age, height, and gender (Table 20-6). A typical normal value for a 20-year-old healthy man is 40 ml/min/mm Hg.[21] Factors known to affect test results should be controlled or standardized; these include body position, activity, PAO_2, Hb and carboxyhemoglobin (COHb) levels, and pulmonary blood volume. To focus the test on diffusion through the alveolar-capillary membrane, the patient should be tested at rest in a seated position, should not breathe supplemental O_2 for 10 minutes before testing, and should not have an abnormal level of COHb before the test. Mathematical corrections can be applied for patients who cannot abstain from O_2. Performing the diffusing capacity on patients who have recently smoked a cigarette or who have been exposed to environmental CO may hinder test validity. Patients should refrain from smoking on the day of the test. All patients undergoing diffusing capacity should have their Hb concentration measured, and a mathematical correction should be applied if it is abnormal. In addition, DLCO measurement may be altered in patients on supplemental O_2, or at high altitude. Provision of formulas that

20-3 Single-Breath Carbon Monoxide Diffusing Capacity

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

Tests of diffusing capacity may be indicated in the following situations:

- Evaluation and follow-up of parenchymal lung diseases associated with dusts (e.g., asbestos) or drug reactions (e.g., amiodarone) or related to sarcoidosis.
- Evaluation and follow-up of emphysema and cystic fibrosis.
- Differentiation among chronic bronchitis, emphysema, and asthma in patients with obstructive patterns.
- Evaluation of pulmonary involvement in systemic diseases (e.g., rheumatoid arthritis, lupus erythematosus).
- Evaluation of cardiovascular diseases (e.g., pulmonary hypertension, pulmonary edema, thromboembolism).
- Prediction of arterial desaturation during exercise in chronic obstructive pulmonary disease.
- Evaluation and quantification of disability associated with interstitial lung disease.
- Evaluation of the effects of chemotherapy agents or other drugs known to induce pulmonary dysfunction.
- Evaluation of hemorrhagic disorders.

CONTRAINDICATIONS

The following are relative contraindications to performing a diffusing capacity test:

- Mental confusion or incoordination preventing the subject from adequately performing the maneuver
- A large meal or vigorous exercise immediately before the test.
- Smoking within 24 hours of test administration (may have effect on diffusion capacity of the lung for carbon dioxide [DLCO] independent of carboxyhemoglobin [COHb]).

HAZARDS AND COMPLICATIONS

- Single-breath DLCO requires breath holding at total lung capacity; some patients may perform either a Valsalva (high intrathoracic pressure) or Müller (low intrathoracic pressure) maneuver. Either of these maneuvers can result in alteration of venous return to the heart.
- Transmission of infection is possible via improperly cleaned mouthpieces or from the inadvertent spread of droplet nuclei or body fluids (patient to patient or patient to technologist).

ASSESSMENT OF NEED

The need for DLCO testing exists when any of the aforementioned indications are present.

ASSESSMENT OF TEST QUALITY

Individual test maneuvers and results should be evaluated according to the American Thoracic Society recommendations. In particular, the following recommendations are pertinent:

- The inspiratory volume should exceed 90% of the largest previously measured vital capacity (forced vital capacity [FVC] or vital capacity [VC]).
- Breath hold time should be between 9 and 11 seconds, with a rapid inspiration.
- The washout volume (dead space) should be 0.75 to 1 L, or 0.50 L if the subject's VC is <2 L. If a washout volume other than 0.75 to 1 L is used, it should be noted.
- Two or more acceptable tests should be averaged. The maneuvers should be reproducible to within 10% or 3 ml of CO/min/mm Hg, whichever is greater.
- The subject should have refrained from smoking for 24 hours before the test.
- Corrections for Hb and COHb should be included; correction for tests performed at high altitude is recommended.
- If Hb correction is made, both the corrected and the uncorrected DLCO values should be reported.
- Equipment calibration and quality control measures specific to measuring diffusing capacity should be applied and documented.

MONITORING

- The final report should contain a statement about test quality.
- The final report should contain the DLCO, the corrected DLCO (Hb, COHb, altitude), and the Hb value used for correction. The alveolar volume (VA) and DL/VA (i.e., the ratio of diffusing capacity to the lung volume at which the measurement was made) may be included in the report. These values are helpful for purposes of interpretation.

**For complete guideline, see American Association for Respiratory Care: Clinical practice guideline: single-breath carbon monoxide diffusing capacity.*

are used to obtain the raw DLCO measurement or to correct it for all of these variables is outside of the scope of this chapter and is given in the references.[5]

Some clinicians argue that if the DLCO measurement has to be corrected for variables that have nothing to do with the gas transfer across the membrane, then it must not be the true diffusion that we are measuring with the DLCO. In fact, in European respiratory communities, the DLCO, as we have been describing in this chapter, is called K_{CO}, or transfer factor for CO, to differentiate it from the true diffusion properties of the lung.[5]

The DLCO may be reduced from the predicted normal in patients with obstructive or restrictive lung diseases. With destruction of alveoli in pulmonary emphysema, with small lung volumes, and with fibrosis of alveoli in asbestosis, the DLCO may be less than normal. Pulmonary embolism also may decrease the DLCO. The DLCO may be useful in identifying which patients with obstructive impairment are likely to

TABLE 20-6

Box 20-2 Effect of Various Factors on Diffusing Capacity of the Lung for Carbon Monoxide

FACTORS THAT DECREASE DLCO
- Anemia
- Carboxyhemoglobin
- Pulmonary embolism
- Diffuse pulmonary fibrosis
- Pulmonary emphysema

FACTORS THAT INCREASE DLCO
- Polycythemia
- Exercise
- Congestive heart failure

DLCO, Diffusing capacity of the lung for carbon monoxide.

experience desaturation during exercise and which may benefit from O_2 therapy. The DLCO may be increased in patients with polycythemia, congestive (left) heart failure (resulting from an increase in pulmonary vascular blood volume), and elevated cardiac output. Variables in health and disease that can alter the DLCO are summarized in Box 20-2.

The **diffusing capacity ratio of the lung-to–effective total lung capacity ratio (DLCO/VA)** differentiates between diffusion abnormalities caused by having a small lung volume compared with diffusion abnormalities caused by alveolar-capillary membrane pathologies. Patients whose only problem is small lungs would have a decreased DLCO, but their DLCO/V_A ratio would be normal. Patients with pulmonary emphysema or fibrosis would have a decreased DLCO and a decreased DLCO/V_A ratio. In contrast, patients with neuromuscular disease will similarly have restrictive lung volumes and reduced DLCO, but DLCO/V_A will likely be normal, because they will likely have normal diffusion.

INTERPRETATION OF THE PULMONARY FUNCTION REPORT

Interpretive strategies for pulmonary function testing abound. Most computer-based pulmonary function testing systems have algorithms in their software programs for computer-assisted interpretations of the pulmonary function report. Table 20-7 summarizes pulmonary function changes that may occur in advanced obstructive and restrictive patterns of lung diseases, and Figure 20-16 presents a simple algorithm to assess pulmonary function test results in clinical practice.[22,23]

MINI CLINI

Diffusing Capacity of the Lung for Carbon Monoxide in Chronic Obstructive Pulmonary Disease

PROBLEM: A patient has spirometry and lung volumes typical of the obstructive pattern. FEV_1, FEV_1/FVC, and FEFs are significantly reduced, and FRC and TLC are increased. Two common obstructive diseases are chronic bronchitis and pulmonary emphysema. How can pulmonary function data differentiate between these two diseases? The answer is the DLCO.

SOLUTION: Chronic bronchitis involves mostly airways and is characterized by chronic inflammation of the mucosa, hypertrophy of mucous glands, excessive mucus, and possibly bronchospasm, all of which narrow the airways. Pulmonary emphysema primarily involves alveolar structures and is characterized by destruction of alveolar architecture, elastic fibers, and alveolar-capillary membranes. Emphysema decreases gas-exchange surface area. Chronic bronchitis does not involve alveoli and does not change surface area for gas exchange. For these reasons, a decreased diffusion capacity is associated with emphysema rather than with chronic bronchitis. DLCO is a useful way to determine the extent to which emphysema may be present in a patient with COPD.

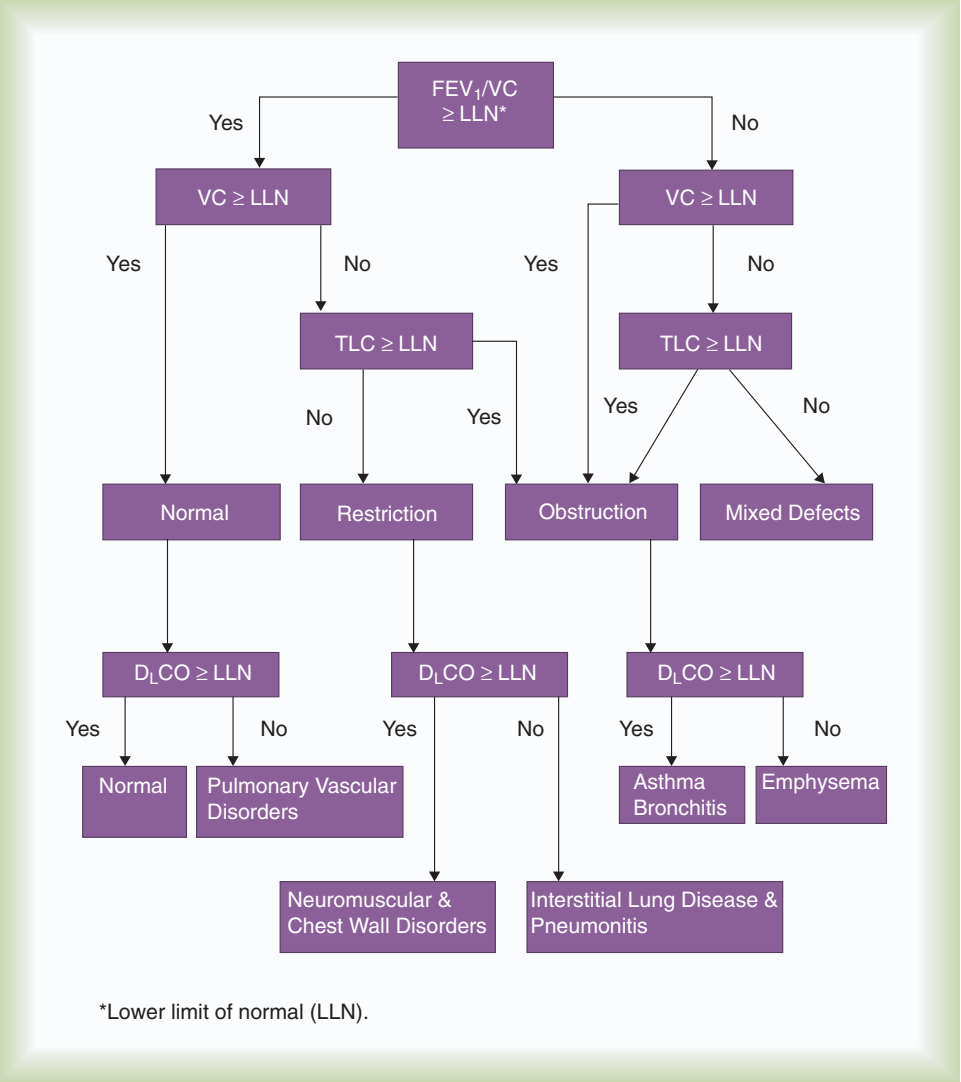

FIGURE 20-16 A simple algorithm to assess pulmonary function test results in clinical practice. *LLN,* Lower limit of normal; *ULN,* upper limit of normal. (From Gardner RM, Crapo RO, Morris AH, et al: Computer guidelines for pulmonary laboratories. Am Rev Respir Dis 134:628, 1986.)

When considering a pulmonary function report, the FEV_1/VC ratio is a good place to start because it provides an initial focus as normal, restrictive, or obstructive impairment. When the FEV_1/FVC is reduced, there is airway obstruction. FEV_1/FVC is normal in healthy individuals and patients with restriction. The LLN for FEV_1/FVC can be determined directly for various populations using regression equations in Table 20-8. However, most clinicians use an arbitrary value of 70%.

The next to consider is TLC. If the TLC is less than the LLN, often defined as less than 80% predicted normal, the patient has a restrictive impairment according to this algorithm. Patients with obstruction will often have normal or elevated TLC. Naturally, some patients may have a mixed obstructive/restrictive pattern. In those patients, TLC may be reduced, normal, or elevated.

Once obstructive/restrictive pattern is ascertained, DLCO will help differentiate between the diseases that do and do not

affect the gas transfer across the alveolar-capillary membrane. If the percent predicted normal DLCO is less than 80%, the patient has a diffusion impairment. Some laboratories also report the DLCO/V_A ratio, which indices the DLCO for lung volume measured during the single-breath test.

According to most recent ATS/ERS guidelines on PFT interpretation, the severity of obstructive *and* restrictive impairment is judged by the patient's FEV_1, and the severity of gas transfer is based on the DLCO.[21] Severity categories, based on percent predicted values, are outlined in Table 20-2. Use of other indices, such as FRC or TLC, to quantify the severity is controversial[23] and will not be discussed here. Although FEV_1 is used to quantify the severity of illness across the disease categories, it is important to note its limitations.[21] FEV_1 is a poor measurement of upper airway obstruction; it may not be suitable comparing different pulmonary conditions, it may not be reliable in the extremes of severity assessment, it has poor correlation with clinical symptoms or progression.

MINI CLINI

Identifying Patterns of Pulmonary Impairment

PROBLEM: Following are three pulmonary function reports that show three distinct examples of pulmonary impairment. Using the algorithm in Figure 20-16, identify the patterns typical of asthma, pulmonary fibrosis, and COPD.

PULMONARY FUNCTION REPORT 1

Pulmonary Measurements	Predicted Normal Value	Measured Baseline Conditions	Percent Predicted
SVC (L)	5.00	3.00	60
FVC (L)	5.00	3.00	60
FEV_1 (L)	4.00	2.80	70
$\%FEV_1/FVC$	80%	94%	—
$FEF_{25\%-75\%}$ (L/sec)	4.00	3.75	94
PEF (L/sec)	8.00	8.25	103
TLC (L)	7.20	3.96	55
FRC (L)	4.10	2.00	49
RV (L)	2.20	1.40	60
DLCO (ml/min/mm Hg)	34.0	15.9	47
DLCO/V_A (ml/min/mm Hg/L)	7.20	3.50	49

SOLUTION REPORT 1: Although FEV_1 is less than 80% of predicted, because the FEV_1/FVC is greater than 70%, there is no apparent airway obstruction. FEV_1 is reduced because FVC is reduced. The patient's measured FVC is less than the predicted FEV_1. Because TLC is less than 80% predicted, the data suggest a restrictive impairment, and because DLCO is less than 80% predicted, there is also a diffusion impairment. The low DLCO/V_A suggests that the diffusion impairment is out of proportion to the lung volume. This finding implies that the impairment to normal diffusion is the result of abnormal lung tissue. Overall, this report shows a mild to moderate restrictive pattern consistent with pulmonary fibrosis.

PULMONARY FUNCTION REPORT 2

Pulmonary Measurements	Predicted Normal Value	Measured Baseline Conditions	Percent Predicted Baseline	Measured After Bronchodilator Treatment	Percent Predicted After Treatment
SVC (L)	5.00	3.50	70	4.25	85
FVC (L)	5.00	3.30	66	4.00	80
FEV_1 (L)	4.00	2.00	50	2.50	62
$\%FEV_1/FVC$	80%	57%	—	62%	—
$FEF_{25\%-75\%}$ (L/sec)	4.00	1.00	25	2.00	50
PEF (L/sec)	8.00	6.00	75	6.50	81
TLC (L)	5.27	5.51	105	5.36	102
FRC (L)	3.11	4.55	146	3.60	116
RV (L)	1.67	2.60	156	2.00	120
DLCO (ml/min/mm Hg)	28.7	25.25	88	—	—
DLCO/V_A (ml/min/mm Hg/L)	5.45	5.17	96	—	—

SOLUTION REPORT 2: The FEV_1/FVC is less than 70%; there is airway obstruction. FEV_1 is 50% of predicted; the obstruction is moderate. Because the $FEF_{25\%-75\%}$ is 25% of predicted, the major site of obstruction is in the bronchioles. After bronchodilator inhalation, FEV_1 improved by 24% (remember to compute percent change), showing effective treatment and partial reversibility of the obstruction. The large FRC and RV show hyperinflation and air trapping, which also improved after bronchodilator therapy. Diffusing capacity is in the normal range, indicating no diffusion impairment and no alveolar problems. Overall, this report shows a moderately severe obstructive pattern with hyperinflation and air trapping responsive to bronchodilators and consistent with acute hyperreactive airways disease, such as asthma.

MINI CLINI

Identifying Patterns of Pulmonary Impairment—cont'd

PULMONARY FUNCTION REPORT 3

Pulmonary Measurements	Predicted Normal Value	Measured Baseline Conditions	Percent Predicted Baseline	Measured After Bronchodilator Treatment	Percent Predicted After Treatment
SVC (L)	5.00	4.00	80	4.25	85
FVC (L)	5.00	3.50	70	4.00	80
FEV_1 (L)	4.00	2.00	50	2.20	55
$\%FEV_1/FVC$	80%	57%	—	55%	—
$FEF_{25\%-75\%}$ (L/sec)	4.00	1.75	50	2.00	50
PEF (L/sec)	8.00	6.00	75	6.50	80
TLC (L)	5.27	5.51	105	5.36	102
FRC (L)	3.11	4.55	146	3.79	122
RV (L)	1.67	2.60	156	2.24	134
DLCO (ml/min/mm Hg)	28.7	14.25	56	—	—
$DLCO/V_A$ (ml/min/mm Hg/L)	5.45	3.17	58%	—	—

SOLUTION REPORT 3: This case is similar to case 2, but there are some important differences. The FEV_1/FVC is less than 70%; there is airway obstruction. FEV_1 is 50% of predicted; the obstruction is moderately severe. After a single bronchodilator treatment, FEV_1 improved by 10% (remember to compute percent change)—not enough to show that bronchodilator therapy was immediately effective. The large FRC and RV show hyperinflation and air trapping, which did improve after bronchodilator therapy. DLCO and $DLCO/V_A$ are reduced, suggesting alveolar involvement. This report shows a moderately severe obstructive pattern with hyperinflation and air trapping not responsive to bronchodilators. There is diffusion impairment and alveolar disease. Overall, this report is consistent with COPD, the combination of chronic bronchitis and pulmonary emphysema.

PULMONARY FUNCTION REPORT 4

Pulmonary Measurements	Predicted Normal Value	Measured Baseline Conditions	Percent Predicted Baseline	Measured After Bronchodilator Treatment	Percent Predicted After Treatment
SVC (L)	5.38	4.84	90		
FVC (L)	5.38	4.92	92	5.16	109
FEV_1 (L)	4.33	2.95	68	3.24	75
$\%FEV_1/FVC$	80%	54%	—	63%	
$FEF_{25\%-75\%}$ (L/sec)	5.23	1.20	23	1.08	21
PEF (L/sec)	9.96	6.32	63	7.53	76
TLC (L)	7.51	6.38	85		
FRC (L)	4.10	3.51	86		
RV (L)	2.10	1.58	75		
DLCO (ml/min/mm Hg)	37.22	29.60	89		
$DLCO/V_A$ (ml/min/mm Hg/L)	4.96	4.06	82		

SOLUTION REPORT 4: This case is similar to Case 3, but there are some important differences. The FEV_1/FVC is less than 70%; there is airway obstruction. FEV_1 is 68% of predicted; the obstruction is mild. After a single bronchodilator treatment, FEV_1 improved by only 9.8% (remember to compute percent change)—not enough to show that the bronchodilator therapy was immediately effective. Lung volumes and diffusing capacity are within the normal range, so there is no hyperinflation, air trapping, or diffusion impairment. This report shows a moderate obstructive pattern not responsive to bronchodilators. Overall, this report is consistent with chronic bronchitis.

PULMONARY FUNCTION REPORT 5

Pulmonary Measurements	Predicted Normal Value	Measured Baseline Conditions	Percent Predicted Baseline
SVC (L)	3.85	1.93	50
FVC (L)	3.85	2.01	52
FEV_1 (L)	3.01	1.66	55
$\%FEV_1/FVC$	78%	86%	—
$FEF_{25\%-75\%}$ (L/sec)	3.40	1.85	55
PEF (L/sec)	6.50	4.55	70
TLC (L)	5.65	3.39	60
FRC (L)	3.01	2.11	70
RV (L)	1.80	1.35	75
DLCO (ml/min/mm Hg)	22.13	13.28	60
$DLCO/V_A$ (ml/min/mm Hg/L)	3.91	3.60	92

SOLUTION REPORT 5: The FEV_1/FVC is greater than 70%, so there is no apparent airway obstruction even though the FEV_1 is less than 80% of predicted. The patient's measured FVC is less than the predicted FEV_1, and FEV_1 is reduced because FVC is reduced. Because TLC is less than 80% predicted, the data suggest a restrictive impairment. Although DLCO is less than 80% predicted, there is no apparent diffusion impairment involving lung tissue because the $DLCO/V_A$ suggests that the diffusion impairment is proportional to the low lung volume. This finding implies that the diffusion impairment is due to the subject having small lungs. Overall, this report shows a moderately severe restrictive pattern consistent with neuromuscular weakness or other extrapulmonary restriction.

SUMMARY CHECKLIST

- Pulmonary function testing includes measurements of airway mechanics, lung volumes and capacities, and the diffusing capacity of the lung.
- The results of pulmonary function testing can aid in the diagnosis of disease and include patterns of obstructive and restrictive impairments.
- Pulmonary function testing provides objective data on which decisions may be made regarding the status of the patient, the selection of appropriate therapy, and the evaluation of therapeutic outcomes.
- There are specific guidelines published by the AARC and other authorities for performance of pulmonary function testing which must be followed by RTs conducting such procedures.
- Patients with obstructive lung disease exhibit reduced expiratory flows and possibly lung hyperinflation, whereas patients with restrictive lung disease exhibit reduced lung volumes and capacities.
- While pulmonary function testing cannot definitively diagnose any disease, when combined with the results of astute patient assessment, such testing can be useful in uncovering and determining the severity of obstructive disorders such as asthma (reversible) and COPD, or restrictive illnesses such as pulmonary fibrosis.

CHAPTER 21

Review of Thoracic Imaging

JOSEPH T. AZOK AND JAMES K. STOLLER

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- List the four tissue densities seen on a chest radiograph.
- Describe how to evaluate the technical quality of a chest radiograph.
- List the anatomic structures seen on the chest radiograph.
- List the steps used to interpret thoracic imaging studies.
- Understand the value of a computed tomography scan and the use of intravenous contrast.
- Describe the common radiographic abnormalities seen in the pleura, lung parenchyma, and mediastinum.
- Understand the role of ultrasound and magnetic resonance imaging in imaging the chest.

CHAPTER OUTLINE

KEY TERMS

air bronchogram
atelectasis
cephalization
chest radiograph
computed tomography
empyema
hydropneumothorax
infiltrates
interstitial lung disease
Kerley B lines
pleural effusion
pneumomediastinum
pneumothorax
radiograph
radiolucent
radiopaque
roentgenogram
solitary pulmonary nodule

Chest imaging is crucial in the practice of pulmonary and critical care medicine. It is essential that the respiratory therapist (RT) have a solid understanding of chest imaging to accurately assess patients. Various chest imaging techniques exist, including the conventional chest film (more accurately called a **radiograph** or **roentgenogram** after Conrad Wilhelm Roentgen, who first discovered the x-ray), computed tomography (CT) scanning, ultrasound, and magnetic resonance imaging (MRI).

A separate branch of medicine that uses radioactive material to produce images is referred to as *nuclear medicine*. Radioactive material is administered to patients by intravenous (IV) injection, inhalation, or oral ingestion. In the chest, the most commonly performed nuclear medicine studies are called *ventilation-perfusion ($\dot{V}/\dot{Q}$) scans* and *positron emission tomography-CT (PET-CT)*. $\dot{V}/\dot{Q}$ scans have historically been used to diagnose pulmonary emboli, although chest CT is now the preferred examination for diagnosing pulmonary emboli.[1]

PET-CT combines a nuclear medicine study, the injection of radioactive glucose, with a chest CT and is used to diagnose and stage disease in patients with cancer.

This chapter summarizes important concepts in chest imaging for the RT. The basic elements of chest radiography are addressed first, followed by more advanced techniques such as ultrasound, CT, and MRI. The role of various imaging techniques used to evaluate the different components of the chest (e.g., pleura, mediastinum, lung tissue [lung parenchyma]) will be described, and examples of abnormal findings will be shown.

OVERVIEW OF THE CHEST RADIOGRAPH

A chest radiograph is produced by passing x-rays through the chest to photographic film or a detector. The resulting image is formed as x-rays strike the film or digital screen and darken/expose it. A radiograph is similar to a negative from an old-fashioned black and white film camera. X-rays that pass directly through low-density tissue (e.g., lung) strike the film in greater numbers and cause the resulting shadow to turn darker. X-rays that strike denser tissue (e.g., bone) are absorbed by the tissue to a greater extent and leave the exposed film lighter. The shadows on the radiograph vary in shades of gray based on the density of the tissue through which the x-rays have passed.

Four different tissue densities are visible on a normal **chest radiograph.** The tissue types that generate these densities are *air, fat, soft tissue* (*water density* because soft tissues, similar to muscle, are mainly composed of water), and *bone.* Each tissue type absorbs different proportions of the x-ray beam, which results in a different appearance on the chest radiograph. Air in the lung, stomach, or intestines absorbs very few x-rays and appears virtually black (**radiolucent**). Fat absorbs a small amount of the x-ray beam and is usually seen as a light gray shadow. Soft tissue absorbs a slightly greater amount of the x-ray beam and is usually seen as a medium gray shadow. Bone absorbs a large fraction of the x-ray beam and is seen as a nearly white (**radiopaque**) shadow.

X-ray images have traditionally been recorded on film. Once developed, x-ray films were displayed by placing the film over a viewbox to illuminate the film for the observer. Currently, most radiographs are recorded, displayed, and stored in digital format on a computerized picture archiving and communication system. To record a digital image, an x-ray detector (digital film) replaces the photographic film. A computer takes the data from the x-ray detector and creates the image. The resulting image is displayed on a computer monitor.

Compared with images recorded on traditional film, digital images have advantages for interpreting and retrieving the image. The display of digital images can be manipulated by adjusting the contrast, brightness, and magnification. These adjustments allow findings that would be subtle and difficult to perceive on a traditional photographic film to be seen more easily. Digital images also allow multiple people to view the image simultaneously and in different locations. For example, an RT in a critical care unit, a radiologist in the imaging department, and a critical care physician in another location may collaborate by simultaneously viewing a chest radiograph on a rapidly deteriorating patient. Digital images also can be easily copied and recorded on compact discs so that patients can obtain digital copies of studies to take to their physicians. These technologic advancements facilitate the transmission of patient information as patients move from one hospital to another.

The structures visible on a chest radiograph are seen only when tissue of one density is next to tissue of a different density. The heart is visible as a soft tissue density in the middle of the chest because the lungs, which are primarily air density, normally surround it. If the lungs on either side of the heart fill with water (pulmonary consolidation or pleural effusion), the normal adjacent heart shadow would be invisible on the radiograph. This obscuring of the margin of adjacent structures of the same density is called the *silhouette sign* and can be useful to localize abnormalities within the chest. For example, the right middle lobe is adjacent to the right heart border, so the disappearance of the right heart border on the chest radiograph indicates an airspace opacity (such as pneumonia or atelectasis) in the right middle lobe. Stated simply, a right middle lobe pneumonia or atelectasis would "silhouette" the right heart border (Figure 21-1)

When to obtain a chest radiograph is the decision of the attending physician. However, because the RT is at the bedside, the physician will often welcome the RT's suggestion to obtain a chest x-ray radiograph, such as when a patient in the intensive care unit (ICU) suddenly deteriorates for no apparent reason. The RT needs to be familiar with the common clinical indications for obtaining a chest radiograph (Box 21-1).

Although a chest radiograph is important in evaluating patients with lung disease, it does have limitations. A chest radiograph may appear normal in a patient in respiratory failure; this is common in patients with acute (e.g., pulmonary embolism) or chronic obstructive lung disease (e.g., emphysema that is not apparent on a chest radiograph). In addition, the chest radiograph may lag behind the clinical condition of the patient. This situation is common in pneumonia, with which the patient may present with high fever and cough typical for pneumonia, but an airspace opacity or infiltrate may not appear on a chest film until 12 to 24 hours later. Similarly, the infiltrate on the chest film may persist for days to weeks after the resolution of symptoms.

Approach to Reading a Plain Chest Radiograph

A disciplined approach is required to obtain the maximal information from any diagnostic imaging study. Interpreting the chest radiograph provides an excellent example of this statement. An obvious abnormality such as a 6-cm mass is easily identified, even by the untrained observer. However, more subtle abnormalities, often with equal or even greater diagnostic importance, may go unnoticed if the observer is distracted by a more obvious abnormality. To avoid this pitfall, the observer must develop a step-by-step approach that is applied to interpreting a chest radiograph in a disciplined and consistent

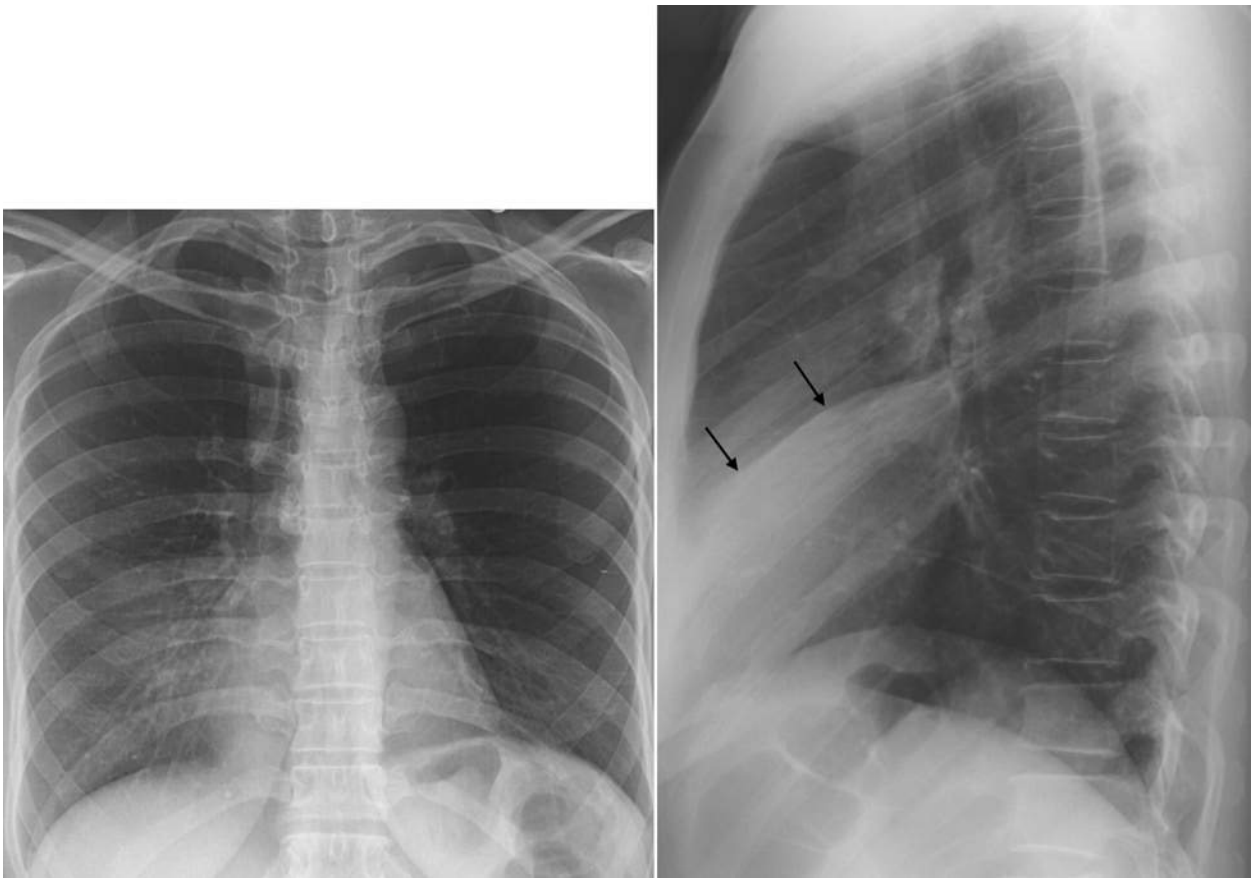

FIGURE 21-1 Posteroanterior view of the chest demonstrates obscuration or silhouetting of the right heart border because of airspace opacity in the right middle lobe. On the lateral view, there is right middle lobe collapse *(arrows)* secondary to an obstructing primary lung neoplasm (adenocarcinoma).

Box 21-1 Clinical Indications for Obtaining a Chest Radiograph

OUTPATIENT
Unexplained dyspnea
Severe persistent cough
Hemoptysis
Fever and sputum production
Acute severe chest pain
Positive tuberculosis skin test

INPATIENT
Placement of endotracheal tube
Placement of pulmonary artery catheter
Placement of central venous pressure catheter
Sudden onset of dyspnea or chest pain
Elevated or changing plateau pressure during mechanical ventilation
Sudden decline in oxygenation

fashion until it becomes routine. The following suggestions are broad guidelines, and each observer must formulate an approach that he or she finds comfortable.

In broad terms, the steps in reviewing a chest film are as follows:

- Confirm the correct patient's name on the radiograph.
- Review the technique and quality of the examination: Is the radiograph well centered (i.e., do the spinous processes project, overlying the trachea on a posteroanterior [PA] film), and is the degree of penetration of the beam adequate, too high (i.e., the lung parenchyma is too dark to see subtle changes), or too low (i.e., the lung parenchyma is too white, causing normal lung markings to appear abnormal)?
- Systematically review the anatomic structures on the chest film to assess their normality or abnormality.

In later sections of this chapter, the following areas will be reviewed: (1) evaluation of the technical quality and adequacy of the film, (2) normal anatomic structures on a chest radiograph, (3) more sophisticated imaging techniques, and (4) major anatomic components seen on the radiograph.

Chest Radiograph Technique and Quality

Several technical factors should be routinely assessed when interpreting a chest radiograph:

1. Is the radiograph appropriately labeled?
2. Is the study performed with PA and lateral views, or is it an anteroposterior (AP) portable examination?

3. Is the entire chest imaged (i.e., are any structures not included)?
4. Was the patient properly positioned?
5. Were the optimal settings for the x-ray beam selected when the film was taken (the term used is *penetration,* which is similar to *exposure* on camera film)?

As the first step, the RT should check the patient's identity and all labels visible on the film. This step helps to avoid the mistake of interpreting a chest radiograph for the wrong patient and establishes which side is which because labels are often placed to indicate the patient's left or right side; such labeling of the side is important in cases in which the patient's chest or abdominal contents are reversed—known as *situs inversus* or *dextrocardia*.

MINI CLINI

Evaluating the Heart Size on a Portable Chest Radiograph

A standard chest radiograph is obtained with the patient standing and facing the film cassette. The x-ray beam first enters the patient's back and then passes through the chest to the film. This standard technique is called the *PA chest radiograph*. The heart is located very close to the film with the standard PA view, and magnification of the heart shadow is minimal.

PROBLEM: In the ICU, patients are generally too ill for a PA chest film to be obtained. The chest film is obtained with the patient lying in bed and the film cassette placed behind the patient. The x-ray beam passes from anterior to posterior, producing an AP portable chest film. In examining an AP portable chest film, how is the appearance of the heart size affected?

DISCUSSION: An AP portable radiograph is obtained with the patient's heart farther from the film, producing a heart shadow that is artificially magnified compared with the shadow produced with a PA chest film; this may give the appearance of an enlarged heart in some cases. The clinician interpreting an AP portable radiograph must keep this in mind to avoid misinterpreting the film as showing that the heart is enlarged heart (cardiomegaly). To illustrate this point, hold a flashlight 3 feet from a wall and turn it on. While holding the flashlight steady, place one hand in the beam. The shadow created by the hand becomes smaller as the hand is moved closer to the wall and farther from the light source (equivalent to a PA film) and bigger as the hand approaches the light source (equivalent to an AP film).

RULE OF THUMB

When evaluating a plain chest radiograph, first assess the technical quality of the chest radiograph—that is, is there rotation or is the patient positioned well? Is the x-ray beam penetration appropriate? Then, use a step-by-step approach to view all the structures on the chest radiograph.

A chest radiograph is taken using one of two techniques: the PA view or the AP view. The views are named for the path of the x-ray beam. In the PA view, the patient puts his or her back to the x-ray source and the chest against the film. The x-ray beam leaves the source, passes through the posterior side of the patient, through the patient, then through the patient's anterior surface, and finally to the film. The PA view is usually performed in the radiology department with equipment that standardizes the distance (typically 6 feet) from the x-ray source to the film and where the x-ray technician can maximize the quality of each film. In addition, as noted, taking the film with the anterior chest closest to the film minimizes magnification of the heart.

The AP film is usually taken with a portable x-ray machine. The AP technique places the x-ray source in front of the patient, with the film behind the patient's back. The source of the x-ray beam is usually much closer to the patient than with a PA film, although the distance varies from patient to patient. The closer x-ray source and the position of the patient both lead to a magnification of the heart shadow. The AP film is usually taken in the ICU because these patients are too ill to travel to the radiology department or to stand for a PA film. Overall, AP portable films are usually of lesser quality than PA films. During the interpretation of the chest radiograph, the RT needs to take into account the view (AP or PA) when evaluating the heart size and subtle findings that may be influenced by film quality and technique.

When a chest radiograph examination is performed, it is sometimes difficult to align the patient properly, and a portion of the chest may not be imaged. Although these problems are more common with portable (AP) examinations, they also may occur with PA and lateral radiographs as well. The RT should ask the following questions: (1) Is the entire chest included on the film? (2) Is the patient well positioned?

Patient rotation can make interpretation more difficult by projecting *midline* structures (e.g., the trachea) to the right or left. The observer can assess for rotation by comparing anterior structures such as the *medial* (toward the middle) ends of the clavicles with a posterior structure such as the spinous processes of the spine. In a perfectly positioned or aligned chest film, the spinous process should be seen midway between the medial ends of the clavicles and in the middle of the tracheal air column (Figure 21-2). Patient rotation makes the mediastinum appear unusually wide and obscures or distorts the appearance of the pulmonary arteries as they emerge from the mediastinum into the lung parenchyma.

The RT also must ensure that the film is adequately penetrated. An improperly penetrated film may conceal important details. A chest radiograph with proper exposure should show the intervertebral disc spaces through the shadow of the heart and should allow the blood vessels in the peripheral regions of the lungs to be visualized. A chest radiograph that is underexposed or underpenetrated (i.e., owing to too-low kilovoltage of the x-ray beam) does not allow visualization of the intervertebral discs through the heart shadow and may make identification of abnormalities in the soft tissue areas such as the mediastinum more difficult. Specifically, an underpenetrated

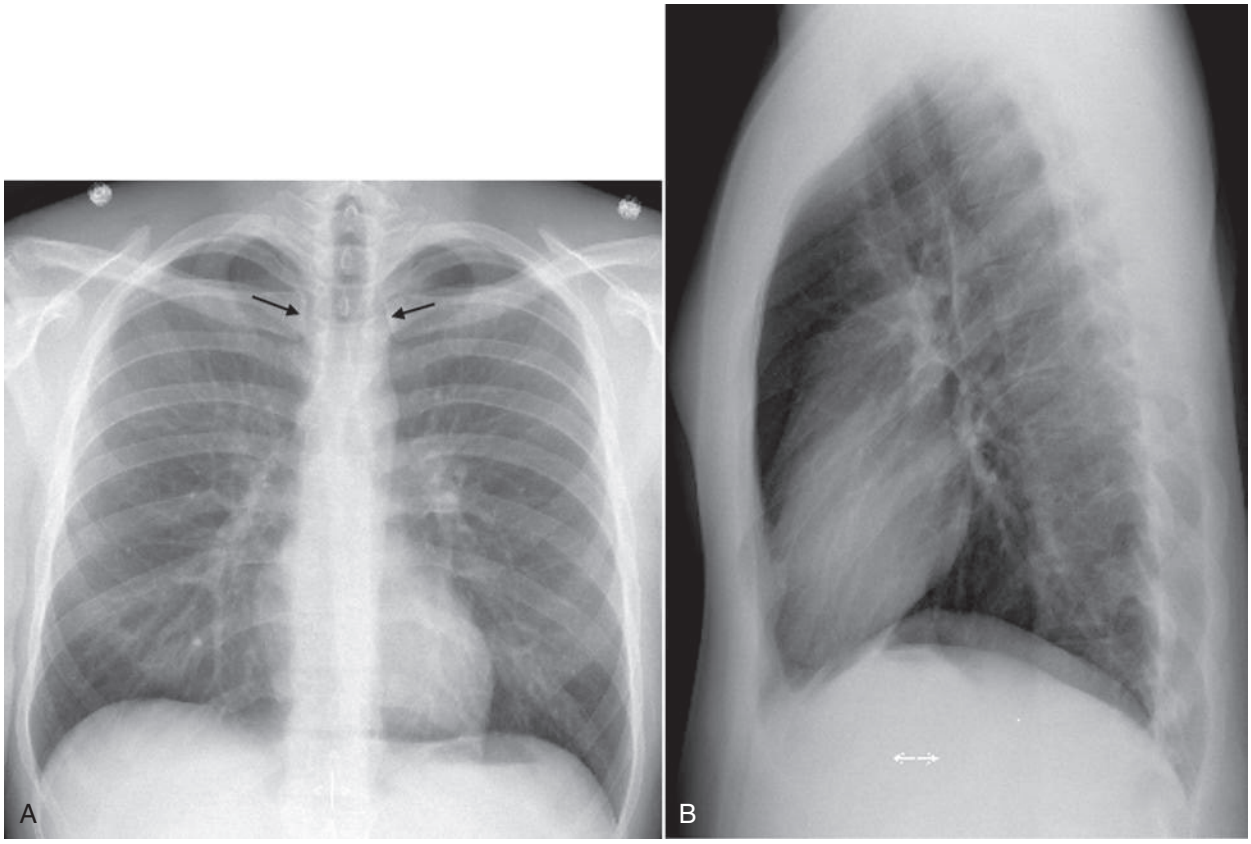

FIGURE 21-2 Normal frontal **(A)** and lateral **(B)** views of the chest radiograph. Note the medial ends of the clavicles *(arrows)* with the spinous process *(arrowhead)* framed between them **(A).**

film may cause the normal branching of the pulmonary arteries in the lung to appear abnormal and be misinterpreted as evidence of interstitial infiltrates. Similarly, an overpenetrated radiograph overexposes the film, leaving the lung parenchyma black and making it difficult to visualize the peripheral blood vessels or abnormalities that may be present (e.g., infiltrates secondary to pneumonia, pulmonary nodules). This overpenetration makes evaluation of the lung parenchyma far more difficult. Adjustment of the contrast and brightness of the chest film on the computer display of a digital image improves the ability to see certain aspects of a chest x-ray with improper penetration. However, adjusting the display cannot completely overcome the loss of important details caused by an improperly penetrated film.

MINI CLINI

Value of Proper Technique on a Chest Radiograph

Careful attention to the technical quality of a chest radiograph is key in both acquiring and interpreting the study. If the settings when the examination is taken are incorrect or if the patient is improperly positioned, this can lead to important changes in the appearance of the chest radiograph that can either hide important details or lead to a misinterpretation.

PROBLEM: A patient presents to the emergency department with chest pain. The initial radiograph obtained demonstrates decreased lung markings (Figure 21-3), which the inexperienced observer may interpret as emphysema or a pneumothorax.

DISCUSSION: The astute observer realizes that the findings on the chest radiograph may be due to overpenetration rather than an abnormality with the lung parenchyma. When radiographs were previously obtained on film, errors in either underpenetration or overpenetration were difficult to overcome. As this study was obtained using a digital detector, inadequate penetration often can be compensated for by changing the contrast or brightness on the digital screen. However, in some instances in which the overpenetration or underpenetration is so severe, changing the contrast and brightness cannot correct the initial error and a repeat study may be necessary. A repeat radiograph (see Figure 21-3) demonstrates normal lung markings without evidence of emphysema or a pneumothorax.

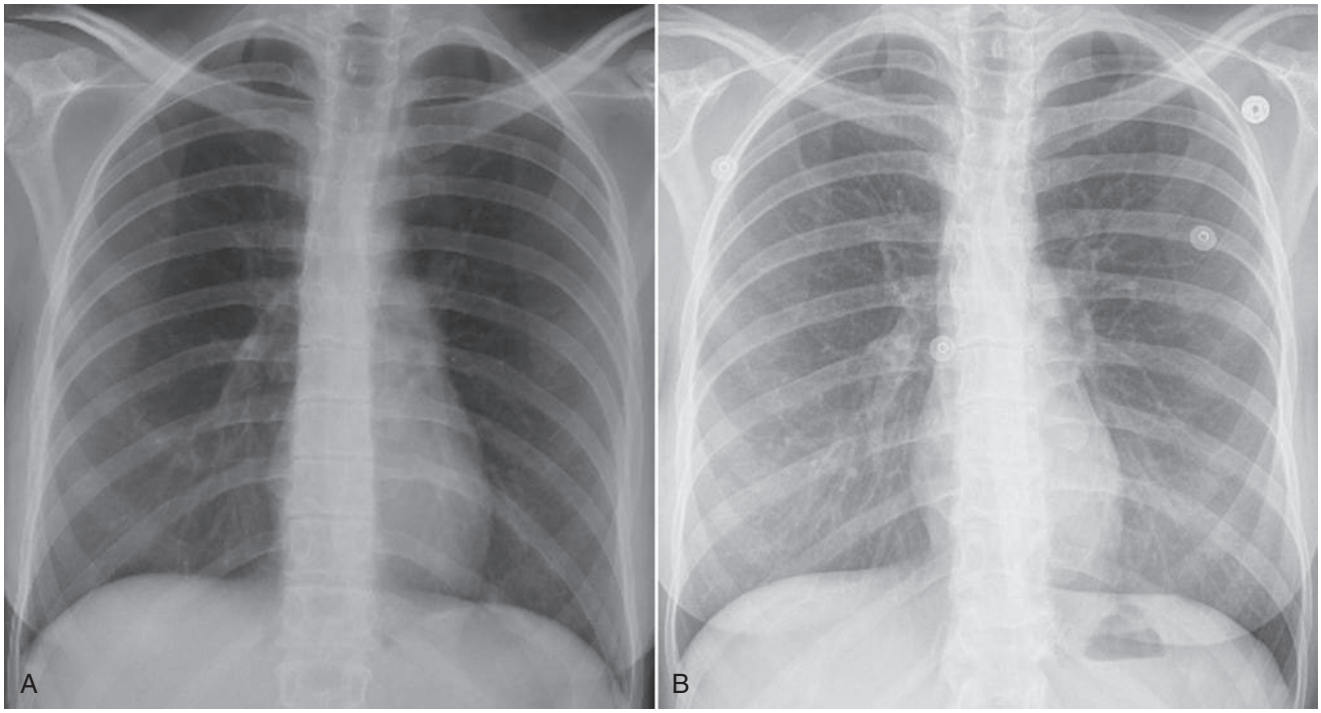

FIGURE 21-3 Radiographs of the chest performed several hours apart. **A,** The chest radiograph is overpenetrated. The lung markings are difficult to visualize which can simulate emphysema or a pneumothorax. **B,** A repeat radiograph performed with adequate penetration demonstrates normal lung markings bilaterally without evidence of emphysema or a pneumothorax.

Anatomic Structures Seen on a Chest Radiograph

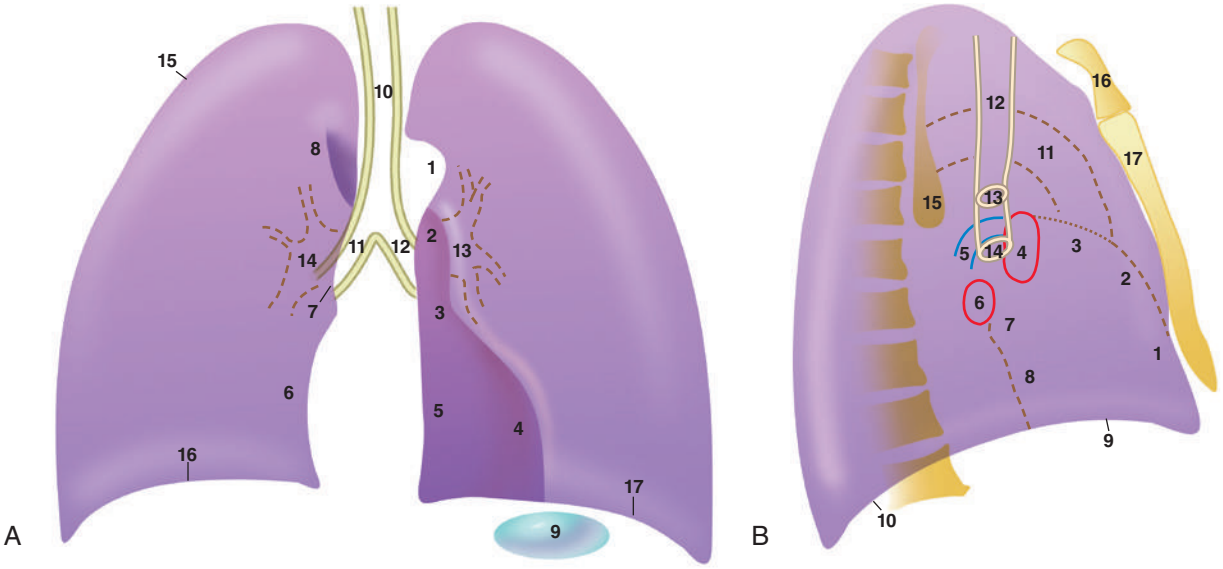
After the RT has reviewed the technical aspects of the chest radiograph, it is time to review the anatomic findings on the film. The main structures imaged on a routine chest radiograph are listed next and illustrated in Figure 21-4:

1. Bones (e.g., ribs, clavicles, scapulae, vertebrae)
2. Soft tissues (e.g., tissues of the chest wall, upper abdomen, lymph nodes)
3. Lungs (including the trachea, bronchi, and lung tissue or parenchyma)
4. Pleura (membranous covering of the lung, including the *visceral pleura* [the part attached to the lungs] and the *parietal pleura* [the part lining the inside of the chest wall]; although normally occupied by only a small amount of fluid, the space between the parietal and visceral pleura is called the *pleural space*)
5. Heart, great vessels, and mediastinum (i.e., the tissues between the lungs in the center of the chest, bordered by the sternum anteriorly and the vertebral column posteriorly in the AP dimension and by the thoracic inlet superiorly [where the trachea enters the chest] and the diaphragm inferiorly in the craniocaudal [moving from the head to the feet] direction)
6. Upper abdomen
7. Lower neck

The anatomy seen on the chest radiograph should be reviewed in a thorough, systematic manner. All of the previously listed anatomic structures must be individually assessed. When first interpreting radiographs, it is helpful for the RT to create a list of the anatomic structures that must be assessed and to check off the structures as they are reviewed. With experience, the checklist becomes second nature and automatic.

Assessment of the chest wall should include evaluating for symmetry, rib fractures, or other bone abnormalities. Lung evaluation begins by assessing the lung volumes (size) and density. Any obvious differences in symmetry must be explained. Of the lung parenchyma, 80% to 90% is overlaid with bone in the form of ribs, clavicles, and the thoracic spine. The overlying bone may obscure important lung abnormalities. A lateral view is helpful in clarifying the presence or absence of suspicious lung abnormalities on frontal (PA or AP) projections. The RT must pay specific attention to areas where subtle abnormalities may be hiding; these include the lung apexes (behind the clavicles), the area of lung that projects behind the heart, and the portion of lung that lies deep in the posterior sulcus (the extreme bottom of the lung projecting behind the dome of the diaphragm on the frontal view).

Review of the lung periphery on both frontal and lateral views discloses any pleural abnormalities, such as fluid in the pleural space (e.g., hydrothorax, hemothorax [blood in the pleural space]) and air in the pleural space (pneumothorax). Evaluation of the mediastinum should include assessment of the heart size. On the PA projection, the diameter of the heart shadow (cardiac silhouette) should not exceed one-half the diameter of the chest. An enlarged cardiac silhouette may occur



1. Aortic arch

with congestive heart failure or with a pericardial effusion (fluid within the space that surrounds the heart encased within the pericardium). The lateral contours of the mediastinum should correspond to normal anatomic structures, as outlined in Figure 21-5.

Advanced Chest Imaging Techniques

Computed Tomography of the Chest

Computed tomography (CT) scanning is an essential and commonly used imaging technique to assess the chest. Advantages include its excellent anatomic detail, wide availability, and short examination time to acquire the images. Structures as small as 1 mm can be visualized, allowing for detailed anatomic depiction of the structures of the chest. Modern CT scanners are fast, with images of the entire chest obtained in less than 10 seconds, allowing for accurate and rapid assessment of critically ill ICU patients in the ICU.

To perform a CT scan, a patient lies on a table called a **gantry.** The gantry is passed through a circular opening in the CT scanner. X-ray sources and detectors surround the opening in the scanner. When the scanning begins, the x-ray source and detectors pass quickly around the patient in a circular motion with the x-ray beam passing through the patient to detectors on the opposite side. The information from the detectors is sent to a computer, which generates a two-dimensional image from the detector data. Each image created by the scan looks like a slice of the patient. Historically, after each CT image was obtained, the patient was advanced in a step-wise fashion until the entire chest was imaged. Modern CT scanners use numerous detectors (typically between 16 and 256) all connected to a highly capable image processing computer. Patients pass rapidly through the CT scanner without stopping for each image. The term *spiral* or *helical* is applied to these more current CT scanners.

TABLE 21-1

Radiation Dose of Common Thoracic Imaging Studies

Study	Radiation Dose (mSv)	Equivalent Normal Background Radiation
Chest radiograph (PA and lateral)	0.1 mSv	10 days
Chest CT (low-dose screen)	1.5 mSv	6 mo
Chest CT (standard dose)	7.0 mSv	2 yr
Coronary CT angiogram	12.0 mSv	4 yr

CT, Computed tomography; *PA,* posteroanterior.

CT scans depict the anatomy in the chest better than the standard chest radiograph but expose the patient to more radiation, which varies depending on the specific CT technique used (Table 21-1). For example, a standard-dose chest CT examination exposes the patient to the equivalent of 70 chest x-rays. Ongoing research and technologic advancements will likely continue to lower the radiation dose of CT scans.

Chest CT provides an excellent view of the chest and allows imaging of portions of the chest that are poorly seen on chest radiographs. Areas such as the mediastinum, the lung apexes and costophrenic sulci of the lungs (the normally sharp shadows where the diaphragm contacts the rib cage laterally), and the pleural surfaces all are easily seen with CT scanning. Chest CT is commonly performed to evaluate lung nodules and masses, the lung parenchyma, great vessels of the chest, the mediastinum, and pleural disease. To evaluate blood vessels and soft tissue structures in close proximity, such as hilar lymph nodes, iodinated contrast can be helpful because contrast makes blood appear denser (radiopaque or white) and allows blood vessels to be distinguished from soft tissue.

Currently, chest CT examinations are generally displayed with a slice thickness of 1 to 5 mm. Each image therefore will include everything within the 1- to 5-mm slice of tissue. Thin slices allow for maximal spatial resolution (i.e., the ability to separate objects that are close together). For example, to evaluate the lung parenchyma in a patient with suspected interstitial lung disease, thin slices, typically 1 mm, are used to evaluate the fine architecture of the lung, referred to as a high-resolution chest CT (HRCT). Thin slices are also helpful in the evaluation of small pulmonary nodules or to evaluate for pulmonary emboli on a pulmonary embolism study. A disadvantage of thin slices is that they have more image noise and there are more images to interpret. For example, pulmonary embolism studies performed with a 1-mm slice thickness generally have approximately 1000 images per study.

Recent evidence suggests that low-dose chest CT scans may be useful in screening high-risk individuals for lung cancer. Specifically, patients who are between the ages 55 and 74, who have smoked more than 30 pack-years, and who are currently smoking or who stopped smoking fewer than 15 years earlier may prolong survival from lung cancer. A large study of greater than 50,000 patients demonstrated that the mortality rate or risk for death from lung cancer was reduced by 20% in patients who underwent screening chest CT compared to a chest radiograph examination.[2] This technique uses a lower peak kilovoltage than standard studies, so the images are grainier than a with standard CT. The benefit is that the radiation dose is approximately one-fifth that of a standard chest CT.

Computed Tomography Angiography

The rapid scanning that can be performed on helical CT scanners has made CT angiography possible. To perform CT angiography, IV contrast dye is injected at a high rate to darken or opacify the vascular structures. A large-bore peripheral IV in an antecubital vein or a peripherally inserted central catheter (PICC) line that can handle a high contrast injection rate is required. CT angiography of the chest has been used for years to identify pulmonary embolism, although advances in technology now allow for visualization of pulmonary emboli in tiny peripheral arteries that were not visible on older models of CT scans (Figure 21-6).[1] Technologic advancements have made possible CT angiography of the coronary arteries, which can serve as an alternative to routine coronary angiography by catheterization in many patients.[3]

Three-Dimensional Reconstruction

The imaging processing capabilities of modern CT scanners allow for reconstruction of the chest in any direction and production of three-dimensional (3-D) representations of some areas of the body (Figure 21-7). These 3-D images can be helpful for surgeons before surgery to visualize how anatomic structures may appear at surgery. The images also can simulate what a physician would see during a bronchoscopy, referred to as *virtual bronchoscopy*.

Magnetic Resonance Imaging of the Chest

MRI has many uses in the chest and is typically used as a problem-solving tool to answer specific clinical questions that cannot be answered by other imaging examinations such as a chest x-ray, chest CT, or ultrasound examination. MRI is generated by placing patients into a strong magnetic field. The physics of MR are complicated and are beyond the scope of this chapter. Briefly, the strong magnetic field aligns nuclei with nonzero spins (nuclei that have an odd number of protons and neutrons), such as hydrogen atoms, with the magnetic field. Because hydrogen atoms are present in high concentration throughout the body, they provide an excellent target for MRI evaluation. Pulses of radio waves are directed at the hydrogen nuclei, resulting in the alignment of hydrogen nuclei to change in orientation with the magnetic field. After the radio signal is stopped, the nuclei flip back to their original alignment and release their own radio waves. MRI uses the radio waves from the realigning nuclei to generate an image.

MRI has advantages over other imaging techniques in the chest that are useful in specific circumstances. MRI does not use x-rays and therefore does not expose patients to ionizing radiation. MRI has superb soft tissue characterization, allowing for detailed analysis of soft tissue masses. The most common uses for MRI in the chest are for imaging the mediastinum, large vessels in the chest (e.g., for pulmonary emboli or

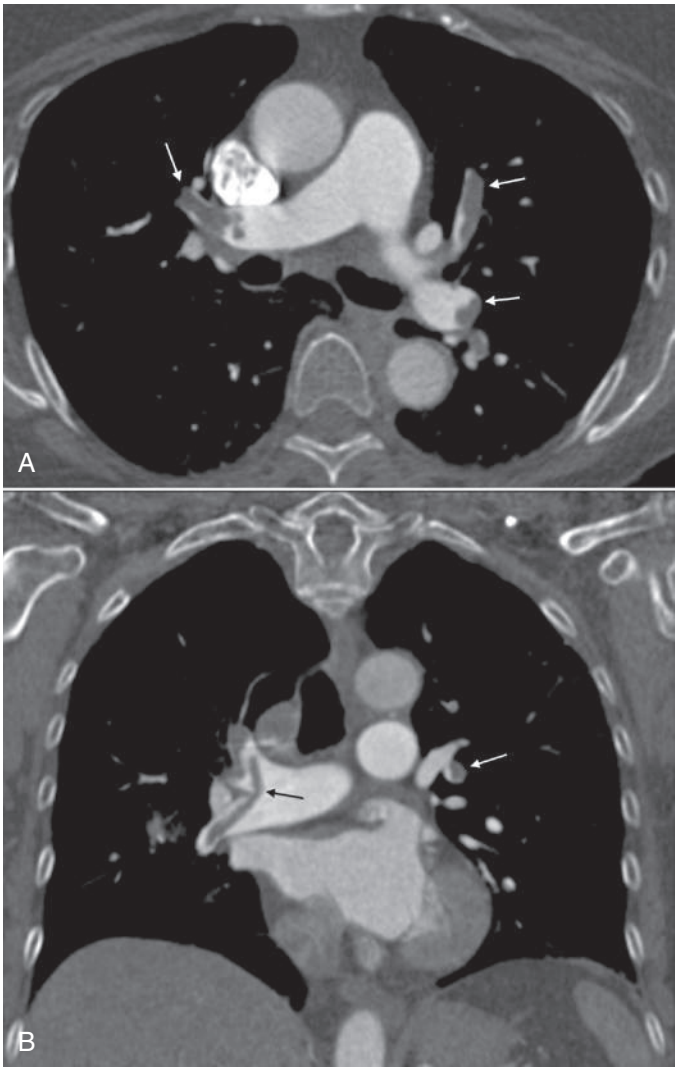

FIGURE 21-6 Computed tomography angiogram of a patient with bilateral acute pulmonary emboli. **A,** The pulmonary emboli are seen as the dark filling defects *(arrows)* outlined by the white contrast-enhanced blood vessels *(arrows)*. Coronally reformatted image **(B)** is helpful to visualize clot entering both the right upper and right lower lobar pulmonary arteries *(arrows)*.

vascular abnormalities), and the heart.[4] The superior soft tissue characterization of MR allows for the confident diagnosis of a benign mediastinal mass (such as a thymoma) and can spare patients surgery to establish a diagnosis.[5] In patients in renal failure in whom there is clinical concern for a pulmonary embolism who cannot receive IV contrast, an MR examination can be performed without contrast to establish a diagnosis. MR has limited uses for imaging the lung parenchyma. For example, in a patient with lung cancer undergoing evaluation for possible resection, MR can determine whether the tumor invades the chest wall by determining if the lesion moves independently of the chest wall during both inspiration and expiration.

However, MRI does have significant limitations when applied to imaging the chest. MRI examinations take longer to acquire (at least 10 minutes and up to 1 hour) than other examinations (such as radiographs or CT), which makes respiratory and cardiac motion more significant obstacles. Imaging of critically ill ICU patients is thus difficult because these patients may be unable to lie in the MR scanner for a long period. The lungs are primarily composed of gas; therefore there is little signal to generate images as is required by MR, making the MRI less useful to evaluate the lung parenchyma.

In addition, the large magnet required for MR examinations makes it generally contraindicated in patients with pacemakers or other significant metal objects in their bodies to undergo MRI. A patient with a small metal object in a crucial place, such as a surgical clip in the brain or eye generally cannot undergo MRI. The powerful magnet will pull metallic objects into the magnet with great force, exposing both patients and health care providers in its path to life-threatening risk. Medical equipment containing metal such as ventilators and gas cylinders also cannot be brought near the MR scanner. Deaths have been reported when metal objects (e.g., oxygen cylinders) have been brought into the magnetic field of the MRI, and RTs must be especially vigilant about this issue. MRI units usually have well-marked warnings and areas beyond which conventional metal objects absolutely must not pass.

Ultrasound

Ultrasound images are created by passing high-frequency sound waves into the body and detecting the sound waves that bounce back (echo) from the tissues of the body. The pattern of the returning sound waves is used to generate an image of the tissue studied. Ultrasound of the chest is excellent for evaluating the heart (echocardiogram) or pleural fluid.[6]

Ultrasound imaging using small portable machines has become common practice in critical care units. Portable ultrasound units allow for the rapid assessment of heart function and volume status and are used to assist in many critical care procedures.[7] Because it can localize excessive pleural fluid which characterizes a pleural effusion, ultrasound can be using in performing a thoracentesis. Ultrasound is also commonly used to guide placement of central venous and arterial catheters. Blood vessels are easily identified using ultrasound. The compressibility of veins is used to differentiate veins from arteries (Figure 21-8). Because the path that the needle is taking is clearly seen on the ultrasound screen, using ultrasound guidance for venous and arterial puncture allows the procedure to be more easily accomplished with less time, risk, and patient discomfort.

The remainder of the chapter outlines commonly encountered abnormalities involving the pleura, lung parenchyma, and mediastinum. The reader is encouraged to fine-tune his or her observational powers for assessing imaging studies because, as noted by Pasteur, "In the field of observation, chance favors the prepared mind."

RULE OF THUMB

Three general steps to assessing a chest film are as follows:

1. Content assurance: Is the entire chest visible on the film?
2. Quality assurance: Is the chest radiograph properly exposed and centered?
3. Disciplined application of a personalized, consistent search pattern

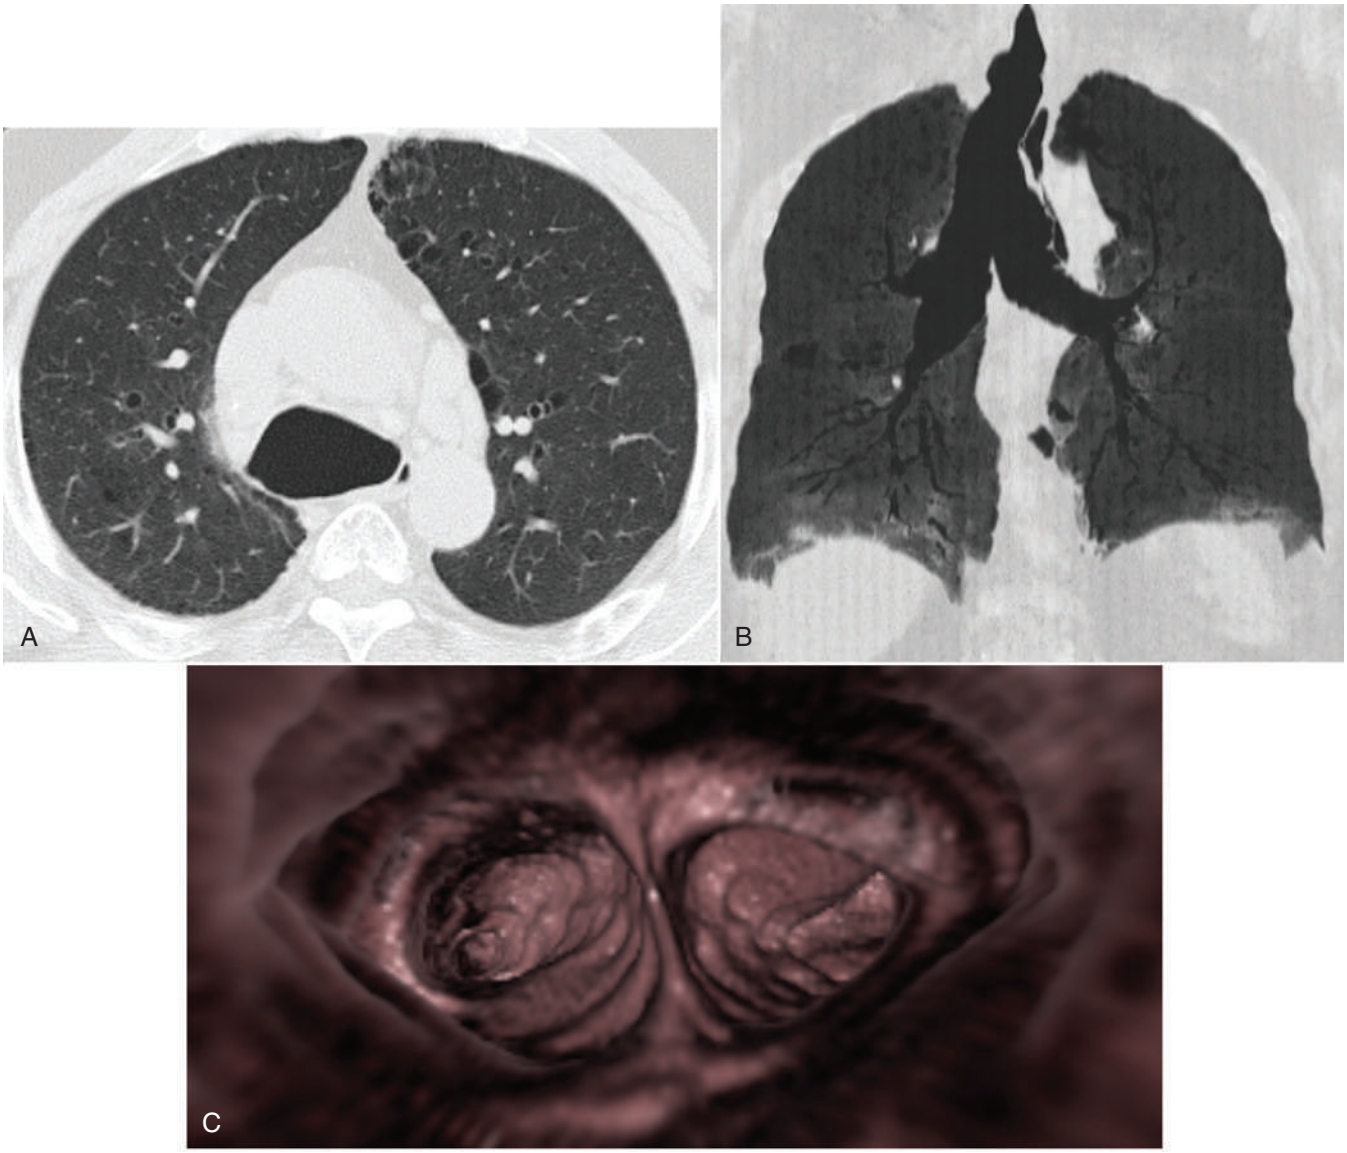

FIGURE 21-7 Use of 2-D and 3-D images for visualization of the trachea. Axial CT **(A)** image demonstrates a massively dilated trachea in a patient with tracheobronchomegaly (Mounier-Kuhn). A coronally reformatted minimum intensity projection (minIP) image **(B)** allows for visualization of the entire trachea and main stem bronchi. A 3-D image **(C)** endoluminal view of the inferior trachea looking downward at the carina with the left and right main stem bronchi located on each side of the carina. The 3-D image, termed *virtual bronchoscopy,* can aid the bronchoscopist in planning a bronchoscopic procedure.

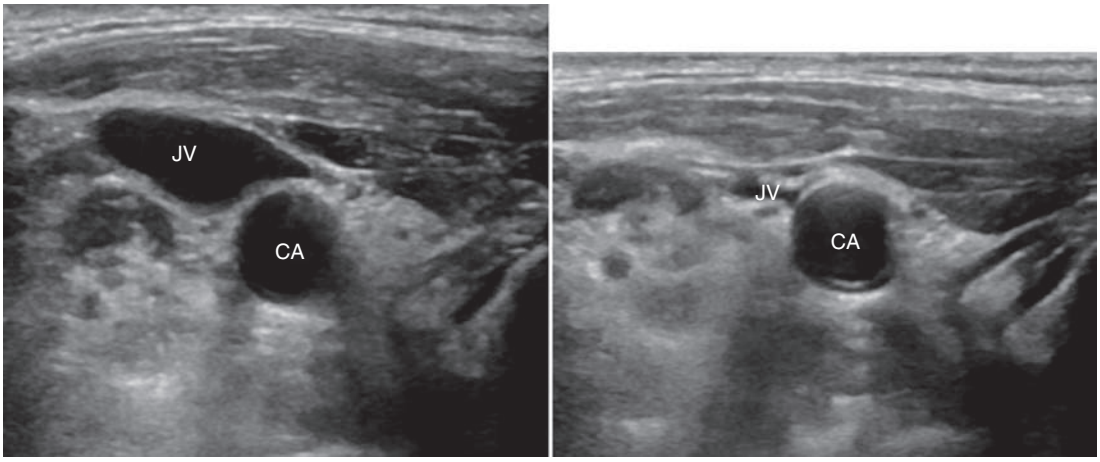

FIGURE 21-8 Two ultrasound images of the right internal jugular vein *(JV)* and right carotid artery *(CA)*. In the first image, the jugular vein is distended; in the second image, the jugular vein is collapsed by gently applying pressure with the ultrasound transducer. The carotid artery did not compress.

PLEURA

The thin membrane surrounding the lung parenchyma is referred to as the *pleura*. The lungs are surrounded by two thin pleural membranes. The outer pleural membrane, known as the *parietal pleura,* adheres to the inside of the chest wall, the upper surface of the diaphragm, and the lateral aspect of the mediastinum. The inner pleural membrane, or *visceral pleura,* closely adheres to the surface of each lung. The visceral pleura extends along the fissures that separate the lobes. The pleural membranes around the lung cannot be seen on a chest radiograph because they blend into the water density of the chest wall, diaphragm, and mediastinum. However, the visceral pleura separating the lobes can be seen if the pleural surface is parallel to the x-ray beam (as with the "minor" or "horizontal" fissure separating the right upper lobe from the right middle lobe on a PA chest x-ray). Although very thin, the visceral pleura separating the lobes is visible because it is contrasted with aerated lung on either side.

Pleural Effusion (Hydrothorax)

A **pleural effusion** refers to the accumulation of excess fluid within the pleural space. In healthy individuals, it is estimated that 1 to 8 ml of pleural fluid is normally present.[8] Normally, the diaphragm forms a dome that curves downward to attach to the chest wall on the lower ribs and thoracic and lumbar vertebra. On a chest radiograph, the arch of the diaphragm and the chest wall meet to form a point called the *costophrenic angle.* The costophrenic angle is seen on both PA and lateral views (see Figure 21-2). If the point of the costophrenic angle is rounded rather than sharp, it usually indicates that a pleural effusion is present (Figure 21-9).[9] For a pleural effusion to cause blunting of the costophrenic angle on the frontal (PA/AP) view, at least 175 to 200 ml of pleural fluid must have accumulated. The lateral film detects smaller pleural effusions than are detected with the frontal view. The posterior costophrenic angle becomes blunted with 75 to 100 ml of fluid. The best view for detecting small amounts of pleural fluid is the lateral decubitus view, which is a frontal view taken as the patient is lying on the side of the suspected effusion; 5 ml of pleural fluid can be detected on a decubitus radiograph.[10] As discussed later, ultrasound is also useful for detecting a pleural effusion.

Sometimes, fluid can accumulate between the lung and the diaphragm and maintain a sharp costophrenic angle, hiding up to 500 ml of fluid.[11] Fluid that accumulates between the lung and the diaphragm is said to be in a *subpulmonic* location. The subpulmonic location is the first place pleural effusions accumulate in an upright patient.[12] The earliest sign of a left-sided pleural effusion on an upright chest radiograph is an increased distance between the inferior margin of the left lung and the stomach gas bubble. With a subpulmonic effusion, there may be an associated slight lateral shift of the point at which the diaphragm dips downward on the frontal chest radiograph (i.e., similar to a hockey stick with the blade toward the lateral chest wall).

If both air and fluid are contained within the same space, the interface between the air and the fluid forms a soft tissue density with a straight, horizontal border that has air density above it. The interface may have a small meniscus on both sides. These straight, level interfaces between air and fluid are called *air-fluid levels*. An air-fluid level in the pleural space indicates a **hydropneumothorax** (Figure 21-10), or both air and fluid in the pleural space.

Occasionally, fluid accumulates in an unusual position, such as within an interlobar fissure (which separates lobes of the lung). Fluid is most commonly seen in the minor fissure, which is between the right middle lobe and the right upper lobe. Fluid within a fissure can be diagnosed on a chest radiograph by a

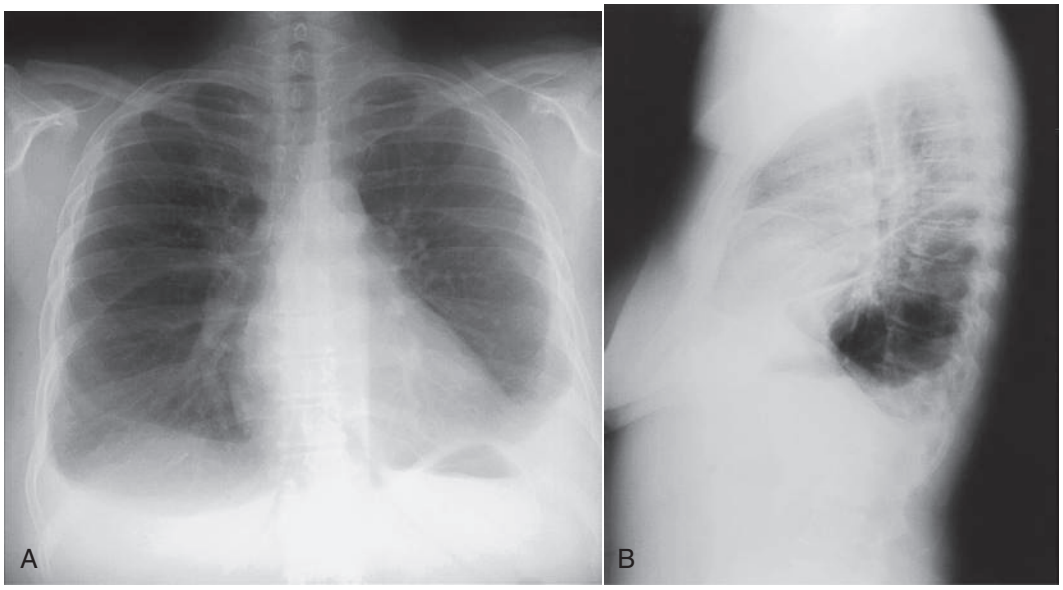

FIGURE 21-9 Pleural effusion. Posteroanterior **(A)** and lateral **(B)** chest films in a 43-year-old patient with long-standing bilateral pleural effusions resulting from rheumatoid arthritis. Note the bilateral meniscus sign is also visualized posteriorly on the lateral view.

characteristic biconvex lenslike, elliptical shape on either the PA or the lateral projection (Figure 21-11).

An increased volume of pleural fluid generally is categorized as either a *transudate* or an *exudate* (see Chapter 27). However, an exudate cannot be distinguished from a transudate on a chest radiograph or chest CT. This distinction requires analyzing a sample of the pleural fluid. *Loculation* of pleural fluid (or trapping so that the fluid does not move freely with changing positions) is more commonly seen in exudative effusions, hemothorax (blood in the pleural space), and empyema (infection of the pleural fluid).

Clues as to whether a pleural exudate results from inflammation or from cancer may be present on the chest radiograph. Clues that favor a malignant cause for a pleural effusion include pleural-based nodules, pulmonary nodules, or evidence of prior malignancy, such as surgical absence of the breast in a patient with breast cancer.

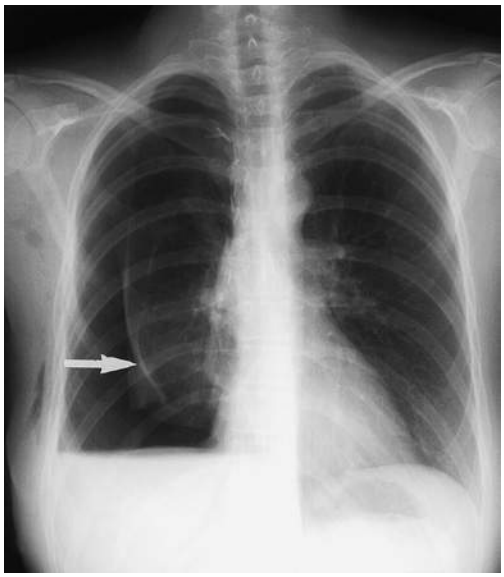

FIGURE 21-10 Hydropneumothorax. Single posteroanterior view of the chest in a patient with a hydropneumothorax. Note the air-fluid level in the pleural space. The arrow points to the visceral pleura (lung border) being compressed by both air and fluid.

Ultrasound for Evaluating Pleural Fluid

Ultrasound reliably detects both small and large pleural effusions (Figure 21-12). It is also very useful in separating pleural

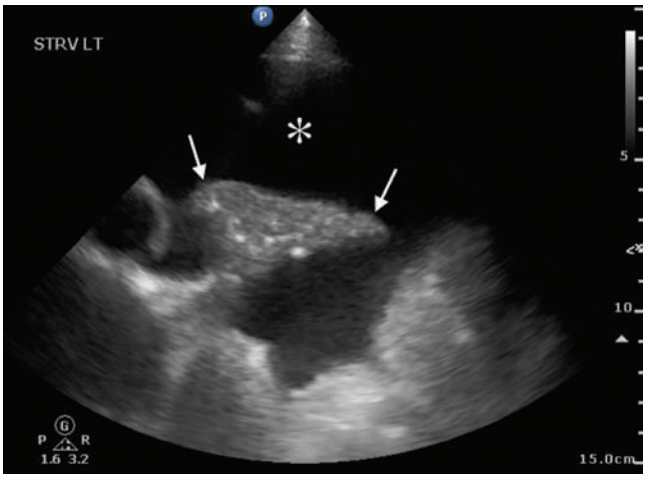

FIGURE 21-12 Pleural effusion. Ultrasound image demonstrates a large pleural effusion (asterisk). Adjacent to the pleural effusion is collapsed lung *(arrows)*.

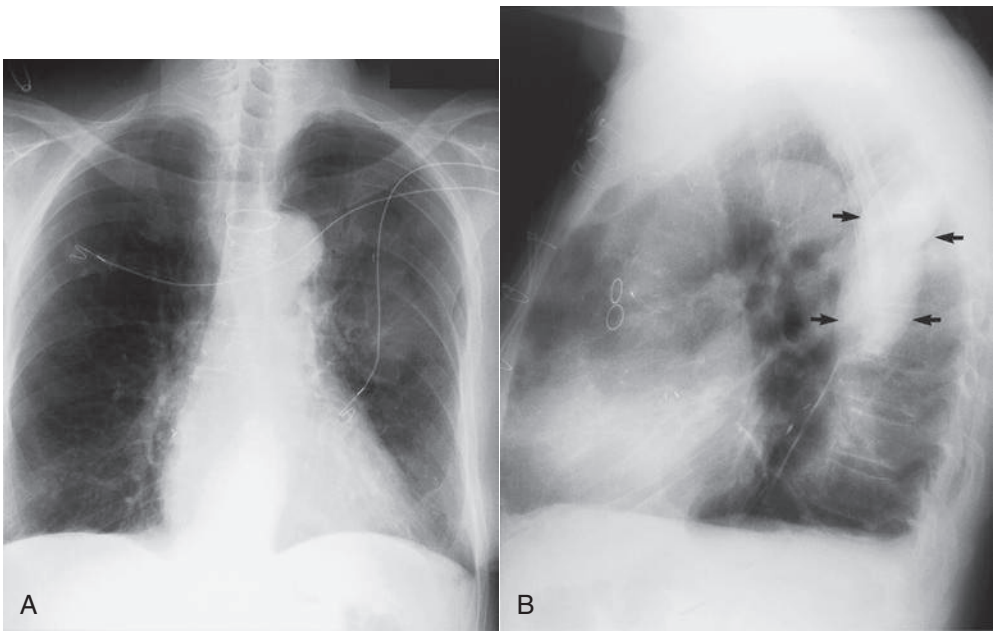

FIGURE 21-11 Intrafissural fluid. Two views of the chest showing fluid accumulating within the superior portion of the major fissure. In the posteroanterior view, the fluid is seen as vague increased density in the left upper lobe. Note the typical elliptic shape of the fluid on the lateral projection *(arrows)*.

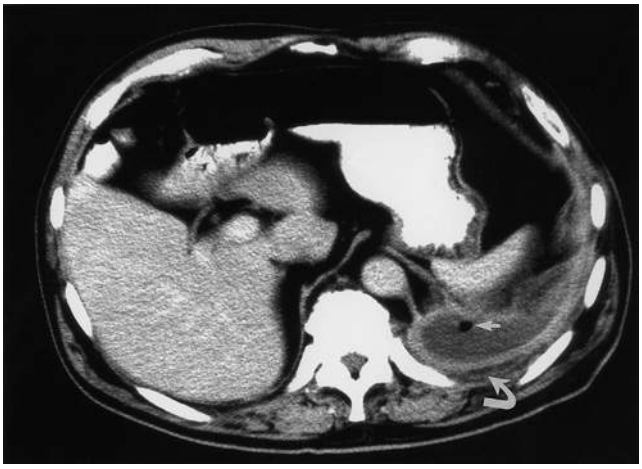

FIGURE 21-13 Empyema. Cross-sectional computed tomography image shows an elliptic pleural fluid collection surrounded by thickened enhancing pleura (split pleural sign). The presence of the gas bubble *(short arrow)* within the fluid and the thickened extrapleural subcostal tissues *(curved arrow)* is strongly suggestive of empyema.

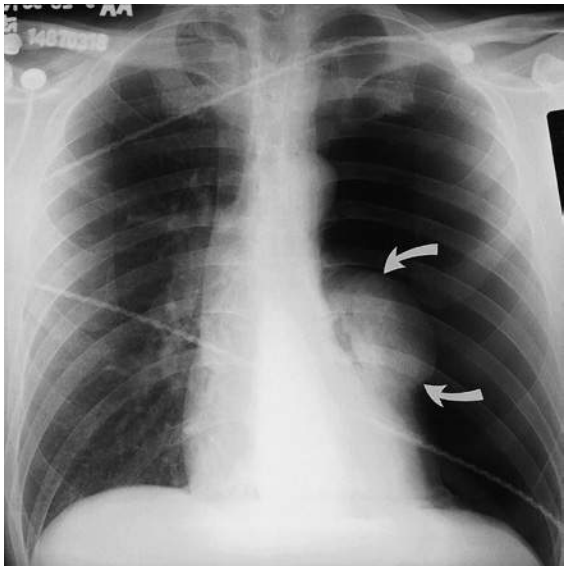

FIGURE 21-14 Pneumothorax. Complete atelectasis of the left lung *(curved arrows)* resulting from a large left pneumothorax.

fluid from solid tissue[13] and readily identifies tissue bands associated with loculated effusions. Ultrasound is also helpful in guiding thoracentesis, in particular, for small or loculated pleural effusions.

Computed Tomography

Pleural fluid can be identified easily on CT scans of the chest. In a supine patient, free fluid accumulates in the most dependent area of the pleura, which is posteriorly. Pleural fluid that does not flow to the posterior thorax is loculated.

The pleural lining is enhanced by contrast media with some forms of pleural disease. Pleural thickening and nodularity are well seen with contrast-enhanced CT scan. An elliptical pleural fluid collection with thickening and enhancement of the surrounding pleura suggests an **empyema,** which is infected pleural fluid.[14] The presence of gas within the pleural fluid without prior surgery or needle insertion (which can introduce air) establishes the diagnosis of empyema (Figure 21-13).

Pneumothorax

The term **pneumothorax** refers to the presence of air within the pleural space. The visceral pleura surrounding the lung becomes visible when air accumulates in the pleural space. A pneumothorax may occur spontaneously because of rupture of a *bleb* (a thin-walled subpleural gas-containing space deep to the pleura—a form of pulmonary air cyst) or may result from trauma or invasive procedures that puncture the pleura, such as transbronchial biopsy or a percutaneous (CT-guided) lung biopsy. Pneumothorax also may occur as a complication of positive pressure ventilation (which is called *barotrauma*). When the patient is upright, the air within the pleural space typically accumulates along the top of the lung (apex) and displaces the lung away from the chest wall. The clinician can detect a pneumothorax by seeing the thin pleural line at the lung margin and noting the absence of lung markings between the lung margin and the inner aspect of the chest wall (Figure 21-14). If a diagnosis of pneumothorax is suspected, an upright chest radiograph should be obtained. Visualizing a small pneumothorax may be assisted by taking the chest radiograph when the patient exhales. When the patient is supine, the air within the pleural space moves to the highest point in the chest, which is the anterior cardiophrenic sulcus.[15] Because air in this region does not create a visible edge between the pleura and the x-ray beam, radiographic clues to the presence of pneumothorax are more subtle in a supine patient.[15] A supine patient with a pneumothorax may have a *deep sulcus sign* (Figure 21-15),[16] which refers to air accumulating anteriorly and outlining the heart border below the dome of the diaphragm. In addition, the upper abdomen on the same side often shows increased lucency. If the diagnosis remains in doubt, a decubitus radiograph or a cross-table lateral radiograph (in which the patient lies face up while the x-ray is directed across the body) can help make the diagnosis of pneumothorax. Ultrasound is an alternative to chest radiograph and has been shown to be highly accurate in the diagnosis of a pneumothorax.[17]

A pneumothorax may be difficult to diagnose if a patient has bullous emphysema. If, after carefully examining the chest film, there is uncertainty about the presence of a pneumothorax, a chest CT can resolve the question. Skin folds can mimic a pneumothorax. To avoid mistaking a skin fold for a pneumothorax, the clinician needs to look carefully at what appears to be the lung margin. The absence of the pleural line at the lung margin and the presence of bronchovascular markings between the lung margin and the chest wall suggest a skin fold rather than a pneumothorax.

Occasionally, air within the pleural space may be under pressure or tension (Figure 21-16); this is called a *tension pneumothorax*. A tension pneumothorax is an emergency that occurs

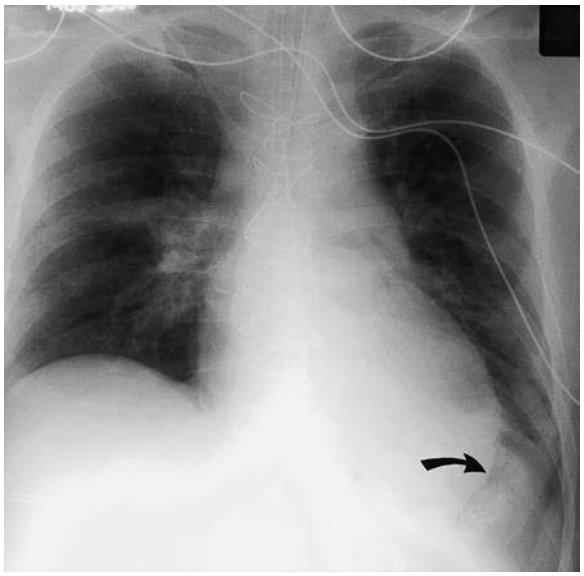

FIGURE 21-15 Deep sulcus sign. Portable supine radiograph in a patient status-post median sternotomy. Note the increased lucency in the left upper quadrant. The highest portion of the thorax in a supine patient is the anterior cardiophrenic sulcus; this accounts for the well-defined low cardiac border *(arrow)* and the adjacent fat pad.

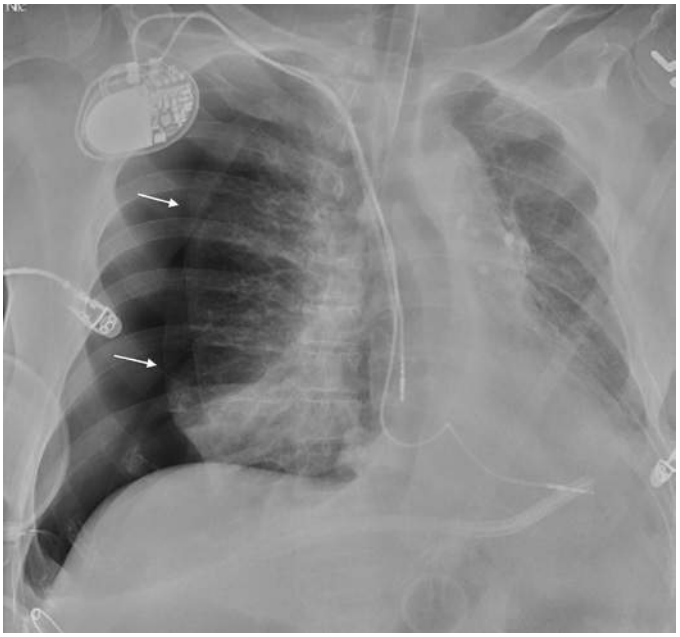

FIGURE 21-16 Tension pneumothorax. Portable chest radiograph after a recent liver transplant. Note the large right pneumothorax displacing the mediastinum to the left and the right hemidiaphragm inferiorly. These findings indicate the presence of a tension pneumothorax on the right requiring immediate chest tube placement.

when the tear in the pleura (which allows air to leave the lung and enter the pleural space) opens on inspiration but closes on expiration. Air continues to accumulate in the pleural space and can compress the heart and adjacent lung. Imaging features of a tension pneumothorax include inferior displacement of the hemidiaphragm on the side of the pneumothorax or mediastinal shift away from the pneumothorax. A tension pneumothorax requires immediate decompression with a chest tube, Heimlich valve, or needle aspiration of the air within the pleural space.

MINI CLINI

Use of the Silhouette Sign

PROBLEM: A patient has an airspace opacity in the lower half of the right lung that is secondary to pneumonia. It is unclear if this abnormality is located in the right middle lobe or in the upper portion of the lower lobe. Is there a way to identify the location of this infiltrate?

DISCUSSION: If the right heart border is visible next to the infiltrate, the pneumonia is located in the lower lobe behind the heart. If the right heart border is invisible, the infiltrate must be located in the right middle lobe next to the right side of the heart. The disappearance of the right heart border in this circumstance is due to the silhouette sign. In this instance, pneumonia is considered a water density, and when two structures of similar density are touching each other in the same plane, the border between the two structures (or the silhouette of the heart border) is not seen. Pneumonia in the upper segments of the lower lobe appears to be next to the heart on the PA chest film but does not obliterate the heart border in such cases because the water density of the pneumonia in the lower lobe is not adjacent to the water density of the heart. In this instance, the heart border or silhouette is seen because the silhouette sign is not present.

LUNG PARENCHYMA

The lung parenchyma is made up of two main components: air sacs (alveoli) and interstitium (the supporting structures of the lung). Lung parenchymal disease involves both components, although one component is usually affected more than the other.

Alveolar Disease

When alveoli are filled with material denser than air, they have a characteristic radiographic appearance regardless of the material that fills them. The type of fluid that fills the alveoli varies depending on the disease process. In the case of pulmonary edema, the alveoli are filled with a watery fluid that contains few cells. With bacterial pneumonia, the alveoli are filled with an exudative fluid containing numerous white blood cells (pus). In the case of pulmonary hemorrhage, the alveoli fill with blood. Both pneumonia and pulmonary hemorrhage can cause identical-appearing patchy, increased density shadows that tend to coalesce over time on the chest radiograph. These shadows are often referred to as *airspace opacities* or ***infiltrates***. Although the term *infiltrate* is commonly used to describe an airspace opacity, caution should be used because some clinicians equate infiltrates with pneumonia whereas others take infiltrates to

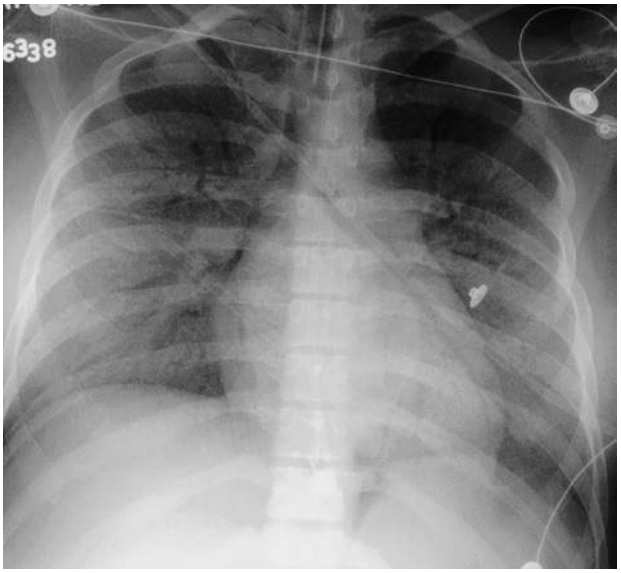

FIGURE 21-17 Air bronchograms. This portable radiograph shows diffuse increased density throughout both lungs highlighted by tubular lucencies. These are air bronchograms. They are visualized because of the alveolar filling that surrounds them. This typical alveolar filling pattern (airspace disease) suggests acute pneumonia, pulmonary hemorrhage, or pulmonary edema.

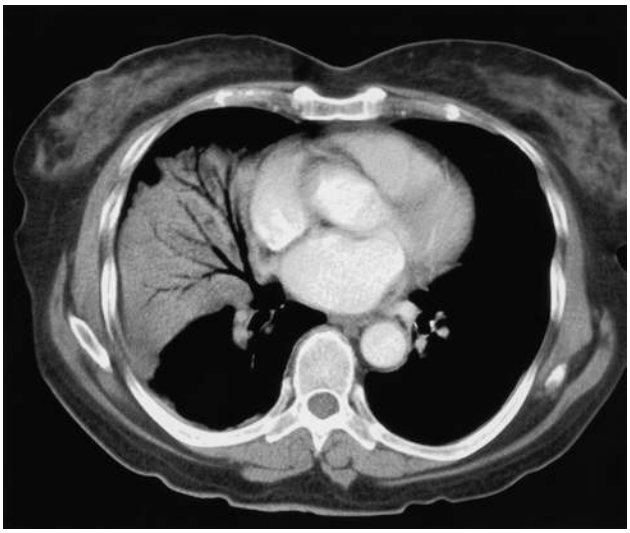

FIGURE 21-18 Right middle lobe pneumonia. Computed tomography slice shows an alveolar filling process in the right middle lobe with tubular air bronchograms running through it. The patient is a 73-year-old woman with right middle lobe pneumonia.

mean a much broader differential diagnosis, including pulmonary edema, pneumonia, and hemorrhage.

The lucent tubular structures that course through dense airspace opacities or infiltrates on both chest radiographs and chest CT images are referred to as **air bronchograms** (Figure 21-17). Normally, patent airways are invisible in the outer two-thirds of the lung on a chest radiograph because of the lack of contrast between air in the airway and air in the lung. However, the increased contrast produced by filling of the surrounding alveoli with fluid makes the airways more visible and causes the air bronchogram sign. Air bronchograms are the hallmark of infiltrates that fill alveoli (so-called *airspace disease*) (Figure 21-18 and Box 21-2).

Box 21-2 Radiographic Features of Alveolar Versus Interstitial Processes

ALVEOLAR (AIRSPACE) DISEASE
Air bronchograms
Fluffy opacities
Rapid coalescence
Acinar nodules
Segmental/lobar distribution

INTERSTITIAL DISEASE
Nodules
Linear/reticular opacities
Septal lines
Cysts
Honeycombing

RULE OF THUMB

Air bronchograms indicate that the imaging abnormality is located in the lung parenchyma and not in the pleural space and suggest that the findings may be secondary to pneumonia.

Pulmonary Edema

Pulmonary edema is one of the most common chest radiographic findings in critically ill patients. Pulmonary edema can be caused by vascular congestion, rupture of the pulmonary capillaries, or a combination of both factors. Edema from vascular congestion can be caused by failure of the left heart (cardiogenic pulmonary edema), renal failure, or fluid overload. Breakdown in the integrity of the lung capillaries also can cause pulmonary edema as in acute respiratory distress syndrome (ARDS; see Chapter 29).

The development of cardiogenic pulmonary edema can be described through a series of changes on the chest film. Before pulmonary edema develops, the pressure in the pulmonary veins increases. The increasing pressure in the pulmonary veins can be seen on the chest film as enlarging blood vessels that extend to the lung apexes. If the blood vessels in the upper lung zones are the same size or larger than the blood vessels in the lower lung zones, the vessels are said to be "cephalized" (Figure 21-19). **Cephalization** of the pulmonary blood flow is often caused by left-sided heart failure.

As fluid builds up from the high venous pressures, thickening of bronchial walls *(peribronchial cuffing)* (see Figure 21-19) and edema in the walls or septa that separate the lung lobules become evident. The thickened septa are most clearly seen as thin lines. Fluid also may accumulate in the lymphatics that drain the lung. Such accumulation within the lymphatics may

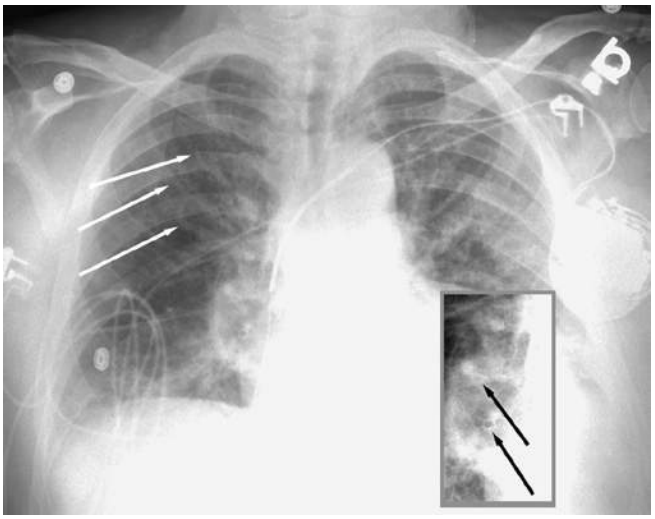

FIGURE 21-19 Moderate pulmonary edema. Cephalization of blood flow is visible *(white arrows)*. The blood vessels to the apex of the lung are enlarged and similar in size to the blood vessels to the base of the lungs. The *inset* displays peribronchial cuffing *(black arrows);* the *inset* is from the right hilum of the same film but is enhanced to make the peribronchial cuffing easier to see.

appear on the plain radiograph as thin lines against the pleural edge that run perpendicularly away from the pleural edge. These lines are called **Kerley B lines** (Figure 21-20).

RULE OF THUMB

Radiographic signs of cardiac decompensation include the following:

- Cardiac enlargement
- Pleural effusions, usually bilateral
- Redistribution of blood flow to the upper lobes (cephalization of blood flow)
- Poor definition of the central blood vessels (perihilar haze)
- Kerley B lines
- Alveolar filling

NOTE: These findings are shown in Figure 21-20.

The development of pulmonary edema in the lung is seen first in the hila of the lungs by blurring of the normally distinct walls of the hilar blood vessels; this is followed by blurring and increased haziness caused by the edema progressing outward toward the pleura. The term *bat wing appearance* is applied to the predominance of edema in the hilar regions of both lungs with progressively less edema in the more peripheral areas of the lungs (Figure 21-21).

In addition to the previously mentioned classic signs of pulmonary edema, many patients with long-standing heart failure have enlargement of the heart and pleural effusions. Pleural effusions from heart failure are usually bilateral but if the effusion is visible only on one side, it is more common on the right side than on the left.

The radiographic appearance of ARDS can appear similar to other forms of pulmonary edema. Although they may appear similar, there are some key differences to help distinguish ARDS from pulmonary edema caused by high vascular pressures or congestive heart failure. The edema of ARDS is patchy and bilateral and does not predominate in the central hilar regions. A chest film of a patient with ARDS also lacks cardiomegaly, cephalization, and Kerley B lines, which are often seen in cardiogenic pulmonary edema.

Interstitial Disease

Diseases that primarily involve the interstitium of the lung have a different radiographic appearance than alveolar diseases (see Box 21-2). The interstitium of the lung represents the framework or scaffolding of the lung that supports the vessels and bronchi. The secondary pulmonary lobule is the smallest functional unit of the lung.[18] The *secondary pulmonary lobule* contains alveoli and alveolar ducts built around a central pulmonary arteriole and bronchiole, all surrounded by a thin sheet of fibrous connective tissue called the *intralobular septa*. Intralobular septa are invisible on a normal chest radiograph. Pulmonary edema secondary to poor left-sided heart function causes edema of the intralobular septa. As noted, short thin lines from the edematous intralobluar septa can be seen perpendicular to the pleura (see Figure 21-19); these are Kerley B lines.

Interstitial lung disease (see Chapter 26) refers to a group of diseases that involve the lower respiratory tract. Chest radiographs of patients with interstitial lung disease may have several different appearances, depending on the stage and type of interstitial lung disease (see Box 20-2). A chest radiograph of a patient with interstitial lung disease usually has diffuse, bilateral opacities. The opacities may resemble scattered, poorly defined nodules (nodular); a collection of scattered lines (reticular); or a combination of both lines and nodules (reticulonodular); or *honeycombing,* which is the development of cystic spaces with well-defined walls seen in the periphery of the lung and resembling a bee's honeycomb. Honeycombing is thought to represent irreversible scarring and indicates end-stage lung disease (Figure 21-22). Lung volumes are generally decreased in patients with interstitial lung disease, a key finding that can aid in the diagnosis on a chest radiograph examination.

There are many types of interstitial lung disease. Causes include *infectious* (e.g., viral pneumonia), *occupational* exposures (e.g., to asbestos [asbestosis] or to silica [silicosis]), and *collagen vascular disease* (e.g., rheumatoid arthritis, scleroderma). The two most common interstitial lung diseases, *sarcoidosis* and *idiopathic pulmonary fibrosis,* have no known cause and are said to be idiopathic. Because many different types of interstitial lung diseases have similar appearances on the chest radiograph, the chest film rarely establishes the specific cause of interstitial disease. Clues to specific causes of interstitial lung disease on a plain chest film are reviewed in Table 21-2. HRCT has become an important tool in establishing the specific form of interstitial lung disease that a patient may have. HRCT is particularly helpful in diagnosing idiopathic pulmonary

FIGURE 21-20 Posterior **(A)** and lateral **(B)** chest films show an enlarged cardiac silhouette. The lateral lung margins are slightly displaced away from the inner chest wall in both costophrenic angles, which is consistent with bilateral effusions. There is thickening of the fissures on the lateral projection, indicating that the pleural fluid is extending into the interlobar fissures. Numerous Kerley B lines are seen as linear densities extending to the pleural surface in the right lower chest. The definition of the central vessels is suboptimal, indicating interstitial edema. **C** and **D,** The same patient after therapeutic diuresis. Note the decreased heart size, disappearance of Kerley B lines, and improved definition of the central pulmonary vasculature.

fibrosis because of a characteristic pattern with changes in the lower lobes exceeding those in the apexes, a subpleural location, and the presence of honeycombing.[19,20]

Assessing Lung Volume

Volume loss, or *atelectasis,* is a common abnormality on chest radiographs, and the location and extent of volume loss produce characteristic chest radiograph patterns. The degree of atelectasis can be described as subsegmental (involving less than a segment of lung), segmental (involving one or more segments of lung), or lobar (involving one or more lobes of the lung). A specific type of subsegmental atelectasis that has a classic radiographic appearance is called *platelike* or *discoid* ***atelectasis*** (Figure 21-23). Atelectasis commonly occurs after abdominal or thoracic surgery, adjacent to pleural effusions, or after pleural irritation from a rib fracture or pulmonary infarction.

Volume loss involving an entire lobe (lobar atelectasis) is usually caused by central airway obstruction.[21] The collapsed lobe assumes the shape of a wedge with the apex of the wedge at the hilum and the base of the wedge on the pleural surface. This wedge is visible on a PA or lateral x-ray film, depending on which lobe is collapsed (Figure 21-24). The central bronchial

obstruction may be caused by cancer, a foreign body, or a mucous plug (Figure 21-25). As shown in Figure 21-26, a bulging convexity to the apex of the wedge indicates a central tumor.

Atelectasis causes changes to the surrounding structures. As lung volume decreases, surrounding tissues collapse in to fill the space of the collapsed lung. The diaphragm becomes elevated on the side of the atelectasis, the mediastinum shifts toward the atelectasis, and poor expansion of the chest causes narrowing of the rib spaces. If the collapsed segment of the lung is in the upper lobe, the hilum is displaced upward, and the minor fissure on the right is displaced upward.

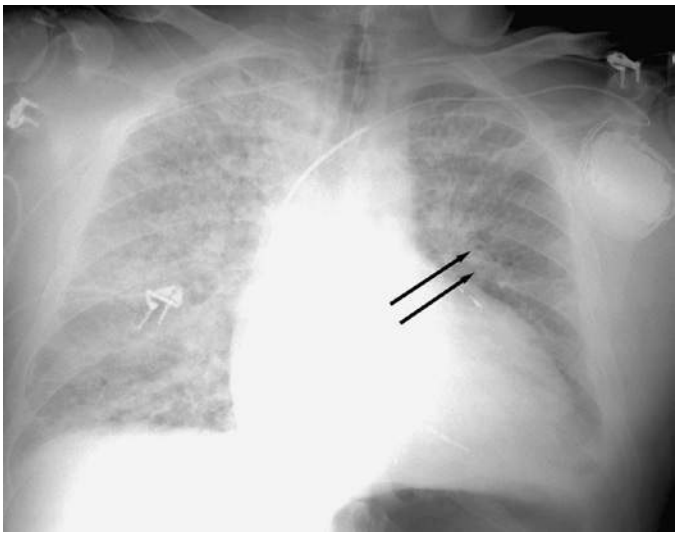

FIGURE 21-21 Severe pulmonary edema. Both lungs are opacified in a bat's wing distribution. The hilar vessels are invisible because of the edema in the lung tissue surrounding these vessels. Peribronchial cuffing is indicated by the *black arrows*.

RULE OF THUMB

Radiographic signs of volume loss include the following:

- Unilateral diaphragmatic elevation
- Mediastinal shift toward the atelectasis
- Narrowing of the space between the ribs
- Hilar displacement toward the atelectasis

See Figures 21-23, 21-24, 21-25, and 21-26.

TABLE 21-2

Clues on Plain Chest Radiograph Indicating the Specific Cause of Interstitial Lung Disease

Clues on Radiograph	Cause of Disease
Pneumothorax	Lymphangioleiomyomatosis, Langerhans cell histiocytosis
Pleural effusion	Rheumatoid arthritis, systemic lupus erythematosus
Dilated esophagus	Scleroderma, CREST syndrome*
Erosive arthropathy (shoulder joints, clavicles)	Rheumatoid arthritis
Mediastinal adenopathy	Sarcoidosis, progressive systemic sclerosis (scleroderma), metastatic cancer
Soft tissue calcification	Dermatomyositis, progressive systemic sclerosis (scleroderma)
Pleural plaque	Asbestosis

*Calcinosis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasia.

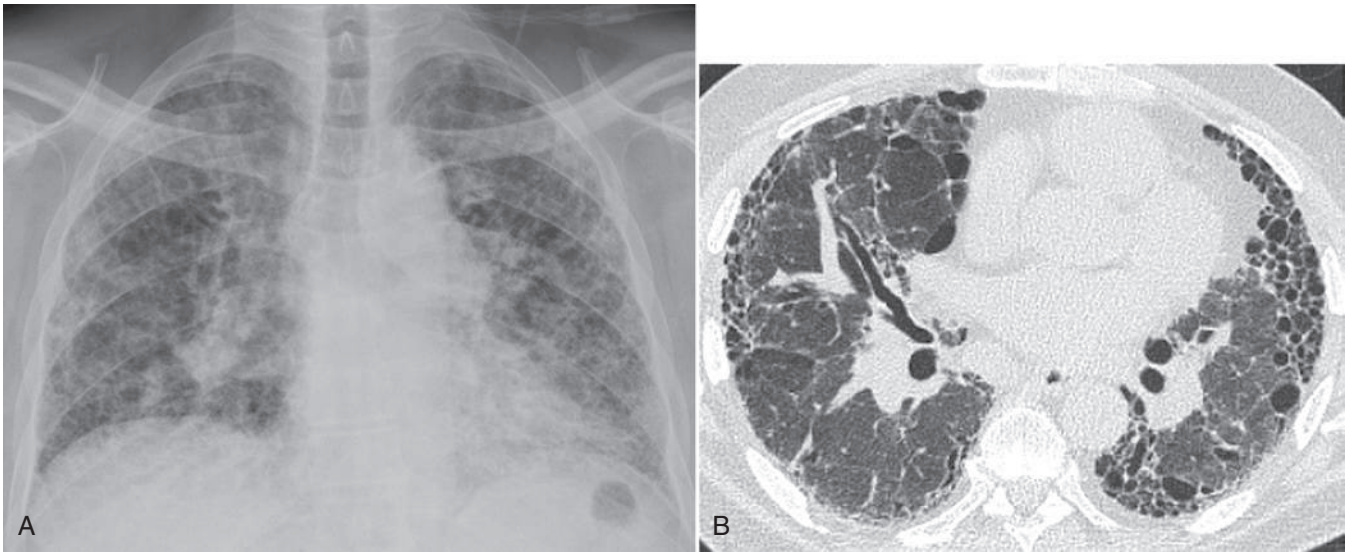

FIGURE 21-22 Posteroanterior view **(A)** of the chest in a patient with shortness of breath. The chest radiograph shows interstitial lung disease. The lung volumes are small. Coarse linear and cystic lucencies represent pulmonary fibrosis. These findings are better visualized on the chest computed tomography image **(B)** where there is bronchiectasis, architectural distortion, and honeycombing. The patient has interstitial pulmonary fibrosis, the most common type of pulmonary fibrosis.

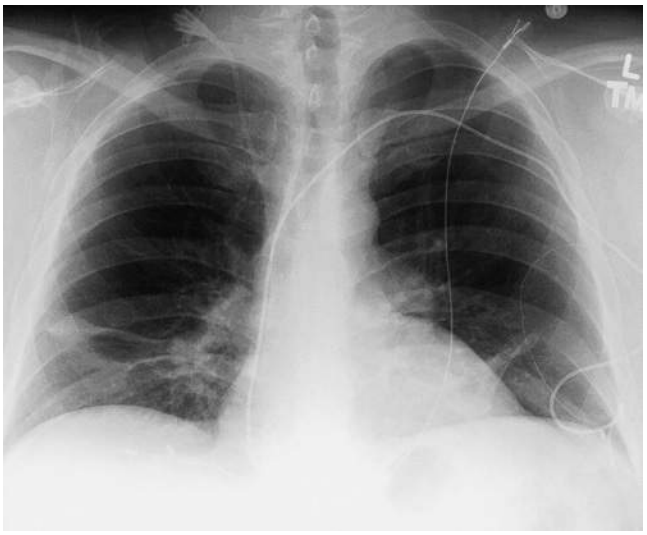

FIGURE 21-23 Plate atelectasis. Posteroanterior chest radiograph shows linear areas of plate atelectasis in both lower lobes.

Assessment of lung volumes on a chest radiograph requires several observations. Rib counting is a popular method to assess lung volume. With a good inspiration, the sixth and sometimes the seventh anterior rib should project above the diaphragm. If more than seven anterior ribs are visible above the diaphragm, *hyperinflation* is present. Obstructive pulmonary disease is classically associated with increased lung volumes (hyperinflation). In patients with chronic obstructive pulmonary disease, there also may be an increase in the AP diameter of the chest, with associated enlargement of the retrosternal and retrocardiac (behind the sternum and the heart, respectively) airspaces and flattening of the hemidiaphragms. These findings all are secondary signs of *pulmonary emphysema*. The only primary signs of emphysema are loss or shifting of pulmonary vessel markings and the appearance of the walls of bullous airspaces (Figure 21-27).

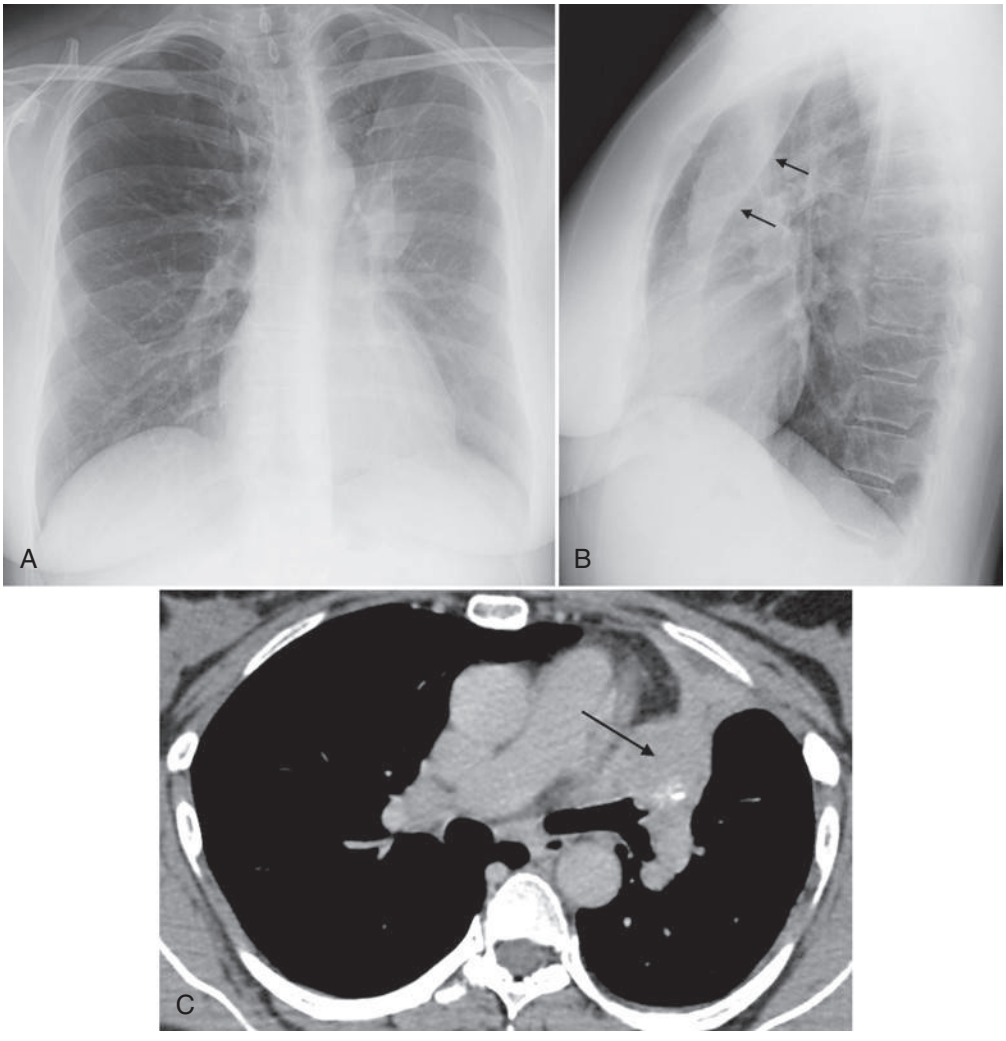

FIGURE 21-24 **A,** Posteroanterior view of the chest shows leftward mediastinal shift, a left hilar mass, and increased density overlying the left chest. **B,** Lateral view shows a wedge of increased density *(arrows)* anteriorly with its apex at the hilum and its base on the pleural surface representing the collapsed left upper lobe. **C,** Computed tomography image shows a partially calcified left hilar mass *(arrow),* with the collapsed left upper lobe distally. Biopsy of the mass revealed carcinoid tumor.

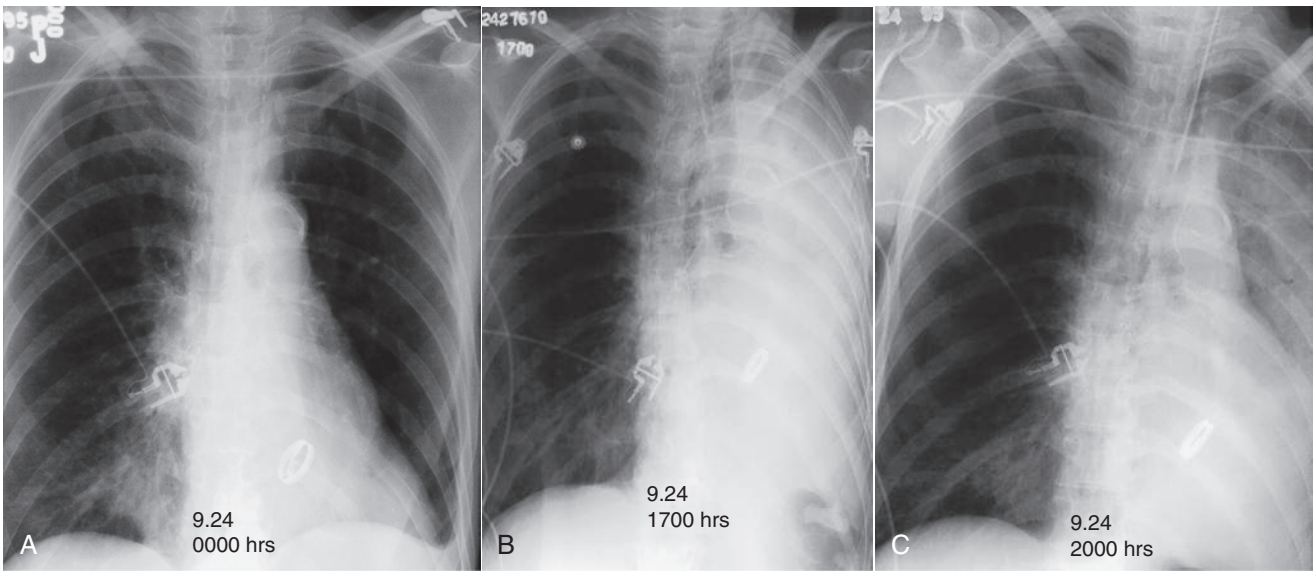

FIGURE 21-25 Three portable chest films obtained within a 20-hour time span. **A,** Good aeration of both lungs. **B,** Film obtained 17 hours later shows complete opacification of the left hemithorax. Bronchoscopy performed after this film revealed a mucous plug in the left main bronchus. It was removed at bronchoscopy. **C,** Partial reexpansion.

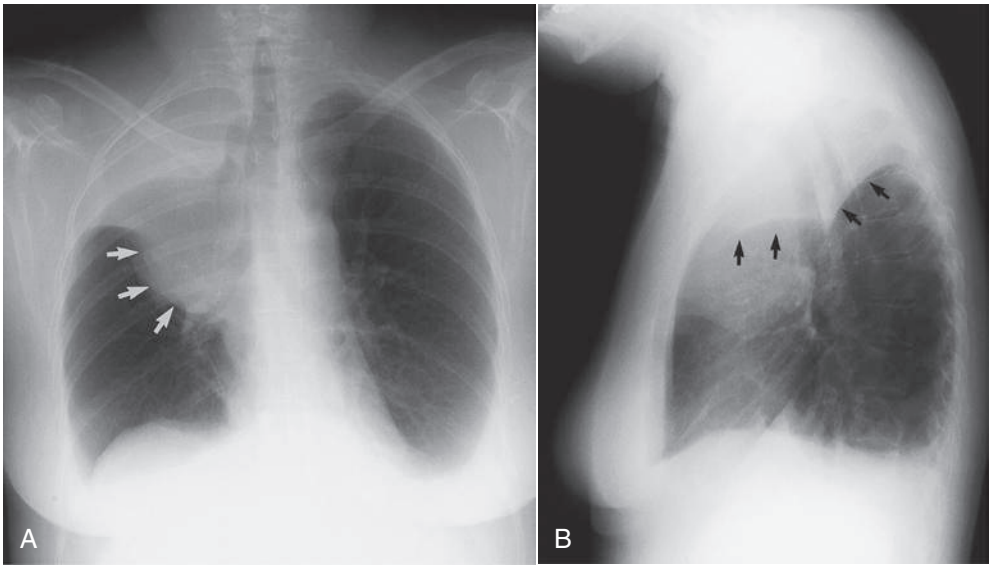

FIGURE 21-26 Posteroanterior **(A)** and lateral **(B)** views of the chest in a patient with right upper lobe collapse. **A,** Note the wedge opacity of the right upper lobe and the inferior bulge *(arrows)* of the minor fissure on the PA film. This bulge indicates the presence of a central mass. **B,** The wedge shape of right upper lobe atelectasis *(arrows)* is well seen on the lateral film.

RULE OF THUMB

A good inspiratory effort by the patient is needed to obtain a good-quality chest radiograph examination. Visualization of 6 anterior or 10 posterior ribs above the level of the diaphragm on the PA view indicates a good inspiratory effort by the patient.

Because radiographic signs of emphysema are apparent only with more advanced disease, the chest radiograph is generally considered insensitive for detecting obstructive lung disease. However, CT is far more sensitive and may show evidence of emphysema even when pulmonary function test results are normal.[22] Emphysema is often anatomically described in three patterns depending on which part of the secondary pulmonary lobule is affected. When only the central part of the lobule is affected, the pattern is called *centrilobular* or *centriacinar emphysema*. When the entire lobule is affected, the pattern of emphysema is called *panlobular* or *panacinar*. Finally, when the emphysema is confined to areas near the pleura, the pattern is called *paraseptal emphysema*. Figure 21-28 shows a case of upper lobe paraseptal emphysema, characterized by cystic areas along the pleural surface. A chest CT scan may prove useful to

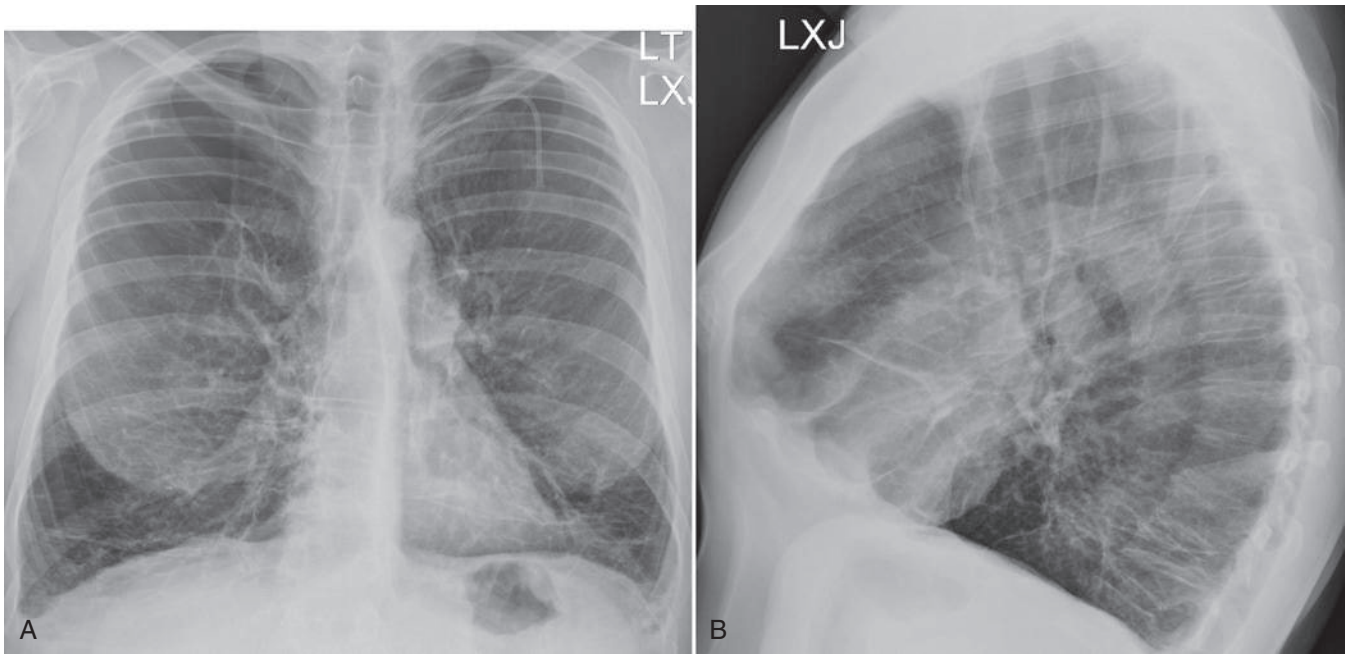

FIGURE 21-27 Posteroanterior **(A)** and lateral **(B)** views of the chest of a patient with bullous emphysema, worse on the right. The lungs are hyperinflated with flattening of the diaphragms, increased retrosternal clear space, and areas in the upper lung zones that are devoid of any vascular markings.

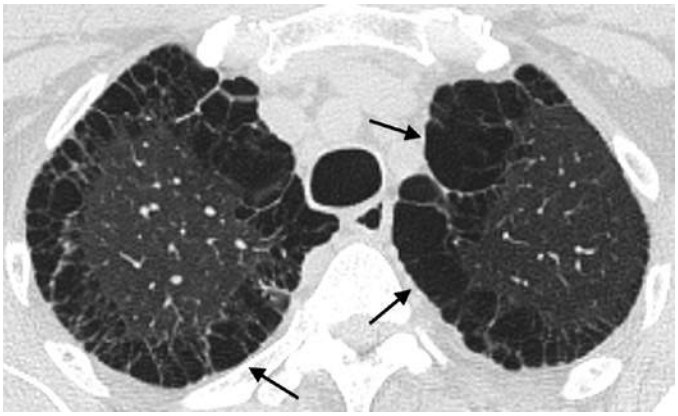

FIGURE 21-28 Computed tomography image through the upper lobes in a patient with pulmonary emphysema. Numerous cystic lucencies are present in both lungs. Note the absence of bronchovascular markings within the lucencies. Most of the emphysematous areas are located in a peripheral distribution *(arrows)* along the pleural surface, representing paraseptal emphysema.

help define which patients may benefit from treatments such as lung volume reduction surgery. Results of the National Emphysema Treatment Trial showed that patients with heterogeneous upper lobe-predominant emphysema (i.e., emphysema that is greater in the apexes of the lung than in the bases) are good candidates for lung volume reduction surgery.[23]

Solitary Pulmonary Nodule

A **solitary pulmonary nodule** (SPN) is a parenchymal opacity smaller than 3 cm in diameter that is surrounded by aerated lung. One or two SPNs are encountered in every 1000 chest radiographs. SPNs are important to identify because they may be caused by lung cancer. The reported prevalence of malignancy in SPN ranges from 3% to 6% in large surveys of the general population. In patients with SPN who have surgical resection, 30% to 60% of the nodules are malignant.[24]

When first encountered, a SPN should be assessed for features listed in Table 21-3 that may help to establish a nonmalignant cause. The goal of imaging SPNs is to avoid resecting benign nodules, while encouraging surgical removal of all potentially curable cancers. The axial anatomic display of CT, along with better density-discriminating powers, makes CT a favored tool for evaluating the SPN. CT provides a detailed

TABLE 21-3

Features Useful in Distinguishing Benign from Malignant Solitary Pulmonary Nodules

Feature	Favoring Malignant Nodule	Favoring Benign Nodule
Patient age	>40 yr old	<40 yr old
Smoking status	Current or former smoker	Lifetime nonsmoker
Size of nodule	>3 cm	<3 cm
Shape of nodule	Lobulated	Spherical
Margins of nodule	Spiculated	Well defined
If cavity	Thick-walled	Thin-walled
Doubling time*	7-465 days	<7 or >465 days
Calcification	Rare, usually eccentric	Central, lamellar, popcorn

*Time necessary for the nodule to double in volume.

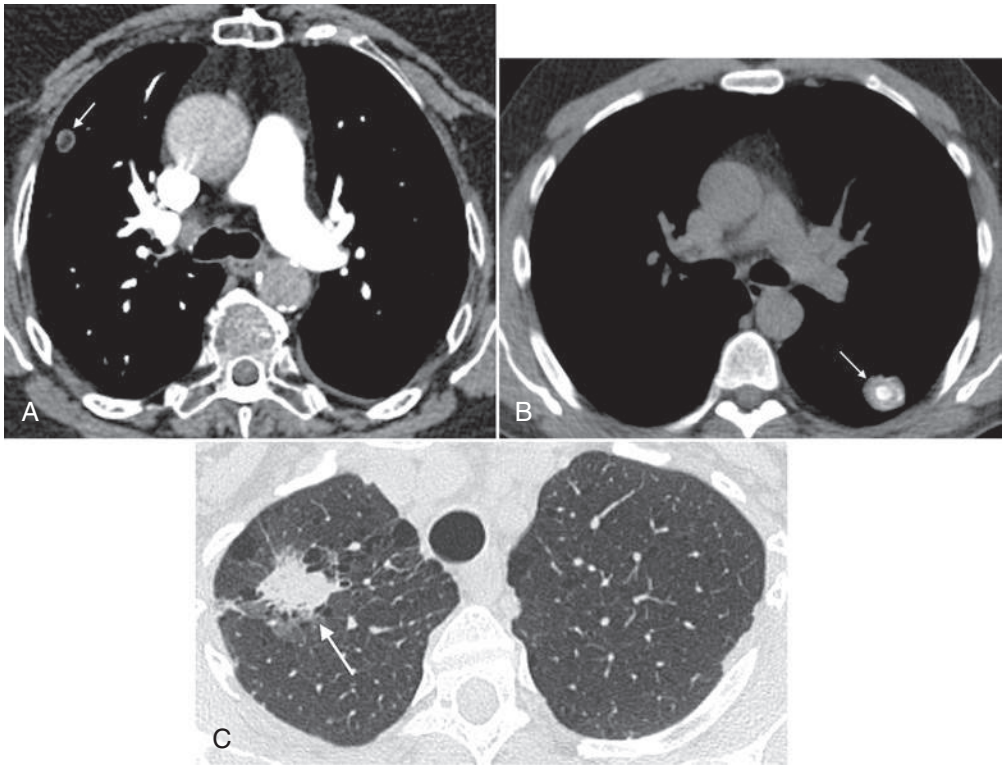

FIGURE 21-29 Computed tomography examples of solitary pulmonary nodules. **A,** Nodular density in the right lung that contains fat. Note the same density within the nodule as the subcutaneous fat. This finding is diagnostic of a pulmonary hamartoma, a benign diagnosis, requiring no further follow-up. **B,** There is central calcification with this pulmonary nodule, a benign form of calcification, and consistent with a granuloma. **C,** The spiculated edge of this nodule *(arrow)* is suggestive of malignancy in this biopsy-proved primary lung adenocarcinoma.

evaluation of the size, shape, border, and density of a nodule. For example, the presence of fat or the pattern of calcification can help to establish that a pulmonary nodule is benign (Figure 21-29).

Central or lamellar (swirls of concentric rings) often result from calcification and strongly suggests a benign cause of an SPN or a granuloma. Eccentric (off-center), speckled, or amorphous calcification may be seen in lung cancer. A smoothly marginated round nodule more often is benign, whereas a lobulated, irregular, or spiculated edge is more likely to be a malignant nodule (see Figure 21-29). PET-CT is often very helpful in evaluating SPNs. Nodules greater than 1 cm in diameter that take up the isotope used in PET-CT studies, fluorodeoxyglucose (FDG), are metabolically active and are more likely to be malignant than nodules without uptake. Unfortunately, FDG uptake by a pulmonary nodule on a PET-CT is not specific for malignancy because infectious or inflammatory nodules (such as nodules caused by fungal infection with *Histoplasmosis*) may also be FDG-avid and "light up." Similarly, slow-growing cancers (such as adenocarcinoma in situ) or small cancers (<1 cm) may not take up FDG or be visible on the PET-CT scan.

MEDIASTINUM

The mediastinum consists of the heart, great vessels, trachea, and other soft tissue structures that lie between the lungs. The mediastinum is divided into three compartments: anterior, middle, and posterior. When a mediastinal abnormality is discovered, determining the precise location of the mediastinum is important to narrow the differential diagnosis. Radiographically, the mediastinal compartments are best defined on a lateral view (see Figure 21-5). A line extending from the diaphragm along the posterior margin of the heart and the anterior margin of the trachea to the neck divides the anterior mediastinum from the middle compartment. A second line traversing the vertebral bodies 1 cm posterior to their anterior margins and extending from the neck to the diaphragm divides the middle from the posterior compartment. Some mediastinal masses are visible on both front and lateral projections, and the specific location within the mediastinum offers the first clue to diagnosis.

Table 21-4 lists the common causes of masses in the three mediastinal compartments. CT is the preferred imaging examination for evaluating most mediastinal masses. Figure 21-30 shows the normal axial anatomic display on contrast-enhanced CT scan at the levels of the great vessels, aortic arch, carina, and cardiac chambers. The CT appearance of an anterior mediastinal mass (thymoma) is shown in Figure 21-31. Figure 21-32 shows a middle mediastinal mass (bronchogenic cyst) on an MRI examination. A large hiatal hernia in the posterior mediastinum can be easily confused with a mass on the frontal chest film but is easily seen on CT in Figure 21-33.

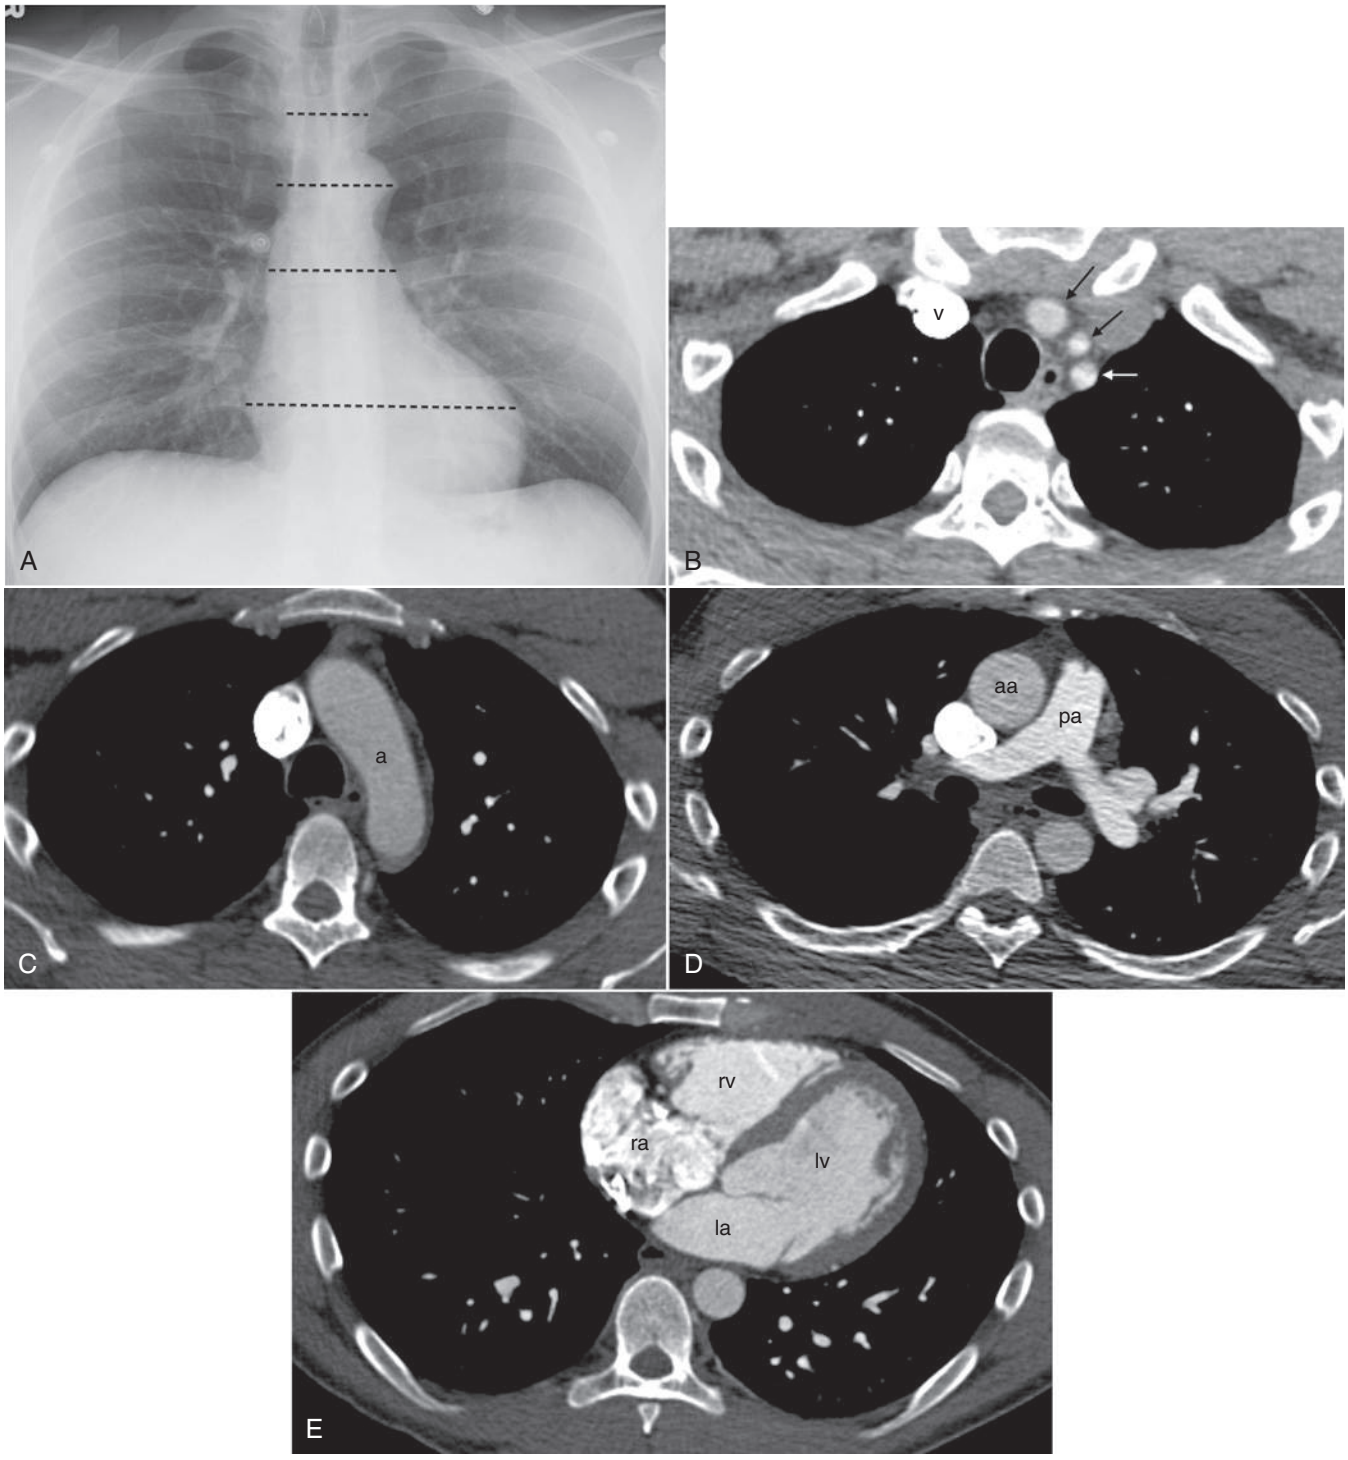

FIGURE 21-30 **A,** Posteroanterior chest radiograph indicating the four levels at which computed tomography scan slices **B** to **E** were obtained. **B,** The most superior image is at the level of the great vessels. Contrast material fills the right brachiocephalic vein *(v)* and the three arch vessels, the right brachiocephalic, left common carotid, and left sublavian arteries. **C,** At this level, the arch of the aorta *(a)* lies on the left side of the airway. The esophagus is seen in front of the vertebral body behind the airway. The opacified superior vena cava lies to the right of the arch anteriorly. **D,** At the level of the pulmonary artery bifurcation, the right pulmonary artery crosses the mediastinum anterior to the right main bronchus. The vena cava lies to the right of the ascending aorta *(aa)*. The descending aorta is seen next to the vertebral body. **E,** At the level of the heart, contrast material is seen filling the right atrium *(ra)* and crossing the atrioventricular (tricuspid) valve into the right ventricle *(rv)*. The thick, muscular left ventricular *(lv)* wall is visualized as it contracts. The left atrium *(la)* is seen anterior to the esophagus.

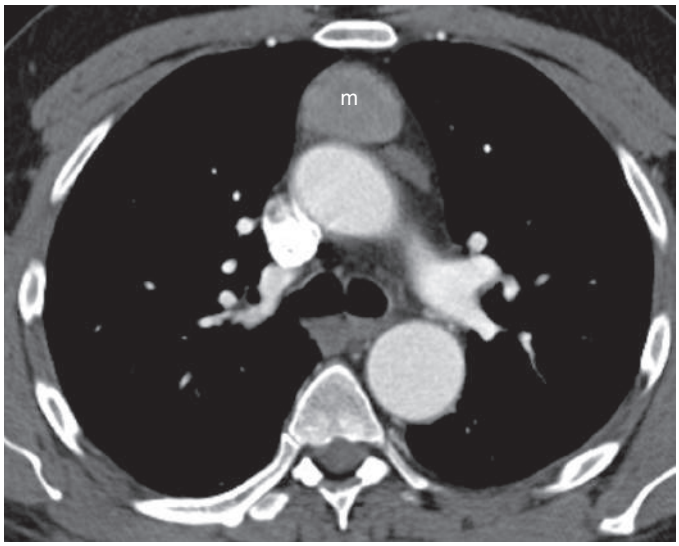

FIGURE 21-31 Anterior mediastinal mass. Computed tomography slice at the level of the aortic arch shows a homogeneous encapsulated anterior mediastinal mass *(m)*. The diagnosis was thymoma.

TABLE 21-4

Mediastinal Abnormalities by Compartment

Anterior Mediastinum	Middle Mediastinum	Posterior Mediastinum
Thyroid or parathyroid mass	Aortic aneurysm (ascending/arch)	Aortic aneurysm (descending)
Thymic lesions	Lymphadenopathy	Neurogenic tumors
Lymphoma	Bronchogenic cyst	Lymphoma
Pericardial cyst/fat pad	Tracheoesophageal masses	Neurenteric cyst
Teratoma	Hiatal hernia	Bochdalek hernia*
Morgagni hernia*		
Ventricular aneurysm		

*Hernia in which the abdominal contents press through a gap in the diaphragm.

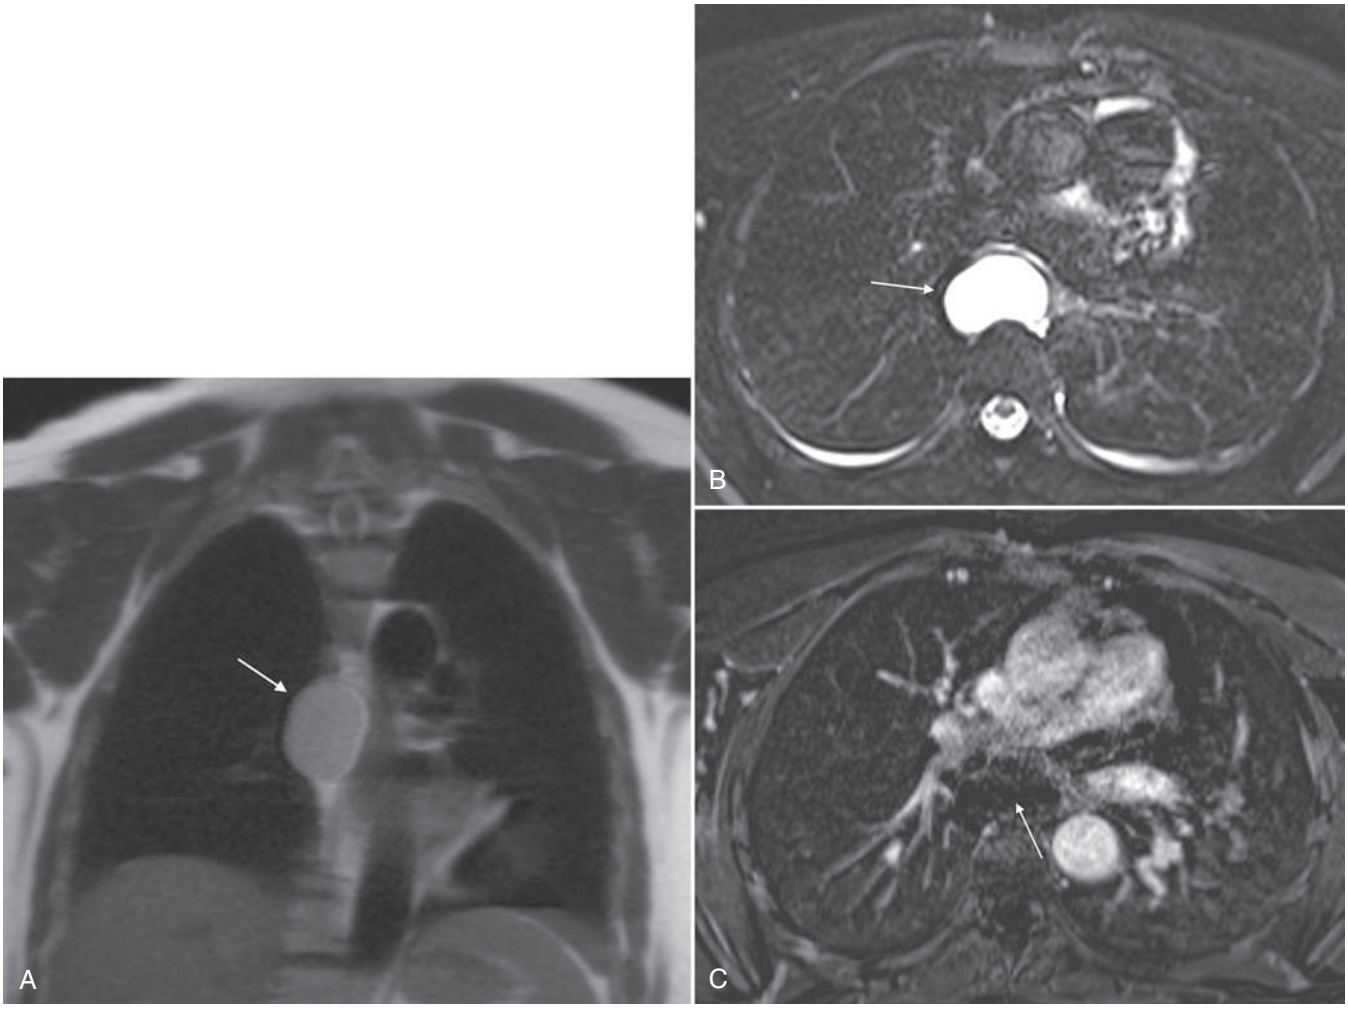

FIGURE 21-32 Middle mediastinal mass. Magnetic resonance images demonstrate a subcarinal mass *(arrows).* Coronal HASTE **(A)** and axial STIR **(B)** images demonstrate increased T2 signal (appearing gray or white) intensity in this mass, suggestive of a cystic lesion. Substraction VIBE image **(C)** shows no enhancement (the mass is black) confirming no contrast enhancement. The diagnosis is a bronchogenic cyst, a benign lesion.

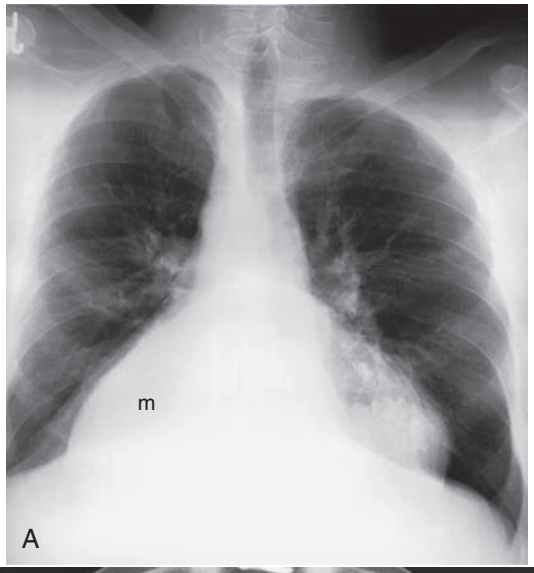

FIGURE 21-33 Posterior mediastinal mass. **A,** Posteroanterior chest film shows a large soft tissue density *(m)* obscuring the right heart border and the right hemidiaphragm. **B,** Computed tomography image at this level shows a large retrocardiac diaphragmatic hernia containing omentum and stomach.

Pneumomediastinum

Pneumomediastinum, a form of barotrauma, may result from movement of air into the mediastinum, as also may be seen in cases of esophageal rupture (Figure 21-34). This condition usually occurs in the distal portion of the esophagus in patients who undergo procedures to stretch or dilate the esophagus. Chest trauma may cause rupture of the trachea or a mainstem bronchus, also allowing movement of air into the mediastinum. Rarely, air dissects down from the soft tissues of the neck after thyroid, parathyroid, or tonsillar surgery. Gas associated with a retrotonsillar abscess may extend inferiorly into the mediastinum through the fascial planes of the neck. Air that accumulates in the retroperitoneum may enter the mediastinum via openings in the diaphragm for the aorta or esophagus.

Catheters, Lines, and Tubes

A common use of a chest radiograph is to evaluate the position of catheters, lines, and tubes after insertion. RTs must be skilled at examining the chest radiograph to determine the position of the endotracheal tube, chest tubes, central and peripheral catheters, and hemodynamic monitoring lines.

FIGURE 21-34 Pneumomediastinum. Posteroanterior view of the chest of an 11-year-old child with asthma shows linear lucencies (free air) in the mediastinum and extending into the soft tissues of the neck bilaterally. Note the free air around the lateral aspect of the right clavicle *(arrow)*.

Endotracheal Tube

Endotracheal tubes are radiopaque or have an opaque marker indicating the end of the tube. Radiographs are routinely obtained at the bedside after intubation to assess correct tube position. The radiograph shows the distal tip of the endotracheal tube and the carina. The position of the patient's neck is important. The neck position usually is neutral, but the position of the tip of the endotracheal tube can vary with neck position. Specifically, the endotracheal tube position can move appropriately 4 cm toward the main carina as the neck moves from full extension (high position) to full neck flexion (low position), which is one-third the length of the average adult trachea. Though there is some variability in the literature, several studies suggest that when the head and neck are in the neutral position, the endotracheal tube should be positioned in the midtrachea approximately 3 to 7 cm above the carina. Although it may be difficult to see on some chest images, the carina is generally located at the space between T-4 and T-5 in most adults.[25] Placement below the thoracic inlet (usually at C5-6 for adults) ensures that the tube is beyond the vocal cords. (usually at C5-6). Figure 21-35 shows a malpositioned endotracheal tube in the right mainstem bronchus.

RULE OF THUMB

The distal tip of the endotracheal tube should be positioned approximately 3 to 7 cm above the level of the carina in an adult patient.

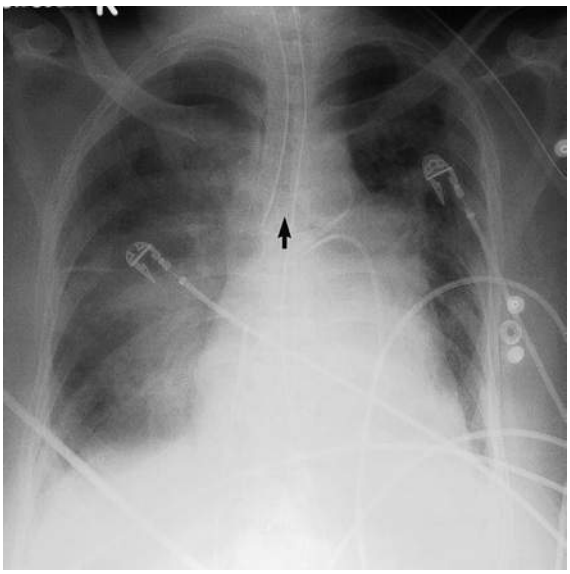

FIGURE 21-35 Portable supine chest film shows malposition of an endotracheal tube in the right main stem bronchus *(arrow)*.

RULE OF THUMB

When the patient flexes his or her neck, the tip of the endotracheal tube moves down (into the lung). When the neck is extended, the endotracheal tube moves up (out of the lung toward the vocal cords). Thus, a well-positioned endotracheal tube is important to prevent migration of the endotracheal tube into a mainstem bronchus (usually the right main stem bronchus) when neck flexion occurs or to prevent accidental extubation when neck extension occurs.

Tracheostomy Tube

Tracheostomy tubes should be two-thirds the diameter of the trachea and should project within the borders of the trachea on the radiograph. The tip should extend beyond half the distance from the stoma to the carina.

Central Line

A central venous catheter is typically placed via either the internal jugular vein or subclavian vein. A chest radiograph should be obtained after placement to assess the position and to exclude a procedural complication (e.g., pneumothorax, hemothorax). Ideally, the tip of the central venous pressure catheter should be in the superior vena cava. This vessel usually forms at the level of the first anterior intercostal space where the brachiocephalic veins come together. The brachiocephalic veins contain valves, and these catheters ideally should be placed central to any valves.

Peripherally Inserted Central Venous Catheter

An alternative to placement of a central venous catheter is a peripherally inserted central venous catheter (PICC), which is placed via a peripheral vein in either the left or right upper extremity. Advantages of a PICC are that it does not have the risk for a pneumothorax as with central venous catheters, it can be used long term (often for several weeks), and it has a lower rate of infection than central venous catheters. The preferred location for a PICC is similar to a central venous catheter, with the tip of the catheter in the superior vena cava.

Pulmonary Artery (Swan-Ganz) Catheter

A Swan-Ganz catheter is used to measure hemodynamic and central pressure variables such as pulmonary artery occlusion pressure (sometimes called the "wedge pressure"). Pulmonary artery catheters are placed at the bedside and ideally should reside in the proximal right or left main pulmonary arteries. They are floated into position using an inflatable balloon on the catheter tip. Because of this floating, they are placed in the right pulmonary artery more than 90% of the time. When measuring the so-called "wedge" or pulmonary artery occlusion pressure, the balloon is inflated, and the catheter moves out into a more peripheral vessel. As soon as the reading is accomplished, the balloon should be deflated, and the catheter should be pulled back to a central location. Persistent peripheral placement (i.e., when the catheter tip is far out in the lung parenchyma) can cause infarction of lung beyond (distal to) the wedged catheter (Figure 21-36) or result in injury to the pulmonary artery such as formation of a pseudoaneurysm or even rupture.

Chest Tube

Chest tubes are small-bore to large-bore tubes placed into the pleural space from outside the chest wall. The most common indications for a chest tube are for a pneumothorax (air in the pleural space) or an empyema (pus in the pleural space), although chest tubes also may be used to drain blood *(hemothorax)* or fluid *(hydrothorax)* or to install a sealant (e.g., the antibiotic doxycycline) to achieve closure of the pleural space, preventing recurrent pneumothorax or hydrothorax. Radiographically, most chest tubes have radiopaque stripes along their axis so they can be seen on the chest radiograph. The chest tube should be within the pleural space; it usually follows the contour of the chest wall or diaphragm on the chest radiograph.

Intraaortic Balloon Pump

The intraaortic balloon pump (IABP) is a counterpulsation device used to improve cardiac output and blood pressure in patients in cardiogenic shock. It is inserted through the femoral artery and advanced into the thoracic aorta. The device is approximately 26 cm long, and a radiopaque tip allows for radiographic verification of position. The balloon inflates during diastole and deflates during systole to enhance perfusion of the coronary arteries and cardiac output. The radiopaque tip should reside just beyond the origin of the left subclavian artery within the proximal descending thoracic aorta. The carina can be used as a landmark with the tip of the IABP approximately 2 cm above the carina.[26] Correct positioning is important as placement too proximal (superiorly) can occlude the branch

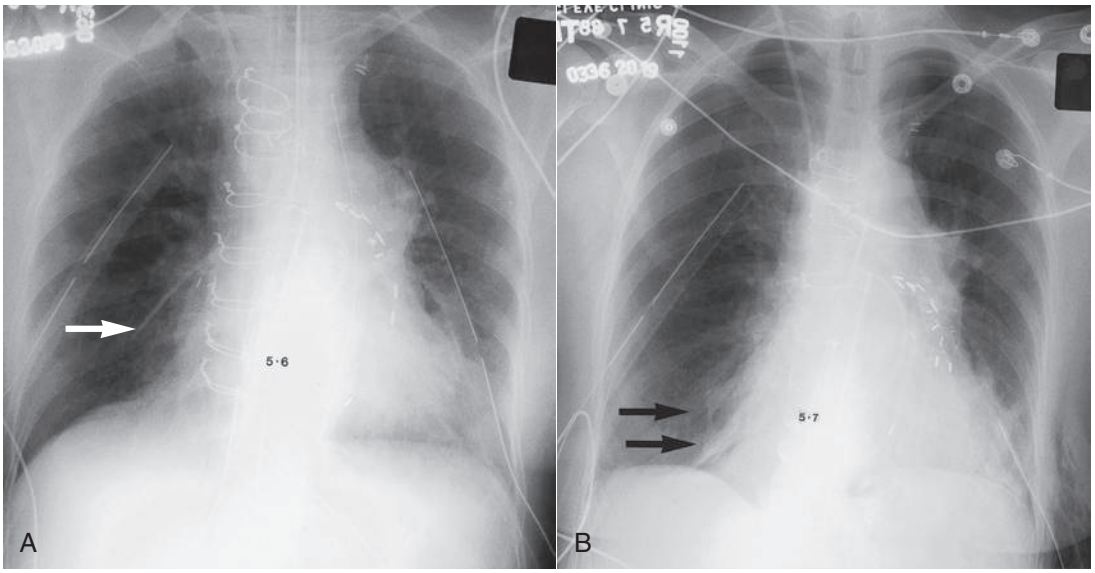

FIGURE 21-36 Two portable supine chest films obtained 30 hours apart. **A,** Wedged Swan-Ganz (pulmonary artery) catheter in the right lower lobe *(arrow)*. **B,** Film obtained after retraction of the catheter shows increased density at the site, reflecting an area of infarction caused by prolonged inadvertent wedging of the catheter *(arrows)*.

aortic vessels to the neck and upper extremities and placement too low (inferiorly) can occlude vessels to the abdominal organs and intestines.

SUMMARY CHECKLIST

- Thoracic imaging is an important tool for evaluating the cause and degree of various pulmonary diseases. Various thoracic imaging techniques are available to assist assessment of patients with lung disease.
- The tissue densities seen on the plain chest radiograph are air, fat, soft tissue (water), and bone.
- The steps in interpreting the chest film include (1) reviewing the technique and quality of the chest film (rotation and penetration) and (2) taking a step-by-step, disciplined approach to reviewing all the anatomic structures seen on the chest film (e.g., bones, soft tissue, heart, lower neck, airways and lungs, pleura, mediastinum, upper abdominal contents).
- The lungs are considered radiolucent and the bones are radiopaque.
- The chest film is useful for detecting pleural diseases such as pleural effusion or pneumothorax.
- Airspace opacities in the lung represent alveolar filling caused by water (pulmonary edema), blood (pulmonary hemorrhage), or pus (pneumonia).
- Air bronchograms are seen when air-filled airways are surrounded by consolidated (infiltrated) lung.
- Radiographic signs of pulmonary edema secondary to heart failure include (1) redistribution of blood flow to the upper lobes, (2) Kerley B lines, and (3) alveolar filling.
- Signs of long-standing heart failure include cardiac enlargement and pleural effusions, which are usually bilateral.
- Signs of volume loss (atelectasis) in the lungs include: (1) unilateral diaphragmatic elevation, (2) mediastinal shift, (3) narrowing of the rib spaces, (4) hilar displacement, and (5) fissure displacement.
- The chest film is useful in identifying the position of catheters and tubes. The tip of the endotracheal tube should be 5 to 7 cm above the carina when the neck is in a neutral position.
- CT has superb anatomic detail compared to chest radiographs but exposes patients to more radiation.
- Ultrasound can be useful in placing central lines, visualizing the presence of pleural fluid (e.g., to help guide thoracentesis), and detecting a pneumothorax.
- MRI is used less commonly for imaging the chest, but has a role in evaluating vascular structures, mediastinal masses, and cardiac structures.

CHAPTER 22

Flexible Bronchoscopy and the Respiratory Therapist

DANAI KHEMASUWAN AND ATUL C. MEHTA

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Understand the preprocedure assessment, type of sedation, and patient monitoring during bronchoscopy.
- Understand the indications, contraindications, and complications of various diagnostic and therapeutic bronchoscopic techniques.
- Recognize the difference between each thermal ablation technique.
- Recognize the difference between silicone and metallic stents.
- Identify the emerging bronchoscopic treatment options for patients with steroid-dependent asthma and for patients with severe emphysema.
- Describe the role of the respiratory therapist in assisting with bronchoscopy.
- Identify special considerations for bronchoscopy during mechanical ventilation.

CHAPTER OUTLINE

KEY TERMS

airway stents
argon plasma coagulation
brachytherapy
bronchial washings
bronchial brushings
bronchoalveolar lavage
cryotherapy
electromagnetic navigational bronchoscopy
endobronchial biopsy
fiberoptic bundles
laser photocoagulation
Mallampati classification
methemoglobinemia
moderate sedation
narrow band imaging
transbronchial biopsy
transbronchial needle aspiration
ultrathin bronchoscopy

Besides thoracentesis, bronchoscopy is one of the most commonly performed procedures in pulmonary medicine. Bronchoscopy allows physicians to access the inside of the airways for both diagnostic and therapeutic purposes. The procedure can be performed using either a rigid or a flexible instrument. This chapter focuses is mainly on flexible bronchoscopy because it is much more commonly performed than the rigid variation.

The first bronchoscopy was performed by a German laryngologist, Gustav Killian, in the early nineteenth century. He

removed a foreign body via the translaryngeal route with direct bronchoscopy[1] using a rigid esophagoscope. In the United States, Chevalier Jackson is considered to be the pioneer of rigid bronchoscopy. He reported the first bronchoscopic resection of an endobronchial tumor in 1917.[2] Over time, the technology has progressed remarkably. In 1966, the flexible bronchoscope (FB) was introduced by Shigeto Ikeda, a Japanese thoracic surgeon. In 1970, Olympus introduced the first FB for commercial purposes. Since then, the technologic advancements have led to a wide array of minimally invasive endoscopic diagnostic and therapeutic techniques that will be discussed in this chapter.

This chapter will focus on the essential elements of the procedure, including the equipment, indications, contraindications, and variations in the procedures and emerging trends. In addition, the role of the respiratory therapist and special considerations when performing bronchoscopy on patients under specific conditions (e.g., during mechanical ventilation) are also described.

FIGURE 22-1 Flexible bronchoscope. *Left, inset:* Anteflexion *(top),* retroflexion *(middle),* and distal tip *(bottom).*

FLEXIBLE BRONCHOSCOPY

The FB uses **fiberoptic bundles** to illuminate the endobronchial tree. Based on the imaging system, FBs are divided into fiberoptic, video, or hybrid. The fiberoptic bronchoscope carries a second fiberoptic bundle that gathers the images from the distal tip of the instrument, which is visualized through the eye piece. The video bronchoscope uses somewhat different technology which employs a miniaturized charge-coupled devices (CCDs) chip at its distal tip to gather the images from the endobronchial tree and transmit them to the image-processing unit. The hybrid instrument uses a fiberoptic imaging system but also has a CCDs chip to convert the information in a digital format. Most modern FBs use video technology, whereas thinner bronchoscopes are hybrid in nature.

The proximal end of the FB is the controlling unit of the instrument, which helps the operator perform desired maneuvers to control the distal tip of the FB (Figure 22-1). The distal tip of FB can be flexed in two directions up to 180 degree in anteflexion and up to 130 degree in retroflexion positions (see Figure 22-1). In addition to these controls, the operator rotates the instrument on its axis using the wrist. More recently, Olympus also added a feature that allows axial rotation of the instrument without relying on wrist movement (Figure 22-2).

Today, flexible bronchoscopy has become a standard procedure because of its diagnostic value, safety, and ease of performance. The procedure can be done in an outpatient setting, under local anesthesia and moderate (or conscious) sedation. The indications for FB have grown over the past years (Box 22-1) and are extensive. Box 22-2 presents the contraindications to performing FB. There are a few absolute contraindications for FB, which include severe hypoxemia, hemodynamics instability, acute bronchospasm, and the inability to obtain informed consent for the procedure.

The discussion as to whether the bronchoscopy is indicated involves the physician and often other members of the bronchoscopy team, including the respiratory therapist. However, in the end, the final decision whether to perform the procedure must be individualized in a conversation between the physician and the patient, based on an open discussion about the risks and benefits of the procedure.

FIGURE 22-2 New Olympus scope with rotating function. (From Olympus. http://www.olympusaustralia.com.au/Document/Detail/328/Advancing-Control-Respiratory.)

Procedure, Sedation, and Monitoring

FB can be performed on spontaneously breathing patients via the oral or the nasal route and occasionally through a tracheostomy stoma. FB can also be done on patient with artificial airways such as endotracheal or tracheostomy tubes. Most procedures are performed under moderate or deep sedation. When deep sedation is used, the procedure is performed via either a laryngeal mask airway or an endotracheal tube of the appropriate size. Rigid bronchoscopy is performed under deep sedation with muscle relaxation.

The goal of sedation is to improve the patient's comfort during the procedure. In addition to risks for arrhythmias and fluctuations in blood pressure related to the procedure, airway manipulation during bronchoscopy may lead to coughing, hypoxemia, vomiting, bleeding, laryngospasm, and bronchospasm. All of these responses can affect the outcomes of the

Box 22-1 Indications for Flexible Bronchoscopy

- Hemoptysis
- Wheeze and stridor; suspected upper airway obstruction
- Pulmonary infiltrate of unknown cause
  - Infiltrates not responding to conventional treatment
  - Infiltrates in an immunocompromised host
  - Recurrent or unresolved pneumonia
  - Cavitary lesions
  - Interstitial infiltrates
  - New pulmonary nodule
- Unexplained lung collapse
- Suspected or known bronchogenic carcinoma
  - Staging
  - Follow-up after endobronchial treatments
- Mediastinal and hilar lymphadenopathy
- Lung transplantation
  - Evaluate airway anastomosis
  - Rejection surveillance
  - Cultures
- Endotracheal intubation
  - Confirm endotracheal tube position
  - Evaluate tube-related injury
- Evaluation of foreign body aspiration, chemical-related, or burn-related injury to the airway
