- Unexplained superior vena cava syndrome
- Unexplained vocal cord paralysis or hoarseness
- Suspected fistulas (e.g., bronchopleural, tracheoesophageal and bronchoesophageal, trachea or bronchoaortic)

Box 22-2 Contraindications to Flexible Bronchoscopy

CONTRAINDICATIONS

Absolute

- Uncorrectable hypoxemia
- Lack of patient cooperation
- Lack of skilled personnel
- Lack of appropriate equipment and facilities
- Unstable angina
- Uncontrolled arrhythmias

Relative

- Unexplained or severe hypercarbia
- Uncontrolled asthma attack
- Lack of patient cooperation
- Uncorrected coagulopathy
- Recent myocardial infarction
- Unstable cervical spine and impaired neck mobility
- Need for large tissue specimen

procedure. Therefore adequate sedation is an important part of the procedure.

There is a wide range in the level of sedation that can be provided, including light sedation (anxiolysis), **moderate (conscious) sedation**, and deep sedation with general anesthesia. Moderate sedation is most commonly used during FB. At this level of sedation, patients can respond to verbal stimuli and demonstrate preserved protective airway reflexes. Several intravenous forms of benzodiazepines and opioids are commonly used during FB. Diazepam, midazolam, lorazepam, morphine sulfate, and fentanyl have been used either as a single agent or in combination based on the availability and physician preference.[3] The combination of a benzodiazepine (like midazolam) and an opioid (like morphine sulfate or fentanyl) has been shown to be safe and effective for sedation during FB.[4]

Several techniques are used to apply local anesthetic agents to the upper and the lower airway. Using approximately 10 mL of 2% viscous lidocaine, "swish and swallow" is a simple and effective method to numb the upper airways. Another common method involves nebulizing 5 mL of 4% lidocaine. The nasal passage is usually anesthetized using 5 mL of 2% lidocaine jelly. In addition, 1% to 2% of lidocaine is instilled directly in to the lower airways through the working channel of the instrument in 2-mL aliquots during the procedure. The drug lidocaine has a very narrow therapeutic range. To help avoid unwanted hazards such as **methemoglobinemia**, the total dose of lidocaine should be limited to 5 to 7 mg/kg in adults (maximum of 400 to 500 mg in a 150-lb adult), during the procedure, with added caution in the elderly and in those with liver or cardiac disease.[5]

MINI CLINIC

Methemoglobinemia During Bronchoscopy

PROBLEM: A respiratory therapist (RT) is assisting during a flexible bronchoscopy. The patient had local anesthesia with lidocaine nebulization and benzocaine spray. The patient developed central cyanosis and his oxygen saturation dropped to 85% via pulse oximetry. The procedure was aborted. An arterial blood gas check showed pH, 7.43; PCO_2, 43; and PO_2, 279; with an O_2 saturation of 85%. What condition should an RT consider in this situation?

DISCUSSION: Methemoglobinemia should be suspected. Benzocaine is a common cause of methemoglobinemia during endoscopic procedures. Benzocaine, which is used as a local anesthetic, is a common source of methemoglobinemia during such procedures. Benzocaine causes oxidization of the iron in hemoglobin (Hb) from the ferrous (Fe^{2+}) to the ferric state (Fe^{3+}). Fe^{3+} Hb is unable to carry O_2. The PO_2 is within normal range as shown by the machine measurement of dissolved O_2 in the blood, not in the Hb. Therefore methemoglobinemia causes hypoxemia at the cellular level that is not detected by measuring PO_2 but can be uncovered by co-oximetry to measure methemoglobin directly. In terms of management, a methemoglobin level less than 30% usually resolves spontaneously over 15 to 20 hours after removal of the offending agent and with O_2 administration. Intravenous administration of methylene blue is the management of choice in patients when the methemoglobin levels exceed 30%.

RULE OF THUMB

For patient safety, to help avoid methemoglobinemia, the total dose of lidocaine should not exceed 7 mg/kg of body weight during a routine (<45 min) FB procedure.

The assessment of the upper airway before the procedure helps identify those patients in whom it may be difficult to secure an airway in case of hypoventilation. The **Mallampati classification** is one of the most commonly used methods to identify individuals who may pose difficulty during intubation. The Mallampati score is assessed by having the patient open his or her mount and protrude the tongue as much as possible without phonation (Figure 22-3).

RULE OF THUMB

The Mallampati score should be assessed in every spontaneously breathing patient before flexible bronchoscopy.

Several maneuvers (e.g., chin-lift, jaw-thrust) may become necessary if the patient becomes oversedated during FB. In addition to an unfavorable Mallampati score, comorbidities can also affect the safety and outcome of the procedure. The recommendation from the American Society of Anesthesiologists (ASA) is to categorize patients based on their ASA score, which considers comorbid conditions and their impact on the patient's daily living (Table 22-1).[6]

During the FB procedure, continuous monitoring of oxygenation and hemodynamic stability are important. Pulse oximetry, heart rate, and blood pressure are monitored throughout the procedure. One of the most difficult parameters to monitor during FB is the depth of sedation. Intermittent boluses of sedation may be needed to ensure the adequate depth of sedation during the procedure. However, the depth of sedation must be balanced with the side effects of oversedation during and after the procedure. To monitor the patient, the respiratory therapist or other member of the bronchoscopy team should keep track of the patient's responses to verbal commands or spontaneous movements. Notably, chest movement may continue despite near total obstruction of the airway. To prevent the patient's slipping into deep sedation, the ASA also recommends capnography monitoring while performing FB under moderate sedation.[7]

RULE OF THUMB

Continuous cardiac, blood pressure, and oximetry monitoring must be carried out during bronchoscopy. Capnography is highly recommended.

DIAGNOSTIC BRONCHOSCOPY

A computed tomography (CT) scan of the chest is performed before all elective bronchoscopic procedures being performed for lung cancer diagnosis. The information is very valuable in increasing the diagnostic yield of the procedure among patients suspected to have lung cancer. The scan also may eliminate the need for preforming the procedure in 7% of patients.[8]

Diagnostic bronchoscopy begins with the examination of the upper airways. Proper upper airway examination is crucial to identify lesions involving nasal passages, pharyngeal, and laryngeal structures, including vocal cords. After examination of the

TABLE 22-1

American Society of Anesthesiologists Classification: Comorbid Conditions and Impact on Daily Living

ASA Class	Class Definition
I	A normally healthy patient
II	A patient with mild systemic disease
III	A patient with systemic disease that is not incapacitating
IV	A patient with an incapacitating systemic disease that is a constant threat to life
V	A moribund patient who is not expected to survive for 24 hr with or without operation

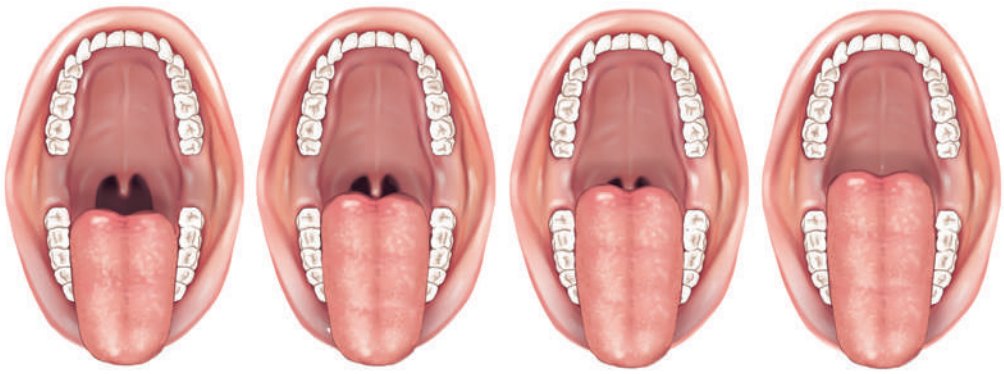

FIGURE 22-3 Mallampati classification.

upper airway structures, the lower airways are examined at least until the fifth- or sixth-generation bronchi. Examining bronchi deeper than this depends on the diameter of the bronchoscope. For diagnostic purposes, besides examining the airways, several different types of specimens can be collected through the working channel of the bronchoscope.

RULE OF THUMB

A CT scan of the chest is generally performed before all elective bronchoscopic procedures done for patients with, or suspected of having, lung cancer.

Bronchoalveolar Lavage

Bronchoalveolar lavage is used to obtain specimens from the alveolar level of the lung. BAL is performed by instilling a small volume (up to 50 mL) of normal saline solution deep into the airways and then suctioning the instilled liquid back. BAL fluid contains both cellular and noncellular components of alveolar lining fluid (Figure 22-4). As a form of "liquid lung" sample, the BAL fluid is thought to represent millions of alveoli as well as respiratory epithelial lining and colonizing organisms. BAL has become a standard diagnostic procedure in patients with pulmonary infiltrates of uncertain cause (Box 22-3). As cellular content, a normal BAL sample includes 95% macrophages; 3% lymphocytes; 1% to 2% neutrophils, eosinophils and basophils; and few epithelial cells. In addition to routine culture and cell count, an estimation of the CD4/CD8 ratio of lymphocytes in the lavage fluid can be helpful in establishing the diagnosis of sarcoidosis and hypersensitivity pneumonitis.

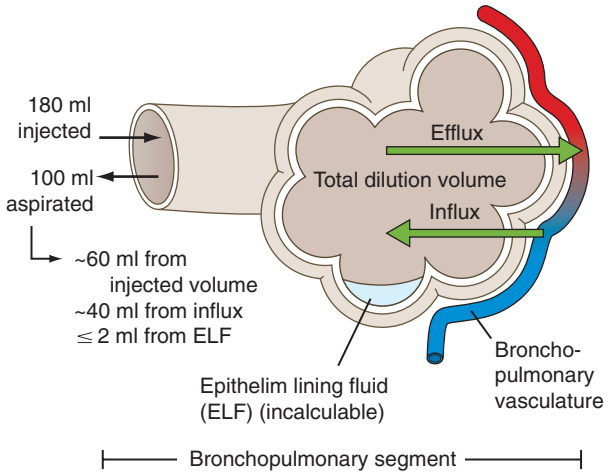

FIGURE 22-4 Schematic presentation of the constituents of the bronchoalveolar lavage.

Box 22-3 Role of Bronchoalveolar Lavage in Diagnosis for Pulmonary Diseases

- Infection (e.g., bacteria, fungus, virus, and mycobacteria)
- Pulmonary hemorrhage
- Malignancy (e.g. solid tumor, lymphoma)
- Eosinophilic lung disease
- Pulmonary alveolar proteinosis
- Langerhans cell histiocytosis
- Lipoid pneumonia
- Diffuse alveolar hemorrhage

Bronchoalveolar Lavage Technique

It is important to avoid suction while inserting the FB through the nasopharynx and central airways, to minimize contamination of the working channel of the bronchoscope with the local organisms.[9–11] The amount of lidocaine used should be minimized both to prevent its bacteriostatic properties from interfering with BAL fluid cultures used to identify infectious organisms and to avoid altering the cellular contents of the lavage fluid. The right middle lobe or the lingua is generally used to perform BAL in patients with diffuse diseases. With the patient in a supine position, gravity helps to augment BAL return from these locations.[9,10] Meanwhile, in localized lung diseases, lavage is performed from the area of the focal abnormality.[10]

To obtain the lavage fluid, the bronchoscope is wedged at the level of fourth- or fifth-generation bronchus. A "good wedge" position means that the bronchoscope is advanced as far as possible while the distal lumen is still visible. In this position, BAL return is maximal. Fluid (20 to 60 mL) is instilled into the appropriate bronchial segment and aspirated back manually for laboratory testing. In general, 15 to 20 mL of BAL volume is enough to conduct common laboratory tests such as microbiologic and cytologic tests.[11]

Several complications are associated with BAL. Hypoxemia is common, and its severity generally depends upon three factors: the volume of fluid administered,[12] the number of segments lavage, and the duration of the procedure. Introduction of 100 mL of lavage fluid can cause O_2 desaturation up to 7%, whereas 200 mL of lavage fluid can drop O_2 saturation up to 15% from the baseline value.[12] O_2 supplementation during BAL may mitigate the degree of O_2 desaturation. However, the volume of lavage fluid and the duration of the procedure are important factors to determine the risk of this complication. Cases of pneumothorax from BAL have also been reported in patients with *Pneumocystis jirovici* pneumonia and during therapeutic BAL for pulmonary alveolar proteinosis (PAP).[13,14]

RULE OF THUMB

BAL should be obtained from the nondependent part of the lung to optimize the fluid return.

RULE OF THUMB

Supplemental O_2 should be administered in all patients undergoing bronchoscopy, to help avoid or minimize hypoxemia.

Mini-BAL is defined as nonbronchoscopic BAL. Mini-BAL is most frequently performed in intubated patients when a catheter is passed through an endotracheal tube into the bronchi until the catheter lodges, after which saline is instilled for the lavage and then withdrawn. The volume of saline instillation is usually 25 mL or less. The return of fluid by aspiration is highly variable. Mini-BAL is a simple procedure for acquiring quantitative lower airway cultures in mechanically ventilated patients.[15] In some settings, RTs perform the procedure. As an example of the impact of mini-BAL, approximately, 46% of mini-BAL cultures are found to contain at least one organism potentially contributing to a suspected episode of ventilator-assisted pneumonia.[16]

Bronchial Washings

Bronchial washings are generally obtained for the cytologic examination for cancer and for microbiologic analysis to diagnose mycobacterial or fungal infections. Unlike BAL, bronchial washings are obtained from the large airways. Bronchial washing is easy to perform, but is not very effective in diagnosing malignancy, successfully diagnosing only 22% to 29% of peripheral lesions[17,18] and is slightly higher for central lesions.[19,20] Bronchial washings are an inexpensive by-product of the bronchoscopy and are routinely obtained in patients suspected to have airway malignancy.[21]

Bronchial Brushings

Bronchial brushings have been used as an adjunct diagnostic test in addition to endobronchial and transbronchial biopsies and transbronchial needle aspiration (TBNA). It involves brushing the surface of the suspicious lesion back and forth 5 to 10 times while rotating the handle. Brushes of various different diameters and bristle strengths are available in the market. Brushing is usually performed under direct visualization or with fluoroscopic guidance to avoid trauma to the bronchial mucosa and pneumothorax, respectively. Brushing establishes a diagnosis in 72% (range 44% to 94%) of patients with central lung cancers and in 45% of patients with peripheral lesions.[22] Bronchial brushing is usually performed after obtaining all the other specimens to avoid bleeding or cellular degradation that may affect the overall interpretation of FB specimens. Once the specimen is collected, the cells are smeared onto a slide and the end of the brush is cut off and placed in a fixative solution for cytologic examination.[23]

Endobronchial Biopsy

Endobronchial biopsy (EBBx) is a technique whereby flexible forceps are used to obtain a tissue sample from a visible endobronchial lesion. It provides specimens for histologic examination. EBBx has been shown to successfully diagnose between 51% and 97% of neoplasms.[24,25] The number of biopsy specimens that should be obtained depends on the diagnosis suspected. In patients suspected to have bronchogenic carcinoma, three biopsy specimens are often able to successfully diagnose almost all such cases.[26] If the specimen is obtained from the surrounding necrotic tissue, the EBBx can fail to contain cancerous cells despite the patient having a malignancy. In such cases, debridement of the necrotic tissue with the forceps or performing a TBNA may improve diagnostic value. Endobronchial biopsy of a highly vascularized lesion may lead to significant bleeding and must be undertaken with caution. The physician may take precautions such as instilling ice cold saline or using the TBNA approach.

Transbronchial Biopsy

Transbronchial biopsy is a technique of obtaining a specimen of the lung parenchyma by using flexible forceps positioned distally through the working channel of the bronchoscope. A fenestrated alligator forceps is most commonly used to obtain the TBBx. Six to ten tissue specimens are obtained, depending on the suspected diagnosis. TBBx can be performed with or without fluoroscopic guidance (Figure 22-5). The latter is a common practice while performing the TBBx in the intensive care unit setting.

The diagnostic value of TBBx varies depending on the underlying lung diseases and the patient population. For infectious diseases, the 88% to 97% of cases of *P. jiroveci* pneumonia[27] and 57% to 79% of cases of *Mycobacterium tuberculosis* have been successfully diagnosed.[28] In lung transplant surveillance, the TBBx can detect a presence of allograft rejection in approximately 70% of the cases.[29] In interstitial lung diseases, the diagnostic value is relatively low compared with the experience in infectious diseases. TBBx can successfully diagnose 40% to 90% of sarcoidosis cases[30] and only 10% to 40% of those with Langerhans cell histiocytosis.[31] In a peripheral pulmonary nodule (PPN), the diagnostic value of TBBx depends upon the size and the location of the nodule. The presence of an airway leading to the nodule as seen on the Computed Tomography scan of the chest is called a "positive bronchus sign" and when combined with TBBx increases successful diagnosis from 31% to 79% for the PPN.[32]

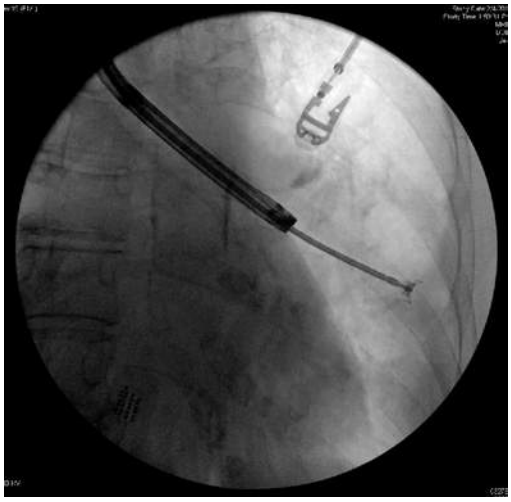

FIGURE 22-5 Transbronchial biopsy under direct visualization with fluoroscopy.

TABLE 22-2

Antithrombotic Therapies and Recommended Interval Between Last Dose and Procedure [Baron]

Agents	Interval from Last Dose Before Procedure
Warfarin	3-5 days; or goal international normalized ratio <1.5
Unfractionated heparin	Intravenous 2-6 hr
Low molecular weight heparin	24 hr; depending on creatinine clearance
Dabigatran	1-2 days with creatinine clearance >50 ml/min 3-5 days with creatinine clearance <50 ml/min
Rivaroxaban	1 day with normal renal function 2-4 days with impaired renal function
Desirudin	2 hr
Clopidogrel, ticlopidine, prasugrel, ticagrelor	5 days
Aspirin and dipyridamole	7-10 days

Data from Baron TH, Kamath PS, McBane RD: Antithrombotic therapy and invasive procedures. N Engl J Med 369:1079–1080, 2013.

The two major complications of TBBx are pneumothorax and bleeding. Adequate sedation and cough suppression are important to reduce the risk for pneumothorax arising from cough-induced barotrauma. Whenever available, fluoroscopy should be used to guide the TBBx, especially in patients with localized lesions. Fluoroscopy is also used to screen for pneumothorax after the TBBx.[33] The risk for developing pneumothorax is three times higher in mechanically ventilated patients compared to that among spontaneously breathing patients.[34,35] To reduce the risk for pneumothorax among the former group, the positive end-expiratory pressure (PEEP) level should be maintained below 5 cm H_2O. Also, the capability of promptly placing a chest tube should be available.

Meanwhile, the incidence of bleeding from TBBx is low (2% to 9%) in the absence of a bleeding tendency or coagulopathies. Risk factors for bleeding after TBBx include renal insufficiency with blood urea nitrogen less than 30 mg/dL and creatinine greater than 3 mg/dL, pulmonary hypertension with a mean pulmonary pressure of greater than 40 mm Hg, thrombocytopenia with platelets less than 50,000/mL and international normalized ratio (INR) greater than 1.5 are considered risk factors for bleeding after TBBx.[36]

TBBx can be safely performed in patients who are receiving aspirin or nonsteroidal inflammatory drugs. However, several antithrombotic and antiplatelet therapies should be withheld for a specific period before TBBx (Table 22-2).[37] In an event of bleeding, wedging the bronchoscope in the involved subsegment helps tamponade, or compress, the bleeding site. Alternatively, 5 to 10 mL of ice cold saline (−4° C) or 2 to 4 mL of either epinephrine or norepinephrine (1:10,000) solution can be instilled through the working channel of the bronchoscope to lessen the bleeding.

MINI CLINIC

Sudden Chest Pain and Clinical Deterioration During Bronchoscopy

PROBLEM: An RT is assisting during a FB on a young female with suspected sarcoidosis. The patient is very anxious and despite an adequate amount of narcotics and anxiolytic agents, continues to cough violently. The physician is performing TBBx under the fluoroscopic guidance from the left lower lobe. In seven attempts, he manages to obtain three pieces of tissue before giving up the procedure. During the last attempt, the patient winced with mild pain. Soon after the last biopsy the patient became tachypnic (respiration rate [RR] 30 breaths/min), with heart rate of 110 beats/min, and SpO_2 dropped to 82% on O_2 6 L/min via nasal cannula. Examination of the chest showed that it was tympanic on percussion with reduced breath sounds on auscultation. What condition should the RT consider in this situation?

DISCUSSION: The RT should consider pneumothorax in this situation and should also consider ruling out a tension pneumothorax. Pneumothorax is a potential complication following a TBBx.[38] The risk is further increased in the situation in which the patient cannot cooperate for the procedure and continues to cough during the biopsy procedure. In this case, fluoroscopic examination can help confirm or rule out the condition. Meanwhile the patient should receive an adequate amount of supplemental O_2, if required via a nonrebreather mask. The RT should be prepared to assist the pulmonologist place either a Heimlich valve or a chest tube, depending on the size of the pneumothorax and the symptoms of the patient. If a tension pneumothorax is suspected, any size needle can be inserted into the pleural space and the air would be expected to rush out as the pressure is relieved.

Transbronchial Needle Aspiration: Conventional and Ultrasound-Guided Procedures

Transbronchial needle aspiration (TBNA) is the technique that allows sampling tissue from the mediastinum or the peripheral lung by inserting needles through the bronchial wall. TBNA can be used to determine the cause of mediastinal lesions and PPNs in a minimally invasive fashion.[39,40]

With the advent of endobronchial ultrasound (EBUS), the accuracy of TBNA has improved dramatically. EBUS is essentially a bronchoscope with a linear ultrasound probe attached at its distal end. EBUS provides real-time ultrasonographic guidance for TBNA of target structures (Figures 22-6 and 22-7). It has recently been found that in patients with potentially operable lung cancer, the diagnostic accuracy of EBUS-TBNA is far superior (98% diagnostic accuracy) to either positron-emission tomography or CT scans of the chest.[41,42] Recently the use of EBUS-TBNA has greatly expanded in the diagnosis and staging of non–small cell lung cancer because of the minimally invasive nature of EBUS-TBNA. Notably, subcarinal lymph

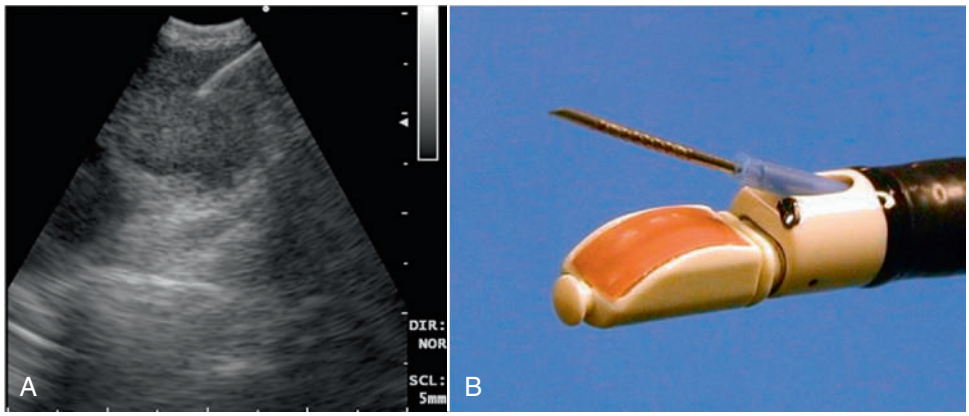

FIGURE 22-6 **A,** The distal tip of the endobronchial ultrasound endoscope with an aspiration needle. **B,** Sonographic image of EBUS-TBNA demonstrating needle inside lymph node. FIGURE 22-8 Electromagnetic navigation monitor. Location of the pulmonary lesion is displayed in three different axis of computed tomography imaging.

nodes can be assessed more accurately with EBUS-TBNA than with conventional mediastinoscopy. Reported complications of EBUS-TBNA include pneumomediastinum, pneumothorax, mediastinitis, bacteremia, and, rarely, death.[43–46]

In the current era, in which genetic profiling of lung cancer is essential to identify biomarkers that significantly influence treatment decisions and responses, EBUS-TBNA can provide adequate tissue for genetic analysis.[47] The utility of EBUS-TBNA also has been investigated for restaging of lung cancer after chemotherapy, and evidence supports it use for this purpose. [48]

Electromagnetic Navigational Bronchoscopy

Recently, an advanced CT imaging technology has been innovatively combined with an electromagnetic navigation system to guide the biopsy of PPNs that lie beyond the reach of standard flexible bronchoscopy. **Electromagnetic navigational bronchoscopy** (ENB), peripheral EBUS, virtual bronchoscopy, ultrathin bronchoscopy, and their combination have significantly increased the diagnostic value of FB for peripheral lesions, with an acceptably low complication rate of bleeding and pneumothorax.[49]

The ENB system uses low-frequency electromagnetic waves transmitted from a magnetic board placed below the patient's chest. As a result, the lesion can be visualized in real time with computer-generated guidance in three dimensions.

ENB is performed in several steps. The first step is planning the procedure by uploading high-quality CT images into the planning software. The software will generate the plan markers from the main carina to the lesion via multiple bronchial subsegments. The next step is aligning the virtual images to the patient's endobronchial anatomy, which is called the *registration* phase. Then, the navigation is conducted by driving the locatable guide probe with its extended working channel (EWC) to the lesion, by following the three dimensional CT images and the "tip view" (Figure 22-8). Once the lesion is reached, the guide probe is removed, leaving the EWC in place. The position

of the tip of the EWC may be confirmed by using the radial EBUS probe to determine the location of the lesion (Figure 22-9). Various diagnostic tools such as a needle, brush, or forceps for biopsy can be used through the EWC to obtain a tissue specimen. In terms of diagnostic value, ENB can successfully diagnose almost 75% of peripheral lesions, but pneumothorax occurs in approximately 3.5% of such cases. The combination of radial probe EBUS with ENB can further increase the diagnostic value.[50]

Ultrathin Bronchoscopy

The normal tracheobronchial tree divides approximately 24 times before it reaches the respiratory bronchioles. The external diameter of the adult FB is approximately 5.7 to 6 mm, which allows the physician to reach the fourth- or fifth-order bronchi. The ultrathin bronchoscope is approximately 2.8 mm in external diameter and can reach up to at least the eighth-order bronchi (Figure 22-10). **Ultrathin bronchoscopy** can be helpful in diagnosing PPNs and can be used to inspect peripheral airways or to examine the airway beyond a pathologic airway narrowing.

The major technical challenge of performing ultrathin bronchoscopy is maintaining proper anatomic orientation in the peripheral airways. The instrument is seldom used without a real-time CT guidance, virtual bronchoscopy,[51] or a specially designed peripheral EBUS system. Another drawback of the ultrathin bronchoscope is its narrow working channel (1.7 mm) and miniaturized accessories (1 to 1.2 mm). These limit its diagnostic value because the specimens that can be obtained are very small.

FIGURE 22-10 Comparison of the diameter of the tip of the ultrathin bronchoscope (2.8 mm) *(right)* with that of a standard-size bronchoscope *(left).*

Narrow Band Imaging

Narrow band imaging is a technique that uses specialized filters to separate wavelengths of white light and selectively emits red, green, and blue bands. The intensification of the blue band detects vessel growth and complex vessel networks in the bronchial mucosa and therefore may be useful to detect early malignant lesions (Figure 22-11). The system involves two narrow band filters, one to detect 415-nm light that is absorbed by the surface level capillaries and a second to detect 540-nm light that is absorbed below the surface layer. This permits visualizing abnormal distribution and dilatation of blood vessels in the mucosa, which can be an early sign of malignancy.[52]

THERAPEUTIC BRONCHOSCOPY

In the past decades, FB has been widely used for therapeutic purposes. Although the role of rigid bronchoscopy (RB) has declined, RB remains an invaluable tool for the control of a compromised airway, massive hemoptysis, and silicone stent placement and for removing asphyxiating foreign bodies (Box 22-4). The major indication for RB is in managing central

Box 22-4 Indications for Rigid Bronchoscopy

- Large foreign body extraction
- Large volume tissue biopsies
- Management of massive hemoptysis
- Silicone or self-expandable stent placement
- Mechanical coring of lesion using beveled tip and sequential mechanical dilation
- Using of adjunct therapies in management of endobronchial obstruction
  - Laser: Nd:YAG, KTP, CO_2
  - Argon plasma coagulation (APC)
  - Electrocautery
  - Cryotherapy
  - Balloon dilation
  - Microdebrider

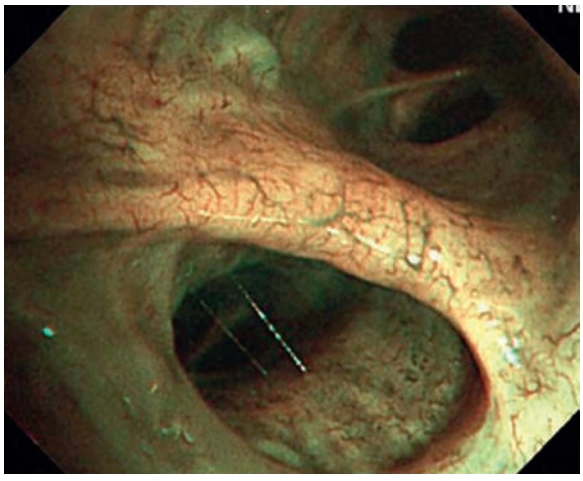

FIGURE 22-11 Narrow band imaging.

airway obstruction. Approximately 30% of patients with lung cancer may present with airway obstruction and its complications, such as hemoptysis, post-obstructive pneumonia, and asphyxia.[53] Reducing the size of a tumor or establishing airway patency with or without stent placement can produce rapid relief of symptoms, improved quality of life, and increased survival.[54] There are very few contraindications to RB. These include the inability to hyperextend the neck and an unstable facial fracture.

Some of the common bronchoscopic therapeutic procedures that are performed through the FB are discussed in the following section.

Thermal Ablation of the Endobronchial Lesion

Newer modalities such as endobronchial electrocautery, **argon plasma coagulation** (APC) or **laser photocoagulation** can be used to coagulate, carbonize, or vaporize lesions that protrude into the airway lumen and obstruct the central airways. These modalities increase the temperature of the tissue by molecular agitation and can be applied either through a flexible or an RB. By applying the appropriate power density, the desired tissue reaction can be achieved.

Application of electrocautery requires use of accessories such as knives, snares, or probes. Argon plasma coagulation is a noncontact technique to apply electric current to the endobronchial lesion. The modalities involved application of an electrically charged argon gas via a special disposable catheter.[55] Presence of a pacemaker or a defibrillator is a relative contraindication for using electrical modalities.[56]

Lasers can produce tissue reaction by thermal, photochemical, or electromagnetic effects. As stated earlier, it is the thermal effect of the laser is mainly use to remove the endobronchial lesion. Most commonly used lasers for this purpose are neodymium:yttrium-aluminum-garnet (Nd-YAG) and neodymium:yttrium-aluminum-perovskite (Ng-YAP) lasers. Lasers produce more précised tissue reaction than the electrosurgery units.[57,58]

The thermal ablation of the endobronchial lesion in properly selected patients produces some relief in close to 90% of patients. Improper use of the thermal modalities can lead to perforation of the airway, vascular structures, or esophagus. In addition, hypoxemia, pneumothorax, bronchopleural and bronchoesophageal fistulas are other reported complications.[57] In the presence of high FiO_2, endobronchial ignition has been reported as a rare complication of such therapies. Refractory hypoxemia (i.e., an O_2 requirement of $FiO_2 > 40\%$) and extrinsic compression of the airway without an endobronchial lesion are contraindications to thermal ablation.

RULE OF THUMB

During the application of "hot therapies" (thermal ablation) such as laser, electrosurgery, or argon plasma coagulation, the FiO_2 always should be maintained below 40% to prevent endobronchial ignition.

Cryotherapy

Cryotherapy is a method of destroying tissue by freezing it. Cryotherapy leads to extracellular ice crystal formation and extraction of intracellular water. In addition, extreme cold induces vasoconstriction, and endothelial injury leading to microthrombus formation and eventually tissue necrosis. The cryoprobe can be used through either a flexible bronchoscope or RB. The cryogen (the agent that causes the freezing) is released from very-high-pressure storage to atmospheric pressure. The sudden drop in the pressure leads to expansion of the cryogen and a drop in its temperature. This effect is also called the *Joule-Thompson effect*. The cryoprobe is placed in contact with the target and the cryogen is released, producing a tissue temperature of −80° C. The temperature increases approximately 10° C per millimeter from the tip. Thus the effective zone is approximately 5 to 8 mm. Multiple cycles of rapid freezing and gradual thawing are applied to cover the entire treatment area. The effects of cryotherapy depend on the sensitivity of the tissue. The cryoresistant structures are fat, cartilage, nerve sheath, and connective tissue, whereas, neoplasms, granulation tissue, skin, mucous membranes, nerves, and endothelium are cryosensitive. The inherent sensitivity of the tissue mainly depends on its water content. Therefore selection of a cryosensitive tumor is essential for a successful outcome with this technique.[59,62]

Cryotherapy has been used as a therapeutic tool for the patients with central airway obstruction. Cyotherapy is ideal for treating stent-related granulation tissue when the stent is made of an inflammable material. It can be used to remove organic foreign bodies, blood clots, and mucus plugs by cryoadhesion; ice crystal formation between the probe and the object that holds them together. In addition, cryotherapy can be used in a high-O_2 requirement. Recently, there is a growing interest in its use for obtaining larger pieces of lung tissue compared to conventional TBBx and EBBx (cryobiopsy) approaches. Further trials are required to prove the safety of this method.

Brachytherapy

The term **brachytherapy** describes a method to deliver short distance radiation therapy. Brachytherapy involves temporary placement of encapsulated radioactive sources within or near the tumor via a bronchoscope. It is used as both an adjuvant to external-beam radiation and a palliative radiation option for lung cancer located near the airways. It also can be used in the management of superficial endobronchial squamous cell carcinoma. In brachytherapy, a catheter is placed adjacent to the lesion and the location is confirmed by fluoroscopy. The catheter is then loaded with the radioactive source, usually radium or iridium, reaching a total dose of 500 to 4000 Gray over a precise duration.[60,61]

The main advantage of brachytherapy is that a higher dose of radiation can be delivered to the tumor cells while minimizing radiation to the normal tissue, thereby reducing complications. Brachytherapy is indicated in patients with inoperable lung cancer or cancer metastatic to the airways.

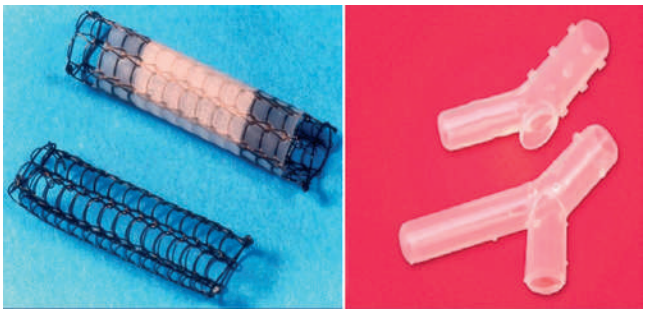

FIGURE 22-12 Self-expanding metallic stents *(left)* and silicone stents *(right)*.

Endobronchial Stents

Stents are the devices designed for internal splinting of the airway lumen. **Airway stents** have been used to help reduce airway obstruction from malignant or benign processes that compress the airway from the outside. Airway stenting can offer immediate relief of acute respiratory distress, can allow successful extubation, and may prolong survival.[62,63] There are two major types of airway stents, metallic and silicone. Self-expanding metallic stents (SEMS) are commercially available in covered and uncovered forms (Figure 22-12). Covered stents are designed primarily to prevent the growth of granulation tissue into the lumen of the stent. Current SEMS are made from nitinol; a nickel-titanium alloy that is well adapted for endobronchial applications. At room temperature, nitinol is extremely elastic. It can tolerate the extreme folding that is required when using a small deployment system but still return to its original shape without compromising its resistance to compression. The advantages of SEMS are ease of deployment, small internal-to-external diameter ratio, better conformity to complex airway shapes, and ventilation across a lobar bronchial orifice (Table 22-3). The indications for SEMS placement include (1) extrinsic compression of central airways; (2) stabilizing airway patency after endoscopic removal of an intrinsic tumor; (3) sealing fistula between the lung and the gastrointestinal tract; and (4) managing of post–lung transplant anastomotic complications. SEMS is rarely used in benign central airway obstruction because there is high-risk for stent-related granulation tissue formation. In 2005 the U.S. Food and Drug Administration issued a medical device safety warning against using self-expanding metallic stents for benign airway obstruction unless all other therapeutic options have been explored.[64]

Silicone stents have two major designs, straight and Y-shape (for disease involving the carina). The stents are either made of transparent silicone (radiolucent) or silicone blended with barium sulfate (to make the stent radiopaque). The silicone stent is usually placed through an RB. The advantages of silicone stents include easy customization, ease of repositioning/removal, minimal granulation tissue overgrowth, and lower cost than metallic stents. The indications for placing a silicone stent are similar to SEMS and include internal splinting for external compression/intraluminal growing cancer, benign strictures, collapsing airways, and tracheoesophageal fistulas. In terms of complications, mucous impaction (3.6%), bacterial colonization, migration (9.5%), and formation of granuloma (7.9%) are most common. After stent placement, the patient should be given a stent alert card with details regarding the type, length/diameter, and location of the stent.

TABLE 22-3
Comparison of Silicone and Metallic Stent Properties

Comparison Factors	Metallic Stents	Silicone Stents
General Considerations		
Deployment	Flexible or rigid bronchoscopy	Rigid bronchoscopy only
Customization	No	Yes
Repositioning	Difficult	Easier
Conforms to complex airway	Yes	No
Internal-to-external diameter	Low	High
Elasticity	Excellent for nitinol	Poor
Mucociliary clearance	Yes for uncovered stents	No
Cost	More	Less
Complications		
Granulation tissue	More	Less
Migration	Less common	Significant
Fracture	Significant	Rare
Infection	More common	Less common
Tracheobronchial fistula formation	Possible	Very rare
Mucus impaction	Uncommon	Common

RULE OF THUMB

SEMS should not be used in benign conditions unless all other therapeutic options have been exhausted.

Bronchoscopy in Difficult Intubation

It may be difficult to establish an artificial airway by conventional means in patients with cervical and oropharyngeal trauma or redundant supraglottic soft tissue. The American Society of Anesthesiologists Task Force on difficult airway recommends alternative techniques to overcome such an airway challenge, including flexible bronchoscopy.[65]

Using an FB can help place an endotracheal tube (ETT) through the mouth or the nose. The ETT is placed over the FB, the vocal cords are visualized, and the ETT is then advanced into the trachea. Using the FB to aid ETT placement also allows for awake intubations with topical anesthesia and is particularly useful in patients with cervical injuries, in which immobilization of the neck is crucial.[66] The bronchoscope also may help identify causes of acute hypoxia and help remove secretions or blood in the airway. The limitations of this approach include operator inexperience and the need for patient cooperation.

THE ROLE OF THE RESPIRATORY THERAPIST IN BRONCHOSCOPY

The respiratory therapist (RT) has a major supportive role in the bronchoscopic procedures. The RT may collaborate with other members of the patient care team to determine if the procedure is indicated. The RT often is responsible for ensuring that all documentation is in place before the procedure and that a preprocedure "time-out" takes place to ensure the correct procedure is being done on the right patient. During preprocedure evaluation, the RT helps recognize the patient's O_2 requirement and anticipates appropriate O_2 supplement during the procedure. The RT also administers inhaled bronchodilators before or during the procedure if the patient exhibits bronchospasm. The FB is usually performed on spontaneously breathing patients via a transoral or transnasal route. The RT assists preparing upper as well as lower airways for the procedure using local anesthetic agents. In mechanically ventilated patients, the RT may help to optimize the length and the size of the endotracheal tube, place a bite-block in place to protect the equipment and adjust ventilator settings before and during the procedure. In addition to monitoring vital signs and O_2 saturation during the procedure, the RT may assist the physician in operating the bronchoscopic accessories, including brush, forceps, needles, laser fibers, cryoprobe, and APC probes. In patients with suspected ventilator-associated pneumonia, the RT may perform mini-BAL, which may guide the escalation and de-escalation of antibiotic therapy. Furthermore, the RT often identifies and can assist in responding to an adverse event associated with FB, such as hypoxemia. These and other aspects of the role of the RT are summarized in Box 22-5.

MINI CLINIC

Bronchoscopy-Induced Hypoxemia

PROBLEM: An RT is assisting during a flexible bronchoscopy on a spontaneously breathing patient that is taking longer than expected because other adjunctive procedures, including BAL. Shortly after instilling the lavage solution into the airway through the bronchoscope, the patient's O_2 saturation drops from 97% to 88% via pulse oximetry, their heart rate increases from 90 to 118 and the patient's skin color changes from pink to pale. What condition that an RT should consider in this situation?

DISCUSSION: Hypoxemia should be suspected in this case. Given that the bronchoscope occupies a significant amount of the anatomic airway during this procedure, additional airway resistance can partially impede ventilation during the procedure. In addition, the BAL solution introduced during into the airway can temporarily interfere with ventilation and gas exchange and hypoxemia can occur. Pausing the procedure and administering a higher FiO_2 or even 100% O_2 will generally alleviate this problem and boost the pulse oximetry to more acceptable levels (mid-90%). Once monitored blood O_2 levels return to normal, the procedure can generally be resumed and the patient's oxygenation and overall clinical status should be monitored for the balance of the procedure and for a period following it.

SPECIAL CONSIDERATIONS FOR BRONCHOSCOPY DURING MECHANICAL VENTILATION

In addition to the role of the RT described earlier, they play an even more important role when this procedure is being performed on patients receiving mechanical ventilation. It is most important to note that FB carries a higher risk when done on patients with reduced cardiopulmonary reserve, particularly

Box 22-5 Role of the Respiratory Therapist in Bronchoscopy

- Preprocedure
  - Help identify potential need for a bronchoscopy such as retained secretions or foreign body removal.
  - Verify, physician's order or protocol; review medical record for contraindications (e.g., excessive clotting times), hazards, and informed consent.
  - Prepare/ensure proper function of equipment, including bronchoscope, light source, TV monitor, video recorder, medications, specimen traps.
  - Outline plan for adequate oxygenation during the procedure.
  - Evaluate patient for bronchospasm and administer aerosolized bronchodilators if required.
  - Assist nursing staff in the application of topical anesthesia to the upper airways (nasal passages, oropharynx, hypopharynx).
  - Identify patient and perform preprocedure "time-out."
  - Mechanically ventilated patients/bedside bronchoscopy
    - Establish adequacy of the length and the diameter of the endotracheal or the tracheostomy tube based on the indication.
    - Ensure a bite-block is in place to avoid equipment damage.
    - Adjust ventilator settings for the safety of the procedure while maintaining proper oxygenation.
- During the procedure
  - Monitor vital parameters during the procedure, including capnography (if available).
  - Help identify and respond to adverse reactions (e.g., hypoxemia or pneumothorax).
  - Administer adequate amount of supplemental oxygen all throughout the procedure by choosing proper appliances (nasal cannula, mask, bilevel positive airway pressure)
  - Provide proper positioning of the patient to maintain patency of the upper airways (jaw-lift etc.).
  - Assist use of endobronchial accessories (bite block, oral airways, nasopharyngeal tube, biopsy forceps, brushes, etc.).
  - Set up instruments for rigid bronchoscopy and silicon stent placement.
  - Attend to emergent situations (pneumothorax, bleeding).
  - Place chest or endotracheal tubes.
- Postprocedure
  - Determine adequate oxygenation and ventilation and respond to adverse reactions.
  - Disinfect and properly store equipment.
  - Document procedure and relevant details.

those requiring mechanical ventilation. In such patients, the RT must ensure the airway is properly secured, verify adequate ventilation and gas exchange, monitor the patient, and quickly communicate the development of any complications to the physician and any other members of the bronchoscopy team.

In mechanically ventilated patients, it is important to consider that the bronchoscope will occupy a greater proportion of the airway than for spontaneously breathing patients. The external diameter of a standard fiberoptic bronchoscope is 5.7 mm, but in some situations a smaller (5 mm or less) or larger (6.4 mm) diameter scope may be used. The narrowest point in the upper airway (and point of maximal resistance) is the cricoid space, the diameter of which averages 14 mm in women and 18 mm in men.[67] Thus, in nonintubated, spontaneously breathing patients, inspiratory and expiratory effort (measured by tracheal pressure) appear minimally affected in most patients (−5 and +3.5 cm H_2O, respectively). However, in intubated, spontaneously breathing patients, the resistance imposed by the bronchoscope may cause tracheal pressures to increase noticeably (−10 and +9 cm H_2O) and may reach clinically unacceptable levels (−20 and +20 cm H_2O) in some patients.[68] Therefore the minimum appropriately sized ETT for a standard 5.7-mm bronchoscope is an 8.0-mm inner diameter.[69]

RULE OF THUMB

The minimal sized endotracheal tube that can be used with a standard 5.7-mm bronchoscope has an 8.0-mm internal diameter.

PHYSIOLOGIC AND MECHANICAL ALTERATIONS ASSOCIATED WITH FLEXIBLE BRONCHOSCOPY IN INTUBATED PATIENTS

Complications associated with flexible bronchoscopy in intubated patients are infrequent (<10%) and usually mild.[70] However, serious complications may occur (Table 22-4). These include the following (along with their reported incidence): transient hypoxemia with SpO_2 less than 90% (8%), tension pneumothorax (14%), bronchial hemorrhage greater than 30 mL (6%), hypotension with mean arterial pressure less than 60 mm Hg (7%), and tachycardia greater than 140 (4%).[70] Pneumothorax is primarily associated with lung biopsy procedures,[71,72] whereas the risk for significant bleeding after biopsy increases when the platelet count is below 50,000/mm^3.[70]

As noted elsewhere in this chapter, some degree of hypoxemia may occur during FB. In those with normal lungs the PaO_2 can decrease by 10 to 30 mm Hg, whereas in critically ill patients, the PaO_2 may be reduced by 60 mm Hg.[70,71] Hypoxemia during FB is partly caused by suctioning through the bronchoscope. This decreases PEEP and functional residual capacity and promotes atelectasis. For example, setting the vacuum at 100 mm Hg through a standard 2-mm suction port can evacuate approximately 7 L/min of gas.[70] The problem is accentuated if tidal volume delivery also is significantly compromised during FB. In fact, frequent suctioning during FB also causes pronounced tidal volume loss.[68] Because FB commonly is used to remove mucus plugs, this problem may be unavoidable. Both the RT and physician performing bronchoscopy need to be mindful of

TABLE 22-4

Physiologic and Mechanical Alterations Associated With Flexible Bronchoscopy in Intubated Patients

System	Effects	Comments/Interventions
Respiratory mechanics	High peak inspiratory pressures and pressure cycling	Obstruction by the bronchoscope causes back-pressure that is not transmitted to the lungs. Use of high inspiratory flow rates/brief inspiratory time will accentuate the problem and may greatly reduce minute ventilation. **Intervention:** *Volume control ventilation:* Use a lower peak flow rate or decreasing ramp pattern and increased inspiratory time. *Pressure control ventilation:* Increase the pressure control level and extend the inspiratory time. *Before bronchoscopy:* Assess minute ventilation demand and blood gases with the physician to determine if the patient might tolerate mild to moderate respiratory acidosis during the anticipated procedure duration. Monitor peak inspiratory pressure.
	Intrinsic PEEP	Increased expiratory resistance can cause a 30% increase in functional residual capacity and may cause high levels of intrinsic PEEP to develop. With an 8-mm endotracheal tube, intrinsic PEEP levels are generally <20 cm H_2O, but have been reported to rise to 35 cm H_2O when bronchoscopy has been attempted with a 7-mm tube. *Consider* removing or reducing PEEP by 50% during the procedure. Monitor blood pressure as a signifier for possible intrinsic PEEP buildup. Either a sustained downward trend or abrupt drop in systolic blood pressure may indicate decreased cardiac output.

TABLE 22-4

Physiologic and Mechanical Alterations Associated With Flexible Bronchoscopy in Intubated Patients—cont'd

System	Effects	Comments/Interventions
	Circuit leak, suctioning, and tidal volume loss	Circuit leaks with substantial loss of tidal volume were a common problem until the creation of specialized bronchoscopy port endotracheal tube adapters. These are commercially available and have largely eliminated the problem. When encountered, the rule of thumb has been to increase the preset tidal volume by 30%-40% to compensate for the leak.[71] Use lower peak inspiratory flow rate and longer inspiratory time. Frequent, prolonged suctioning during FB can greatly reduce tidal volume regardless of ETT size. Monitor: • Expired tidal volume • End-tidal PCO_2 and VCO_2 (CO_2 excretion) if volumetric capnography is available, particularly in those with baseline hypercarbia, acidosis, or hemodynamically unstable.
Gas cxchange	Hypoxemia	Preoxygenate for 15 min on FiO_2 of 1.[71] Ensure adequate sedation before and during FB. Ensure continuous pulse oximetry. *Consider* using recruitment maneuvers to improve functional residual capacity before and (if necessary) after FB in patients with marginal oxygenation. To the extent possible: • Minimize tidal volume loss • Avoid using a brief inspiratory time. • Limit the frequency and duration of suctioning.
	Acute hypercapnia and acidosis	On average, $PaCO_2$ tends to increase by 8 mm Hg during FB.[71] This would decrease arterial pH by only 0.06; and even less in patients with chronic hypercapnia. This mild change in $PaCO_2$ should be interpreted in the context of clinicians adjusting mechanical ventilator settings to attempting to maintain adequate ventilation. Given the relatively brief procedure time for FB, concern over the impact of hypercapnia should be focused on clinically unstable patients. *In at-risk patients:* The procedure time should curtailed. Periodic withdrawal of the bronchoscope to ensure adequate ventilation. Clinicians should determine the limits of what an acute rise in $PaCO_2$ and decrease in pH would be acceptable during the procedure and use clinical equations to estimate the minimum acceptable minute ventilation that must be maintained (see MINI CLINI for details). When FB must be attempted in patients with significant acidosis, consideration should be given to preprocedure buffer therapy with a non–CO_2 generating agent (i.e., THAM) often used for procedures requiring apneic oxygenation.
Hemodynamics	Heart rate and cardiac arrhythmias	Hypoxemia and hypercapnia increase sympathetic tone, which can lead to tachycardia, myocardial ischemia, and arrhythmias may result in hypotension and/or cardiac arrest. Heart rate tends to increase by ~40% during FB.[73] The occurrence of major arrhythmias is 3%-11%. *Reduce the risk for arrhythmias by:* • Preoxygenation with an FiO_2 of 1 • Minimizing procedure time • Periodic withdrawal of the bronchoscope to ensure adequate ventilation Ensure continuous cardiac monitoring.
	Alterations in blood pressure and cardiac output	Mean blood pressure and cardiac output tend to increase during FB by ~30%.[73] Hemodynamic variables tend to return to normal ~15 min after completion of FB.[71]

ETT, Endotracheal tube; *FB,* fiberoptic bronchoscopy; *PEEP,* positive end-expiratory pressure; *THAM,* tris-hydroxymethyl aminomethane.

TABLE 22-5

High-Risk Patients for Flexible Bronchoscopy

Conditions	Considerations
Asthma	Greater tendency for laryngospasm and bronchospasm[72,73] Tendency for greater reduction in lung function after FB when lavage or biopsies are done. Hypoxemia not uncommon. Pretreatment with bronchodilators immediately before FB In patients with unstable lung function, consider pretreatment with steroids several days before FB in.
Acute brain injury	Intracranial hypertension is a predominant concern. Procedural Goal: intracranial pressure <20 mm Hg with Cerebral Perfusion Pressure ≥70. Causes of increased intracranial pressure include sympathetic stimulation from discomfort and hypercapnia, hypoxemia. Build-up of intrinsic PEEP decreases venous return causing cranial venous pooling. Procedural sedation and strategies to maintain minute ventilation assume even greater importance. Employing continuous drainage when subdural catheters are present should be considered. Either curtailing procedure time or frequent periods bronchoscope withdrawal to resume baseline minute ventilation also should be considered.
Acute respiratory distress syndrome (ARDS)	Tendency is for severe hypoxemia and respiratory acidosis, particularly in those with severe ARDS (PaO_2/FiO_2 < 100) secondary to low lung volumes and high dead-space ventilation. Risk is increased if hemodynamic instability is present (e.g., mean arterial pressure <65 mm Hg and/or high vasopressor requirements). Loss of PEEP is particularly problematic. Consideration should be given to preprocedure use of recruitment maneuvers to optimize lung volumes and oxygenation and THAM to control acidosis.
Coronary artery disease	Adrenergic discharge during FB in response to undersedation, hypoxemia, and/or acute respiratory acidosis may cause myocardial ischemia, arrhythmias, hypotension are cardiac arrest. In nonintubated patients, the need for high doses of topical anesthesia with lidocaine may cause sinus arrest and atrioventricular block.

FB, Fiberoptic bronchoscopy; *THAM,* tris-hydroxymethyl aminomethane.

the frequency and duration of suctioning, along with the total procedure time to limit the potential for severe, prolonged hypoxemia. The risk for significant hypoxemia is elevated in those with acute respiratory distress syndrome (ARDS) and in those insufficiently sedated.[68] Patients undergoing FB should be preoxygenated on FiO_2 of 1 for 15 minutes. Resolution of hypoxemia depends on the presence and severity of underlying pulmonary disease. For example, hypoxemia tends to resolve within 15 minutes after FB in those with normal lungs, whereas hypoxemia may persist for several hours in those with severe lung disease.

RULE OF THUMB

Hypoxemia during FB on mechanically ventilated patients is related to several factors, including loss of lung volume during suctioning, particularly if tidal volume delivery also is compromised. It occurs more frequently in those with ARDS and in those insufficiently sedated.

It is the RT's responsibility to effectively manage the most common of these complications (see Table 22-4). In addition, the RT must anticipate which patients are most likely to suffer significant adverse events during bronchoscopy (Table 22-5). Before the procedure, the members of the bronchoscopy team, including the RT, should assess the patient's condition, discuss which adverse effects most likely will occur, and how they should be managed. This discussion should include the anticipated procedure time, whether the original plan for the procedure should be modified, sedation strategy, hemodynamic management, and ventilator management. A particular emphasis for the RT should be the minimum clinically acceptable level of minute ventilation necessary to complete the procedure. Depending on the procedure goal (e.g., diagnostic, removal of secretions), bronchoscopy tends to last between 7 and 17 minutes.[73,74]

EMERGING BRONCHOSCOPIC INTERVENTIONS

In addition to the interventions described earlier, others are emerging and hold promise for the future. One such intervention is bronchial thermoplasty, which is still considered a novel procedure for patients with bronchial asthma. Also, endobronchial valves and coil placement are being studied in the management of patients with severe emphysema. If shown to be effective, they could represent an alternative to lung volume reduction surgery for severe emphysema.

MINI CLINI

Estimating Minimum Minute Ventilation Requirements During Flexible Bronchoscopy in a Patient With Severe Respiratory Failure

PROBLEM: A patient with ARDS has deteriorating oxygenation associated with a new infiltrate on chest radiograph. Gram-negative bacterial ventilator-associated pneumonia is strongly suspected, and FB is deemed necessary before adjusting antibiotic therapy because the suspected pathogen is likely to be multidrug resistant. The patient has a high minute ventilation demand of 13 L/min to maintain a pH of 7.40 and $PaCO_2$ of 40 mm Hg. The patient has sepsis and currently requires norepinephrine at 12 mcg/min to maintain a mean arterial pressure of 65 mm Hg. The physician decides that during FB, a pH of 7.25 would be tolerable for the estimated procedure time of 10 minutes. The RT is asked if there is a clinical formula to *estimate* what rise in $PaCO_2$ would likely produce the target minimum pH. In addition, the RT is asked to estimate the minimum minute ventilation needed during FB that would likely maintain pH at 7.25.

DISCUSSION: In patients without chronic hypercapnia, an acute rise in $PaCO_2$ of 10 produces a decrease in pH of 0.008.[74] Because tidal volume can be greatly reduced during FB, the RT can reasonably begin with an estimated $PaCO_2$ increase of 20 mm Hg. This would yield an *estimated* drop in pH of 0.16 units (20×0.008) and a pH of 7.26 ($7.40 - 0.16$). The clinical formula for corrected minute ventilation then can be used to estimate the minimum acceptable minute ventilation.[73]

$$VE_{min} = VE_{measured} \times (PaCO_2 \text{ measured} \div PaCO_2 \text{ upper limit})$$
$$VE_{min} = 13\ L/min \times (40 \div 60)$$
$$VE_{min} = 13\ L/min \times 0.67$$
$$VE_{min} = 8.7\ L/min$$

Patients with high minute ventilation demand who require vasopressor support to maintain adequate perfusion may be particularly sensitive to sudden respiratory acidosis. The fact that this patient already requires the highest recommended dose of norepinephrine to maintain an adequate blood pressure is cause for concern about the safety of performing FB. The steps described previously are *only estimates* useful for guiding management during FB and assessing the risk-to-benefit ratio. For example, a preprocedure pH that was substantially lower (e.g., $\leq$7.30) may change the management strategy, including shortening the FB procedure or performing the procedure in steps.

CONCLUSION

Bronchoscopy is a common diagnostic and therapeutic procedure that has reduced the need for procedures such has percutaneous needle aspiration, mediastinoscopy, thoracoscopy, and open lung biopsy. In many settings, RTs play a major role in identifying patients who may benefit from it, setting up the equipment, and assisting with bronchoscopy procedure and patient monitoring.

SUMMARY CHECKLIST

- FB has been used for most diagnostic and therapeutic indications in patients with pulmonary diseases. The goal of sedation is to improve the patient's comfort during the procedure. Continuous monitoring of oxygenation and hemodynamic stability are important during the procedure.
- BAL, biopsy, and TBNA are the most commonly used diagnostic procedures in FB. BAL obtains samples from the alveoli. Needle aspiration has a role in sampling mediastinal lymph nodes to diagnose lung cancer, sarcoidosis, and some infectious processes. Biopsy has value in the diagnosis of infiltrative pulmonary diseases.
- Various thermal ablation techniques have been used along with FB as treatments. The most important point is to ensure a low FiO_2 environment before the use of any thermal ablative therapy.
- Airway stenting has been used to maintain airway patency after dilation of any obstructed major airways. It is important to recognize the difference between silicone and metallic stents.
- Bronchial thermoplasty is a novel bronchoscopic technique for patients with steroid-dependent asthma. Also, endobronchial valves and coil placement are being studied in the management of patients with severe emphysema as a minimally invasive lung volume reduction therapy.
- The RT plays a vital role in assisting before, during, and after bronchoscopy. There are many aspects to this role, but they include ensuring appropriate documentation (e.g., physician's order), preparing the patient and the equipment, patient monitoring, and responding to adverse events.
- There are special considerations the RT and other members of the bronchoscopy team must consider when performing this procedure on mechanically ventilated patients, who are more susceptible to adverse events. These considerations include ensuring adequate ventilation and gas exchange before, during, and after the procedure.

CHAPTER 23

Nutrition Assessment

JAMI E. BALTZ

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe how a comprehensive nutrition assessment is conducted.
- Calculate and interpret body mass index.
- Distinguish between two forms of protein-energy malnutrition.
- List the biochemical indicators of nutrition status.
- Describe the clinical manifestations of malnourishment.
- Describe how to obtain and evaluate a nutrition history.
- Estimate daily resting energy expenditure.
- List the indications, contraindications, hazards, and limitations of indirect calorimetry.
- Describe how to prepare a patient for indirect calorimetry.
- Interpret the results of indirect calorimetry.
- Adjust resting energy expenditure values to reflect the actual patient energy needs.
- Describe the effects of malnutrition on the respiratory system.
- Describe how to identify patients at high risk for malnutrition.
- State when enteral nutrition and parenteral nutrition are needed.
- Identify and minimize common respiratory complications of enteral feedings.
- List specific nutrition guidelines for specific pulmonary diseases.
- Explain how common pulmonary medications affect nutrition.

CHAPTER OUTLINE

KEY TERMS

anergy
anthropometrics
azotemia
basal metabolic rate
body mass index
cachexic
indirect calorimetry
kwashiorkor
marasmus
normometabolic
protein-energy malnutrition
resting energy expenditure

Nutrition is vital to life, health, and well-being. Second to the provision of oxygen is the provision of nutrients to sustain the function, growth, maintenance, and repair of the body. A human deprived of O_2 for minutes can no longer function. Similarly, a human deprived of food for days to weeks can no longer function.

Adequate nutrition is essential for health. The relationship between nutrition and respiratory status is reciprocal. A balanced supply of nutrients is needed for proper respiratory function; O_2 is required for adenosine triphosphate synthesis and muscle function, including the respiratory muscles. Poor or inadequate nutrient intake disrupts energy use and impairs normal organ function. Conversely, disease can impair nutrient intake or alter metabolism, causing malnutrition.

Traumatized tissue requires the provision of nutrients for healing. To achieve healthy living requires daily, consistent attention to providing essential nutrients. Patients with respiratory disease are particularly challenged because it is difficult to breathe and swallow at the same time. This chapter focuses on nutrition assessment—determining the nutrient needs of individuals.

NUTRITION ASSESSMENT

Nutrition assessment is the process of collecting and evaluating data to determine the nutrition status of an individual. Typically, a registered dietitian gathers data to compare various social, pharmaceutical, environmental, physical, and medical factors to evaluate the nutrient needs of an individual. The purpose of nutrition assessment is to develop a *nutrition care plan* that ensures continual adequate nutrition for health.

Data are obtained from numerous sources for nutrition assessment. Interviewing the individual or the caregiver to determine past and current eating practices is most helpful. Reviewing the patient's medical record provides additional information regarding pertinent social, pharmaceutical, environmental, and medical issues. Information gathered for a nutrition assessment is grouped into five domains: (1) food/nutrition-related history, (2) anthropometric measurements, (3) biochemical data and tests/procedures, (4) nutrition-focused physical findings and (5) client history (Box 23-1).[1]

Box 23-1 Components of a Comprehensive Nutrition Assessment

MEDICAL CHART
- History and physical examination
- Present diseases
- Current medications
- Activity level
- Physical assessment
- Social history

ANTHROPOMETRICS
- Usual weight and height
- History of weight loss
- Actual versus ideal body weight
- Body mass index
- Body composition (triceps skin fold, arm muscle area)

PHYSICAL ASSESSMENT
- Signs of weight loss (cachexia)
- Edema that may mask weight loss
- Hair, skin, mouth, and tongue

CLINICAL LABORATORY TESTS
- Visceral proteins
- C-reactive protein
- Creatinine-height index
- Immune-related tests
- Nitrogen balance

DIETARY HISTORY
- Usual food intake
- Food likes and dislikes
- Appetite

TOTAL CALORIC REQUIREMENTS
- Resting energy expenditure predictive equations
- Indirect calorimetry

ACCESS TO FOOD
- Income
- Education
- Mobility
- Mechanical impediments

Food-Related and Nutrition-Related History

Past dietary practices are identified to determine the pattern of food intake. Numerous means are available to determine food consumed by an individual. A registered dietitian may use a 24-hour recall or a usual daily intake recall, a food diary or food record, or a food frequency questionnaire. The 24-hour recall and the usual daily intake recall depends on past information in which the patient states the foods and amount consumed in an average day. This technique is easily incorporated into a clinical setting. Food frequency questionnaires incorporate information on the frequency and amount of the specific foods consumed and can help identify eating patterns. Patients are asked to write down daily everything they have eaten. The patient may record food intake over an extended time, most frequently, a 3-day or 7-day period.

Evaluation of Nutrition History

The information from a diet history may be evaluated for nutrient intake using MyPlate, a nutrient analysis handbook, or a nutrient analysis software package.

MyPlate. The U.S. Department of Agriculture and the U.S. Department of Health and Human Services recommend balanced nutrition for U.S. citizens.[2] The clinician or patient can go to http://www.choosemyplate.gov and compare diet history information to estimate the adequacy of the patient's diet.[3]

Nutrient Analysis Handbook. A handbook listing the nutrient content of specific foods may be used to calculate manually the adequacy of a 24-hour recall. This is a tedious and time-consuming task.

Nutrient Analysis Software. Computer programs can determine total calories, percent of calories of macronutrients

(protein, carbohydrate, and fat), and units of micronutrients and fiber. The patient's individual foods and serving size are entered into a computer file to determine quickly the nutrient content of a diet history.

Anthropometrics

Anthropometrics refers to body measurements; the most frequently used are height and weight. Skin fold thicknesses, arm muscle measurements, waist and hip measurements, head circumference, and wrist diameter are useful body composition measurements when assessing nutrition status.

Height and Weight

A measured height and weight is preferred, but the clinician may ask the patient or caregiver for the height and weight. When recording this data note the date and whether the height and weight were stated or measured.

Body Mass Index. **Body mass index** (BMI) expresses the relationship between weight and height and is used to classify patients as underweight, healthy weight, overweight, obese, or morbidly obese. The formula for calculating BMI in kilograms and meters is:

$$\text{BMI} = \frac{\text{Actual body weight (kg)}}{\text{height}^2\ (\text{m}^2)}$$

And when using pounds and inches is:

$$\text{BMI} = \frac{\text{Actual body weight (lb)} \times 703}{\text{height}^2\ (\text{in}^2)}$$

An Internet calculator for BMI is available at: http://www.cdc.gov/bmi.

RULE OF THUMB

BMI categories for adults and children (male and female, age 2 to 20 years) are as follows[4,5]:

	Adult (BMI)	Children (BMI for Age)
Underweight	<18.5	<10th percentile
Healthy weight	18.5-24.9	10th-85th percentiles
Excessive weight	25.0-29.9	85th-95th percentiles
Obesity	>30	>95th percentile
Morbid obesity	>35	>99th percentile

Overweight and Obesity. Simply defined, overweight and obesity occur over time with the consumption of too many calories or too little expenditure of calories through activity or exercise or both overconsumption and underexpenditure. Other contributory factors include rare diseases, genetic predisposition, and loss of mobility through trauma or disease. Regardless, too many calories are ingested for the amount of energy (calories) expended.

Kwashiorkor and Marasmus. Undernutrition classifications include kwashiorkor and marasmus. Typically seen in children 6 to 18 months of age residing in impoverished areas of the world, **marasmus** results from a prolonged, extreme lack of calories and protein associated with food shortage, early weaning, or infrequent feeding of infants.[6] "Matchstick" arms and obvious lack of muscle and fat characterize a child or adult with marasmus. Table 23-1 compares the two forms of protein energy malnutrition (PEM). **Kwashiorkor** results from a more sudden lack of protein and calories, as in a first-born infant weaned suddenly on the arrival of a new sibling, when a diet of nutrient-rich breast milk is traded for a nutrient-poor, cereal-based diet.[6] The protruding belly and edematous face and limbs characteristic of kwashiorkor result from decreased plasma proteins needed to maintain fluid balance and transport fat out of the liver.

TABLE 23-1

Comparison of Two Primary Forms of Protein-Energy Malnutrition

Parameter	Starvation (Marasmus)	Hypercatabolism (Kwashiorkor)
Cause	Inadequate energy intake	Response to injury or infection
Examples	Cancer, pulmonary emphysema	Sepsis, burns
Body habitus	Thin, wasted, cachexic	May be normal, edematous
Rate of malnutrition	Slow	Rapid
Metabolic rate	↓	↑
Fuel	Glucose/fat	Mixed
Catabolism	↓	↑
Gluconeogenesis	↑	Markedly ↑
Glucagon	↑	Markedly ↑
Insulin	↓	↑
Ketogenesis	↑	Slightly ↑
Catecholamines	Unchanged	↑
Cortisol	Unchanged	↑
Growth hormone	Increased	↑
Visceral proteins	Normal	Decreased ↓
Cytokines	Variable	Increased
Immune function	Normal	Impaired
Clinical course	Adequate responsiveness to short-term stress	Infections, poor wound healing, decubitus ulcers, skin breakdown
Mortality	Low unless related to underlying disease	High

Body Composition

Other anthropometric measurements useful in nutrition assessment evaluate body weight variations in individuals. Someone with similar height may differ in the proportion of lean body mass, fat mass, and skeletal size. Common measurements are *arm muscle area* (index for muscle), *skin folds* (measures of fat), and waist-to-hip ratios. More sophisticated imaging technologies such as bioelectric impedance analysis or dual-energy x-ray absorptiometry scans determine body fat, body mass, ratio of intracellular water to extracellular water, and bone density. These methods are generally expensive and time-consuming and are not clinically relevant but may be used in research.

Skin Fold. Skin-fold thickness measures subcutaneous fat with the assumption that it compromises 50% of total body fat. Usually, the triceps and subscapular skin folds are the most useful for evaluation.[7] Skin-fold thickness measurements have limited clinical application in the acute care setting because of proper equipment and examiner technique.

Arm Muscle Area. The triceps skin-fold measurement with the midarm circumference is used to calculates arm muscle area (AMA). The AMA indicates muscle stores available for protein synthesis or energy needs. AMA changes over time may signify protein or caloric deprivation and is useful as a predictor of mortality.[8]

Waist Circumference. An alternative to BMI, waist circumference, can be a more accurate predictor of excess body fat and risks associated with obesity.[9,10] According to the U.S. Department of Health and Human Services, the following individuals are at increased risk for developing chronic diseases:

- Women with a waist circumference of more than 35 inches
- Men with a waist circumference of more than 40 inches

The World Health Organization has recommended lower thresholds for waist circumference for Asian populations.[11] Therefore those at increased risk for developing chronic disease include:

- Asian women with a waist circumference of more than 31 inches
- Asian men with a waist circumference of more than 35 inches

Biochemical Indicators

Particularly significant laboratory values used in assessing nutrition status include serum proteins. PEM may be reflected in low values for albumin, transthyretin (prealbumin), and retinol-binding protein. Blood levels of these markers indicate the level of protein synthesis and yield information on overall nutrition status. However, inadequate intake may not be the cause of low values; certain disease states, level of hydration, liver and kidney function, pregnancy, infection, and medical therapies may alter laboratory values for each of the circulating proteins.[12] Diagnosing a nutritional disorder cannot be done based on a single laboratory value but should be used with other assessment data to determine the nutritional status of the patient. The majority of laboratory values used in nutritional assessments lack sensitivity and specificity for malnutrition.[13]

Albumin

Albumin is the largest constituent protein in plasma. Because its half-life is only 14 to 21 days, its usefulness for monitoring the effectiveness of nutrition in the critical care setting is limited.[14] Albumin often reflects the metabolic response to and severity of disease, injury, or infection and can be a useful prognostic indicator. Albumin synthesis is affected by both nutrition and inflammation. Proinflammatory states diminish albumin production, and the combination of inflammation and hypoalbuminemia is linked with increased morbidity, mortality, and longer hospitalization.[15]

Transthyretin and Retinol-Binding Protein

Transthyretin, or *prealbumin,* has a half-life of 2 to 3 days, and retinol-binding protein has a half-life of 12 hours. Each of these proteins responds to nutrition changes more quickly than either albumin. However, numerous metabolic states, diseases, therapies, and infections influence the laboratory values.[16]

Levels of each protein are influenced by many factors other than nutrition status. Because these conditions are so common among critically ill patients, visceral protein markers are of limited usefulness for assessing nutrition deficiency. *Nonetheless, plasma proteins are useful in assessing illness severity and the risk for future malnutrition.*[16] Inflammatory metabolism causes a 25% decrease in the synthesis of these visceral proteins; causing lean body mass depletion and anorexia. Therefore it is important to evaluate their values with biomarkers of inflammation where there is a reverse relationship.

RULE OF THUMB

Nutritional disorders cannot be made from a single laboratory value because, by themselves, they are not sufficiently sensitive or specific to diagnose malnutrition. Instead, laboratory test results are used with other data as part of a holistic assessment of a patient's nutritional status.

RULE OF THUMB

Increased metabolism associated with inflammation causes a 25% decrease in protein synthesis resulting in loss of lean body mass.

In proinflammatory states the combination of inflammation and hypoalbuminemia is linked with increased morbidity, mortality, and longer hospitalization.

Biomarkers of Inflammation

Inflammation adversely affects a patient's nutritional status by both increasing catabolism and causing albumin leakage out of the vascular compartment. Inflammation triggers a chemical cascade that causes loss of appetite or anorexia, thereby decreasing dietary protein intake and further catabolism.[13]

The most commonly used clinical biomarker of inflammation is C-reactive protein (CRP), which increases with infection and inflammation while the production of albumin and prealbumin decreases.[17] Increased levels of C-reactive protein during stress, illness, and trauma have been linked to increased nutrition risk.[18] Other common biomarkers of inflammation include white cell count and erythrocyte sedimentation rate (ESR).[19]

Other Tests and Procedures

Creatinine-Height Index

Because the rate of creatinine formation in skeletal muscle is constant, the amount of creatinine excreted in the urine every 24 hours reflects skeletal muscle mass. Predicted values are

based on gender and height, with reference values of approximately 18 mg/kg body weight per day for women and approximately 23 mg/kg body weight per day for men.[7] Factors that influence creatinine excretion and complicate its interpretation include age, diet, exercise, stress, trauma, fever, and sepsis.[17]

Nitrogen Balance (Protein Catabolism)

Approximately 16% of protein is nitrogen, and nitrogen is a major by-product of protein catabolism. Therefore measuring nitrogen balance is an important aspect of nutritional assessment. The urinary excretion rate of nitrogen is used to assess protein adequacy. Nitrogen balance is calculated as follows:

$$\text{Nitrogen balance} = \text{Nitrogen intake} - \text{Nitrogen losses}$$

$$\text{Nitrogen intake} = \frac{\text{Protein intake}}{6.25}$$

$$\text{Nitrogen losses} = \text{UUN excretion in grams} + 3\text{-}5\ \text{g (for insensible losses)}$$

The dietary protein conversion factor is 6.25 g of nitrogen per 1 g of protein. The amount of nitrogen excretion in the urine is typically measured as the 24-hour urinary urea nitrogen. Between 3 g/day and 5 g/day is added to the 24-hour urinary urea nitrogen to estimate the average daily unmeasured nitrogen lost through other sources (skin and gastrointestinal [GI] sloughing, hair loss, sweat, feces). Theoretically, increasing exogenous protein, reduces endogenous protein loss. However, the accuracy of 24-hour urine collection is limited by alterations in renal or liver function, large insensible losses (burns, high-output fistulas, wounds, or ostomies), and inflammatory conditions.[20]

Immune Status

Impaired immunity (**anergy**) is common in malnutrition, especially the kwashiorkor type. Two laboratory values, white blood cell count and percentage of lymphocytes, are indices of compromised immunity. The result is often a reduction in the total lymphocyte count. Many nonnutrition variables, including disease states and drugs, influence these laboratory values, so their usefulness in assessing nutrition status is questioned.[21]

Pulmonary Function

Pulmonary function test results may change with malnutrition. Respiratory muscle weakness reduces both maximal inspiratory and expiratory pressures and reduced vital capacity. These limitations in turn reduce the ability to maintain sufficient lung volumes to prevent atelectasis and produce an effective cough to clear secretions. Diminished strength and endurance of respiratory muscles increases the susceptibility to respiratory muscle fatigue and the inability to maintain effective spontaneous breathing. The negative effects of malnutrition on both respiratory muscle function and immunologic function increase the risk for respiratory infections and pneumonia.[22]

Nutrition-Focused Physical Findings

The physical signs of malnutrition often appear first in specific tissues where high cell turnover occurs[23] (e.g., hair, eyes, lips, mouth and gums, skin and nails), so incorporating the appearance of these features into the physical examination can alert the clinician to signs of nutrient deficiencies (see Table 23-2 for physical signs of nutrition status). In addition to malnutrition, other causes of these abnormalities include medical therapies, anemia, allergies, sunburn, medications, poor hygiene practices, aging, or various pathologic processes.[24] Patients with persistent malnutrition often appear very thin. When the bony structures of the chest are conspicuously visible, a patient is said to be **cachexic.** Special attention should be given to fluid retention because this can mask weight loss.[25] Other physical findings such as skeletal muscle depletion can be clinical indicators of inflammation or signs of systemic inflammatory response.

TABLE 23-2

Physical Signs of Malnutrition

	Normal	Abnormal
Demeanor	Alert, responsive Positive outlook	Lethargic Negative attitude
Weight	Reasonable for build	Underweight Overweight, obese
Hair	Glossy, full, firmly rooted Uniform color	Dull, sparse; easily, painlessly plucked
Eyes	Bright, clear, shiny	Pale conjunctiva Redness, dryness
Lips	Smooth	Chapped, red, swollen
Tongue	Deep red Slightly rough One longitudinal furrow	Bright red, purple Swollen or shrunken Several longitudinal furrows
Teeth	Bright, painless	Caries, painful, mottled, or missing
Gums	Pink, firm	Spongy, bleeding, receding
Skin	Clear, smooth, firm, slightly moist	Rashes, swelling Light or dark spots Dry, cracked
Nails	Pink, firm	Spoon-shaped or ridged Spongy bases
Mobility	Erect posture Good muscle tone Walks without pain or difficulty	Muscle wasting Skeletal deformities Loss of balance

OUTCOMES OF NUTRITION ASSESSMENT

With nutrition intervention, patients improve their nutrient intake and reduce mortality and morbidity. Improved nutrition status increases the patient's tolerance of therapeutic regimens in the treatment of disease and decreases recovery time. The resulting economic benefits are multifaceted and include shorter and less frequent hospital stays, reduced need for medication or medical care or extended care, and increased years of productivity.[26]

MACRONUTRIENTS AND ENERGY REQUIREMENTS

The nutrition assessment determines a nutrition care plan for the patient. Calorie or energy needs are fundamental to these recommendations. Several means are available to determine calorie needs. These include calculating total calories using a mathematical formula or predictive equation.

Macronutrients supply the energy requirements of the body. The three macronutrients are *protein, carbohydrate,* and *fat*. Each contributes to calorie intake with 4, 4, and 9 calories (kcal) per gram. Alcohol is the only other calorie source, with approximately 7 kcal/g. Box 23-2 outlines the factors influencing energy and macronutrient needs.

Estimating Energy Requirements

An individual's energy requirement represents the ratio of energy intake to energy expenditure relative to body weight, activity level, and stressors. The classic measure of energy expenditure is the **basal metabolic rate (BMR)**. Obtained after 10 hours of fasting, the BMR measures the number of calories (kcal) expended at rest per square meter of body surface per hour (kcal/m^2/hr). BMR varies by body size, age, and sex. Caloric needs for energy expenditure increase beyond the BMR based on activity level, stage of growth (pregnancy, lactation), and extent of injury.

In clinical practice, interest is focused on a patient's *daily* energy requirements (kilocalories per day). Multiple methods are available for estimating daily energy needs. The "quick method," based on a 1997 equation provided by the American College of Chest Physicians, estimates daily energy needs based on a simple body weight factor of 20 to 35 kcal/kg.[27] Alternatively, predictive equations (Box 23-3) such as the classic *Harris-Benedict equation* estimate daily **resting energy expenditure (REE)**.

Several other predictive equations focus on specific patient populations and medical conditions. Additional data such as injury-stress, activity, medications received, and obesity have been added to improve accuracy. The *Mifflin-St. Jeor equation* is the most reliable in both nonobese and obese ill patients.[28] Other equations, such as the *Ireton-Jones* and *Penn State equations* are used specifically in intubated patients to account for temperature and ventilation parameters. Although the predicted REE averages approximately 10% higher than the BMR, predictive equations may still tend to overestimate or underestimate actual energy need.[29]

Box 23-2 Factors Influencing Energy and Macronutrient Needs

ENERGY NEEDS
- Height and weight
- Activity level
- Growth state: Infants through teens, pregnancy, and lactation
- Presence of infection or fever
- Surgery
- Trauma and fractures
- Presence of infection or inflammation

PROTEIN NEEDS
- State of growth
- Surgery, trauma, fractures, and infection
- Renal (kidney) function
- Liver function
- Corticosteroid administration

FAT NEEDS
- Total energy needs
- Hyperlipidemia, and diabetes mellitus
- Liver, gallbladder, and pancreatic disorders
- Cardiovascular disease

Box 23-3 Predictive Equations

HARRIS-BENEDICT EQUATIONS

Men: Resting metabolic rate (RMR) = 66.47 + 13.75(W) + 5(H) – 6.76 (A)
Women: RMR = 655.1 + 9.56 (W) + 1.7 (H) – 4.7 (A)
Equation uses weight (W) in kilograms (kg), height (H) in centimeters (cm), and age (A) in years.

IRETON-JONES ENERGY EQUATIONS (IJEE) 1992

Spontaneously breathing IJEE
(s) = 629 – 11 (A) + 25 (W) – 609 (O)
Ventilator dependent IJEE
(v) = 1925 – 10 (A) + 5 (W) + 281 (S) + 292 (T) + 851 (B)
Equations uses age (A) in years, body weight (W) in kilograms, sex (S, male = 1, female = 0), diagnosis of trauma (T, present = 1, absent = 0), diagnosis of burn (B, present = 1, absent = 0), obesity more than 30% above initial body weight from 1959 Metropolitan Life Insurance tables or body mass index (BMI) more than 27 kg/m^2 (present = 1, absent = 0).

MIFFLIN-ST. JEOR EQUATIONS

Men: RMR = (9.99 × weight) + (6.25 × height) – (4.92 × age) + 5
Women: RMR = (9.99 × weight) + (6.25 × height) – (4.92 × age) – 161
Equations use weight in kilograms and height in centimeters.

PENN STATE EQUATIONS (PSU)

Also known as *PSU 2010* (Modified Penn State Equation)

$$RMR = Mifflin\,(0.71) + \dot{V}_E\,(64) + T_{max}\,(85) - 3085$$

Used for patients with BMI over 30 and older than 60 years old. Validated in 2010 by the ADA Evidence Analysis Library (EAL).

PSU 2003b (Penn State Equation)

$$RMR = Mifflin\,(0.96) + \dot{V}_E\,(31) + T_{max}\,(167) - 6212$$

Used for patient of any age with BMI below 30 or patients who are younger than 60 years with BMI over 30. This equation was validated in 2009 by the EAL and is also referred to as the Penn State equation.

PSU 2003a (Penn State 2003a)

Invalidated in 2007 and 2009 by EAL

$$RMR = HBE\,(0.85) + \dot{V}_E\,(33) + T_{max}\,(175) - 6433$$

(Use actual weight in all patients.)

From Academy of Nutrition and Dietetics. Evidence analysis library, 2014. Available http://www.andeal.org. Accessed September 2014.

To overcome the limitations of estimating formulas, energy needs can be measured using O_2 consumption and carbon dioxide production. From these data, an actual REE can be quickly computed. Indirect calorimetry is described in more detail later.

Energy needs vary according to activity level and state of health. Energy needs of sick patients can be significantly greater than predicted normal values. Energy needs for obese individuals are less because adipose tissue uses less energy than muscle. Energy needs should be reevaluated and adjusted whenever weight changes more than 10 lb.

RULE OF THUMB

To estimate the energy needs of an average adult in kilocalories per day, identify the goal and multiply the individual's actual body weight in kilograms times the factor listed as follows[27]:

Goal	Energy Needs (kcal/kg)
Weight maintenance	25-30
Weight gain	30-35
Weight loss	20-25

Indirect Calorimetry

Indirect calorimetry is the estimation of energy expenditure by measurement of O_2 consumption and CO_2 production. Data obtained can be used to assess a patient's metabolic state, to determine nutrition needs, or to assess response to nutritional therapy.[30] To guide practitioners in using indirect calorimetry, the American Association for Respiratory Care (AARC) has published the Clinical Practice Guideline: Metabolic Measurement Using Indirect Calorimetry During Mechanical Ventilation. Excerpts appear in Clinical Practice Guideline 23-1.[31]

In regard to the indications for indirect calorimetry, the determination of energy and protein needs by an empiric formula is sufficient for most patients. However, the use of indirect calorimetry improves nutritional care and reduces complications associated with underfeeding and overfeeding.[30] Specific clinical conditions supporting the need for indirect calorimetry as a tool in nutrition assessment are listed in Box 23-4.[30]

Box 23-4 Clinical Situations in Which Indirect Calorimetry May Be Indicated

- Patients with morbid obesity
- Patients who are difficult to wean from ventilatory support
- Patients for whom weight estimates are unclear
- Patients with severe malnutrition
- Patients with high level of stress
- Patients at the extremes of weight or age
- Patients failing to respond to nutrition support

Equipment and Technique

Good calorimetry results require extensive preparation. Box 23-5 outlines the key preparatory steps to be taken before testing.[32] Indirect calorimetry can be performed with a Douglas bag, a Tissot spirometer, and CO_2 and O_2 gas analyzers. The patient's expired gas is collected in the Douglas bag, where it is sampled for O_2 and CO_2 concentrations; the Tissot spirometer measures expired volume. Commercially available metabolic carts are much easier to use. These automated systems either use a mixing chamber or perform breath-by-breath analysis. The breath-by-breath method provides real-time data, which may aid in ensuring optimal measurement conditions, particularly in mechanically ventilated patients.[33]

Figure 23-1 shows the basic configuration for open-circuit indirect calorimetry during mechanical ventilation using a metabolic cart with mixing chamber. Gas sampled from the inspiratory limb of the ventilator circuit is assessed for fractional inspired oxygen (FiO_2) using a paramagnetic or zirconium oxide O_2 analyzer. Volume exhaled by the patient is measured using a flow transducer. The patient's exhaled gas enters a mixing chamber, from which a sample is drawn to measure fractional expired carbon dioxide ($FeCO_2$) by infrared analysis and fractional expired oxygen (FeO_2). Exhaled gas is returned to the ventilator after volume and gas concentration measurements. After all measurements are obtained, O_2 consumption, CO_2 production, and *respiratory quotient (RQ)* are computed using the equations shown in Box 23-6. *All measurements must be corrected to standard temperature and pressure and dry conditions (STPD) before computation.*[31] The values are used in the abbreviated Weir equation to determine REE:

$$REE = [(O_2 \times 3.9) + (CO_2 \times 1.1)] \times 1.44$$

Box 23-5 Preparation for Indirect Calorimetry

30 HOURS BEFORE TEST
- 24-Hour urine urea nitrogen collection (with sufficient time to receive result) if determination of carbohydrate, fat, and protein use desired

10 HOURS BEFORE TEST
- Patient fasting if measuring energy requirements; if feeding is continued, results will reflect the patient's energy expenditure in response to feeding (may be spuriously high if patient is being overfed)

4 HOURS BEFORE TEST
- Patient resting and avoiding physical activity, physical therapy, dressing changes

2 HOURS BEFORE TEST
- Endotracheal tube suctioned for the last time before test; further ventilator changes or suctioning avoided

1 HOUR BEFORE TEST
- Supine position, complete rest; analgesic or sedative administered if needed

23-1 Metabolic Measurement Using Indirect Calorimetry During Mechanical Ventilation

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

Metabolic measurements may be indicated:

- In patients with known nutrition deficits or derangements
- When patients fail attempts at weaning from mechanical ventilation to measure the O_2 cost of breathing in mechanically ventilated patients
- When the need exists to assess the $\dot{V}/\dot{Q}_2$ to evaluate the hemodynamic support of mechanically ventilated patients

CONTRAINDICATIONS

When a specific indication is present, there are no contraindications to performing a metabolic measurement using indirect calorimetry, unless short-term disconnection of ventilatory support for connection of measurement lines results in hypoxemia, bradycardia, or other adverse effects.

HAZARDS AND COMPLICATIONS

Performing metabolic measurements using an indirect calorimeter is a safe, noninvasive procedure with few hazards or complications. Under certain circumstances and with particular equipment, the following hazards or complications may be seen:

- Closed-circuit calorimeters may cause a reduction in alveolar ventilation secondary to increased compressible volume of the breathing circuit.
- Closed-circuit calorimeters may decrease the trigger sensitivity of the ventilator and result in increased patient work of breathing.
- Short-term disconnection of the patient from the ventilator for connection of the indirect calorimetry apparatus may result in hypoxemia, bradycardia, and patient discomfort.
- Inappropriate calibration or system setup may result in erroneous results causing incorrect patient management.

ASSESSMENT OF NEED

Metabolic measurements should be performed only on the order of a physician after review of indications (see earlier) and objectives.

ASSESSMENT OF TEST QUALITY

Test quality can be evaluated by determining whether:

- Respiratory quotient is consistent with the patient's nutrition intake.
- Respiratory quotient is in the normal physiologic range (0.67 to 1.3).
- Variability of the measurements of $\dot{V}O_2$ and $\dot{V}CO_2$ should be 5% or less for a 5-minute data collection.
- The measurement is of sufficient length to account for variability in $\dot{V}O_2$ and $\dot{V}CO_2$ if these conditions are not met.
- Outcome may be assessed by comparing the measurement results with the patient's condition and nutrition intake. Outcome also may be assessed by observation of the patient before and during the measurement to determine if the patient is at steady state.

MONITORING

The following should be evaluated during the metabolic measurement to ascertain the validity of the results:

- Clinical observation of the resting state
- Patient comfort and movement during testing
- Values in concert with the clinical situation
- Equipment function
- Results within the specifications of test quality (see earlier)
- FiO_2 stability

Measurement data should include a statement of test quality and list the current nutrition support, ventilator settings, FiO_2 stability, and vital signs.

*For the complete guidelines, see American Association of Respiratory Care: Clinical practice guideline. Respir Care 49:1073, 2004. http://www.rcjournal.com/contents/09.04/09.04.1073.pdf. Accessed June 1, 2014.

Box 23-6 Equations Used to Calculate $\dot{V}O_2$ and $\dot{V}CO_2$ Using the Gas-Exchange Method

$$\dot{V}O_2 = \dot{V}_E \times (3\,FiO_2 4) - (\dot{V}_E \times FeO_2)$$
$$\dot{V}CO_2 = \dot{V}_E \times FeCO_2$$
$$RQ = \dot{V}CO_2/\dot{V}O_2$$

Indirect calorimetry is more difficult to perform on spontaneously breathing patients, especially patients breathing supplemental O_2. Although a mouthpiece with nose clips or a mask can be used to collect expired gas, these items tend to alter the patient's steady state and invalidate results.[33] Instead, most clinicians recommend using a plastic canopy that covers the patient's head. Expired gases are cleared from the canopy by a preset flow of air; expired gas concentrations are sampled and corrected for the air dilution.

Because standard modes of O_2 therapy do not deliver a consistent FiO_2 to spontaneously breathing patients, special delivery systems must be used. To overcome this problem, the clinician can substitute a precise O_2 mixture for the gas used to clear the canopy. Alternatively, a large gas reservoir (e.g., a Douglas bag) can be placed between an O_2 flow source and the subject[33] to ensure a stable FiO_2 throughout the test procedure.

Problems and Limitations

Indirect calorimetry is a technically complex procedure requiring rigorous attention to both instrument and procedure quality

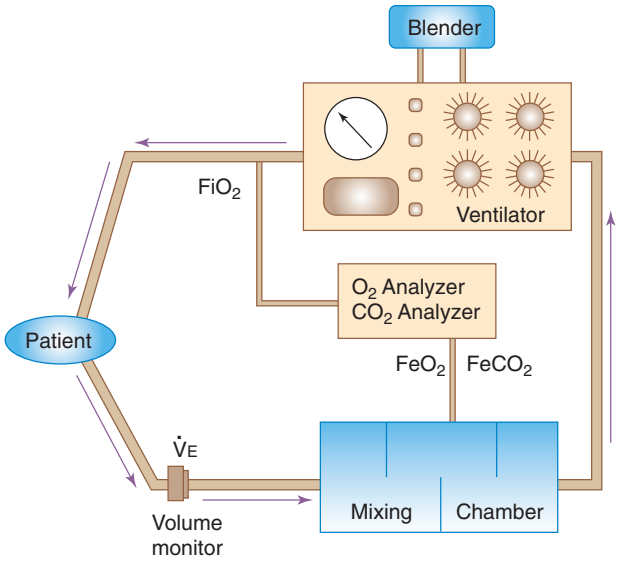

FIGURE 23-1 Open-circuit indirect calorimetry in a mechanically ventilated patient. Inspiratory gas is sampled for determination of FiO_2, volume is measured in the expiratory limb of the ventilator circuit, and mixed exhaled gas is drawn from the mixing chamber for analysis of FeO_2 and $FeCO_2$. *Arrows* indicate direction of gas flow. (Modified from Witte MK: Metabolic measurements during mechanical ventilation in the pediatric intensive care unit. Respir Care Clin N Am 2:573, 1996.)

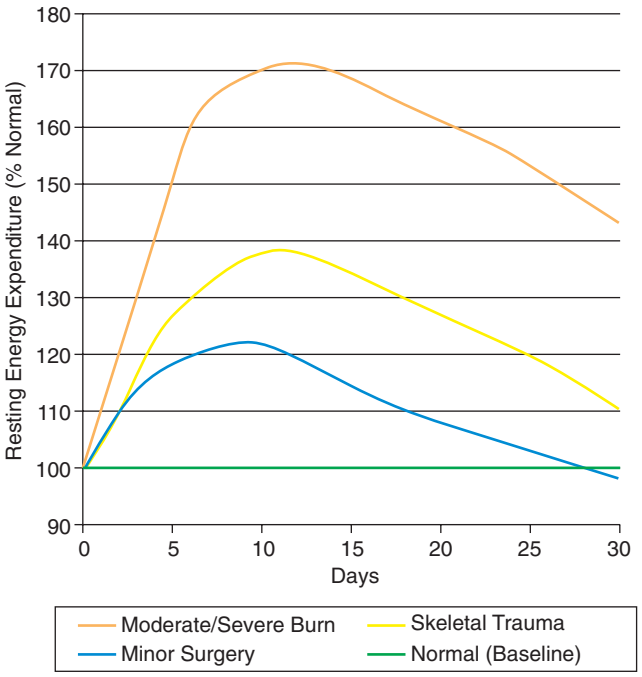

FIGURE 23-2 Resting energy expenditure variation during illness and injury.

control. Regarding instrumentation, small errors in measurements can result in large errors in calculated O_2, CO_2, and therefore energy expenditure. For this reason, the calorimeter's gas analyzers and volume measurement device must be properly calibrated before each patient use. Gas analyzers should be accurate to the hundredth percent and linear over the clinical range of O_2 concentrations.[32]

Regarding procedure quality control, it is essential that measurements be made during steady-state conditions. Although proper patient preparation (see Box 23-5) is helpful in this regard, steady-state conditions can be confirmed only during the test procedure itself. A common standard for ensuring steady-state conditions is five consecutive 1-minute averages with a variability of 5% or less.[33]

Perhaps the most significant problem in performing indirect calorimetry on mechanically ventilated patients is the presence of leaks (circuit, tracheal tube cuff, chest tubes).[31] Because any leak invalidates test results, no procedure should begin until a leak-free patient-ventilator-calorimeter system is confirmed. Other sources of error during open-circuit indirect calorimetry of mechanically ventilated patients are listed in Box 23-7.[31]

Box 23-7 Sources of Error During Open-Circuit Indirect Calorimetry of Mechanically Ventilated Patients

- Instability of FiO_2 because of changes in source gas pressure or ventilator or blender variability
- Delivery of high FiO_2 levels (>0.60)
- Inability to separate inspired and expired gases because of bias flow from flow-triggering systems, intermittent mandatory ventilation systems, or specific ventilator characteristics
- Presence of anesthetic gases or gases other than O_2, CO_2, and nitrogen in the ventilation system
- Presence of water vapor resulting in sensor malfunction
- Inappropriate calibration
- Adverse effect on functions of some ventilators (triggering, expiratory resistance, pressure measurement)
- Total circuit flow exceeding internal calorimeter flow (if using dilutional principle)
- Concurrent peritoneal dialysis or hemodialysis

Interpretation and Use of Results

Results obtained from indirect calorimetry are used to assess metabolic status and plan nutrition support. Energy expenditure varies during illness and injury (Figure 23-2),[34] which occurs in three phases: the stress response, the catabolic phase and the anabolic phase. Because of the changing metabolic rate, it is important to reassess metabolic needs when there is a change in clinical status. Indirect calorimetry is an important tool because it can demonstrate these changes in energy expenditure. Energy expenditure can vary on a daily basis by 15% to 30%.[33]

In regard to assessing metabolic status, the first step is to compare the REE obtained by calorimetry with the REE predicted by predictive equations. If the calorimetry REE is within 10% of the predicted value, the patient is considered **normometabolic.** Measured REEs greater than 10% above predicted values indicate a hypermetabolic state, whereas values less than 90% of predicted indicate hypometabolism.

TABLE 23-3

Traditional Interpretation and Use of the Respiratory Quotient

Value	Interpretation	General Nutrition Strategy
>1.00	Overfeeding	Decrease total kilocalories
0.9-1.00	Carbohydrate oxidation	Decrease carbohydrates or increase lipids
0.8-0.9	Fat, protein, and carbohydrate oxidation	Target range for mixed substrate
0.7-0.8	Fat and protein oxidation Starvation	Increase total kilocalories

NOTE: Acute hyperventilation or acute metabolic acidosis increases the respiratory quotient (RQ) and can lead to misinterpretation. Metabolism of ketones or ethyl alcohol decreases RQ to less than 0.7.

The second step in metabolic assessment is to interpret the RQ. The RQ is the ratio of moles of CO_2 expired to moles of O_2 consumed. Traditionally, the RQ has been used to determine substrate use, where carbohydrates have an RQ of 1.0, protein has an RQ of 0.82, and fat has an RQ of 0.7. Table 23-3 outlines the basic significance of the RQ relative to substrate use and traditional nutrition strategies.[33] RQ has been shown to have low sensitivity and reduced specificity in critically ill patients.[35,36] This finding limits the RQ as an indicator for substrate use and should be used only as a measure of test validity. If the RQ is outside its physiologic range of 0.67 to 1.3, this should alert the clinician to assess the validity of the study.

RULE OF THUMB

RQ	0.67 to 1.3	Ideal range for test validity

Alternative Resting Energy Expenditure Measures

In patients with pulmonary artery catheters, REE can be measured using a modification of the Fick equation[37]:

$$\text{REE (kcal/day)} = \text{Cardiac output} \times \text{Hemoglobin} \times (SaO_2 - S\bar{v}O_2) \times 95.18$$

In a patient with cardiac output of 4.2 L, hemoglobin of 11 g/dl, SaO_2 of 89%, and SVO_2 of 69%, the REE would be computed as follows:

$$\text{REE} = 4.2 \times 11 \times (0.89 - 0.69) \times 95.18$$
$$\text{REE} = 4.2 \times 11 \times (0.20) \times 95.18$$
$$\text{REE} = 879 \text{ kcal/day}$$

MINI CLINI

Comparison of Resting Energy Expenditure from Predictive Equations and Indirect Calorimetry

PROBLEM: A 57-year-old male construction worker fell three stories and after being intubated and mechanical ventilation initiated was admitted to the intensive care unit for multiple orthopedic injuries, several rib fractures, and a pulmonary contusion. On hospital day 2, after the patient was stabilized, a nasogastric feeding tube was placed and a nutrition consult was requested for enteral nutrition recommendations. Anthropometrics: Height: 5 ft, 9 inches; measured body weight: 127.3 kg; BMI: 43.8 kg/m^2.

The dietitian used and compared the follow predictive equations to determine the patient's energy expenditure:

Predictive Equation:	kcal/day
Harris-Benedict × 1.3-1.6*	2269-2792
Mifflin-St. Joer × 1.3	2718
Ireton-Jones	3081
Penn State	2137

*Factor to correct for stress and/or activity levels.

The initial goal recommended by the dietitian for the tube feeding would provide 2280 calories. An indirect calorimetry study was also requested by the dietitian because the patient is a perfect candidate for the indirect calorimetry because of his BMI and clinical status.

The indirect calorimetry study was conducted on a weekly basis and the results were as follows:

Hospital Day	Measured Metabolic Rate (kcal/day)	RQ
3	1980	1.1
10	3150	0.83
17	2700	0.85

Interpret the results and compare to the predictive equations. Based on the results, suggest what changes would be made.

DISCUSSION: The following conclusions can be made based on retrospective data review. Overall, the predictive equations estimations vary widely. Initially the Penn State equation was the most accurate equation compared to the indirect calorimetry study results. The RQ is within physiologic range of 0.67 to 1.3, suggesting a valid study; however, it further indicates the patient is possibly being overfed. As a result the tube feed goal was adjusted to provide 1980 calories to match the patient's current metabolic phase. However, as the patient moved into the catabolic phase, if the patient continued to receive 2280 calories as initially recommended by the dietitian (or the adjusted level of 1980 calories) and subsequent indirect calorimetry was not done on day 10, resulting in a tube feed increase to 3150 calories, the patient would be significantly underfed. Finally, entering into the anabolic phase, the patient's energy expenditure begins to decrease, as shown by the indirect calorimetry on day 17. As a result, the tube feed regimen should be further adjusted (decreased) to match the measured metabolic rate.

Modified from Wooley JA, Frankenfield D: Energy. In: Mueller CM, Merritt RJ, McClave S, et al, editors: The ASPEN adult nutrition support core curriculum, ed 2, Silver Spring, MD, 2012, American Society for Parenteral and Enteral Nutrition.

RULE OF THUMB

Although predictive equations are highly useful tools in calculating a patient's energy expenditure needs, they do not always replace the need for performing indirect calorimetry, which is generally more accurate and provides additional information, including calculation of the RQ.

GENERAL ASPECTS OF NUTRITION SUPPORT

The primary goal of nutrition support is the maintenance or restoration of lean body (skeletal muscle) mass. This goal is accomplished by (1) meeting the patient's overall energy needs and (2) providing the appropriate combination of substrates to do so. The route of administration used to provide the support is also important.

Meeting Overall Energy Needs

When the patient's REE is derived, it needs to be adjusted to account for variations in activity and stress levels. If using a predictive equation, such as the Harris-Benedict or Mifflin-St. Joer equations, the predicted REE should be corrected for stress, activity levels, or both.[20] When the REE is derived from the Penn State equations or indirect calorimetry, a stress or activity factor should not be used.

Insufficient Energy Consumed

Malnutrition from undernutrition results from insufficient energy (calorie) intake over time. This insufficient intake leads to a state of impaired metabolism in which the intake of essential nutrients falls short of the body's needs. Certain factors may place a patient at risk for malnutrition (Box 23-8).

Protein-Energy Malnutrition

Protein-energy malnutrition (PEM) has adverse effects on respiratory musculature and the immune response.[24] PEM may be either primary or secondary. Primary PEM results from inadequate intake of calories, protein, or both and is typically seen only in developing countries.[20]

Secondary PEM is due to underlying illness. Illness may cause (1) decreased caloric or protein intake (e.g., anorexia, dysphagia), (2) increased nutrient losses (e.g., malabsorption or diarrhea), and (3) increased nutrient demands (e.g., injury or infection).[38]

Box 23-8 Patients at High Risk for Malnutrition

- Underweight (BMI <18.5) or recent loss of 10% or greater of usual body weight
- Poor intake: Anorexia, food avoidance (e.g., psychiatric condition), nothing allowed by mouth (NPO) status for greater than 5 to 7 days
- Protracted nutrient losses: Malabsorption, enteric fistulas, draining abscesses or wounds, or renal dialysis
- Hypermetabolic states: Sepsis, protracted fever, extensive trauma, or burns
- Chronic use of alcohol or drugs with antinutrient or catabolic properties: Steroids, antimetabolites (e.g., methotrexate), immunosuppressants, antitumor agents
- Impoverishment, isolation, advanced age, limited mobility

RULE OF THUMB

Fifty percent of hospitalized patients present with secondary PEM.

When PEM is due to inadequate nutrient intake or excessive loss, the body responds by decreasing its metabolic rate, ventilatory drive, thyroid function, and adrenergic activity.[38] As calorie intake decreases, energy for metabolic processes is initially supplied by converting liver glycogen stores into glucose *(gluconeogenesis)*. However, liver reserves of glycogen are adequate for less than 1 day at rest and only a few hours during exercise.[14] Thereafter endogenous fat stores are mobilized in the form of free fatty acids *(ketogenesis)*. When fat stores are depleted, nutrient needs must be met by catabolizing skeletal muscle protein. This type of PEM usually manifests as a gradual wasting process, as seen in patients with chronic diseases such as cancer and emphysema. The primary clinical sign is progressive weight loss.

When PEM results from increased nutrient demand, metabolism, thyroid function, and adrenergic activity all increase. Visceral protein levels tend to decrease early in the course of illness and are associated with impaired immunity.[37] This type of PEM typically occurs with acute catabolic disease, such as in sepsis, burns, or trauma. The two types of PEM are often referred to as *marasmus* and *kwashiorkor,*[6,20] as previously described (see Table 23-1).

Micronutrient Malnutrition

The same problems causing PEM can produce deficiencies in micronutrients. Deficiencies of nutrients that are stored only in small amounts (e.g., water-soluble vitamins) or lost through external secretions (e.g., zinc in diarrhea, fluid or burn exudate) are quite common.[20] Although the causes and results of micronutrient deficiencies are beyond the scope of this chapter, a few of the most common problems are described.

Signs of scurvy (vitamin C deficiency) may be observed in chronically ill patients and patients with alcoholism hospitalized for acute illnesses. Low folic acid blood levels are common whenever illness, alcoholism, or poverty is present. Alcoholism is also associated with thiamin deficiency. Zinc deficiencies impair immunity, clotting, and slow wound healing. Magnesium deficiencies can result in cardiovascular, neurologic, and electrolyte abnormalities (hypocalcemia, hypokalemia) and decreased respiratory muscle strength. Hypophosphatemia is seen frequently with cachexia or alcoholism, especially in patients receiving intravenous glucose or taking antacids. Severe

Box 23-9 Respiratory Consequences of Malnutrition

RESPIRATORY MUSCLE DYSFUNCTION
- Loss of diaphragmatic mass and contractility
- Loss of accessory muscle mass and contractility

EFFECT ON CONTROL OF VENTILATION
- Decreased hypoxic and hypercapnic response

INCREASED INCIDENCE OF RESPIRATORY INFECTIONS
- Decreased lung clearance mechanisms
- Decreased secretory immunoglobulin A
- Increased bacterial colonization

CHANGES IN LUNG PARENCHYMAL STRUCTURE
- Unopposed enzymatic digestion
- Reduced production of surfactant

hypophosphatemia can result in decreased muscle strength and contractility and acute cardiopulmonary failure.

Respiratory Consequences of Malnutrition

Malnutrition affects all organ systems. In addition, malnutrition seems to interact with disease processes to increase the morbidity and mortality of respiratory, cardiac, and renal failure.[39] Specific effects of malnutrition on the respiratory system are listed in Box 23-9.[40]

Approximately one-third of all patients with acute respiratory failure have malnutrition. In these patients, the underlying diseases (e.g., sepsis, burns, trauma) increase energy expenditure and promote skeletal muscle catabolism. These patients are prone to hypercapnia and can be difficult to wean from mechanical ventilation. Malnourished patients who require mechanical ventilation also have higher mortality rates than patients with normal nutrition status.[41]

Malnutrition also plays a role in chronic obstructive pulmonary disease (COPD). The combined effect of increased energy expenditure (because of high work of breathing) and inadequate caloric intake contributes to a marasmus-type malnutrition. The resulting progressive muscle weakness and dyspnea can limit caloric intake further, as can several profound psychosocial factors. Box 23-10 summarizes factors contributing to malnutrition in patients with COPD.[42] The RT may notice signs that could lead to malnutrition in patients for whom they provide care (Box 23-11).

Box 23-10 Underlying Causes of Malnutrition in Patients With Chronic Obstructive Pulmonary Disease

INCREASED ENERGY EXPENDITURE
- Increased caloric cost of breathing
- Increased systemic inflammation
- Thermogenic effect of medications (e.g., bronchodilators)

INADEQUATE CALORIC INTAKE
- Dyspnea while eating
- Chewing and swallowing difficulties
- Early satiety
- Taste alterations from medications, nasal cannulas, or a tracheostomy
- Suppressed appetite from medications (e.g., theophylline)

PSYCHOSOCIAL FACTORS
- Depression
- Poverty
- Difficulty shopping
- Tire easily when preparing food

Box 23-11 Nutrition Status Changes Observable by Respiratory Therapists

- Mechanics of breathing can be affected by cachexia, obesity, pregnancy.
- Increased coughing effort may indicate poor nutrition.
- Viscosity of sputum, jugular venous pressure, ascites, and edema suggest fluid imbalance.
- Lung crackles relate to fluid overload or oncotic pressure changes (loss of blood protein).
- Wheezing may be associated with food intolerances, alcohol, or aspirated food particles.
- Late inspiratory crackles of atelectasis may result from decreased surfactant production from malnutrition.
- S_3 heart sounds of congestive heart failure may indicate fluid imbalance.
- S_4 heart sounds may be associated with severe anemia.
- Pulmonary function measures may be related to:
  FVC or FEV_1 decrease: Severe malnutrition
  FVC: Excess fat weight
  PEP and PIP decrease: Poor nutrition
  Lung compliance: Fluid and serum albumin changes acutely or chronic malnutrition
- Arterial blood gas values may be related to:
  $PaCO_2$ increases: Excess glucose, inadequate ventilation from lack of muscle energy
  O_2 saturation, O_2 content, hemoglobin: Nutrition status
- Meal acceptance may be related to visible equipment—suction bottles, sputum specimens.
- Lack of O_2 may increase difficulty of eating—ensure availability of O_2 via cannula if needed.

FEV_1, Forced expiratory volume in 1 second; *FVC,* forced vital capacity; *PEP,* positive expiratory pressure; *PIP,* peak inspiratory pressure.

Providing the Appropriate Combination of Substrates

After estimating energy requirements, the physician or registered dietitian determines the appropriate combination of macronutrients (protein, carbohydrate, fat) needed.

Protein

Amino acids or proteins are essential to maintaining or restoring lean body mass. Because illness usually increases protein catabolism and protein requirements, the Recommended Dietary Allowance (RDA) of 0.8 g/kg/day is generally insufficient for sick patients. Based on the assessment of the protein catabolism rate, protein intake may need to be doubled or tripled above the RDA (1.5 to 2.5 g/kg/day).[43] Ideally, approximately

20% of a patient's estimated caloric needs should be provided by protein. Higher percentages of protein may be needed in patients who are cachexic, have severe infections, or are otherwise critically ill. However, whenever high protein intake is administered, the patient should be monitored for progressive **azotemia** (blood urea nitrogen >100 mg/dl).[14]

Too much protein is harmful, especially for patients with limited pulmonary reserves. Excess protein can increase O_2 consumption, REE, minute ventilation, and central ventilatory drive.[43] In addition, overzealous protein feeding may lead to symptoms such as dyspnea.

Carbohydrate

Carbohydrates are the main source of fuel for the body. Adequate amounts of carbohydrates and fat help prevent protein catabolism. Glucose (dextrose) is the most commonly administered intravenous carbohydrate. Total calories per day from carbohydrates can range from 45% to 65%. In an average-sized patient, daily glucose provision is generally estimated at 200 g/day.[44]

For patients with pulmonary disease or patients requiring mechanical ventilation, high carbohydrate loads were initially blamed for increased CO_2 production and the RQ, resulting in increased ventilatory demand, O_2 consumption, and work of breathing.[45] More recent evidence indicates that this problem is probably more closely related to total calorie load (overfeeding) than to the proportion of carbohydrate in the diet.[46,47] Therefore overfeeding should be carefully avoided in patients with pulmonary disease and patients requiring mechanical ventilation.

Fat

The remaining calories (20% to 30%) should be provided from fat.[48] A minimum of 2% to 4% is needed to prevent essential fatty acid deficiency. Fat intakes greater than 50% of energy needs are associated with fever, impaired immune function, liver dysfunction, and hypotension.[14]

The initiation of nutrition support is determined by the patient's nutrition status and the estimated length of time the patient will be unable to consume a diet by mouth to meet nutrition needs. To ensure satisfactory nutrition and metabolic response, early enteral nutrition begun within 24 to 48 hours provides significant benefits to critically ill patients, including reduced infectious complications and lengths of stay.[49]

RULE OF THUMB

Begin enteral nutrition within 24 to 48 hours of intubation

ROUTES OF ADMINISTRATION

The two primary routes for supplying nutrients to patients are *enteral* (oral and tube feeding) and *parenteral* (peripheral or central venous alimentation). Box 23-12 provides guidelines for initiating nutrition support as recommended by the American Society for Parenteral and Enteral Nutrition.[49-51]

Box 23-12 Guidelines for Initiation of Nutrition Support

CLINICAL SETTINGS IN WHICH ENTERAL NUTRITION SHOULD BE PART OF ROUTINE CARE

- Protein-calorie malnutrition (>10% loss of usual weight) with inadequate oral intake of nutrients for previous 5 to 7 days
- Normal nutritional status with less than 50% of required nutrient intake orally for previous 7 to 10 days
- Severe dysphagia
- Moderate to severe pancreatitis (bowel rest anticipated beyond 5 to 7 days)
- Burns of greater than 15% total BSA in infants and children and greater than 25% total BSA in older children and adults
- Massive small bowel resection in combination with administration of total parenteral nutrition
- Low output (<500 ml/day) enterocutaneous fistulas

CLINICAL SETTINGS IN WHICH PARENTERAL NUTRITION SHOULD BE PART OF ROUTINE CARE

- Patients with inability to absorb nutrients by the GI tract
- Severe malnutrition in the face of a nonfunctional GI tract (within 1 to 3 days)
- Severely catabolic patients with or without malnutrition when the GI tract is not usable within 7 to 10 days

From Mueller CM, Merritt RJ, McClave S, et al, editors: The ASPEN adult nutrition support core curriculum, ed 2, Silver Spring, MD, 2012, American Society for Parenteral and Enteral Nutrition.
BSA, Body surface area; *GI,* gastrointestinal.

Enteral Feeding

Enteral feedings are the route of choice: "If the gut works, use it." The enteral route is safer and cheaper than the parenteral route. Enteral feeding stimulates gut hormones, subjects nutrients to the absorptive and metabolic controls of the intestinal tract and liver, and produces less hyperglycemia (providing for better immune function) than the parenteral route. In addition, the buffering capacity of enteral feeding can improve resistance against stress ulcers.[52] Finally, enteral feeding maintains a more normal intestinal mucosa than the parenteral route (the intestinal mucosa may undergo atrophy during parenteral nutrition).[53]

Enteral Tube Routes. There are six primary routes for enteral tube feeding: (1) nasogastric, (2) nasoduodenal, (3) nasojejunal, (4) gastrostomy, (5) jejunostomy, and (6) esophagotomy. Site selection depends on GI function, respiratory status, surgical state, and anticipated length of time the patient will be receiving tube feeding.

Gastric feedings are indicated if there are no physiologic factors affecting GI function (e.g., gastroparesis, delayed gastric emptying, or obstruction or upper GI tract surgery). Small bowel (duodenum and jejunum) feedings are indicated if the upper GI tract cannot be used. Intestinal feeding tube placement is recommended to minimize aspiration risk because it is believed to decrease the risk for gastric distention and gastroesophageal reflux; however, this remains controversial.[54]

Nasogastric and *nasoenteric* tubes are indicated for short-term enteral therapy (<30 days). The tubes are placed at the bedside and generally have a large internal diameter, which helps deliver viscous feedings and medications. *Nasoduodenal* and *nasojejunal* tubes are placed through the nose past the pylorus.

Long-term feeding tubes can be placed endoscopically and surgically. Percutaneous endoscopic placement of a feeding tube can be done to establish gastric (percutaneous endoscopic gastrostomy) or intestinal (percutaneous endoscopic jejunostomy) access. This method is preferred to surgical placement because of reduced costs associated with operating room time and the need for anesthesia.[55] Surgical laparotomy is indicated if endoscopy is contraindicated.

Tube Feeding Administration. There are three basic methods of tube feeding administration: bolus, intermittent, and continuous drip. *Bolus* feedings involve the rapid infusion of 250 to 500 ml of feeding several times daily. Feedings are provided by a syringe into the feeding tube port. There is an increased risk for aspiration associated with bolus feedings because of the rapid infusion of formula into the stomach. Nausea, vomiting, abdominal pain, and distention can develop in conjunction with this feeding route. This feeding method can be used only with gastric tubes and is primarily applied to patients who are stable and patients receiving enteral nutrition support at home.

Intermittent feedings are also administered several times per day, but are infused over at least 30-minutes. Feedings can be given only into the gastric cavity. Intermittent feedings are associated with the same problems as bolus feedings.

Continuous drip infusion provides a constant, steady flow of formula at a predetermined rate for a set period, generally 12 to 24 hours per day. Drip regulators, roll clamps, or pumps are used to control rates. Because the small bowel lacks storage capacity, feedings delivered beyond the pylorus must be provided by the continuous drip method. This method is preferred for critically ill patients because it is associated with reductions in gastric residual volume, abdominal distention, gastroesophageal reflux, and pulmonary aspiration.[56]

Trophic feeding is the practice of feeding minimal amounts (10 to 30 ml/hr) of enteral nutrition with the primary goal to maintain GI function and integrity. Studies in mechanically ventilated patients with respiratory failure or ARDS show that trophic feedings resulted in fewer episodes of GI intolerance but resulted in similar clinical outcomes compared to early advancement to full enteral feedings.[57]

Enteral Formula Selection. Selection of an enteral formula depends on the patient's medical and surgical state, GI function, energy and nutrient needs, and route of administration. There are eight broad categories of enteral formulas: oral supplements, blenderized, whole-protein lactose-free, fiber containing, nutrient-dense, elemental, disease-specific, and modular. Table 23-4 describes the indications for the various enteral formulas and lists examples of commercial preparations.

Complications of Enteral Therapy. Complications associated with enteral nutrition are categorized as GI, mechanical, or metabolic. These may be avoided by careful selection of formulas, proper administration, and consistent patient monitoring.

Pulmonary aspiration is of particular concern in a critically ill patient with respiratory disease. Aspiration can occur because of one or more of the following factors: if the patient is lying flat, has a depressed gag reflux or vocal cord dysfunction, has delayed gastric emptying, or has improper tube placement. The incidence of pulmonary aspiration varies depending on the patient population and technique used to identify aspiration in the tube-fed patient. The three following practices are proved to minimize aspiration risk[51]: (1) raise the head of the bed at

TABLE 23-4

Enteral Product Reference Guide

Category	Indications	Examples
Oral supplements	Given with an oral diet to increase calorie and protein intake	Boost,* Ensure,† Carnation Breakfast Essentials
Standard/Polymeric	Made with intact nutrients. May vary in concentration (1.0-2.0 kcal/ml) and fiber content	Osmolite,† Jevity,† Promotel HN,† Nutren,† Isosource,† Fibersource,* Replete*
Blenderized	Made from natural foods and usually lower in sucrose and corn syrup than other formulas; beneficial if intolerance to synthetic formulas exists	Compleat,* Compleat Pediatric*
Elemental and semi-elemental	Impaired gastrointestinal function with impaired ability to digest or absorb intact nutrients	Peptamen,† Peptamen 1.5,† Tolerex,† Vivonex,† Vital,* Vital 1.5,* Vital HN*
Disease specific	Liver disease; renal disease; pulmonary disease; glucose intolerance; immune-enhancing; critically ill obese	Nutrihe*; Nepro,* NovaSource Renal,† Suplena,* Renalcal†; Pulmocare,* Oxepa,* Nutren Pulmonary†; Diabetisource AC,† Glucerna,* Glytrol†; Impact,† Pivot*; Peptamen Bariatric† Vital High Protein**
Modular	Need to modify a single nutrient (carbohydrate, protein, fat)	Beneprotein,* Benecalorie,† Promod,* Glutasolve,† Arginaid,†, MCT oil†

†Abbott Nutrition.

least 30 degrees, (2) use of bowel motility agents such as metoclopramide, and (3) using postpyloric feeding with the continuous drip method in patients at risk for gastric atony or gastroesophageal reflux. Tube placement always should be verified by x-ray examination before feeding. Pulmonary aspiration has not been proved to be a result of high gastric residual volumes.[58]

Aggressive suctioning of oropharyngeal secretions can help prevent aspiration. The greatest risk is in patients with endotracheal tubes. Endotracheal tubes increase aspiration risk because they alter sensation, impair glottic closure, increase secretion volume, and act as "wicks" to allow secretions to enter the airway.[59] The use of special endotracheal tubes that provide continuous, low-level suctioning of subglottic secretions reduce the microaspiration common in tube-fed patients.[60] The use of blue dye to detect aspiration is no longer a standard practice because of numerous problems, including a U.S. Food and Drug Administration Public Health Advisory issued in 2003. Blue discoloration of body parts and fluids followed by refractory hypotension, metabolic acidosis, and death were reported in some patients receiving blue food dye.[61]

Parenteral Nutrition Support

When it is impossible to provide nutrition support through the GI tract, intravenous or parenteral nutrition support may be needed. Parenteral nutrition support is administered through a peripheral or central vein. Ideally, the vascular access line should be restricted to nutrition use and maintained as a sterile route. Because the volume and concentration of nutrients given through a small vein are limited, peripheral parenteral nutrition is considered only for short-term support. Mechanical, infectious, and metabolic complications have been reported in patients fed parenterally.[62]

NUTRITION SUPPORT IN SPECIFIC CIRCUMSTANCES

Details on the appropriate nutrition support provided to all the various types of patients seen by RTs are beyond the scope of this chapter. This section emphasizes key points related to nutrition support and management of the most common conditions encountered by practitioners.

General Guidelines for Critically Ill Patients

The general goal of nutrition support in critically ill patients is to provide the energy and protein necessary to meet metabolic demands and to preserve lean body mass. Nutritional support is also an important therapy in critical illness because it attenuates the metabolic response to stress, prevents oxidative cellular injury, and modulates the immune response. Nutritional modulation of the stress response includes early enteral nutrition, appropriate macronutrient and micronutrient delivery, and meticulous glycemic control.[57]

Table 23-5 outlines the general guidelines recommended to achieve these goals.[49]

TABLE 23-5

General Nutrition Guidelines for Chronically Critically Ill Patients

Category	Guideline
Route of delivery	Enteral nutrition is preferred when the gut is functional. Start 24-48 hr after resuscitation. If gut is not functional, consider starting parenteral nutrition. If enteral nutrition cannot provide goal within 7-10 days, consider starting parenteral nutrition.
Energy need	Indirect calorimety should be used when available for estimation of energy goal. Target is 65% of goal within the first week. Hypocaloric feeding recommended for obese (11-14 kcal/kg).
Protein	Provide supplemental protein to achieve 1.2-2.0 g/kg/day; 2.0-2.5 g/kg/day for obese.
Glycemic control	An intensive insulin therapy protocol should be in place Goal: 110-150 mg/dl
Micronutrients	Adequate vitamins and minerals such as vitamins A, B_6, C, E; potassium; magnesium; zinc; iron; selenium; phosphate
Fluid	Approximately 1 ml/kcal
Specialized nutrients	Glutamine (may improve nitrogen stores), arginine (may improve immune system in surgical patients), and omega-3 fatty acids (may reduce inflammatory processes in ARDS/ALI)

Compiled from: McClave SA, Martindale RG, Vanek VW, et al, Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition: Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient. JPEN J Parenter Enteral Nutr 33:277, 2009.
ALI, Acute lung injury; *ARDS,* acute respiratory distress syndrome.

Systemic Inflammatory Response Syndrome

The *systemic inflammatory response syndrome (SIRS)* underlies many critical illnesses, including *sepsis* and *acute respiratory distress syndrome (ARDS)*. Metabolism in systemic inflammatory response syndrome is characterized by increased total caloric requirements, hyperglycemia, triglyceride intolerance, increased net protein catabolism, and increased macronutrient and micronutrient requirements.[39]

Micronutrient requirements also are increased in SIRS. Because of the potential high losses of potassium, zinc, magnesium, calcium, and phosphorus, serum levels of these minerals need to be closely monitored and maintained within the normal range.[39]

Mechanical Ventilation

Adequate nutrition support is crucial for ventilator-dependent patients. During acute illness, proper nutrition helps prevent the loss of lean body mass. After the resolution of the acute phase of illness, good nutrition helps the muscles regain strength and improves the likelihood of successful weaning.[20]

For most patients requiring ventilatory support, following the guidelines provided in Table 23-5 is generally sufficient. As

always, care must be taken to avoid overfeeding and the increased ventilatory demands that follow. Patients with COPD present a special situation, in terms of both nutrition needs and ventilatory support. More details regarding these patients are provided in the next section.

Nutrition support alone is insufficient to ensure weaning of ventilator-dependent patients. For these patients, appropriate nutrition may need to be combined with a tailored exercise program designed to strengthen and retrain muscles. Methods used to wean ventilator-dependent patients are discussed in detail in Chapter 52.

Chronic Obstructive Pulmonary Disease

Malnutrition is common in patients with COPD and can occur in 30% to 60% of inpatients and 10% to 45% of outpatients.[63] Progressive weight loss from malnutrition is common in patients with COPD and appears to have two causes: prolonged periods of insufficient caloric intake coupled with increased nutritional needs resulting from increased metabolism demand associated with chronic disease. Both malnutrition and low body weight seem to be factors associated with a poor prognosis.[64]

The degree of weight loss generally correlates with deterioration of pulmonary function values. COPD can create a cycle in which respiratory dysfunction promotes weight loss and weight loss further hinders respiratory function.[40] Figure 23-3 illustrates the cycle.

Factors contributing to poor intake include fatigue, shortness of breath, frequent coughing, early fullness because of pressure on the abdominal cavity, increased dyspnea during eating, side effects from medications (nausea, vomiting, diarrhea, dry mouth, taste changes), and depression. The increased metabolic rate is due to the added effort to breathe and frequent respiratory infections, both of which increase calorie and fluid needs.

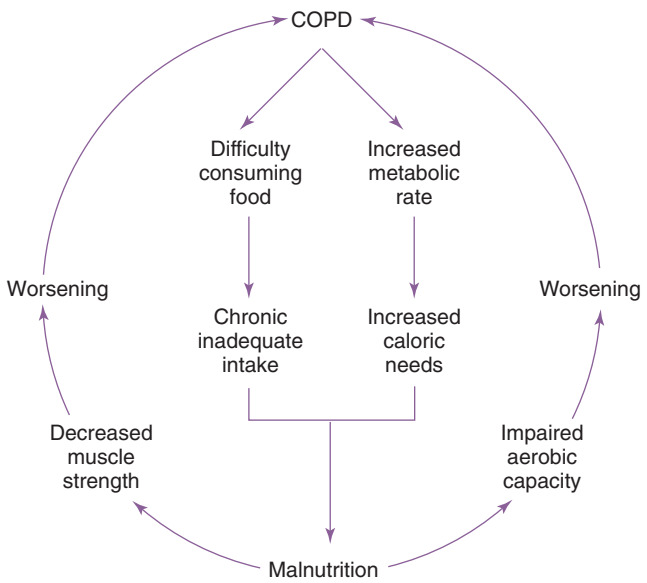

FIGURE 23-3 The vicious cycle of respiratory impairment and malnutrition in chronic obstructive pulmonary disease.

The goal is to increase nutrient intake carefully without overfeeding. Cachexic patients with COPD should be refed cautiously.[65] Functional capacity and the patient's overall health status may improve with an anabolic stimulus, such as exercise, along with nutrition supplementation.[66]

In patients with COPD, satisfactory conventional macronutrient allocations are 15% to 20% as protein, 50% to 60% as carbohydrates, and 20% to 30% as fat. Specialized nutrition formulation consisting of high fat and, reduced carbohydrate have been marketed for patients with COPD; however, there is little evidence to support its use.[63,67] As previously stated, setting an appropriate total calorie load is more important than fine-tuning the ratio of carbohydrates to fat.

Given the positive link between dietary intake and knowledge of diet and health, good patient education is crucial. Patients should be taught to select easy-to-consume, calorically dense foods. Emphasis should be placed on small, frequent feedings, and encourage use of high-calorie, high-protein nutrition supplements. Other considerations in providing nutrition support to patients with COPD are listed in Box 23-13.[68-70]

When patients with COPD are hospitalized for ventilatory failure, the clinical outcome is affected by nutrition support. Patients who receive adequate nutrition support are more readily weaned from mechanical ventilation than patients with diets deficient in protein and energy.

MINI CLINI

Methods to Increase Nutrient Intake in Chronic Obstructive Pulmonary Disease

PROBLEM: An 82-year-old woman with known history of COPD has been hospitalized for several days and treated with multiple inhalers and nebulizers. She lost 12 pounds in the last month. She presents with muscle wasting, sparse hair, dry and cracked lips and skin. She reports decrease in oral intake because of shortness of breath and decreased appetite satiety. The dietitian receives a nutrition consult to evaluate the patient's nutrition status and provides nutrition counseling to prevent further weight loss.

List sample foods and potential strategies the dietitian reviewed with the patient that the RT can reinforce with the patient.

- Dried fruits, nuts, Popsicles, milkshakes
- Whole milk or skim milk powder added to milk, soup, gravies
- Nutrition supplements
- Puddings, custards, yogurt, ice cream
- Cream soups
- Add butter or oil or cheese to vegetables, soups, mashed potatoes, and rice
- Casseroles and egg dishes with sauces and gravies
- Peanut butter or other nut butters, spread on bananas, celery, crackers, apple slices, breads

Box 23-13 Nutrition Support for Patients With Pulmonary Disease

- Perform a complete nutrition assessment.
- Evaluate energy needs and provide an appropriate amount (do not overfeed or underfeed).
- Ensure protein balance.
- Monitor fluids and electrolytes, especially phosphorus.
- Evaluate vitamin and mineral status as indicated.

Asthma

Because breathing and eating are mutually exclusive, feeding should generally be avoided during severe asthma attacks. However, nutrient-dense, small meals high in quality protein, calories, vitamins, and minerals are recommended during prolonged, mild asthma attacks. Foods identified as allergens (most often milk, eggs, seafood, and fish) should be avoided. Fluid intake should be generous, unless contraindicated. Saturated fats may aggravate the airway, whereas omega-3 fatty acids may be beneficial; these are available in walnuts and flaxseed if the patient is allergic to fish.[68]

Cystic Fibrosis

Exocrine gland dysfunction associated with cystic fibrosis causes chronic lung disease with recurrent infections. The same disturbance causes pancreatic insufficiency. Metabolic problems in patients with cystic fibrosis are similar to metabolic problems in patients with COPD, with reduced intake and increased metabolic needs. However, the associated pancreatic insufficiency with cystic fibrosis also causes malabsorption of all nutrients, especially fat. The administration of pancreatic enzyme supplements with meals enhances absorption but requires trial and error and intense education on how to balance the amount of food and the intake of enzymes. In addition, the time spent in various treatment programs reduces the ability to consume small frequent feedings.

The goals of nutrition management in cystic fibrosis are to (1) maximize nutrition intake through calorically dense foods, (2) balance intake with pancreatic enzymes to maximize absorption, and (3) provide a nutrition plan that meets the patient's changing clinical and psychosocial status.[68] Use of calorically dense foods and nutrition supplements consumed throughout the day has proved helpful in achieving weight gain.[68] Because of the malabsorption of micronutrients, vitamin and mineral supplementation is encouraged, especially of fat-soluble vitamins.[68] Helping patients with cystic fibrosis achieve optimal nutritional health may minimize the decline in pulmonary function and improve their quality of life.[71]

SUMMARY CHECKLIST

- Nutrition assessment is the basis for developing a nutrition care plan.
- The components of a nutrition assessment include dietary history, anthropometry, biochemical indicators, nutrition-focused physical assessment, and client history.
- BMI is a comparison of weight to height used to determine underweight, healthy weight, overweight, obesity, or morbid obesity.
- Classifications of undernutrition, called *protein-energy malnutrition,* include kwashiorkor, marasmus, and a combination of the two (lack of circulating protein, starvation, and a mixture of the two).
- Laboratory values of albumin, transferrin, transthyretin, and retinal-binding protein may indicate malnutrition. CRP may be elevated during acute illness, indicating an inflammatory response and causing low values of serum proteins.
- The creatinine-height index reflects skeletal muscle mass.
- Nitrogen balance compares protein intake to nitrogen excretion in the urine.
- Observable signs in hair, eyes, lips, mouth and gums, skin, and nails may indicate malnutrition.
- Resting energy expenditure (REE) may be determined by the predictive equations or indirect calorimetry.
- Estimation of total caloric need involves multiplying the REE by a factor that accounts for activity and stressors.
- Indirect calorimetry involves measurement of whole-body $\dot{V}O_2$, $\dot{V}CO_2$, and respiratory quotient (RQ); results are used to assess a patient's metabolic state, determine nutrition needs, or assess response to nutrition therapy.
- RQ greater than 1.00 indicates overfeeding and the need to decrease total calories; RQ between the ranges of 0.67 to 1.3 should be used as an indicator of test validity.
- Malnutrition is a state of impaired metabolism in which the intake of essential nutrients is less than the body's needs; marasmus is malnutrition associated with inadequate nutrient intake (starvation), and kwashiorkor is the hypercatabolic form.
- Malnutrition can affect the respiratory system by causing loss of respiratory muscle mass and contractility, decreased ventilatory drive, impaired immune response, and alterations in lung parenchymal structure.
- Approximately one-third of all patients with acute respiratory failure have malnutrition, mainly the hypercatabolic form; these patients are prone to hypercapnia, can be difficult to wean from ventilatory support, and have higher mortality rates than patients with a normal nutrition status.
- In chronic lung disease, the combined effect of increased energy expenditure (secondary to increased work of breathing) and inadequate caloric intake contributes to a marasmus-type malnutrition.
- The primary goal of nutrition support is to maintain or restore lean body (skeletal muscle) mass by (1) meeting the overall energy needs of the patient and (2) providing the appropriate combination of macronutrients (protein, carbohydrate, and fat) and micronutrients (vitamins and minerals). Nutrition support also attenuates the metabolic response to stress, prevents oxidative cellular injury, and modulates the immune response.
- For most patients, a balance of 20% of daily calorie needs from protein, 50% to 60% from simple carbohydrate, and 20% to 30% from fat is adequate.
- Nutrients can be supplied enterally (oral and tube feeding) or parenterally (peripheral or central venous alimentation); the enteral route should be used whenever possible.

- The likelihood of aspiration during tube feedings can be minimized by raising the head of the bed at least 30 degrees, use of motility agents, and delivering the feeding beyond the pylorus using the continuous drip method.
- Nutrition support should be individualized according to patient needs and condition or disease process; accepted guidelines for SIRS, COPD, mechanical ventilation, asthma, and cystic fibrosis should be followed.

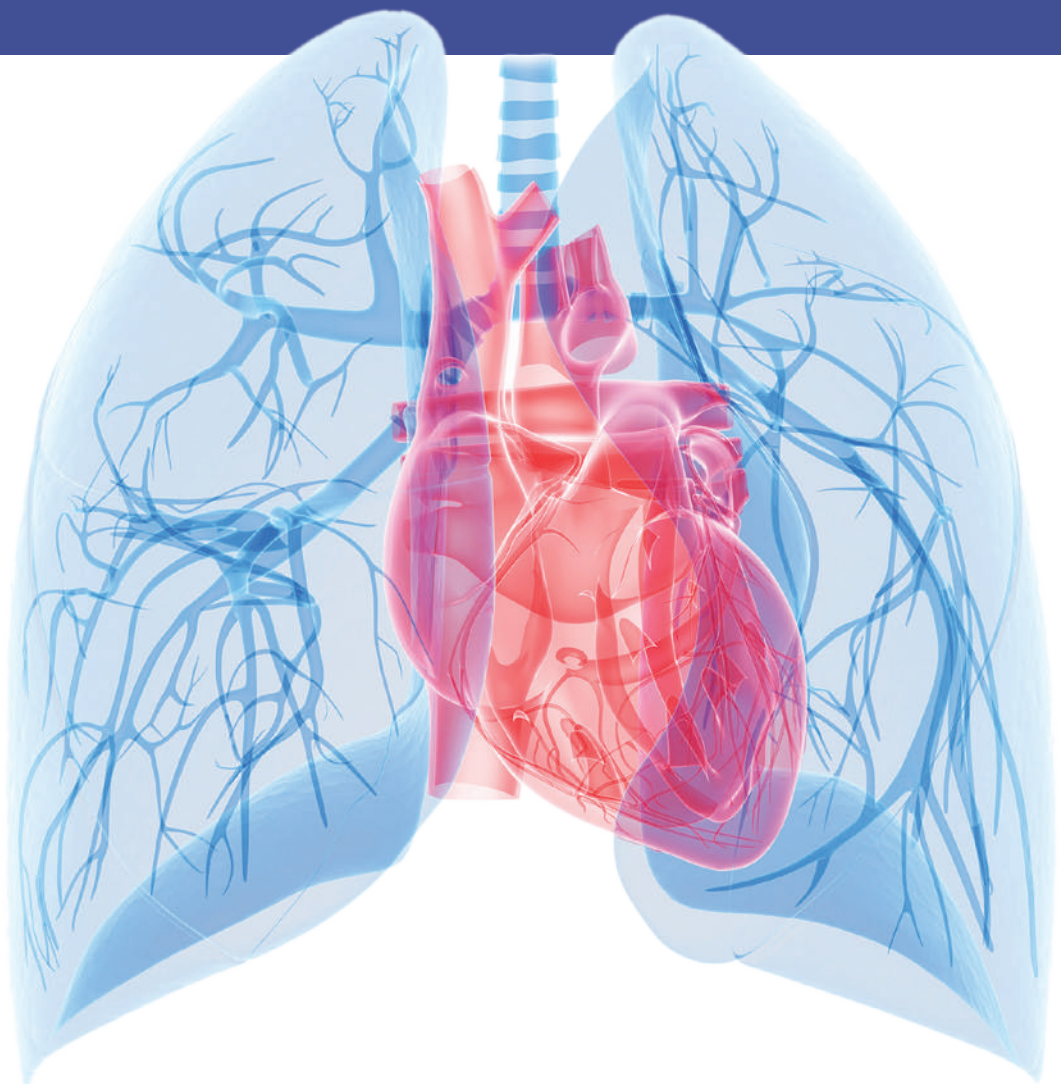
SECTION IV

REVIEW OF CARDIOPULMONARY DISEASE



CHAPTER 24

Pulmonary Infections

SARAH A. LONGWORTH, STEVEN K. SCHMITT, AND DAVID L. LONGWORTH

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- State the incidence and economic impact of pneumonia in the United States.
- Discuss the current classification scheme for pneumonia and be able to define hospital-acquired pneumonia, health care–associated pneumonia, and ventilator-associated pneumonia.
- Recognize the pathophysiology and common causes of lower respiratory tract infections in specific clinical settings.
- List the common microbiologic organisms responsible for community-acquired and nosocomial pneumonias.
- Describe the clinical and radiographic findings seen in patients with pneumonia.
- Describe risk factors associated with increased morbidity and mortality in patients with pneumonia.
- State the criteria used to identify an adequate sputum sample for Gram stain and culture.
- Describe the techniques used to identify the organism responsible for nosocomial pneumonia.
- List the latest recommendations regarding empiric and pathogen-specific antibiotic regimens used to treat various types of pneumonia.
- Discuss strategies to prevent pneumonia.
- Describe how the respiratory therapist aids in diagnosis and management of patients with suspected pneumonia.

CHAPTER OUTLINE

KEY TERMS

antibiotic therapy
atypical pathogens
community-acquired pneumonia
fomites
health care–associated pneumonia
hospital-acquired pneumonia
lower respiratory tract infection
nosocomial pneumonia
pneumonia
tuberculosis
ventilator-associated pneumonia

Infection involving the lungs is termed **pneumonia** or **lower respiratory tract infection** (LRTI) and is a common clinical problem in the practice of respiratory care. Today, pneumonia remains a major cause of morbidity and mortality in the United States and worldwide. Each year, 5 million people die from pneumonia worldwide. Five million cases of pneumonia occur annually in the United States, of which approximately 1.1 million require hospitalization at a projected yearly cost of more than $20 billion.[1] Pneumonia is the ninth leading cause of death in the United States and the leading cause of infection-related mortality.[2]

CLASSIFICATION

Pneumonia can be classified based on the clinical setting in which it occurs (Table 24-1). This classification is useful because it predicts the likely microbial causes and guides empiric antimicrobial therapy while a definitive microbiologic diagnosis is awaited. (The term *empiric therapy* refers to treatment that is initiated based on the most likely cause of infection when the specific causative organism is still unknown.)

TABLE 24-1

Classifications and Possible Causes of Pneumonia

Classification	Likely Organisms
Community-Acquired: Acute	
Typical	*Streptococcus pneumoniae*
	Haemophilus influenzae
	Moraxella catarrhalis
	Staphylococcus aureus
Atypical	*Legionella pneumophila*
	Chlamydophila pneumoniae
	Mycoplasma pneumoniae
	Viruses
	Coxiella burnetii
Community-acquired: Chronic	*Mycobacterium tuberculosis*
	Histoplasma capsulatum
	Blastomycosis dermatitidis
	Coccidioides immitis
Health care-associated	Mixed aerobic and anaerobic mouth flora
	S. aureus
	Enteric gram-negative bacilli
	Influenza
	Mycobacterium tuberculosis
Immunocompromised host	*Pneumocystis jiroveci*
	Cytomegalovirus
	Aspergillus species
	Cryptococcus neoformans
	Reactivation tuberculosis or histoplasmosis
Nosocomial	
Aspiration	Mixed aerobes and anaerobes, gram-negative bacilli
Health care-associated	*S. aureus*
Ventilator-associated	*Pseudomonas aeruginosa*
	Acinetobacter species
	Enterobacter species
	Klebsiella species
	Stenotrophomonas maltophilia
	S. aureus

Community-acquired pneumonia (CAP) can be divided into two types—acute and chronic—based on its clinical presentation. *Acute* pneumonia presents with sudden onset over a few hours to several days. The clinical presentation may be typical or atypical, depending on the pathogen. The onset of *chronic* pneumonia is more insidious, often with gradually escalating symptoms over days, weeks, or months.

Pneumonia acquired in health care settings is often caused by microorganisms different from those that cause CAP. Previously termed **nosocomial pneumonia**, this clinical entity has been further classified as **health care–associated pneumonia** (HCAP), **hospital-acquired pneumonia** (HAP), and **ventilator-associated pneumonia** (VAP).[3] HCAP is defined as pneumonia occurring in any patient hospitalized for 2 or more days in the past 90 days in an acute-care setting or who in the past 30 days has resided in a long-term care or nursing facility; attended a hospital or hemodialysis clinic; or received intravenous antibiotics, chemotherapy, or wound care. HAP is defined as an LRTI that develops in hospitalized patients more than 48 hours after admission and excludes community-acquired infections that are incubating at the time of admission. VAP is defined as an LRTI that develops more than 48 to 72 hours after endotracheal intubation.

HAP is a common clinical problem and represents the second most common nosocomial infection in the United States, accounting for 15% to 22% of all such infections.[4-6] Current estimates suggest that more than 150,000 individuals develop HAP each year. HAP increases hospital length of stay 7 to 9 days at an average incremental per-patient cost of $40,000. In selected populations, such as patients in the intensive care unit (ICU) and bone marrow transplant recipients, the crude mortality rate from HAP may approach 30% to 70%, with attributable mortality of 33% to 50%. Certain microorganisms, such as *Pseudomonas aeruginosa* and *Acinetobacter* species, are associated with higher rates of mortality.[7]

PATHOGENESIS

Six pathogenetic mechanisms may contribute to the development of pneumonia (Table 24-2). Knowledge of these mechanisms is important to both the understanding of the various disease processes and the formulation of effective strategies within the hospital to minimize nosocomial spread. Inhalation of infectious particles is a common route of inoculation; this method of acquiring an infection occurs with pulmonary tuberculosis and justifies the policy of respiratory isolation for patients with suspected or proved tuberculosis who are coughing.

Aspiration of oropharyngeal secretions is the second mechanism that may contribute to the development of LRTI. Healthy individuals may aspirate periodically, especially during sleep. Aspiration of even a small volume of oropharyngeal secretions, which can be colonized with potential pathogens such as *Streptococcus pneumoniae* and *Haemophilus influenzae,*

TABLE 24-2

Pathogenetic Mechanisms Responsible for the Development of Pneumonia

Mechanism of Disease	Examples of Specific Infections
Inhalation of aerosolized infectious particles	Tuberculosis Histoplasmosis Cryptococcosis Blastomycosis Coccidioidomycosis Q fever Legionellosis
Aspiration of organisms colonizing the oropharynx	Community-acquired bacterial pneumonia Aspiration pneumonia Hospital-acquired pneumonia Ventilator-associated pneumonia
Direct inoculation of organisms into the lower airway	Hospital-acquired pneumonia Ventilator-associated pneumonia
Spread of infection to the lungs from adjacent structures	Mixed anaerobic and aerobic pneumonia from subdiaphragmatic abscess Amebic pneumonia from rupture of amebic liver abscess into the lung
Spread of infection to the lung through the blood	*Staphylococcus aureus* pneumonia arising from right-sided bacterial endocarditis Parasitic pneumonia: Strongyloidiasis, ascariasis, hookworm
Reactivation of latent infection, usually resulting from immunosuppression	*Pneumocystis jiroveci* pneumonia Reactivation tuberculosis Cytomegalovirus

may contribute to development of CAP. Certain patient populations are at risk for large-volume aspiration, such as patients with impaired gag reflexes from narcotic use, alcohol intoxication, or prior stroke. Aspiration also may occur after a seizure, cardiac arrest, or syncope.

Aspiration seems to be the major mechanism responsible for the development of some types of mixed aerobic and anaerobic, gram-negative, and staphylococcal HAPs. In intubated patients, chronic aspiration of colonized secretions through a tracheal cuff has been linked to the subsequent occurrence of pneumonia,[4] which led to the development of strategies to prevent HAP, such as continuous suctioning of subglottic secretions in mechanically ventilated patients and elevation of the head of the bed.[8,9]

Direct inoculation of microorganisms into the lower airway is a less common cause of pneumonia. In mechanically ventilated patients who undergo frequent suctioning of lower airway secretions, passage of a suction catheter through the oropharynx may result in inoculation of colonizing organisms into the trachea and subsequent development of VAP.

Contiguous spread of microorganisms to the lungs or pleural space from adjacent areas of infection, such as subdiaphragmatic or liver abscesses, is an infrequent cause of pneumonia. This may occur in patients with pyogenic or amebic liver abscesses involving the dome of the liver in whom rupture of the abscess through the diaphragm leads to the development of pulmonary infection or empyema.

Hematogenous dissemination is the spread of infection through the bloodstream from a remote site; it is an uncommon cause of pneumonia. It may occur in the setting of right-sided bacterial endocarditis, in which fragments of an infected heart valve break off and embolize through the pulmonary arteries to the lungs, producing either pneumonia or septic pulmonary infarcts. Certain parasitic pneumonias, including strongyloidiasis, ascariasis, and hookworm, arise through hematogenous dissemination. In such cases, migrating parasite larvae travel to the lungs through the bloodstream from remote sites of infection, such as the skin or the gastrointestinal (GI) tract.

Pneumonia may develop when a latent infection, acquired earlier in life, is reactivated. This may occur for no apparent reason, as in the case of reactivation pulmonary tuberculosis. However, reactivation is usually attributable to the development of cellular immunodeficiency, as is the case with *Pneumocystis jiroveci* (previously called *Pneumocystis carinii*) pneumonia. In developed countries, most healthy individuals have acquired *P. jiroveci* by age 3 years and show serologic evidence of prior infection. The organism remains dormant in the lung but may reactivate later in life and produce pneumonia in individuals with compromised cell-mediated immunity, such as patients with human immunodeficiency virus (HIV) infection or recipients of long-term immunosuppressive therapy. Cytomegalovirus pneumonia is another example of a latent infection that can reactivate during chronic immunosuppression, especially in solid organ and bone marrow transplant recipients. Immunosuppressive drugs used to modify inflammatory diseases, such as tumor necrosis factor (TNF) inhibitors, have been associated with the development of pulmonary and extrapulmonary tuberculosis.[10]

MICROBIOLOGY

The microbiology of CAP and nosocomial pneumonia has been studied extensively. Knowledge of which organisms are most commonly associated with pneumonia in different settings is essential because the microbial differential diagnosis guides the diagnostic evaluation and the selection of empiric antimicrobial therapy.

In most studies, *S. pneumoniae,* also called *pneumococcus,* is the most commonly identified cause of CAP, accounting for 20% to 75% of cases (Table 24-3). Various other organisms have been implicated with varying frequencies. *H. influenzae, Staphylococcus aureus,* and gram-negative bacilli each account for 3% to 10% of isolates in many reports.[11] Notably, the incidence of *H. influenzae* pneumonia has decreased dramatically since the introduction of the type B *H. influenzae* (also known as *Hib*) vaccine in the 1980s. *Legionella* species, *Chlamydophila pneumoniae,* and *Mycoplasma pneumoniae* together account for 10% to 20% of cases. These latter organisms, called **atypical pathogens**, vary in frequency in more recent reports, depending on the age of the patient population, the season of the year, and

TABLE 24-3

Frequency of Pathogens in Community-Acquired Pneumonia

Cause	Cases (%)
Streptococcus pneumoniae	20-75
Aspiration	6-10
Chlamydophila pneumoniae	4-11
Haemophilus influenzae	3-10
Gram-negative bacilli	3-10
Staphylococcus aureus	3-5
Legionella species	2-8
Viruses	2-16
Moraxella catarrhalis	1-3
Mycoplasma pneumoniae	1-24
Pneumocystis jiroveci	0-13
Mycobacterium tuberculosis	0-5
No diagnosis	25-50

geographic locale. Legionellosis and *C. pneumoniae,* in particular, exhibit significant geographic variation in incidence.

RULE OF THUMB

S. pneumoniae remains the most common cause of CAP.

Many studies examining the epidemiology and microbiology of CAP are potentially biased because they focus on patients requiring hospitalization. In patients with less severe illnesses not requiring hospitalization, more recent studies suggest that *M. pneumoniae* and *C. pneumoniae* account for 38% of cases and may be more common than typical bacterial pathogens such as pneumococcus and *H. influenzae.*[12] In patients who are ill enough to require admission to the ICU, *Legionella* species, gram-negative bacilli, and pneumococcus are disproportionately more common.[13] A virulent strain of methicillin-resistant *S. aureus* (MRSA) has emerged as a cause of severe necrotizing CAP.[14]

In urban settings that have a high incidence of endemic HIV infection, *P. jiroveci* may be an occasional cause of CAP.[15] Viruses such as influenza, respiratory syncytial virus, parainfluenza, and adenovirus can cause CAP, especially in patients with milder illnesses not requiring hospitalization, and are encountered in the late fall and winter months. A worldwide pandemic of H1N1 influenza during 2009 to 2010 and ongoing sporadic cases of transmission of H5N1 influenza from birds to humans have led to heightened international awareness of influenza epidemiology, pathogenesis, and prevention.[16]

Mixed aerobic and anaerobic aspiration pneumonia may account for 10% of cases. This cause of pneumonia is an important consideration for nursing home residents and for individuals with impaired gag reflexes or recent loss of consciousness.

The outbreak in 2000 to 2001 of inhalation anthrax in the United States adds another microbial differential diagnostic consideration in patients with fulminant community-acquired LRTI.[17] To date, inhalation anthrax remains a rare disease. Several new coronaviruses have emerged as important pathogens within the past decade. *Severe acute respiratory syndrome* (SARS) emerged out of Asia and spread globally in 2002 to 2003. Fortunately, no cases have been identified since 2004.[18] More recently, *Middle East respiratory syndrome* (MERS) has arisen as a global health concern. First described in Saudia Arabia in 2012, the virus is found within the Arabian peninsula and causes a severe respiratory illness with a 30% mortality rate. The first cases imported to the United States were confirmed in 2014, both in travelers from Saudia Arabia.[19] Albeit rare in the United States, both viruses also should be considered in the appropriate clinical and epidemiologic setting. In addition, enterovirus D68 is an emerging cause of pneumonia in children.[20]

In most published series, no microbiologic diagnosis is established in 50% of patients. This is attributable to many factors, including:

- Inability of many patients to produce sputum
- Acquisition of sputum specimen after antibiotics have been started
- Failure to perform numerous serologic studies routinely in all patients
- The fact that many organisms (e.g., viruses and anaerobic bacteria) were not routinely sought
- Failure, until more recently, to recognize pneumonia pathogens, such as *C. pneumoniae* and some viral agents.

The common microbial agents producing HCAP, HAP, and VAP are summarized in Table 24-1 and include gram-negative bacilli, *S. aureus, Legionella* species, and rarely viruses such as influenza or respiratory syncytial virus. The last-mentioned viruses are considerations only during the winter months, when they are endemic in the community and may enter the hospital via health care workers, visitors, or patients with incubating or active infections.

The relative frequencies and antimicrobial susceptibilities of these respective bacteria may vary considerably from one institution to another. Knowledge of which nosocomial isolates are most common within one's own institution and community, along with their drug-sensitivity profiles, has important implications with regard to selecting **antibiotic therapy**, formulating infection control policies, investigating potential outbreaks, and selecting antimicrobial agents for the hospital formulary. For example, patients developing severe VAP in ICUs with a high prevalence of carbapenem resistance among gram-negative organisms such as *Klebsiella pneumoniae* and *Acinetobacter baumannii* may warrant empiric antimicrobial therapy for these organisms pending culture information. Similarly, nosocomial legionellosis occurs with variable frequency at different institutions, such that empiric therapy in critically ill patients with nosocomial LRTI may or may not require coverage of this pathogen.

Nosocomial pathogens capable of producing HAP can be transmitted directly from one patient to another, as in the case for tuberculosis. However, transmission from health care

workers (including respiratory therapists [RTs]), contaminated equipment, or **fomites** (objects capable of transmitting infection through physical contact with them) is more common, especially for gram-negative bacilli, *S. aureus,* and viruses. The RT has an important role to play in preventing the transmission and development of nosocomial pneumonia.

MINI CLINI

Distinguishing Between Different Types of Nosocomial Pneumonia

PROBLEM: A 52-year-old man with a history of severe low back pain is admitted to the hospital with a GI bleed in the setting of excessive NSAID use. He has not seen a doctor in 5 years. His presenting symptoms include epigastric abdominal pain, black stools, and dizziness with standing. Admission hemoglobin is 5.2 g/dl and white blood count (WBC) count is 6.2×10^9. He is transfused red blood cells (RBCs) and undergoes upper GI endoscopy, which reveals a large bleeding duodenal ulcer. Three days into his admission, the patient develops a fever to 40.2°C, shortness of breath, and cough. Laboratory testing reveals a WBC count of 16.8×10^9. Chest radiography reveals a patchy infiltrate in the right lower lobe. What type of pneumonia does this patient have? How might this infection have developed?

DISCUSSION: The patient has HAP, because he did not have any evidence of pneumonia at the time of admission and developed his infection more than 48 hours into his hospital stay. He may have developed pneumonia secondary to inhalation of infectious particles via exposure to patients or health care providers working with a respiratory illness. More likely, he aspirated oropharyngeal or gastric secretions during his upper endoscopy procedure or during a vomiting episode. Empiric antimicrobial coverage should target mixed aerobic and anaerobic mouth flora, *S.aureus,* enteric gram-negative bacilli, and potentially influenza, depending on the season.

CLINICAL MANIFESTATIONS

Patients with CAP typically have fever and respiratory symptoms, such as cough, sputum production, pleuritic chest pain, and dyspnea. Not all of these symptoms are present all the time, especially in elderly patients in whom the presentation may be subtle. Other problems, such as hoarseness, sore throat, headache, and diarrhea, may accompany certain pathogens. Fever, cough, and sputum production may occur in other illnesses such as acute bronchitis or exacerbations of chronic bronchitis.

In the past, clinicians often distinguished between typical and atypical clinical syndromes as a means of predicting the most likely microbial causes. A typical presentation consisted of the sudden onset of high fever, shaking, chills, and cough with purulent sputum. Such a presentation was considered more common with bacterial pathogens such as pneumococcus and *H. influenzae.* An atypical presentation was an illness characterized by the gradual onset of fever, headache, constitutional symptoms, diarrhea, and cough, often with minimal sputum production. Cough was often a relatively minor symptom at the outset, and the illness was initially dominated by nonrespiratory symptoms. Such a presentation was thought to be more common with pathogens such as *M. pneumoniae, C. pneumoniae, Legionella* species, and viruses. More recent studies have shown that considerable overlap exists in the clinical presentations of pneumonia with typical and atypical pathogens.[21] The occurrence of concomitant diarrhea, previously considered indicative of legionellosis, is now known to be common in pneumococcal and mycoplasmal pneumonia.

Despite the limitations in predicting the microbial diagnosis based on the clinical presentation, clinicians use certain historical clues and physical findings at the bedside to determine the likely cause of pneumonia in patients presenting from the community. In patients presenting with high fever, teeth-chattering chills, pleuritic pain, and a cough producing rust-colored sputum, pneumococcal pneumonia is the most likely diagnosis. Patients with pneumonia accompanied by foul-smelling breath, an absent gag reflex, or recent loss of consciousness are most likely to have a mixed aerobic and anaerobic infection as a consequence of aspiration. CAP accompanied by hoarseness suggests *C. pneumoniae.* Pneumonia in a patient with a history of splenectomy suggests infection with an encapsulated pathogen such as pneumococcus or *H. influenzae.* Pneumonia occurring after resolution of a flulike illness raises concern for *S. aureus*. Epidemics of pneumonia occurring within households or closed communities, such as dormitories or military barracks, suggest pathogens such as *M. pneumoniae* or *C. pneumoniae.* Pneumonia accompanied by splenomegaly suggests psittacosis (caused by *Chlamydophila psittaci* and associated with bird exposure) or Q fever (caused by *Coxiella burnetii* and associated with exposure to farm animals). Bullous myringitis and erythema multiforme are associated with *Mycoplasma* infection. Relative bradycardia (defined as a heart rate <100 beats/min) in the presence of fever and in the absence of preexisting cardiac conduction system disease or beta-blocker therapy may suggest infection with an atypical pathogen. Pneumonia accompanied by conjunctivitis suggests adenovirus infection.

The clinical presentation of CAP in elderly patients warrants special mention because it may be subtle. Older individuals with pneumonia may not have a fever or cough and may simply present with shortness of breath, confusion, worsening congestive heart failure (CHF), or failure to thrive.

Inhalation anthrax is a rare disease, but warrants mention because of the small epidemic believed to have been an act of bioterrorism.[17] This outbreak affected mainly postal workers who were exposed to mail containing anthrax spores. Most patients presented with a febrile flulike illness of several days' duration accompanied by dry cough and shortness of breath. Some patients went on to develop septic shock, meningitis, and disseminated intravascular coagulation over several days, culminating in death.

Because of a lack of prior host immunity or unique viral virulence factors, patients infected with pandemic influenza

strains may have unusually severe presentations. During the 2009 to 2010 pandemic of H1N1 influenza, clinical presentations varied from mild upper respiratory syndromes to fulminant pneumonias with acute respiratory distress syndrome (ARDS) and shock.[16] SARS manifests with high fever and myalgia for 3 to 7 days followed by nonproductive cough and progressive hypoxemia with progression to mechanical ventilation in 20%.[18] MERS presents similarly, with an added history of travel to or close contact with a symptomatic person who has traveled to the Arabian peninsula within 14 days of symptom onset.[19]

HCAP, HAP, and VAP usually manifest with new onset of fever in hospitalized or institutionalized patients. Nonintubated patients may have a recent history of vomiting, seizure, or syncope, during which aspiration of oropharyngeal or gastric secretions may have occurred. In intubated patients, VAP traditionally manifests with new onset of fever, leukocytosis, purulent endotracheal secretions, and a new pulmonary infiltrate. The diagnosis of HCAP, HAP, or VAP can be extremely difficult to make in patients with preexisting abnormalities on the chest radiograph, such as CHF or ARDS. In mechanically ventilated patients, purulent tracheobronchitis may be accompanied by fever, and in patients with preexisting abnormalities on chest radiograph, the distinction between bronchitis and pneumonia can be especially difficult.

CHEST RADIOGRAPH

In patients with a compatible clinical syndrome, the diagnosis of CAP is established by the presence of a new pulmonary infiltrate on the chest radiograph. Not all healthy outpatients with suspected pneumonia require a chest radiograph, and physicians may choose not to obtain a chest radiograph and treat empirically for CAP in individuals with mild illnesses who are at low risk for morbidity or mortality.

Also, a normal chest radiograph does not exclude the diagnosis of pneumonia. The chest radiograph may be normal in patients with early infection, dehydration, or *P. jiroveci* infection. The pattern of radiographic abnormality is not diagnostic of the causative agent, although specific radiographic findings should suggest specific microbial differential diagnoses (Table 24-4).

Consolidation involving an entire lobe is called *lobar consolidation* (Figure 24-1), whereas *bronchopneumonia* refers to the presence of a patchy infiltrate surrounding one or more bronchi, without opacification of an entire lobe. Both radiographic patterns suggest the presence of a bacterial pathogen. Pleural effusions are common in patients with bacterial pneumonia and uncommon in patients with viral, *P. jiroveci, C. pneumoniae,* or fungal pneumonia. Pleural effusions are seen in approximately 10% of patients with *M. pneumoniae* and *Legionella pneumophila* pneumonia and occur occasionally in patients with reactivation pulmonary tuberculosis. Interstitial infiltrates (Figure 24-2), especially if diffuse, suggest viral disease, *P. jiroveci,* or miliary tuberculosis in patients with CAP. Cavitary infiltrates (Figure 24-3) are seen in reactivation pulmonary tuberculosis;

TABLE 24-4

Radiographic Patterns Produced by Pathogens in Community-Acquired Pneumonia

Pattern	Pathogens
Lobar consolidation	Bacterial
Bronchopneumonia	Bacterial
Pleural effusion	Bacterial
	Inhalation anthrax
Interstitial infiltrates	Viruses
	Pneumocytis jiroveci
Cavities	Mycobacteria
	Fungi
	Nocardia species
	Staphylococcus aureus
	Gram-negative bacilli
	Polymicrobial aerobic and anaerobic lung abscess
	P. jiroveci (rare)
Mediastinal widening without infiltrates	Inhalation anthrax
Rapidly progressive multilobar	*Legionella* species
	Streptococcus pneumoniae
	Endobronchial tuberculosis

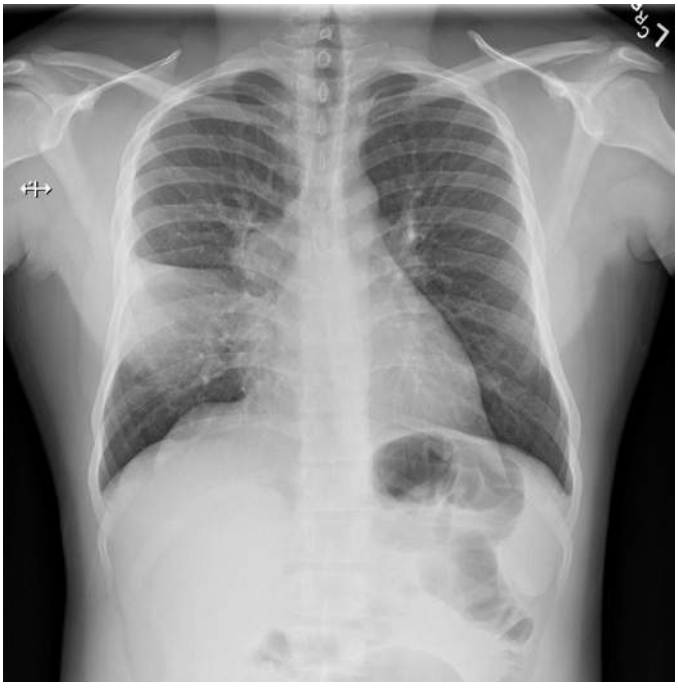


FIGURE 24-1 Lobar pneumonia caused by *Streptococcus pneumoniae.* A 36-year-old previously healthy woman presents with abrupt onset of fevers and shaking chills, cough productive of yellow sputum, and right-sided pleuritic chest pain. Chest radiograph reveals lobar consolidation. Sputum culture yields *S. pneumoniae*.

fungal pneumonias, such as histoplasmosis, blastomycosis, and aspergilosis; nocardiosis; pyogenic lung abscess; and, rarely, *P. jiroveci* pneumonia. Patients with severe staphylococcal or gram-negative pneumonias may develop small cavities called *pneumatoceles.* Legionellosis should be considered in sicker

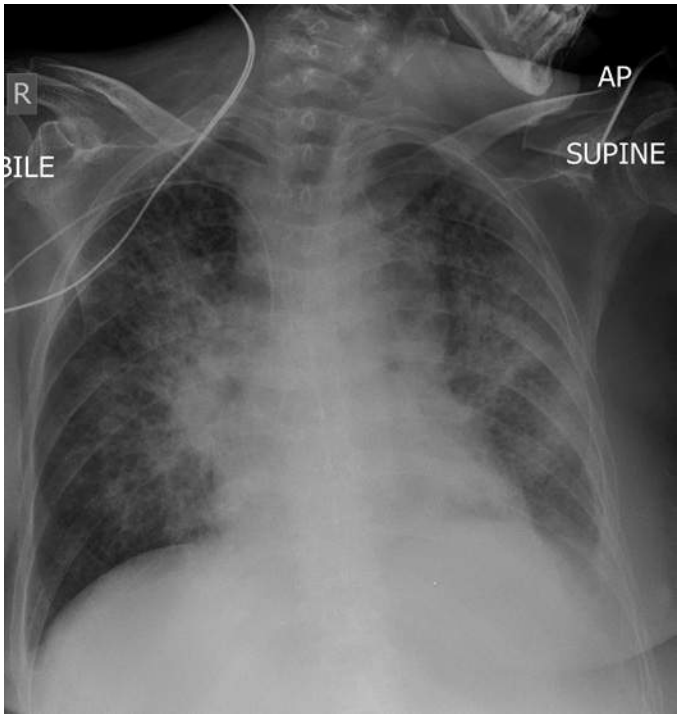

FIGURE 24-2 *Pneumocystis jiorveci* pneumonia (PCP). A 23-year-old male intravenous drug user presents with 2 weeks of dyspnea on exertion, nonproductive cough, and fevers to 40.4° C. The chest radiograph shows an interstitial infiltrate. Human immunodeficiency virus antibody test is positive, serum beta-D glucan level is elevated, and bronchoalveolar lavage toluidine blue O stain is positive for *P. jiroveci.* The interstitial infiltrate in a "bat-wing" distribution is classic for PCP pneumonia.

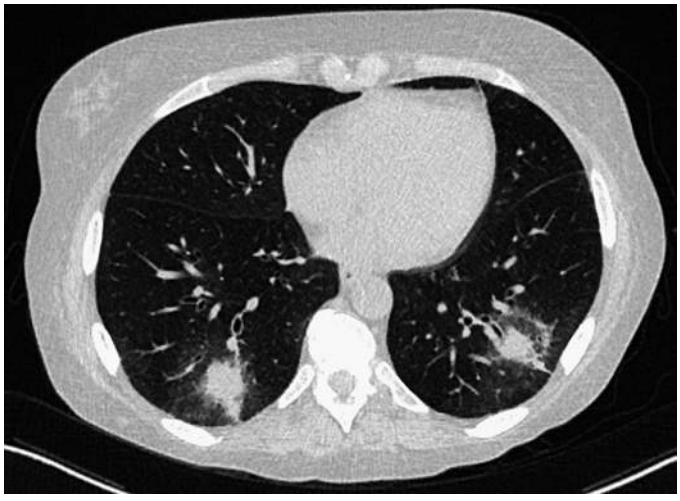

FIGURE 24-3 Cavitary nodular pneumonia caused by *Aspergillus*. A 34-year-old woman undergoing induction chemotherapy for newly diagnosed acute myeloid leukemia presents with persistent neutropenic fevers and cough productive of scant hemoptysis. Sputum cultures are negative, but serum galactomannan antigen is markedly elevated, highly suggestive of *Aspergillus* infection. Computed tomography reveals multicentric cavitary nodules, some of which have a halo of ground glass opacity surrounding them, findings that are classic for invasive pulmonary aspergillosis.

patients with pneumonia of a single lobe, which quickly spreads to involve multiple lobes over 24 to 48 hours.

The chest radiograph may be helpful in diagnosing HCAP or HAP in nonintubated patients with a suspected aspiration event and a prevously normal chest film. In such cases, development of a new infiltrate may confirm the clinical suspicion of aspiration pneumonia. The chest radiograph is often less helpful in the diagnosis of VAP because mechanically ventilated patients often have other reasons for radiographic abnormalities, such as ARDS, CHF, pulmonary thromboembolism, alveolar hemorrhage, or atelectasis. In these patients, the accurate diagnosis of a new nosocomial LRTI can be difficult. *Clinical diagnosis,* defined as the presence of fever, purulent respiratory secretions, new leukocytosis, and a new pulmonary infiltrate, is sensitive but not specific for the diagnosis of VAP. Other strategies to diagnose VAP more accurately have been investigated.

RISK FACTORS FOR MORTALITY AND ASSESSING THE NEED FOR HOSPITALIZATION

Many cases of CAP can be managed successfully on an outpatient basis. The challenge for the clinician is to identify individuals at higher risk of morbidity and mortality for whom hospitalization is indicated. Over the past 20 years, numerous studies have analyzed risk factors for mortality in patients with CAP.[21-23] Risk factors predicting a high risk for death are summarized in Box 24-1.

Fine and associates[23] performed a meta-analysis of 127 cohorts of patients with CAP to examine risk factors for death. The overall mortality for the 33,148 patients in these cohorts was 13.7%. Eleven prognostic variables were significantly associated with mortality, including male sex, absence of pleuritic chest pain, hypothermia, systolic hypotension, tachypnea, diabetes mellitus, cancer, neurologic disease, bacteremia, leukopenia, and multilobar infiltrates on chest radiograph. Mortality varied according to the infecting agent and was highest for *P. aeruginosa* (61.1%), *Klebsiella* species (35.7%), *Escherichia coli* (35.3%), and *S. aureus* (31.8%). Mortality rates for more common pathogens were lower but still substantial: *Legionella* species (14.7%), *S. pneumoniae* (12.3%), *C. pneumoniae* (9.8%), and *M. pneumoniae* (1.4%).

Because some variables are unknown at the time a patient seeks treatment for pneumonia, such as the causative agent and whether bacteremia is present, more recent studies have sought to assess the risk for fatal outcome by using clinical and laboratory data that are readily available at the time of the initial evaluation. Based on an analysis of the 30-day mortality in more than 40,000 patients, Fine and associates[24] proposed a prediction rule to identify low-risk and high-risk patients with CAP. Their algorithm uses the demographic, clinical, and laboratory data available at presentation to stratify the risk for death and the criteria for hospitalization in outpatient groups. Points are assigned for the presence of numerous variables, and cumulative point scores are used to stratify patients into one of five different risk groups with predictable mortality rates

Box 24-1 Risk Factors for Mortality in Community-Acquired Pneumonia from Multiple Studies

I. Patient variables
  A. Age >50 years
  B. Male sex
  C. Comorbid illnesses
    1. Cerebrovascular disease
    2. Cancer
    3. Congestive heart failure
    4. Renal disease
    5. Liver disease

TABLE 24-5
Scoring System for Stratifying Risk of 30-Day Mortality in Adults With Community-Acquired Pneumonia

Variable	Points Assigned
Age	
Men	Age (yr)
Women	Age (yr) – 10
Nursing home resident	+10
Comorbid illnesses	
Cancer	+30
Liver disease	+20
Kidney disease	+10
Cerebrovascular disease	+10
Congestive heart failure	+10
Physical findings	
Altered mentation	+20
Tachypnea >30 breaths/min	+20
Systolic hypotension <90 mm Hg	+20
Temperature <35° C or >40° C	+15
Heart rate >125 beats/min	+10
Laboratory and radiographic findings	
Acidemia (arterial pH <7.35)	+30
Azotemia (blood urea nitrogen >30 mg/dl)	+20
Hyponatremia (sodium <130 mmol/L)	+20
Hypoxia (PaO_2 <60 mm Hg)	+10
Hyperglycemia (glucose >250 mg/dl)	+10
Anemia (hematocrit <30%)	+10
Pleural effusion	+10

Modified from Fine MJ, Auble TE, Yealy DM, et al: A prediction rule to identify low-risk patients with community-acquired pneumonia. N Engl J Med 336:243–250, 1997.
NOTE: Plus sign (+) denotes adding points; minus sign (–) denotes subtracting points (e.g., for women, points assigned equal age in years – 10).

TABLE 24-6
Risk Class Mortality Rates Using Prediction Model Cumulative Point Scores in Patients With Community-Acquired Pneumonia

Risk Class (Cumulative Point Score)	Mortality Rate (%)
I	0.1
II (≤70)	0.6
III (71-90)	2.8
IV (91-130)	8.2
V (>130)	29.2

Modified from Fine MJ, Auble TE, Yealy DM, et al: A prediction rule to identify low-risk patients with community-acquired pneumonia. N Engl J Med 336:243–250, 1997.
NOTE: Patients in risk class I are <50 years old and lack existing illness or physical findings listed in Table 19-5. Points are assigned to patients in risk classes II and higher.

(Tables 24-5 and 24-6). In this model, which has been validated in large prospective cohorts of patients, the patients at the lowest risk for death fall into groups I and II. In most instances, these patients may be treated successfully as outpatients, unless they are hypoxemic, vomiting and unable to take oral antibiotics, noncompliant, or immunocompromised. Patients in group I are patients younger than 50 years of age without comorbid illnesses and abnormal physical findings at presentation (see Box 24-1 and Table 24-5). This group of patients has a 0.1% risk for death.

Because of the complexity of the pneumonia severity index, many practitioners prefer a simpler stratification system, CURB-65. Risk criteria in this system include confusion, blood urea nitrogen greater than 20 mg/dl, respiratory rate greater than 30 breaths/min, systolic blood pressure less than 90 mm Hg or diastolic blood pressure less than 60 mm Hg, and age older than 65 years. Based on their data analysis, the authors recommend that patients with one or two risk criteria should be treated as outpatients, patients with two criteria treated on general hospital wards, and patients with three or more criteria admitted to the ICU.[25]

Many studies have examined risk factors for the development of HAP and VAP, which in broad terms can be divided into (1) factors that interfere with host defense and (2) factors that encourage exposure to large numbers of bacteria.[7] Examples of factors that interfere with host defense include the following:

- Underlying illnesses such as diabetes mellitus, malignancy, chronic heart and lung disease, and renal failure
- Critical illnesses such as sepsis syndrome and ARDS
- Therapeutic interventions such as endotracheal intubation, tracheostomy, and administration of medications such as sedatives and corticosteroids

Factors that promote exposure of the lung to pathogenic microorganisms include the following:

- Use of endotracheal or nasogastric tubes
- Contaminated ventilator equipment or water supplies
- Prior antibiotic therapy
- Neutralization of gastric pH

Although many studies have emphasized the substantial mortality rate (20% to 50%) for patients who develop HAP or VAP, few studies have examined the specific risk factors associated with mortality in hospital-acquired LRTI. For nonventilated patients, risk factors for mortality include bilateral infiltrates, respiratory failure, and infection with high-risk organisms.[26,27] In mechanically ventilated patients, factors associated with fatal outcome include the following[27,28]:

- Infection with high-risk organisms such as *P. aeruginosa, Acinetobacter* species, and *Stenotrophomonas maltophilia*
- Multisystem organ failure
- Nonsurgical diagnosis
- Therapy with antacids or histamine-2 (H_2)-receptor antagonists
- Transfer from another hospital or ward
- Renal failure
- Prolonged mechanical ventilation
- Coma or shock
- Inappropriate antibiotic therapy
- Hospitalization in a noncardiac ICU

Her cumulative point score is 225, she belongs in risk class V, and her estimated risk for mortality is 29.2% (see Table 24-6). She should be admitted to the hospital for treatment.

MINI CLINI

Estimating Risk from Pneumonia

PROBLEM: The RT is called to the emergency department to perform an arterial blood gas analysis on a 70-year-old woman who has been sent from a nursing home with confusion and shortness of breath. Her history is notable for end-stage renal disease caused by hypertension and a recent stroke, which has resulted in left-sided hemiplegia. The emergency physician ordered a chest x-ray examination, which revealed a right lower lobe infiltrate and a right pleural effusion.

On physical examination, the patient is somnolent. Her vital signs are temperature, 35° C; blood pressure, 85/50 mm Hg; and heart rate, 130 beats/min. Additional findings include the following:

- Absent gag reflex
- Right basilar rales (crackles) and left hemiplegia
- Peripheral white blood cell (WBC) count, 3000 cells/mm^3
- Blood urea nitrogen, 100 mg/dl
- Hematocrit, 31%
- Blood glucose, 110 mg/dl
- Serum sodium, 144 mmol/L

The RT collects the arterial blood gas on room air, which shows a pH of 7.30; PaO_2, 58 mm Hg; and PCO_2, 25 mm Hg. Should the patient be admitted to the hospital, or should she be sent back to the nursing home? What is her risk for 30-day mortality?

DISCUSSION: This patient is at substantial risk for dying from pneumonia and should be admitted to the hospital. The Fine prediction rule[24] may be used as follows to estimate the risk for 30-day mortality (see Tables 24-5 and 24-6):

Variable	Points
Age 70 yr	+70
Sex female	−10
Nursing home resident	+10
Cerebrovascular disease	+10
Renal disease	+10
Altered mentation	+20
Systolic hypotension	+20
Hypothermia	+15
Tachycardia	+10
Acidemia	+30
Renal failure	+20
Hypoxemia, with PaO_2 <60 mm Hg	+10
Pleural effusion	+10
Total	*225*

DIAGNOSTIC STUDIES

Community-Acquired Pneumonia

Many patients with CAP who are treated as outpatients never have a microbiologic diagnosis established. Many are treated based on the history and examination findings, with or without a chest radiograph to confirm the presence of an infiltrate. Patients who are sick enough to warrant hospitalization or consideration of hospitalization should undergo appropriate studies to stratify risk for mortality and establish a microbiologic diagnosis (Box 24-2). Complete blood count, blood glucose, serum sodium, and blood urea nitrogen are all necessary to derive a point score for estimating mortality risk. An arterial blood gas analysis is used to detect the presence of hypoxemia and acidemia, which indicate more serious illness.

The value of Gram stain and culture of expectorated sputum has been debated for years.[29] Many patients lack a productive cough, making collection of an adequate specimen difficult. Prior antibiotic therapy reduces the yield from both tests. Only 50% of patients with bacteremic pneumococcal pneumonia have a positive sputum culture.[30] Nevertheless, the finding of a predominant organism on Gram stain in an appropriately collected specimen can be very helpful in selecting appropriate

Box 24-2 Recommended Tests for Adults With Community-Acquired Pneumonia Warranting Consideration of Hospitalization

- Chest radiograph
- Complete blood count
- Blood chemistries
  - Glucose
  - Serum sodium
  - Blood urea nitrogen
- Arterial blood gas
- Sputum Gram stain and culture
- Additional sputum studies as clinically indicated
  - Acid-fast stains and culture for mycobacteria
  - Potassium hydroxide examination and fungal culture
  - Stain for *Pneumocystis jiroveci*
  - Direct fluorescent antibody stain for *Legionella* species
- Blood cultures
- Pleural fluid analysis if sizable effusion is present
  - Cell count with differential
  - Glucose, protein, and lactate dehydrogenase
  - pH
  - Gram stain and routine aerobic and anaerobic culture
  - Acid-fast stain and culture for mycobacteria
- Additional other studies as clinically indicated
  - *Legionella* urinary antigen
  - Pneumococcal urinary antigen
  - Acute and convalescent sera for *Mycoplasma pneumoniae, Legionella* species, and *Chlamydophila pneumoniae*
  - Fungal serologies
  - HIV test for individuals 15 to 65 years old or for individuals engaging in high-risk behavior

antibiotic therapy.[31] A routine sputum culture must be interpreted within the context of the sputum Gram stain. Specimens contaminated with oropharyngeal epithelial cells are unsatisfactory for analysis and specimens lacking neutrophils from non-neutropenic patients are unlikely to be helpful.

RULE OF THUMB

A routine sputum culture can be interpreted only within the context of the sputum Gram stain.

The RT has an important role in collecting an appropriate specimen of expectorated sputum. Patients should be advised to rid the mouth of contaminating saliva by rinsing with water or by spitting and then to expectorate a specimen from deep within the tracheobronchial tree into a collection container. Prompt transportation to the laboratory is essential and improves the diagnostic yield from culture.[12] Most microbiology laboratories screen the adequacy of the specimen by cytologic examination. A satisfactory specimen contains more than 25 leukocytes and fewer than 10 squamous epithelial cells per high-power field.[32] In routine sputum culture, the isolation of bacteria such as *S. pneumoniae* and *H. influenzae* must be interpreted within the context of the Gram stain because these organisms can colonize the oropharynx, and their presence in culture may not signify true LRTI. The culture isolation of other organisms, such as *Mycobacterium tuberculosis, Histoplasma capsulatum, Blastomyces dermatitidis, Coccidioides immitis,* and *Legionella* species is diagnostic of disease because these organisms almost never colonize the respiratory tract.

RULE OF THUMB

The presence of *Candida* species on sputum smear or culture is almost never clinically significant.

Other stains and cultures of expectorated sputum should be obtained as dictated by the clinical circumstance, when management would be changed, or for purposes of tracking unusual or resistant organisms in an institution or population. In patients with suspected tuberculosis, the finding of acid-fact bacilli in stained sputum specimens often prompts initiation of antituberculous therapy because culture isolation of *M. tuberculosis* may take 6 weeks. A direct fluorescence antibody stain of sputum for *Legionella* species may reveal the organism in 25% to 80% of individuals with Legionnaire's disease, and cultures are positive in 50% to 70%.[33] Toluidine blue O stains of sputum may disclose the organism in 80% of patients with *P. jiroveci* pneumonia. Potassium hydroxide preparations of sputum show fungi in only a few patients with histoplasmosis, blastomycosis, or coccidioidomycosis but are very helpful if positive.

Blood cultures should be obtained in hospitalized patients with CAP and may be helpful in establishing the diagnosis in patients with typical bacterial pathogens. Blood cultures are positive in approximately 30% of patients with pneumococcal pneumonia and in 70% of patients with *H. influenzae* pneumonia.[34] Blood cultures are not helpful in patients with legionellosis, *M. pneumoniae, C. pneumoniae, P. jiroveci,* or viral infections. Collection of blood cultures within 24 hours of hospitalization in elderly patients with pneumonia has been associated with improved survival.[35]

Parapneumonic pleural effusions are common and occur in 30% to 50% of patients with CAP.[11] Thoracentesis is indicated for patients with large pleural effusions and patients with smaller effusions who fail to respond to therapy or for whom the microbiologic diagnosis is not established. Pleural fluid should be tested for cell count, glucose, protein, pH, lactate dehydrogenase, Gram and acid-fast bacilli stains, and routine (aerobic and anaerobic) and mycobacterial cultures. Effusions with a fluid pH less than 7.20, a positive Gram stain or culture, or fluid that appear grossly purulent on inspection require tube thoracostomy for drainage.[36]

Other studies may be helpful in establishing a microbiologic diagnosis in the appropriate clinical setting. *L. pneumophila* serogroup 1 accounts for 80% of cases of Legionnaire's disease.[37] The urinary antigen test for *L. pneumophila* serogroup 1 is a sensitive and rapid test and usually becomes positive within 3 days of illness onset, but the test has limitations. First is its

inability to detect the non–serogroup 1 *L. pneumophila* and non–*L. pneumophila* species that account for 20% of cases of Legionnaire's disease. Second, it can be negative if patients present very early in the disease course, potentially misleading clinicians with a negative result and requiring repeat testing if clinical suspicion remains high. Third, the test may remain positive for 1 year, obviating the ability to distinguish new from remote infection in patients with a recent history of pneumonia.

Serologic tests for immunoglobulin M (IgM) and IgG antibodies to *M. pneumoniae, Legionella* species, or *C. pneumoniae* are rarely helpful during the initial stages of pneumonia, but convalescent titers 3 to 4 weeks later may permit a retrospective microbiologic diagnosis by showing a fourfold increase in IgG titer or the development of IgM antibody against a specific pathogen. Acute sera should be analyzed in patients who are critically ill with pneumonia and for whom the microbiologic diagnosis is unavailable. Fungal serologic findings are occasionally helpful in supporting the diagnosis of blastomycosis, histoplasmosis, or coccidioidomycosis, pending culture isolation of the organism.

Fungal antigen assays are increasingly being used in settings in which there is a high clinical suspicion for invasive fungal infection. Invasive aspergillosis is is an important cause of pneumonia in immunocompromised hosts, particularly in those with prolonged neutropenia. Galactomannan is a polysaccharide that is a major constituent of *Aspergillus* cell walls. A large meta-analysis revealed that galactomannan antigen assays have a sensitivity of 71% and specificity of 89% for *Aspergillus* infection.[38] However, the sensitivity of the test is decreased by concomitant administration of antifungal therapy and false-positive results can occur in patients receiving the antibiotic combination piperacillin-tazobactam in infections with other fungi that share cross-reacting antigens (*Fusarium* and *Penicillium* species, *H. capsulatum*) and in patients with chemotherapy-induced mucositis or transplant-associated graft-versus-host disease (in whom bacteria with cross-reactive antigens translocate across the intestinal mucosal wall). Similarly, 1,3-beta-D-glucan is a cell wall component of many fungi, and levels of this molecule are elevated in many types of invasive fungal infection, including those with *Aspergillus, P. jiroveci*, *H. capsulatum*, and *C. immitis*. Beta-D glucan assays have a sensitivity of 77% and specificity of 85% for invasive fungal infection.[39] Like the galactomannan assay, there are some drawbacks to this test. First, the assay cannot distinguish between infections from various fungal pathogens. False-positive results can occur in patients receiving intravenous immunoglobulin or albumin infusions, in patients undergoing hemodialysis or receiving intravenous infusions that use cellulose filters, in patients with glucan-containing gauze packing of serosal surfaces, and patients who are bacteremic with certain organisms, including *Pseudomonas aeruginosa.*[39]

Because pneumococcal and *H. influenzae* pneumonia occur with higher frequency in patients with HIV infection than in the average population, an HIV test is recommended for patients ages 15 to 65 with CAP. HIV testing is also recommended for other individuals who engage in behaviors that put them at risk for HIV infection.

Molecular techniques, such as DNA probes and polymerase chain reaction (PCR), used for detecting specific organisms such as *M. pneumoniae* or *M. tuberculosis* or for confirming the identity of culture isolates, are being developed and used in some larger centers. Rapid diagnostic testing of nasopharyngeal specimens for viral pathogens such as influenza, parainfluenza, and respiratory syncytial virus may be helpful in diagnosing CAP because of these organisms in patients with compatible clinical presentations.

MINI CLINI

Importance of Clinical Setting for Determining the Cause of Pneumonia

PROBLEM: The RT is caring for a 32-year-old man admitted to the hospital 24 hours earlier with fever, shaking chills, and a new left lower lobe infiltrate. His WBC count on admission was 3500 cells/mm^3, with 96% neutrophils and 4% lymphocytes. A sputum Gram stain disclosed many polymorphonuclear leukocytes and lancet-shaped, gram-positive diplococci. Blood cultures have grown *S. pneumoniae* at 24 hours. He remains febrile 24 hours into therapy with penicillin G. While checking pulse oximetry, the RT notes that the patient is emaciated and that multiple needle tracks are present in each antecubital fossa. He tells the RT that he uses intravenous heroin. What other tests are indicated?

DISCUSSION: This patient, who is an intravenous drug user, has bacteremic pneumococcal pneumonia. These findings, along with the presence of cachexia and leukopenia with lymphopenia, should suggest the possibility of underlying HIV infection. An HIV test is indicated and should be performed after the patient's consent is obtained.

Both pneumococcal and *H. influenzae* pneumonia occur with higher frequency in HIV-infected individuals than in the general population. Occasionally, an HIV-infected patient has his or her first contact with the health care system as a result of one of these infections. New guidelines recommend that all average-risk individuals ages 15 to 65 undergo testing for HIV once in their lives and persons at higher risk for HIV infection undergo more frequent testing.[40]

Flexible bronchoscopy is usually reserved for severe cases of CAP, for immunocompromised individuals in whom opportunistic pathogens must be excluded, or for cases in which *P. jiroveci* infection is suspected. The yield from flexible bronchoscopy is higher if performed before starting antibiotic therapy in patients with bacterial pneumonia. Open lung biopsy is rarely indicated for patients with CAP.

Health Care–Associated Pneumonia, Hospital-Acquired Pneumonia, and Ventilator-Associated Pneumonia

The accurate diagnosis of nosocomial pneumonia is challenging and has been the subject of intense investigation over the

Box 24-3 Techniques for Diagnosing Nosocomial Pneumonia

- Clinical diagnosis
- Direct visualization of the airway by bronchoscopy
- Quantitative cultures of:
  - Endotracheal aspirates
  - Protected brush–bronchoscopy specimens
  - Nonbronchoscopic distally protected specimens
  - Conventional or protected BAL specimens, plus microscopic examination of recovered cells
  - PSB and BAL specimens, plus microscopic examination of BAL fluid cells
- RT-directed mini-BAL
- Transthoracic fine-needle aspiration

BAL, Bronchoalveolar lavage; *PSB,* protected specimen brush; *RT,* respiratory therapist.

past three decades. Numerous techniques have been extensively evaluated (Box 24-3); however, none is absolutely sensitive and specific.[41,42] *Clinical diagnosis* has been defined as the development of a new infiltrate on chest radiograph in the setting of fever, purulent tracheal secretions, and leukocytosis in a hospitalized patient. Clinical diagnosis lacks specificity because many other causes of pulmonary infiltrates exist in hospitalized patients, especially in patients on mechanical ventilation.[43] In addition, the upper airway commonly is colonized with nosocomial gram-negative bacilli and staphylococci, even in the absence of pneumonia. The qualitative culture isolation of these organisms from tracheal secretions correlates poorly with the presence or absence of pneumonia.

Direct visualization of the lower airway by bronchoscopy in ventilated patients is sometimes helpful to support the diagnosis of VAP. In one study, the presence of distal, purulent secretions, persistence of secretions surging from distal bronchi during exhalation, and a decrease in the PaO_2/FiO_2 ratio of less than 50 were independently associated with the presence of pneumonia. The presence of two of three of these factors had a sensitivity of 78% in the diagnosing nosocomial pneumonia; these factors were absent 89% of the time when there was no pneumonia (89% specific).[44]

Because the specificity of qualitative sputum cultures has been unreliable, several studies have examined the role of quantitative cultures of endotracheal aspirates using various breakpoints ranging from 10^3 to 10^7 *colony-forming units (CFUs)* per milliliter of respiratory secretions. Results with this technique have been best using a breakpoint of 10^6 CFU/ml, but sensitivities have been only 68% to 82%, with specificities of 84% to 96% with this test.[45,46]

The protected specimen brush (PSB) was developed in the 1970s and uses a special double-catheter brush system to minimize contamination by upper airway flora. Specimens obtained with this technique are cultured quantitatively. Numerous studies have validated the sensitivity of PSB in diagnosing nosocomial pneumonia.[47,48] However, PSB may be less useful in cases in which antibiotics have already been started, in cases of early infection, and in cases in which the wrong lobe is sampled.[41]

Nonbronchoscopic techniques using telescoping protected catheters have also been developed to obtain specimens for quantitative culture from the lower airway. In most studies, sensitivity has been comparable to bronchoscopic techniques, but results have disagreed in 20% of cases.[41]

Bronchoalveolar lavage (BAL), in which a lung segment is lavaged with sterile saline through the bronchoscope and recovered fluid is quantitatively cultured, has been studied extensively as a tool for diagnosing nosocomial pneumonia (see Chapter 24). Some studies have supported the usefulness of this technique, and others have questioned its specificity because of upper airway contamination.[47,48] BAL has proved useful for obtaining alveolar cells for microscopic analysis; several studies have suggested that the presence of intracellular bacteria in 3% to 5% of BAL cells distinguishes patients with nosocomial pneumonia from patients without pneumonia.[47,48] In one study, the combination of PSB cultures and microscopic examination of BAL cells for intracellular bacteria was 100% sensitive and 96% specific in identifying patients with nosocomial pneumonia.[47]

Mini-BAL performed by RTs also has been advocated for diagnosing VAP. In one study, results obtained using this technique were comparable with results obtained by bronchoscopy using PSB.[49] Some centers use this technique as the primary method of sampling respiratory secretions in suspected nosocomial pneumonia. Transthoracic ultrathin needle aspiration of the lung in nonventilated patients with nosocomial pneumonia also has been studied and in one report was found to have a sensitivity of 60%, a specificity of 100%, and a positive predictive value of 100%.[50]

Accurately diagnosing HAP, HCAP, and VAP remains a challenge for the physician and the RT. None of the available diagnostic techniques is 100% sensitive or specific; all are limited in the populations at greatest risk for getting nosocomial pneumonia—mechanically ventilated patients and patients receiving prior antibiotic therapy.

ANTIBIOTIC THERAPY

Community-Acquired Pneumonia

The selection of antibiotic therapy for patients with CAP should be guided by several considerations, including the age of the patient, severity of the illness, presence of risk factors for specific organisms, and results of initial diagnostic studies. Pathogen-specific therapy should be used when clinical circumstances and initial evaluation strongly suggest the microbiologic diagnosis or when cultures or other studies confirm the cause. In many instances, initial studies fail to establish a diagnosis, and empiric therapy must be started. Major classes of antibiotics used to treat pneumonia are listed in Table 24-7. Consensus guidelines for therapy have been published by the American Thoracic Society (ATS) and the Infectious Diseases Society of America (IDSA) (Table 24-8).[51-53] Therapy initiated within 4 hours of hospital admission has been associated with improved survival.[35]

For hospitalized patients who are not critically ill and who are admitted to the ward, an empiric regimen of a respiratory fluoroquinolone alone or an advanced macrolide plus a beta-lactam (cefotaxime, ceftriaxone, or ampicillin) is recommended (see Table 24-8). For critically ill patients requiring admission to the ICU, the IDSA and ATS recommend as empiric therapy a beta-lactam (cefotaxime, ceftriaxone, or ampicillin-sulbactam) plus either an advanced macrolide or a respiratory fluoroquinolone for legionella coverage. Certain pathogens require specific consideration in the ICU setting. If *Pseudomonas* is a concern, recommended regimens include two drugs with antipseudomonal coverage: an antipseudomonal beta-lactam (piperacillin-tazobactam, cefepime, imipenem, or meropenem) and ciprofloxacin or levofloxacin; an antipseudomonal beta-lactam, an aminoglycoside, and azithromycin; or an antipseudomonal beta-lactam, an aminoglycoside, and a respiratory fluoroquinolone (see Table 24-8). When MRSA is a concern, addition of vancomycin or linezolid is recommended.

When a microbiologic diagnosis is established, the antimicrobial regimen should be tailored to the isolated pathogen. Pathogen-specific treatment recommendations from the IDSA and ATS are summarized in Table 24-9. For isolates of *S. pneumoniae* susceptible to penicillin, penicillin remains the preferred agent. Many strains of *H. influenzae* produce beta-lactamase, making them resistant to penicillin. Second- or third-generation cephalosporins and amoxicillin/clavulanate are the agents of choice. Legionellosis should be treated with a macrolide or with a fluoroquinolone alone. Pneumonia caused by *M. pneumoniae* and *C. pneumoniae* should be treated with a macrolide or doxycycline. Trimethoprim-sulfamethoxazole (TMP-SMX) is the drug of choice for *P. jiroveci* pneumonia. However, 50% of HIV-infected patients may develop fever or a rash while taking this medication. For patients with mild to moderate disease, atovaquone, clindamycin, and primaquine, or trimethoprim and dapsone, are treatment alternatives; pentamidine is indicated for severe infection in patients unable to tolerate TMP-SMX. Treatment for staphylococcal or gram-negative pneumonias is dictated by the antibiotic susceptibility profiles of the offending organism. For patients with staphylococcal pneumonia, vancomycin is preferred, pending antibiotic susceptibility results. If the isolate is methicillin-susceptible, a semisynthetic penicillin, such as oxacillin or nafcillin, should be used because these antibiotics kill the bacteria more effectively than vancomycin; in seriously ill patients, rifampin or an aminoglycoside may be added. A detailed discussion regarding the treatment of fungal and viral pneumonias is beyond the scope of this chapter.

The duration of therapy of CAP is guided by the specific pathogen and the patient's clinical course. Recommendations

TABLE 24-7

Major Classes of Antibiotics Used in the Treatment of Pneumonia

Antibiotic Class	Representative Drugs
Penicillins	Penicillin G, ampicillin
Ureidopenicillins	Ticarcillin, piperacillin, mezlocillin
Semisynthetic penicillins	Oxacillin, nafcillin
First-generation cephalosporins	Cefazolin
Second-generation cephalosporins	Cefuroxime
Third-generation cephalosporins	Cefotaxime, ceftriaxone, ceftizoxime
Antipseudomonal cephalosporins	Ceftazidime, cefepime
Carbapenems	Imipenem, meropenem, ertapenem
Monobactams	Aztreonam
Beta-lactam/beta-lactamase inhibitor combinations	Ticarcillin/clavulanate, piperacillin/tazobactam, ampicillin/sulbactam
Quinolones	Ciprofloxacin, levofloxacin, moxifloxacin, gemifloxacin
Macrolides	Erythromycin, clarithromycin, azithromycin
Tetracyclines	Doxycycline
Glycopeptides	Vancomycin
Oxazolidinones	Linezolid

TABLE 24-8

Empiric Regimens for Treatment of Hospitalized Adults With Community-Acquired Pneumonia

Patient Group	Likely Pathogens	Empiric Regimens
Hospitalized on ward	*Streptococcus pneumoniae, Haemophilus influenzae, Chlamydophila pneumoniae, Staphylococcus aureus, Mycoplasma pneumoniae,* anaerobes, viruses	Respiratory fluoroquinolone (levofloxacin, moxifloxacin, gemifloxacin) alone or beta-lactam (cefotaxime, ceftriaxone, ampicillin, ertapenem) and macrolide
Critically ill, ICU	*S. pneumoniae, Legionella* species, *S. aureus,* gram-negative bacilli, *M. pneumoniae, C. pneumoniae*	If *Pseudomonas aeruginosa* unlikely: Beta-lactam (cefotaxime, ceftriaxone, ampicillin-sulbactam) plus either azithromycin or a respiratory fluoroquinolone If *P. aeruginosa* possible: IV antipseudomonal beta-lactam (piperacillin-tazobactam, cefepime, imipenem, meropenem) plus fluoroquinolone (ciprofloxacin or levofloxacin) or IV antipseudomonal beta-lactam plus aminoglycoside plus either IV macrolide or fluoroquinolone

Modified from Mandell MA, Wunderink RG, Anzueto A, et al: Infectious Disease Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. Clin Infect Dis 44:S27–S72, 2007.

TABLE 24-9

Pathogen-Specific Treatment Recommendations for Adults With Community-Acquired Pneumonia: Infectious Disease Society of America Guidelines

Pathogen	Recommended Regimen
Streptococcus pneumoniae	
Penicillin susceptible	Penicillin G or amoxicillin
Penicillin resistant	Ceftriaxone, cefotaxime, fluoroquinolone, or vancomycin
Haemophilus influenzae	Second- or third-generation cephalosporin, azithromycin, or TMP-SMX
Legionella species	Macrolide ± rifampin or fluoroquinolone alone
Mycoplasma pneumoniae	Macrolide or doxycycline
Chlamydophila pneumoniae	Macrolide or doxycycline
Staphylococcus aureus	
Methicillin susceptible	Semisynthetic penicillin ± rifampin or gentamicin
Methicillin resistant	Vancomycin or linezolid
Enterobacteriaceae	Third-generation cephalosporin ± aminoglycoside or carbapenem
Pseudomonas aeruginosa	Aminoglycoside + antipseudomonal beta-lactam or carbapenem
Influenza with suspected secondary pneumococcal or staphylococcal infection	Neuraminidase inhibitor (oseltamivir or zanamivir) and vancomycin or linezolid

From Mandell MA, Wunderink RG, Anzueto A, et al: Infectious Disease Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. Clin Infect Dis 44:S27–S72, 2007.
TMP-SMX, Trimethoprim-sulfamethoxazole.

have evolved from the traditional 14 days to a minimum of 5 days of therapy with clinical stability. Exceptions include Legionnaire's disease or staphylococcal pneumonia, for which a minimum of 2 weeks of therapy is recommended. Older individuals and patients with comorbidities also may require longer courses of treatment. When fever has resolved and patients begin to improve clinically, oral therapy may be used to complete the treatment program. Failure of the patient's temperature to normalize within 4 or 5 days suggests a missed pathogen, a metastatic or closed-space infection (e.g., empyema), drug fever, or the presence of an obstructing endobronchial lesion. Empyema should be treated with tube thoracostomy. Abnormal findings on physical examination may persist beyond 1 week in 20% to 40% of patients, despite clinical improvement. By 1 month, radiographic resolution occurs in 90% of individuals younger than 50 years.[54] After 1 month, radiographic abnormalities may persist in 70% of cases involving older individuals or in patients with significant underlying illnesses.[54]

RULE OF THUMB

Empyema should be ruled out in patients with CAP and a large pleural effusion who fail to respond to therapy. In cases of CAP, patients often get better before the chest radiograph shows any improvement.

MINI CLINI

Evaluating Persisting Fever in Pneumonia

PROBLEM: The RT is caring for a 68-year-old man admitted 1 week ago with bacteremic *H. influenzae* pneumonia. His admitting chest radiograph showed right lower lobe consolidation and a large right pleural effusion. He has a history of chronic obstructive pulmonary disease (COPD) and reports a 100 pack-year smoking history. He was treated initially with erythromycin and ceftizoxime until his blood cultures became positive. The organism was susceptible to ceftizoxime, which was continued as monotherapy (i.e., treatment with one antibiotic drug). Despite treatment, the patient has remained persistently febrile (39° C) and his chest radiograph has not shown improvement. Why is he not responding to therapy?

DISCUSSION: Patients with CAP who have comorbid illnesses such as alcoholism or COPD may recover more slowly than healthy individuals despite appropriate therapy. Nevertheless, persistent fever 7 days into optimal treatment should prompt several considerations.

The two most likely concerns for this patient are (1) an undrained empyema and (2) an obstructing endobronchial malignancy, given his substantial smoking history. Other less likely considerations are drug fever; a new nosocomial infection; a missed pathogen that is not responsive to ceftizoxime, contributing to his pneumonia; or a deep venous thrombosis resulting from bed rest.

The next step should be to repeat the history and physical examination. If these do not reveal a cause of the persistent fever, a thoracentesis should be performed to exclude empyema. If thoracentesis findings are negative, further investigation looking for an endobronchial-obstructing lesion should be considered.

Health Care–Associated Pneumonia, Hospital-Acquired Pneumonia, and Ventilator-Associated Pneumonia

Empiric and definitive therapy of nosocomial pneumonia is determined by institution-specific data regarding the most common organisms and their antibiotic-susceptibility profiles and by patient-specific risk factors. Although general guidelines have been published,[3] the importance of local data cannot be overemphasized because there is great variation across regions and across health care facilities regarding the prevalence and susceptibility profiles of specific pathogens.

Generally, in-hospital aspiration should be treated with a regimen that provides coverage against anaerobes and gram-negative bacilli, such as a beta-lactam/beta-lactamase inhibitor combination or clindamycin with a third-generation cephalosporin. Although vancomycin has been the traditional drug of choice for MRSA pneumonia, evolving data suggest that linezolid may be better than vancomycin. In a randomized controlled trial of vancomycin versus linezolid for treatment of MRSA pneumonia, clinical resolution of pneumonia occurred more frequently in patients treated with linezolid, but there was

no difference in 60-day mortality between the two groups.[55] For VAP, empiric coverage may be targeted at organisms known to colonize the patient's oropharynx or pathogens that are present in the ICU. Patients with *P. aeruginosa* pneumonia usually are treated with two agents, such as a ureidopenicillin or antipseudomonal cephalosporin together with an aminoglycoside or fluoroquinolone. Other gram-negative pneumonias generally are treated with a single agent, except in cases involving critically ill patients, for whom a second drug is sometimes added. If nosocomial legionellosis is present within an institution, a macrolide may be added to the empiric regimen.

Similar to CAP, the duration of therapy for cases of nosocomial pneumonia is dictated by the clinical course. A study comparing 8 days versus 15 days of therapy in patients with VAP found that short-course therapy was associated with comparable outcomes to long-course therapy, although the rate of relapse was slightly higher in patients with *Pseudomonas* or *Acinetobacter* infections.[56] More prolonged courses of therapy may be required in patients who are slow to respond but are associated with a greater risk for new colonization with other organisms. Failure of the patient to improve should prompt the following considerations: the presence of an occult empyema; an unrecognized pathogen; a new, unrelated nosocomial infection; or other noninfectious causes of fever common in the ICU, such as deep venous thrombosis, drug fever, occult pancreatitis, or acalculous cholecystitis (gallbladder inflammation without gallstones).

The RT has an important role in diagnosing and managing patients with CAP and nosocomial pneumonia. Helping patients clear infected secretions aids clinical improvement and maintaining adequate oxygenation is essential. The usefulness of chest physiotherapy in the treatment of pneumonia is still unproved but some patients seem to benefit from it.

PREVENTION

Community-Acquired Pneumonia

Preventive strategies for CAP have focused on immunizing high-risk individuals against influenza and *S. pneumoniae.* Influenza is a risk factor for subsequent development of CAP during the fall and winter months. In 2010, the Advisory Committee on Immunization Practices (ACIP) expanded its recommendation for influenza vaccination to include all individuals older than 6 months.[57] Immunization is particularly important for individuals older than 60 years (because it reduces the incidence of illness for this age group by half[58]) and for those with chronic lung or heart disease in whom the morbidity of influenza may be substantial. Recent studies suggest that widespread immunization of healthy working adults is cost-effective because the number of sick days taken and the number of visits to a physician are reduced.[59] Health care workers, including RTs, should be immunized annually to prevent transmission of influenza to patients.

Currently available pneumococcal vaccines provide protection against the 23 serotypes of *S. pneumoniae,* which cause 85% to 90% of invasive pneumococcal infections in the United States. Vaccination is indicated for all individuals older than 65 years and for individuals older than 2 years who have functional or anatomic asplenia (i.e., lack a spleen). Vaccination is also indicated in patients with chronic illnesses such as CHF, chronic lung disease, or chronic liver disease; alcoholism; cerebrospinal fluid leaks; or conditions characterized by impaired immunity.[60] Routine pneumococcal vaccination of all health care workers is not currently recommended; health care workers who possess one of the specific indications for vaccination outlined previously should be immunized.

Immunity against *Bordetella pertussis* fades over time, leading to transmission from older adults to other adults and infants. Because secondary bacterial pneumonia occurs in a significant number of cases of pertussis, the ACIP has recommended that the tetanus-diphtheria-acellular pertussis (Tdap) vaccine replace the tetanus-diphtheria (Td) vaccine in the adult immunization schedule.[61]

Health Care–Associated Pneumonia, Hospital-Acquired Pneumonia, and Ventilator-Associated Pneumonia

Preventing nosocomial pneumonia has been intensely studied over the past 30 years. Table 24-10 summarizes currently available strategies and their relative efficacy. No preventive strategy is uniformly effective. Many institutions now employ a "ventilator bundle" including several of these measures.

Handwashing is an important but frequently overlooked measure that can reduce transmission of nosocomial bacteria from one patient to another. Handwashing is especially important for RTs who may be caring for several ventilated patients in the ICU. Failure to wash the hands between patient contacts may result in transmission of respiratory pathogens from one patient to another. Handwashing is important even if gloves are worn. Gloves should be changed between patient contacts because they also can become contaminated with and transmit bacteria.

TABLE 24-10

Strategies for Prevention of Nosocomial Pneumonia

Strategy	Efficacy
Handwashing	Probably effective
Isolation of patients with resistant organisms	Probably effective
Infection control and surveillance	Probably effective
Enteral feeding, rather than total parenteral nutrition	Possibly effective
Semierect position	Possibly effective
Sucralfate for bleeding prophylaxis	Possibly effective
Careful handling of respiratory therapy equipment	Possibly effective
Subglottic secretion aspiration	Possibly effective
Selective digestive decontamination	Unproved efficacy
Topical tracheobronchial antibiotics	Unproved efficacy

Infection control surveillance to detect outbreaks of nosocomial pneumonia with specific pathogens and to monitor antibiotic resistance patterns is important. Isolation and caring for infected patients in the same place can limit the scope and duration of outbreaks, especially in ICUs.

In patients requiring nutrition support, the use of enteral feeding via jejunostomy has been associated with a lower risk for nosocomial pneumonia than the use of total parenteral nutrition.[62] In addition, patients who are fed enterally (i.e., using the gut to feed) have a lower incidence of pneumonia if kept semierect rather than recumbent.[8]

Two studies suggest that GI bleeding prophylaxis with sucralfate is associated with a lower risk for pneumonia compared with antacid or H_2-blockers.[63,64] Careful handling of respiratory therapy equipment may reduce the risk for LRTI in ventilated patients. Condensate within the tubing may be colonized with bacteria and should be drained away from the patient because passage of this material into the airway may encourage colonization with nosocomial pathogens. One study found that continuous subglottic aspiration of secretions was effective in reducing the incidence of nosocomial pneumonia in intubated patients.[65] Many studies have failed to show that selective digestive decontamination is effective to prevent nosocomial pneumonia; this is a strategy that uses topical antibiotics in the oropharynx and GI tract along with a brief course of systemic therapy. A meta-analysis suggested that topical oral decontamination may reduce the incidence of VAP but not mortality, duration of mechanical ventilation, or length of ICU stay.[66]

Prevention of nosocomial pneumonia remains a challenge to the RT. Careful attention to basic infection control practices, such as frequent handwashing, using new gloves with each patient contact, and careful handling of respiratory care equipment, is important in preventing nosocomial pneumonia.

TUBERCULOSIS

Tuberculosis, caused by *M. tuberculosis,* can sometimes mimic CAP and poses special management challenges for the RT. Knowledge of the epidemiology, clinical manifestations, diagnosis, infection control management, and treatment of patients with suspected or proved tuberculosis is essential.

Epidemiology

The epidemiology of tuberculosis in the United States has changed over the past 25 years. After the introduction of effective drugs to treat tuberculosis in the 1950s, the incidence of tuberculosis steadily declined. Tuberculosis increasingly became a disease affecting elderly patients, and most cases represented reactivation of old latent disease. With the emergence of the acquired immunodeficiency syndrome (AIDS) epidemic in the early 1980s, there was a resurgence of tuberculosis in the United States and worldwide. This resurgence began in 1985 and peaked in 1992. Since 1992, the incidence of tuberculosis has declined. This resurgence of tuberculosis was accompanied by dramatic shifts in the patients at risk and the clinical manifestations of the disease. Multidrug-resistant tuberculosis, defined as resistance of *M. tuberculosis* to both isoniazid and rifampin, emerged as a major public health problem in some populations and areas. Compared with frequency of the era before AIDS, tuberculosis now more often occurs in younger individuals with HIV infection, especially inner-city minority populations with a history of injection drug use. Foreign-born nationals residing in the United States have accounted for half of cases reported annually in recent years.

Tuberculosis has increasingly become a disease affecting individuals of lower socioeconomic status in whom homelessness or crowded living conditions, poor access to health care, and unemployment have contributed to the persistence of the disease.[67] Other risk factors include the presence of hematologic malignancies, head and neck cancer, celiac disease (a bowel disease characterized by poor absorption), and the receipt of medications such as corticosteroids and TNF-alpha antagonists.[67-70]

Pathophysiology

Tuberculosis is acquired by inhaling airborne droplets containing the responsible microorganism, *M. tuberculosis,* and the lungs are the major site of infection. Microorganism-laden droplets are deposited in the terminal airways and cause a host immune response. Most exposed individuals successfully contain the infection and remain asymptomatic, although they remain at risk for reactivation of infection later in life, especially if they become immunosuppressed.

Patients with tuberculosis can present with pulmonary or extrapulmonary manifestations. The major syndromes of pulmonary tuberculosis include primary, reactivation, and endobronchial tuberculosis and tuberculoma.

Primary Tuberculosis

Symptomatic primary tuberculosis occurs in a few individuals shortly after exposure. Primary tuberculous pneumonia is a more common clinical presentation in children and in HIV-infected individuals compared with non–HIV-infected adults. Fever is the most common symptom and occurs in 70% of patients; it persists for 14 to 21 days on average.[71] Chest pain occurs in approximately 25%; cough is even less common. The chest radiograph shows hilar lymphadenopathy in 65%, pleural effusion in 33%, and an infiltrate in approximately 25%. Diagnosis may be difficult given the infrequency of cough and a pulmonary infiltrate.

Reactivation and Endobronchial Tuberculosis

Reactivation tuberculosis develops months to years after initial infection and may occur spontaneously or in the setting of immunosuppression. In individuals without HIV infection, reactivation disease accounts for 90% of cases of tuberculosis. The most common symptoms include fever, cough, night sweats, and weight loss. Sputum production increases as the infection progresses and is occasionally accompanied by hemoptysis, which is seldom massive. Older patients may

present with a more indolent illness in which fever and night sweats are absent. Physical examination is often unrevealing in patients with reactivation tuberculosis. Chest radiograph shows apicoposterior upper lobe disease in 80% to 90% of patients, and cavities are present in 20% to 40%.

Endobronchial tuberculosis involves the airways and may be seen in both primary and reactivation tuberculosis. In primary tuberculosis, hilar nodal enlargement may impinge on the bronchi, resulting in compression and ultimately ulceration. In patients with reactivation disease, endobronchial involvement may occur as a result of direct extension from the parenchyma or pooling of secretions from upper lobe cavities in the dependent distal airways. Symptoms of endobronchial tuberculosis include a barking cough in two-thirds of patients, sputum production, wheezing, and hemoptysis. On physical examination, wheezing is common. The chest radiograph most often shows an upper lobe cavitary infiltrate with an ipsilateral (i.e., on the same side) lower lobe infiltrate. Extensive endobronchial disease may produce bronchiectasis.

Tuberculomas

Tuberculomas are rounded solitary mass lesions and may occur in primary or reactivation tuberculosis. They are often asymptomatic and may mimic malignancy. Tuberculoma is in the differential diagnosis of solitary pulmonary nodule and may be difficult to diagnose without biopsy or excision because expectorated sputum in patients with tuberculoma rarely shows *M. tuberculosis* on smear or culture.

Complications

Complications of pulmonary tuberculosis include tuberculous empyema, bronchiectasis, extensive pulmonary parenchymal destruction, spontaneous pneumothorax, and massive hemoptysis from rupture of a Rasmussen aneurysm in the wall of a cavity.

Extrapulmonary Tuberculosis

Extrapulmonary tuberculosis is defined as spread of *M. tuberculosis* infection beyond the lung and may involve virtually any organ. The central nervous system, musculoskeletal system, genitourinary tract, and lymph nodes (scrofula) are the most common sites of extrapulmonary tuberculosis. HIV-infected patients who acquire tuberculosis often present with unique clinical manifestations compared with non–HIV-infected patients. HIV-infected patients may develop rapidly progressive primary infection and present with both pulmonary and extrapulmonary disease. In patients with advanced AIDS, tuberculosis may manifest as disseminated disease with involvement of multiple organs, including lymph nodes, bone marrow, liver, and spleen. Symptoms in this setting include high fevers, sweats, and progressive weight loss. Findings on examination may include fever, wasting, and hepatosplenomegaly. Laboratory testing may show pancytopenia (decreased cell counts in WBCs, RBCs, and platelets) and advanced immunodeficiency. Imaging studies often show mediastinal and abdominal lymphadenopathy and hepatosplenomegaly.

Diagnosis

The history is important in diagnosing and managing patients with suspected tuberculosis. In addition to eliciting the patient's symptoms, the clinician should inquire about any history of tuberculosis, the presence of risk factors for acquiring tuberculosis and/or HIV infection, any history of travel, and potential contacts with individuals with known or suspected tuberculosis. In patients with a history of tuberculosis, outside medical records, including drug susceptibility results of prior isolates, should be obtained. If the patient has been previously treated, the drugs chosen, duration of treatment, and adherence to therapy should be evaluated. Risk factors for drug-resistant tuberculosis should be sought, which include prior treatment for tuberculosis, exposure to individuals with known drug-resistant disease, exposure to individuals with active tuberculosis who have been previously treated, travel to parts of the world with a high prevalence of drug resistance, or exposure to individuals with active tuberculosis from those areas.

The gold standard for diagnosing tuberculosis from pulmonary and extrapulmonary sites is culture isolation of the organism on solid or liquid media. The major disadvantage of culture is that *M. tuberculosis* may take 4 to 6 weeks to grow, thereby delaying diagnosis. Acid-fast staining of expectorated sputum, bronchoscopic specimens, and other body fluids or tissues may be used in patients with suspected pulmonary or extrapulmonary disease. In patients with pulmonary tuberculosis, it is estimated that 10^4 organisms/ml is required for the smear to be positive. Acid-fast smears of both sputum and other body sites are less sensitive than culture for detecting disease. The presence of acid-fast bacilli on a smear is not synonymous with a diagnosis of *M. tuberculosis* because nontuberculous mycobacteria (NTM) can produce pulmonary and extrapulmonary disease in selected populations. More rapid diagnostic techniques for identifying *M. tuberculosis* in clinical specimens and for confirming the identity of the organism in culture are being developed and are available in some centers. These techniques include nucleic acid amplification, nucleic acid probes, PCR genomic analysis, and molecular tests for chromosomal mutations associated with drug resistance.

A 5 tuberculin unit purified protein derivative (5 TU PPD) skin test or interferon-gamma release assay (IGRA) may be performed in individuals with suspected tuberculosis. Both tests evaluate for cell-mediated immunity to tuberculosis in individuals with prior exposure to the organism. A PPD consists of intradermal injection of tuberculin material, which stimulates a delayed-type hypersensitivity response mediated by T cells and causes skin induration within 48 to 72 hours. False-positive results can occur in patients with prior bacille Calmette-Guérin (BCG) vaccination or infection with NTM species. IGRAs are blood tests that measure T-cell release of the cytokine interferon-gamma after stimulation by antigens unique to *M. tuberculosis.* IGRAs are unaffected by BCG vaccination status and most NTM infections (except *Mycobacterium marinum* and *Mycobacterium kansasii*) and require only a single patient encounter, all of which are advantages over the PPD.[72] Both tests become positive

3 to 8 weeks after acquisition of infection. A positive skin test or IGRA supports the diagnosis in the appropriate clinical setting, but a negative result does not exclude the diagnosis. Patients with HIV infection, other causes of immunodeficiency, advanced age, or other comorbidities may be anergic and unable to mount either a positive skin test or IGRA result.[72,73]

Precautions

Patients hospitalized with suspected or proved active pulmonary tuberculosis should be placed in respiratory isolation in private negative pressure airflow rooms because they pose a risk for transmitting infection to others by coughing up aerosolized droplets containing *M. tuberculosis*. Individuals entering the patient's room should wear fit-tested National Institute for Occupational Safety and Health–approved N-95 or higher masks or respirators. A surgical mask should be placed on a patient with suspected or proved active pulmonary tuberculosis during transport outside the negative pressure room.

Treatment

Treatment recommendations for tuberculosis have been published by the ATS, U.S. Centers for Disease Control and Prevention (CDC), and the IDSA.[74] The goals of therapy are to cure the patient and prevent transmission of *M. tuberculosis* to others. Treatment must address clinical and social issues and should be customized to the patient's circumstance. At the outset, daily observed therapy (DOT) should be part of the treatment program; this consists of observing the patient taking the antituberculous medications. Treatment programs that use comprehensive case management and DOT have a higher rate of successful completion of therapy than other treatment strategies. Social service support, housing assistance, and treatment for substance abuse may be required for selected individuals with tuberculosis and should be part of the treatment plan. Patients with tuberculosis must be promptly reported to the local department of public health so that contact tracing can be performed. This includes identification, if possible, of the index case from whom the patient has contracted the infection and identification of close personal contacts to whom the patient may have transmitted *M. tuberculosis*.

Isoniazid, rifampin, pyrazinamide, and ethambutol are first-line antituberculous medications. Pending antimicrobial susceptibility results, treatment with four drugs at the outset is recommended. In patients with drug-susceptible pulmonary tuberculosis, many 6- to 9-month treatment regimens have been shown to be effective as outlined in guidelines by the ATS, CDC, and IDSA.[74] Patients with multidrug-resistant tuberculosis require more prolonged courses of therapy with multidrug regimens.

ROLE OF THE RESPIRATORY THERAPIST IN PULMONARY INFECTIONS

The RT plays a key role in managing patients with pulmonary infections, including helping to diagnose and treat the illnesses. Diagnostically, RTs participate in the collection of sputum by expectoration or assisting physicians during bronchoscopy. In some settings, RTs may perform mini-BAL.

RTs often administer chest physiotherapy when indicated, as in patients with bronchiectasis and cystic fibrosis. They also may be involved in counseling patients in other clearance techniques, such as autogenic drainage and positive expiratory pressure (PEP) therapy. RTs also play key roles in modeling optimal infection control and prevention practices (e.g., handwashing, implementing and complying with respiratory precautions, vaccination) and in advising patients about preventive interventions, such as influenza, pneumococcal, and Tdap vaccines.

SUMMARY CHECKLIST

- CAP and nosocomial pneumonia are common and important clinical problems with significant morbidity and mortality.
- *S. pneumoniae* remains the most common cause of CAP. Gram-negative bacilli and *S. aureus* are the most common causes of nosocomial pneumonia, but their relative incidence and antimicrobial susceptibility profiles may vary across institutions.
- The mortality risk can be quantified at presentation for most patients with CAP, which helps in determining the need for hospitalization.
- Routine sputum cultures for patients with CAP must be interpreted within the context of the sputum Gram stain, which provides valuable information regarding the adequacy of the specimen and the predominance of potential pathogens.
- The accurate diagnosis of nosocomial pneumonia remains a challenge; none of the diagnostic methods currently available is completely reliable.
- Guidelines exist for the treatment of CAP and nosocomial pneumonia. When possible, pathogen-specific antibiotic therapy should be used.
- Immunizing high-risk individuals against influenza and *S. pneumoniae* is the major strategy in preventing CAP.
- Strategies for preventing nosocomial pneumonia are not uniformly effective.
- Pulmonary tuberculosis may mimic CAP; the recognition and appropriate isolation, diagnostic evaluation, and management of individuals with possible pulmonary tuberculosis are essential.
- The RT can help prevent nosocomial pneumonia by careful attention to basic infection control procedures such as handwashing.

CHAPTER 25

Obstructive Lung Disease: Chronic Obstructive Pulmonary Disease, Asthma, and Related Diseases

ENRIQUE DIAZ-GUZMAN AND JAMES K. STOLLER

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- State definitions of chronic obstructive pulmonary disease (COPD), asthma, and bronchiectasis.
- Understand the major risk factors associated with COPD.
- Identify the common signs and symptoms associated with COPD.
- Describe a treatment plan for a patient with stable COPD and for a patient with an acute exacerbation of COPD.
- State the typical clinical presentation of a patient with asthma.
- Identify the treatment currently available for a patient with acute asthma.
- Describe the treatment currently available for patients with bronchiectasis.

CHAPTER OUTLINE

KEY TERMS

acute exacerbation of COPD
airway hyperresponsiveness
airway inflammation
airway obstruction
asthma
bronchiectasis
bronchodilator
bronchospasm
chronic bronchitis
cystic fibrosis
emphysema
noninvasive ventilation
supplemental oxygen

The category of obstructive lung diseases is broad and includes chronic obstructive pulmonary disease (COPD) and **asthma** as the most common diseases and **bronchiectasis** and **cystic fibrosis** as less common forms. Airflow obstruction also may be a feature of other lung diseases such as sarcoidosis, lymphangioleiomyomatosis, and congestive heart failure. This chapter reviews the major obstructive lung diseases, emphasizing their defining features, epidemiology, pathophysiology, clinical signs and symptoms, prognosis, and management. Cystic fibrosis is discussed in Chapter 34.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Overview and Definitions

The term *chronic obstructive pulmonary disease (COPD)*, or sometimes *chronic obstructive lung disease (COLD)*, refers to a disease state characterized by the presence of incompletely reversible airflow obstruction. Current guidelines by the American Thoracic Society (ATS) and the Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines recommend the use of the term *COPD* to encompass both chronic bronchitis and emphysema. The ATS guidelines statement regarding COPD defines this entity as follows[1]:

> *Chronic obstructive pulmonary disease (COPD) is a preventable and treatable disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and is associated with an abnormal inflammatory response of the lungs to noxious particles or gases, primarily caused by cigarette smoking. Although COPD affects the lungs, it also produces significant systemic consequences.*

Similarly, the GOLD guidelines define COPD as follows[2]:

> *A disease state characterized by persistent airflow limitation that is usually progressive, and is associated with an enhanced inflammatory response in the airways and the lung to noxious particles or gases. Exacerbations and comorbidities contribute to the overall severity in individual patients.*

The spectrum of COPD is shown in Figure 25-1, which presents a nonproportional Venn diagram representing the major components of COPD—chronic bronchitis and emphysema. Although asthma is no longer conventionally considered to be part of the spectrum of COPD, the diagram shows that there is overlap between asthma and COPD. In actual practice, it may not be possible to distinguish between individuals with a history of asthma but with incompletely reversible airflow obstruction and individuals with COPD.

The two major diseases that make up COPD—emphysema and chronic bronchitis—are defined in different ways. **Emphysema** is defined in anatomic terms as a condition characterized by abnormal, permanent enlargement of the airspaces beyond the terminal bronchiole, accompanied by destruction of the walls of the airspaces without fibrosis. **Chronic bronchitis** is defined in clinical terms as a condition in which chronic productive cough is present for at least 3 months per year for at least 2 consecutive years. The definition specifies further that other causes of chronic cough (e.g., gastroesophageal reflux, asthma, and postnasal drip) have been excluded. Figure 25-1 shows considerable overlap between chronic bronchitis and emphysema and some overlap with asthma—that is, when airflow obstruction is incompletely reversible. Figure 25-1 also shows that chronic bronchitis and emphysema can occur without airflow obstruction, although the clinical significance of these diseases usually comes from obstruction to airflow.

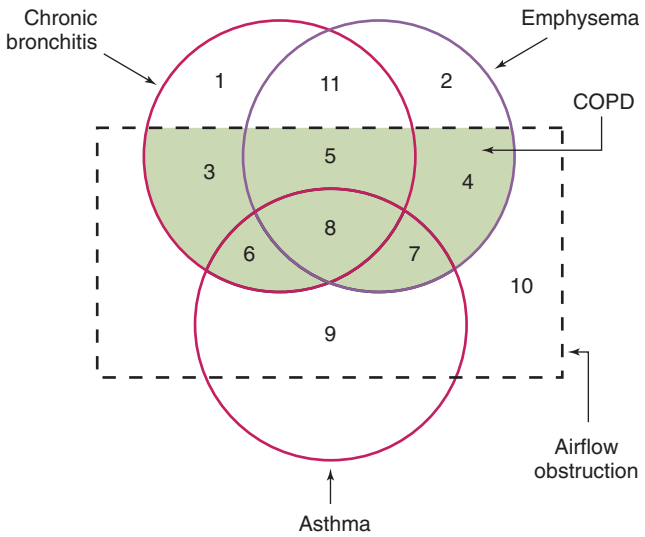

FIGURE 25-1 Schema of chronic obstructive pulmonary disease (COPD). This nonproportional Venn diagram shows subsets of patients with chronic bronchitis, emphysema, and asthma. The subsets constituting COPD are *shaded.* Subset areas are not proportional to actual relative subset sizes. Asthma is by definition associated with reversible airflow obstruction, although in variant asthma special maneuvers may be necessary to make the obstruction evident. Patients with asthma whose airflow obstruction is completely reversible *(subset 9)* are not considered to have COPD. Because in many cases it is virtually impossible to differentiate patients with asthma whose airflow obstruction does not remit completely from patients with chronic bronchitis and emphysema who have partially reversible airflow obstruction with airway hyperreactivity, patients with unremitting asthma are classified as having COPD (*subsets 6, 7,* and *8*). Chronic bronchitis and emphysema with airflow obstruction usually occur together *(subset 5),* and some patients may have asthma associated with these two disorders *(subset 8).* Individuals with asthma who are exposed to chronic irritation, as from cigarette smoke, may develop a chronic, productive cough, a feature of chronic bronchitis *(subset 6).* Such patients are often referred to as having *asthmatic bronchitis* or the *asthmatic form of COPD*. Individuals with chronic bronchitis or emphysema without airflow obstruction (*subsets 1, 2,* and *11*) are not classified as having COPD. Patients with airway obstruction caused by diseases with a known cause or specific pathologic process, such as cystic fibrosis or obliterative bronchiolitis *(subset 10)*, are not included in this definition.

Epidemiology

COPD is one of the most frequent causes of morbidity and mortality worldwide.[3] The World Health Organization predicts

that COPD will become the fifth most prevalent disease in the world and the third leading cause of worldwide mortality by 2030. In the United States, COPD is currently the third leading cause of death; it was responsible for 134,676 deaths and 715,000 hospitalizations in 2010.[4] Estimates suggest that 24 million Americans are affected, though only 15 million U.S. adults have been diagnosed.[4-6] Data from the National Health and Nutrition Examination Survey (NHANES) suggest that among adults 25 to 75 years old in the United States, mild COPD (defined as forced expiratory volume in 1 second [FEV_1]/forced vital capacity [FVC] < 70%, and FEV_1 > 80% predicted) occurs in 6.9% and moderate COPD (defined as $FEV_1/FVC < 79\%$ and $FEV_1 \leq 80\%$ predicted) occurs in 6.6%.[3] COPD prevalence increases with aging, with a five-fold increased risk for adults older than 65 years compared with adults younger than 40 years, and some studies estimate a prevalence of 20% to 30% in adults older than 70 years.[7]

The growing health burden from COPD is caused in part by the aging of the population but mainly by the continued use of tobacco. The socioeconomic burden of COPD is also substantial. In 2010, COPD caused 715,000 hospitalizations (which accounted for 1.9% of all hospitalizations in the United States), and, in 2010, COPD resulted in a total health expenditure of $49.9 billion.[4] In this regard, COPD is a problem that is a frequent challenge for the respiratory clinician.

Risk Factors and Pathophysiology

Although many risk factors exist for COPD (Box 25-1), the two most common are *cigarette smoking* (which has been estimated to account for 80% to 90% of all COPD-related deaths) and *alpha-1 antitrypsin (AAT) deficiency*.[8] Evidence linking cigarette smoking to the development of COPD is strong and includes the following:

- Symptoms of COPD (e.g., chronic cough and phlegm production) are more common in smokers than in nonsmokers.
- Impaired lung function with evidence of an obstructive pattern of lung dysfunction is more common in smokers than in nonsmokers.
- Pathologic changes of airflow obstruction and chronic bronchitis are evident in the lungs of smokers.
- So-called *susceptible smokers,* who represent approximately 15% of all cigarette smokers, experience more rapid rates of decline of lung function than nonsmokers.

Information from the Lung Health Study (Figure 25-2) highlighted the accelerated rate of decrease of FEV_1 in smokers compared with former smokers who have achieved sustained quitting.[9,10] Overall, the strength of evidence implicating cigarette smoking as a cause of COPD has allowed the U.S. Surgeon General to conclude, "Cigarette smoking is the major cause of chronic obstructive lung disease in the United States for both men and women. The contribution of cigarette smoking to chronic obstructive lung disease morbidity and mortality far outweighs all other factors."[11]

As the second well-recognized cause of emphysema, AAT deficiency, sometimes called *genetic emphysema* or *alpha-1 antiprotease deficiency,* is a condition that features a reduced amount of the protein alpha-1 antitrypsin (AAT), which may result in the early onset of emphysema and which is inherited as a so-called *autosomal codominant condition*. AAT deficiency

Box 25-1 Causes of Chronic Obstructive Pulmonary Disease*

COMMON CAUSES
- Cigarette smoking
- Alpha-1 antitrypsin (AAT) deficiency
- Outdoor air pollution
- Long-standing asthma
- Biomass and occupational exposure (e.g., chronic exposure to wood smoke with poorly ventilated indoor cooking)

LESS COMMON CAUSES
- Hypocomplementemic urticarial vasculitis
- Intravenous methylphenidate (Ritalin) abuse
- Ehlers-Danlos syndrome
- Marfan syndrome
- Cutix laxa
- Menke syndrome
- Salla disease†
- Alpha-1 antichymotrypsin deficiency†
- Human immunodeficiency virus infection (emphysema-like illness)

*Multiple causes (e.g., cigarette smoking and alpha-1 antitrypsin deficiency) may coexist in a single patient.
†Putative cause; firm evidence is unavailable.

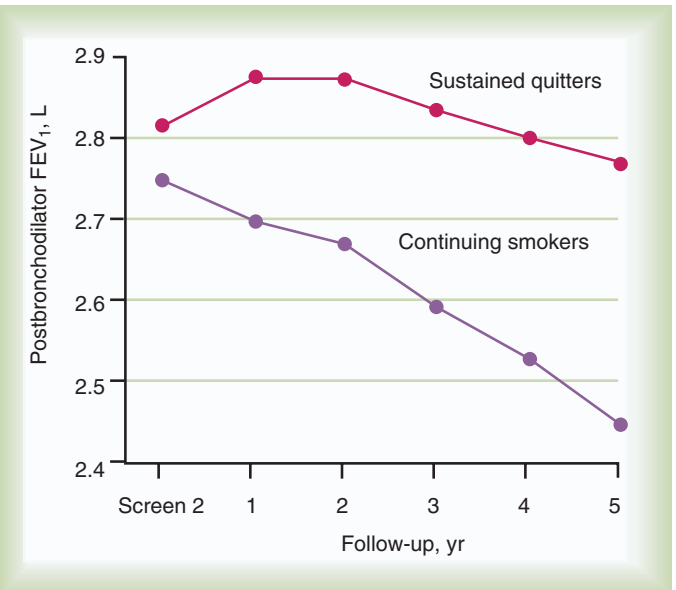

FIGURE 25-2 Mean postbronchodilator FEV_1 for participants in the smoking intervention and placebo groups who were sustained quitters *(red circles)* and continuing smokers *(purple circles).* The two curves diverge sharply after baseline. (From Anthonisen SR, Connett JE, Kiley JP, et al: Effects of smoking intervention and the use of an anticholinergic bronchodilator on the rate of decline of FEV_1: the Lung Health Study. JAMA 272:1497–1504, 1994.)

accounts for 2% to 3% of all cases of COPD and affects 100,000 Americans but is underrecognized by health care providers. In one 1995 survey, the mean interval between the first onset of pulmonary symptoms and initial diagnosis of AAT deficiency was 7.2 years, and 43% of individuals with severe deficiency of AAT reported seeing at least three physicians before the diagnosis of AAT deficiency was first made.[12] More recent studies suggest that underrecognition of AAT deficiency persists and that the diagnostic delay interval has not decreased significantly.[12-15]

Identifying individuals with AAT deficiency is simple, often requiring only a blood test of the serum AAT level. Respiratory therapists (RTs) can contribute importantly to detecting individuals with AAT deficiency (e.g., by suggesting or offering testing when airflow obstruction is diagnosed in the pulmonary function laboratory by an RT performing the test and by making patients aware of available free, home-based testing kits) (see http://www.alpha-1foundation.org). Several observations suggest the importance of detection: (1) first-degree relatives (e.g., siblings, parents, and children) also may be affected but unaware of their risk; (2) early detection allows appropriate monitoring and therapy, including the very important step of smoking cessation; and (3) for individuals with established emphysema, consideration can be given to available specific therapy, called *intravenous augmentation therapy* (which is the administration of purified AAT intravenously to individuals with severe deficiency of AAT). The risk for developing emphysema for individuals with AAT deficiency increases as the serum AAT level decreases to less than 11 µmol/L, or less than approximately 57 mg/dl using a testing technique called *nephelometry;* these levels in serum define the so-called *protective threshold value,* which is the serum level below which the risk for emphysema is felt to increase. Cigarette smoking markedly accelerates the rate of emphysema progression in individuals with AAT deficiency.[14]

Study of AAT deficiency has helped formulate the protease-antiprotease hypothesis of emphysema.[14,16] In this explanatory model (Figure 25-3), lung elastin, a major structural protein that supports the alveolar walls of the lung, is normally protected by AAT, a protein that defends the lung against tissue destruction by neutrophil elastase. Neutrophil elastase is a protein contained within a category of white blood cells called *neutrophils* that is released when neutrophils are attracted to the lung during inflammation or infection. Under normal circumstances of an adequate amount of AAT, neutrophil elastase is counteracted so as not to digest lung elastin. However, in the face of a severe deficiency of AAT (i.e., when serum levels decrease below the "protective threshold" serum value of 11 µmol/L, or 57 mg/dl), neutrophil elastase may go unchecked, causing breakdown of elastin and of alveolar walls. This protease-antiprotease model explains the pathogenesis of emphysema in AAT deficiency, but evidence suggesting its role in COPD in individuals with normal amounts of AAT is conflicting. Also, other enzymes that break down proteins (e.g., matrix metalloproteinases) are thought to contribute to the destruction of alveolar walls that produces emphysema.[17]

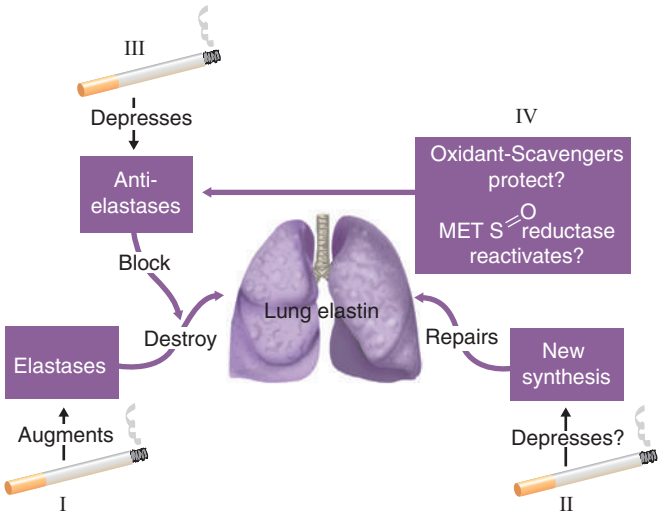

FIGURE 25-3 Proposed biochemical links between cigarette smoking and the pathogenesis of emphysema. *(I)* Smoking recruits monocytes, macrophages, and (through macrophage chemotactic factors) polymorphonuclear neutrophils to the lung, elevating the connective tissue "burden" of elastolytic serine and metalloproteases. *(III)* At the same time, oxidants in smoke plus oxidants produced by smoke-stimulated lung phagocytes (and oxidizing products of chemical interactions between these two) inactivate bronchial mucus proteinase inhibitor and alpha-1 antitrypsin (AAT), the latter representing the major antielastase "shield" of the respiratory units. *(II)* Other, unidentified water-soluble, gas-phase components of cigarette smoke (cyanide, copper chelators) inhibit lysyl oxidase–catalyzed oxidative deamination of epsilon-amino groups in tropoelastin and block formation of desmosine and presumably other cross-links during elastin synthesis, decreasing connective tissue repair. *(IV)* Antioxidants (ceruloplasmin, methionine-sulfoxide-reductase) may protect or reactivate elastase inhibitors, and other unidentified factors may modulate the chemical lesions induced in the lung by smoking to influence the risk for developing COPD. (Modified from Janoff A, Carp H, Laurent P, et al: The role of oxidative processes in emphysema. Am Rev Respir Dis 127[Suppl]:S31, 1983.)

COPD may occur without active cigarette smoking or AAT deficiency (see Box 25-1).[18,19] Factors such as passive smoking, air pollution, occupational exposure, and airway hyperresponsiveness may contribute to airflow obstruction that is not reversible.

The mechanisms of airflow obstruction in COPD include inflammation and obstruction of small airways (<2 mm in diameter); loss of elasticity, which keeps small airways open when elastin is destroyed in emphysema; and active **bronchospasm.** Although traditionally considered to be characteristic of asthma, some reversibility of airflow obstruction has been observed in up to two-thirds of patients with COPD when tested multiple times with inhaled bronchodilators.[20]

Clinical Signs and Symptoms

Common symptoms of COPD include cough, phlegm production, wheezing, and shortness of breath, typically on exertion. Dyspnea is often slow but progressive in onset and occurs later in the course of the disease, characteristically in the late sixth or seventh decade of life. One notable exception is AAT

TABLE 25-1

Clinical Features of Chronic Obstructive Pulmonary Disease: Distinctions Between Chronic Bronchitis and Emphysema, With Emphasis on Distinguishing Features of Alpha-1 Antitrypsin Deficiency

Features	Chronic Bronchitis	Emphysema	Severe Alpha-1 Antitrypsin Deficiency
Symptoms and Signs			
Chronic cough, phlegm	Common	Less common	Less common, but may be present
Dyspnea on exertion	Less common	Common	Common
Cor pulmonale	Present (often with multiple exacerbations)	Present (but often in end-stage emphysema)	Present (but often in end-stage emphysema)
Age of patient at symptom onset	6th-7th decade	6th-7th decade	4th-5th decade (although late onset is possible)
Family history of COPD	Possible but not characteristic	Possible but not characteristic	Common in parents, children, and siblings
History of cigarette smoking	Present, often heavy	Present, often heavy	May be present, but COPD can occur in the absence of smoking
Physiologic Function			
Airflow (FEV_1, FEV_1/FVC)	Decreased	Decreased	Decreased
Lung volumes, residual volume	Normal	Increased, suggesting air trapping	Increased
Gas exchange, diffusion PaO_2	Often decreased	Often preserved until advanced stage	Often preserved until advanced stage
$PaCO_2$	May be increased	Often preserved until advanced disease, then elevated	Often preserved until advanced disease, then elevated
Diffusion capacity	Often normal	Decreased	Decreased
Static lung compliance	Normal	Increased	Increased
Chest radiograph	"Dirty lungs" with peribronchial cuffing, suggesting thickened bronchial walls	Hyperinflation, with evidence of emphysema; greater at lung apex than at lung base	Hyperinflation, with evidence of emphysema; frequently greater at lung base than at lung apex (basilar hyperlucency)

FIGURE 25-4 Posteroanterior plain chest radiograph in a patient with severe deficiency of alpha-1 antitrypsin and emphysema. Note that the emphysematous changes (hyperlucency) are more pronounced at the lung bases than at the apexes.

deficiency, in which dyspnea characteristically begins sooner (mean age approximately 45 years).[8]

Table 25-1 reviews the characteristic features of emphysema and chronic bronchitis and emphasizes traits that should suggest the possibility of AAT deficiency, including early onset of emphysema, emphysema in a nonsmoker, a family history of emphysema, or emphysema with a chest x-ray (Figure 25-4) or computed tomography (CT) (Figure 25-5), in which emphysematous changes are more pronounced at the lung bases than at the apexes (so-called *basilar hyperlucency*). Suspicion of AAT deficiency should lead to a simple blood test by which the serum level can be established.[8,14]

Physical examination of the chest early on in a patient with COPD may reveal wheezing or diminished breath sounds. Later, signs of hyperinflation may be evident—that is, increased anteroposterior diameter of the chest (sometimes called a *barrel chest*), diaphragm flattening, and dimpling inward of the chest wall at the level of the diaphragm on inspiration (called the *Hoover sign*). Other late signs of COPD include use of accessory muscles of respiration (e.g., sternocleidomastoid), edema from cor pulmonale, mental status changes caused by hypoxemia or hypercapnia (especially in acute exacerbations of chronic, severe disease), or asterixis (i.e., involuntary flapping of the hands when held in an extended position, as in "stopping traffic").

RULE OF THUMB

In patients with COPD, $PaCO_2$ is usually preserved until airflow obstruction is severe (i.e., $FEV_1 < 1$ L), when $PaCO_2$ may increase.

RULE OF THUMB

Digital clubbing is not caused by COPD alone, even if hypoxemia is present. Clubbing in a patient with COPD warrants consideration of another cause (e.g., bronchogenic cancer, bronchiectasis).

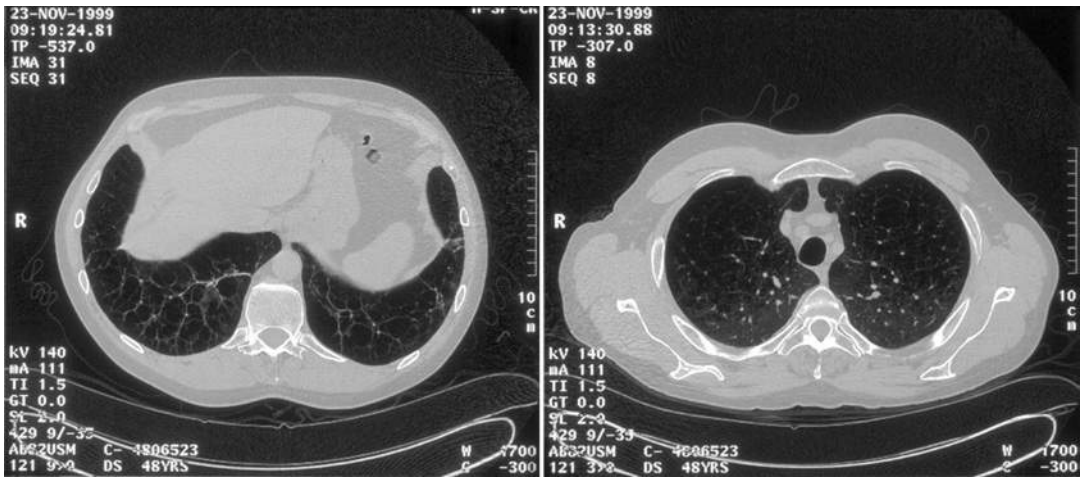

FIGURE 25-5 Computed tomography chest image from an individual with severe deficiency of alpha-1 antitrypsin. Note the changes of emphysema *(arrows)* are more pronounced in the lung bases **(B)** than in the lung apexes **(A).**

RULE OF THUMB

When COPD occurs in a nonsmoker, a young person, an individual with a family history of liver or lung disease, or an individual with emphysematous changes more pronounced at the lung bases than apexes on a chest radiograph (see Figure 25-4) or chest CT (see Figure 25-5), AAT deficiency should be suspected. Guidelines suggest that *all* adult, symptomatic patients with COPD should be tested for AAT deficiency.

Management

In managing patients with chronic, stable COPD, the following goals must guide the clinician[1,2]:

- Establish the diagnosis of COPD.
- Optimize lung function.
- Maximize the patient's ability to perform daily activities.
- Simplify the medical treatment program as much as possible.
- Avoid exacerbations of COPD.
- Prolong survival.

In managing an **acute exacerbation of COPD,** additional considerations are to reestablish the patient to baseline status as quickly and with as little morbidity and mortality as possible.[21,22] Each of the treatments that are discussed in this section is considered in regard to these goals, recognizing differences in management between patients with chronic, stable COPD versus an acute exacerbation of COPD. In patients with COPD, $PaCO_2$ usually is generally preserved until airflow obstruction is severe ($FEV_1 < 1$ L), when the $PaCO_2$ level may increase.

Establishing the Diagnosis

Although a spectrum of diseases can give rise to obstructive lung disease, including some unusual entities such as chronic eosinophilic pneumonia, bronchiectasis, and allergic bronchopulmonary aspergillosis, the major challenge facing the clinician who encounters a patient with airflow obstruction is to distinguish COPD (i.e., emphysema or chronic bronchitis or both) from asthma. Distinguishing asthma from COPD may be very difficult in practice; features that tend to favor COPD include chronic daily phlegm production, which establishes the diagnosis of chronic bronchitis; diminished vascular shadows on the chest radiograph (called *hyperlucency*); and a decreased diffusing capacity. The diagnosis of asthma is favored if the diminished FEV_1 obtained on spirometry returns to normal after **bronchodilator** treatment.

After the diagnosis of COPD is established, another issue is for the clinician to consider whether the patient has an underlying predisposition to COPD, such as AAT deficiency or other cause listed in Box 25-1.[18,19] Underlying causes are present in fewer than 5% of patients with COPD, with AAT deficiency being the most common (2% to 3% of all patients with COPD).

Optimizing Lung Function

Stable Chronic Obstructive Pulmonary Disease

Although airflow obstruction from emphysema itself is irreversible, most (up to two-thirds) patients with stable COPD exhibit a reversible component of airflow obstruction, defined as a 12% and 200-ml increase in post-bronchodilator FEV_1 or FVC or both. For this reason, as shown in an algorithm developed by GOLD (Figure 25-6),[2,22,25,26] bronchodilator therapy is recommended for patients with COPD.

Bronchodilators produce smooth muscle relaxation resulting in improved airflow obstruction, improved symptoms and exercise tolerance, and decrease in the frequency and severity of exacerbations, but they do not enhance survival. The results of the Lung Health Study,[9] which compared the effects of inhaled ipratropium bromide (two puffs four times daily) with placebo in patients with mild, stable COPD, showed that regular,

MINI CLINI

Determining the Severity of Chronic Obstructive Pulmonary Disease

PROBLEM: You are asked to see a new patient in clinic who was recently discharged from the hospital with a COPD exacerbation. The patient describes being hospitalized at least twice per year because of lung problems and complains of severe dyspnea when walking up a hill. Spirometry revealed an FEV_1 of 40% predicted. How do you characterize the severity of COPD in this patient?

DISCUSSION: In 2001 GOLD created a classification system based on the severity of airflow obstruction.[2] According to this staging system, severity of COPD was graded based on the degree of airflow obstruction into one of the following four stages:

Stage	Description
I	Patients with $FEV_1/FVC < 70\%$ and $FEV_1 > 80\%$ predicted
II	Patients with $FEV_1/FVC < 70\%$ and FEV_1 50%-79% predicted
III	Patients with $FEV_1/FVC < 70\%$ and FEV_1 30%-49% predicted
IV	Patients with $FEV_1/FVC < 70\%$ and $FEV_1 < 30\%$ or $FEV_1 <$ 50% predicted plus chronic respiratory failure

The GOLD guidelines were revised in 2011 to include symptoms and exacerbation history, and now COPD severity is graded (A to D) as follows:

A = Low risk, low symptom burden
- Low symptom burden (mMRC of 0 to 1 OR CAT score < 10) AND
- FEV_1 of 50% or greater (old GOLD 1 to 2) AND low exacerbation rate (0 to 1/year)

B = Low risk, higher symptom burden
- Higher symptom burden (mMRC of 2 or more OR CAT of 10 or more) AND
- FEV_1 of 50% or greater (old GOLD 1 to 2) AND low exacerbation rate (0 to 1/year)

C = High risk, low symptom burden
- Low symptom burden (mMRC of 0 to 1 OR CAT score < 10) AND
- $FEV_1 < 50\%$ (old GOLD 3 to 4) AND/OR high exacerbation rate (2 or more/year)

D = High risk, higher symptom burden
- Higher symptom burden (mMRC of 2 or more OR CAT of 10 or more) AND
- $FEV_1 < 50\%$ (old GOLD 3 to 4) AND/OR high exacerbation rate (2 or more/year)

The new classification categorizes patients first by symptom burden and then adds degree of airflow obstruction and exacerbation history to refine risk. This system uses two different scales to define symptom burden, the modified Medical Research Council questionnaire (mMRC)[23] and the COPD assessment test (CAT).[24] Based on severity of airflow obstruction, high symptom burden, and history of exacerbations, this patient is classified as GOLD D, indicating severe COPD with high risk for complications.

mMRC
1. Dyspnea with strenuous exercise
2. Dyspnea when hurrying on the level or walking up a slight hill
3. Walks slower than most people on the level, stops after a mile or so, or stops after 15 minutes of walking at own pace
4. Stops for breath after walking 100 yards or after a few minutes of level ground
5. Too breathless to leave the house, or breathless when undressing

CAT

Cough (none to all the time): Total 0 to 5
Phlegm (mucus) in my chest: Total 0 to 5 (none to severe)
Chest tightness: Total 0 to 5 (none to severe)
Dyspnea walking flight of stairs: Total 0 to 5 (none to severe)
Limitation for home activities: Total 0 to 5 (none to severe)
Confident leaving home despite lung condition: Total 0 to 5 (very confident to nonconfident)
Sleep quality: Total 0 to 5 (sound sleep to no sleep because of lung condition)
Energy: Total 0 to 5 (full energy to none)

long-term use of ipratropium did not change the rate of decline of lung function but offered a one-time, small increase in FEV_1.

Both anticholinergic and adrenergic (beta agonist) bronchodilators can improve airflow in patients with COPD, although some clinicians favor an inhaled anticholinergic medication (e.g., ipratropium bromide or tiotropium[25,26]) as first-line therapy (see Figure 25-6). More recent concerns about the possible adverse cardiovascular effects of anticholinergic therapy in patients with COPD[27,28] have been dismissed by the results of a multicenter trial (Understanding Potential Long-Term Impacts on Function with Tiotropium [UPLIFT]), which found a significantly lower rate of cardiac adverse events and cardiovascular death in patients who received tiotropium.[27]

The GOLD guidelines[2] recommend the use of short-acting beta-adrenergic agents (≤6 hours) for symptomatic management of all patients with COPD. Also, the use of a long-acting beta agonist (e.g., salmeterol) or a long-acting anticholinergic drug (e.g., tiotropium) can lessen the frequency of acute exacerbations of COPD.[26]

Other treatment options to optimize lung function include administering corticosteroids and, as a second-line option, methylxanthines. Systemic corticosteroids can produce significant improvements in airflow in a few (6% to 29%) patients with stable COPD.[29,30] To assess whether airflow obstruction is completely reversible (i.e., the patient has asthma) and whether a patient with COPD is responsive to steroids, a brief course of corticosteroids (20 to 40 mg/day of prednisone or equivalent for 5 to 8 days) is sometimes recommended. Patients with a significant clinical response often are treated with long-term inhaled corticosteroids or, rarely, with the smallest necessary dose of systemic corticosteroids, recognizing that long-term systemic steroid therapy has risks.[31] Also, results of several major clinical trials (e.g., Lung Health Study II, Euroscop, Inhaled Steroids in Obstructive Lung Disease [ISOLDE] study,

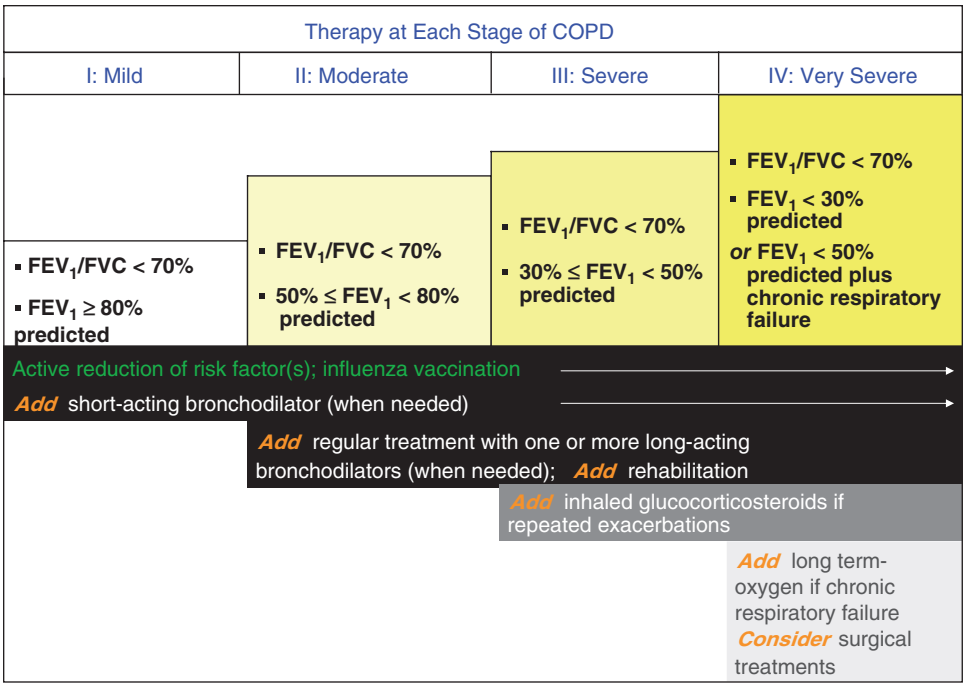

FIGURE 25-6 Initial Pharmacologic Management of COPD. (From The Global Strategy for the Diagnosis, Management and Prevention of COPD. Global Initiative for Chronic Obstructive Lung Disease [GOLD], 2014. http://www.goldcopd.com. Accessed July 29, 2015.)

and Copenhagen City Study, but not another trial, Towards a Revolution in COPD Health [TORCH] study) agree that inhaled corticosteroids do not change the rate of decline of FEV_1 in patients with COPD, although their use is associated with a decreased frequency of acute exacerbations.[32-34]

Studies of combined salmeterol and fluticasone versus placebo in patients with COPD suggest that adding an inhaled corticosteroid (fluticasone) to the long-acting beta agonist (salmeterol) can improve FEV_1 and reduce the frequency of acute exacerbations of COPD but does not improve survival.[32,33] The finding of a higher rate of pneumonia in inhaled corticosteroid users is concerning. Overall, the GOLD guidelines[2] recommend use of inhaled corticosteroids in patients with FEV_1 less than 50% and history of recurrent exacerbations (three episodes in the last 3 years), whereas the ATS/European Respiratory Society (ERS) guidelines recommend use of inhaled corticosteroids in patients with FEV_1 less than 50% who have required use of oral corticosteroids or oral antibiotics at least once within the last year.[3]

Treatment with methylxanthines offers little additional bronchodilation in patients using inhaled bronchodilators and generally is reserved for patients with debilitating symptoms from stable COPD despite optimal inhaled bronchodilator therapy. Controlled trials show lessened dyspnea in methylxanthine recipients despite a lack of measurable increases in airflow.[35] Side effects of methylxanthines include anxiety, jitteriness (tremulousness), nausea, cardiac arrhythmias, and seizures. To minimize the chance of toxicity, current recommendations suggest maintaining serum theophylline levels at 8 to 10 mcg/ml.

Acute Exacerbation of Chronic Obstructive Pulmonary Disease

Strategies for improving lung function during acute exacerbations of COPD generally include inhaled bronchodilators (especially beta-2 agonists), antibiotics, and systemic corticosteroids. Because of their rapid onset of action and efficacy, short-acting beta-2 agonists are first-line therapy for patients with COPD exacerbation. Inhaled beta-2 agonists are frequently administered through a nebulizer, although metered dose inhaler devices may have equal efficacy if administered appropriately.[2] A common practice is to administer 2.5 mg of albuterol by nebulizer every 1 to 4 hours as needed. Higher doses of albuterol (i.e., 5 mg) do not produce further improvement in pulmonary function and may cause cardiac side effects.[36] Similarly, continuous nebulization of short-acting beta-2 agonists in patients with COPD exacerbation is not recommended.

In addition to inhaled bronchodilator therapy, short-term systemic corticosteroids are recommended to reduce inflammation and improve lung function. An early randomized, controlled trial of intravenous methylprednisolone for patients with acute exacerbations showed accelerated improvement in FEV_1 within 72 hours.[37] Larger, more recent trials have confirmed the benefits of systemic corticosteroids in acute exacerbations and have shown that short-term oral courses (i.e., approximately 2 weeks) are as effective as longer courses (i.e., 8 weeks) with fewer adverse steroid effects.[38] For patients with acute exacerbations characterized by purulent phlegm, oral antibiotics (e.g., trimethoprim-sulfamethoxazole, amoxicillin, or doxycycline) administered for 7 to 10 days have produced

accelerated improvement of peak flow rates compared with placebo recipients.[21,39,40] Because of the risk for being infected with more virulent bacteria (e.g., *Pseudomonas aeruginosa*), patients who have severe COPD and an exacerbation may benefit from broader spectrum antibiotics, such as fluoroquinolones or aminoglycosides.

Finally, intravenous methylxanthines offer little benefit in the setting of acute exacerbations of COPD and have fallen into disfavor.[41,42] Taken together, important elements of managing an acute exacerbation of COPD caused by purulent bronchitis include supplemental oxygen (O_2) to maintain arterial saturation at greater than 90%, inhaled bronchodilators, oral antibiotics, and a brief course of systemic corticosteroids.[21]

For patients with hypercapnia and acute respiratory acidemia, the clinician also must decide whether to provide ventilatory assistance. Although intubation and mechanical ventilation historically have been the preferred approach, more recent studies suggest that noninvasive positive pressure ventilation can be an effective and preferred alternative for patients with acute exacerbations of COPD, especially with severe exacerbations characterized by pH less than 7.30.[43] Specifically, based on studies that show that noninvasive positive pressure ventilation can shorten intensive care unit (ICU) stay and avoid the need for intubation, the American Association for Respiratory Care consensus conference and guidelines on noninvasive ventilation from other official societies have endorsed use of noninvasive ventilation for such patients (unless a contraindication to noninvasive ventilation is present).[44,45] Criteria defining candidacy for **noninvasive ventilation** include acute respiratory acidosis (without frank respiratory arrest), hemodynamic stability, ability to tolerate the interface needed for noninvasive ventilation, and ability to protect the airway. Relative contraindications include craniofacial trauma or burns, copious secretions, or massive obesity.[4]

Maximizing Functional Status

In symptomatic patients with stable COPD, maximizing their ability to perform activities of daily living is a priority. Pharmacologic treatments to maximize functional status include administration of bronchodilators to enhance lung function as much as possible and consideration of methylxanthine therapy, based on data that such drugs can lessen dyspnea and improve functional status ratings even though airflow is not increased.[3]

Comprehensive pulmonary rehabilitation is another important treatment for patients with COPD that has the goal of improving patients' ability to function.[46] Pulmonary rehabilitation is a multidisciplinary intervention that consists of lower and upper extremity exercise conditioning, breathing retraining, education, and psychosocial support. Randomized, controlled trials show that although pulmonary rehabilitation does not improve lung function or survival, pulmonary rehabilitation results in decreased dyspnea perception, improved health-related quality of life, fewer days of hospitalization, and decreased health care usage.[47,48]

Finally, transcutaneous neuromuscular electrical stimulation is a newer therapy that has been successfully used to stimulate peripheral muscles in patients with COPD. Studies have shown significant improvements in quadriceps muscle function, exercise tolerance (including walk distance), and health status in patients with severe COPD.[49]

MINI CLINI

Recognizing and Managing an Acute Exacerbation of Chronic Obstructive Pulmonary Disease

PROBLEM: A 70-year-old man with long-standing COPD is admitted to the hospital with an acute exacerbation. On physical examination, he is not dehydrated and examination shows diminished breath sounds bilaterally without wheezing. Pertinent laboratory values show a hematocrit of 54% (normal is 40% to 47%). An arterial blood gas (ABG) analysis performed with the patient on room air showed the following:

PaO_2 = 47 mm Hg
PCO_2 = 67 mm Hg
pH = 7.30
HCO_3^- = 34 mEq/L

How do you describe his current status, what do his current laboratory values suggest about his long-term gas exchange status, and what treatment should be considered?

SOLUTION: The patient has an acute exacerbation of COPD. The acidemia (pH 7.30) on his ABG analysis suggests an acute increase in PCO_2 superimposed on chronic hypercapnia, which is suggested by the elevated serum bicarbonate (HCO_3^-), indicating renal compensation for chronic respiratory acidosis. Although his current hypoxemia may be due to worsened gas exchange accompanying the current flare-up of COPD, his elevated hematocrit, in the absence of dehydration, suggests chronic hypoxemia and secondary erythrocytosis. The goal of therapy is to restore his gas exchange to baseline and to avoid invasive or high-risk interventions, while optimizing survival.

To achieve these goals, treatment would consist of aggressive use of bronchodilators, intravenous corticosteroids, supplemental O_2, and antibiotics (if there is evidence of acute lung infection, either bronchitis or pneumonia). In view of the patient's acute chronic respiratory acidemia, ventilatory support should be implemented. As indicated by several randomized, controlled trials, noninvasive positive pressure ventilation is an effective alternative to intubation.

Preventing Progression of Chronic Obstructive Pulmonary Disease and Enhancing Survival

Cigarette smoking is widely recognized as the major risk factor for accelerating airflow obstruction in smokers who are "susceptible." For these individuals, smoking cessation can generally slow the rate of decline of FEV_1 and restore the rate of lung decline to that seen in healthy, age-matched nonsmokers.

Follow-up data from the Lung Health Study[9] confirm that a comprehensive smoking cessation program (including instruction, group counseling, and nicotine replacement therapy) can

achieve sustained smoking cessation in 22% of participants and that the rate of annual FEV_1 decline in these sustained nonsmokers was significantly less than it was for continuing smokers, even over 11 years of follow-up.[10] Participation in aggressive smoking cessation can enhance survival rates in patients with COPD.[10]

Critical elements in achieving successful smoking cessation include identifying "teachable moments" (i.e., during episodes of illness in which smoking can be identified as a contributing factor[50]), identifying the role of smoking in adverse health outcomes, negotiating a "quit date," and providing frequent follow-up reminders from health care providers.[51] A helpful strategy during counseling is to use the five *A*s of smoking cessation[2]:

*A*sk if they are smoking
*A*dvise to quit
*A*ssess willingness to quit
*A*ssist by providing a plan
*A*rrange a follow-up

In this regard, the RT, who sees the patient frequently, has a special responsibility to provide frequent, constructive reminders about the advisability of smoking cessation.[52]

Among available treatments for COPD, **supplemental oxygen** is important because, similar to smoking cessation and lung volume reduction surgery in selected individuals (see later discussion), it can prolong survival.[53-56] Box 25-2 reviews the indications for supplemental O_2, and Figure 25-7 shows the results of the American Nocturnal Oxygen Therapy Trial[53] and the British Medical Research Council trial of domiciliary O_2 (1980 to 1981).[54,55] Survival was improved when eligible patients used supplemental O_2 for as close to 24 hours as possible; survival improved less for patients using O_2 only 15 hours per day. No survival benefit was observed when O_2 was used during sleeping hours only. Patients should be assessed for supplemental O_2 use only after receiving optimal bronchodilator therapy because one-third of potential O_2 candidates can experience sufficient improvement with aggressive bronchodilation to avoid the need for long-term supplemental O_2. Also, patients prescribed to receive supplemental O_2 during acute exacerbations should be reassessed several months later to determine whether they continue to need supplemental O_2.[57] RTs can play a key role in ensuring compliance with this recommendation and optimizing O_2 therapy.[57,58]

Finally, preventive strategies such as annual influenza and pneumococcal vaccinations are recommended for all patients with chronic debilitating conditions such as COPD.[59] Specific indications for pneumococcal vaccination are presented in Box 25-3. Recent recommendations for those age 65 or older also include a 13-valent pneumococcal vaccine in addition to the existing 23-valent pneumococcal vaccine.

Other measures to prevent exacerbations of COPD include use of long-acting anticholinergic agents (e.g., tiotropium, aclidinium, umeclidinium), inhaled corticosteroids, especially in combination with long-acting beta agonists, macrolide antibiotics (e.g., erythromycin and azithromycin),[60] phosphodiesterase-4 inhibition with roflumilast,[61] and antioxidants such as oral N-acetylcysteine.[62]

Box 25-2 Indications for Long-Term Oxygen Therapy

I. Continuous O_2
   A. Resting $PaO_2 \leq 55$ mm Hg
   B. Resting PaO_2 56 to 59 mm Hg or SaO_2 89% in the presence of any of the following:
      1. Dependent edema, suggesting congestive heart failure
      2. P pulmonale on the electrocardiogram (P wave > 3 mm in standard lead II, III, or aV_F)
      3. Erythrocytosis (hematocrit > 56%)
         a. Reimbursable only with additional documentation justifying O_2 prescription and a summary of more conservative therapy that has failed

II. Noncontinuous O_2
   A. O_2 flow rate and number of hours per day must be specified
      1. During exercise: $PaO_2 \leq 55$ mm Hg or $SaO_2 \leq 88\%$ with a low level of exertion
      2. During sleep: $PaO_2 \leq 55$ mm Hg or $SaO_2 \leq 88\%$ with associated complications, such as pulmonary hypertension, daytime somnolence, or cardiac arrhythmias

From Tarpy SP, Celli BR: Long-term oxygen therapy. N Engl J Med 333:710–714, 1995.

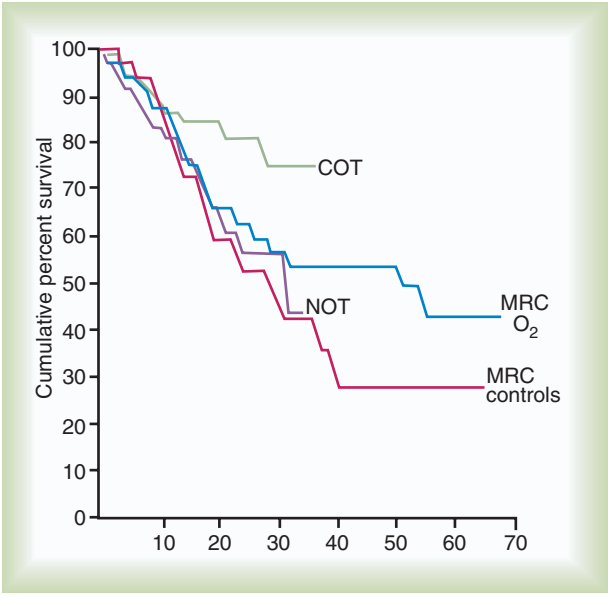

FIGURE 25-7 Cumulative percent survival of patients in the Nocturnal Oxygen Therapy Trial (NOTT) and Medical Research Council (MRC) controlled trials of long-term domiciliary O_2 therapy for men older than 70 years. MRC control subjects *(red line)* received no O_2. NOTT subjects *(purple line)* received O_2 for 12 hours in the 24-hour day, including the sleeping hours. MRC O_2 subjects *(blue line)* received O_2 for 15 hours in the 24-hour day, including the sleeping hours, and continuous O_2 therapy (COT) subjects *(green line)* received O_2 for 24 hours in the 24-hour day (on average, 19 hours). (Modified from Flenley DC: Long-term oxygen therapy. Chest 87:99–193, 1985.)

Box 25-3 Indications for Pneumococcal Vaccine Administration

Vaccination is recommended for the following adults:

- Adults age 65 years and older and adults of all ages with long-term illnesses that are associated with a high risk for contracting pneumococcal disease, including heart or lung diseases, diabetes, alcoholism, cirrhosis, or cerebrospinal fluid leaks
- Adults with diseases or conditions that lower the body's resistance to infections, including abnormal function of the spleen or removed spleen, Hodgkin disease, lymphoma, multiple myeloma, kidney failure, nephrotic syndrome, or organ transplantation, and adults who are taking drugs that lower the body's resistance to infections
- Adults with human immunodeficiency virus infection and acquired immunodeficiency syndrome (HIV/AIDS), with or without symptoms

Revaccination should be considered for the following groups:

- Individuals at the highest risk for fatal pneumococcal infection, such as individuals with abnormal function or removal of the spleen, who received the original pneumococcal vaccination (from 1979 to 1983) or who received the current vaccine (1983 to present) 6 or years or longer ago
- Individuals shown to lose protection rapidly (e.g., individuals with nephrotic syndrome, kidney failure, or transplants), who received the current vaccine 6 years or longer ago
- Children 10 years old or younger with nephrotic syndrome, abnormal function or removal of the spleen, or sickle cell anemia, who received the vaccine 3 to 5 years ago
- Adults age ≥65 should receive the 13-valent pneumococcal vaccine (Prevnar) followed 6-12 months later by the 23-valent vaccine (e.g., Pneumovax)

Additional Therapies

Additional therapies for individuals with end-stage COPD include lung transplantation[63] and lung volume reduction surgery (LVRS),[64-66] in which small portions of emphysematous lung are removed to reduce hyperinflation and improve lung mechanics of the remaining tissue. COPD is the most common current indication for lung transplantation. Lung transplantation is a consideration for patients with severe airflow obstruction (i.e., FEV_1 < 20% predicted and a Body-mass index, Obstruction, Dyspnea, and Exercise [BODE] index > 7 who are younger than 70 years old, and who are psychologically suitable and motivated). Double lung transplantation is preferred; nevertheless, because the supply of donor lungs to transplant is less than the number of patients needing lung transplantation, single-lung transplantation is also frequently performed. Although lung transplantation may be associated with significantly improved quality of life and functional status, major risks include rejection (manifested as bronchiolitis obliterans and progressive, debilitating airflow obstruction), infection with unusual opportunistic organisms, and death from these and other complications. The 5-year actuarial survival rate after lung transplantation in patients with COPD is approximately 54%[63] (Figure 25-8).

LVRS has regained popularity after initial experiences were reported in 1957.[64] Results of randomized controlled trials of LVRS, including the large National Emphysema Treatment

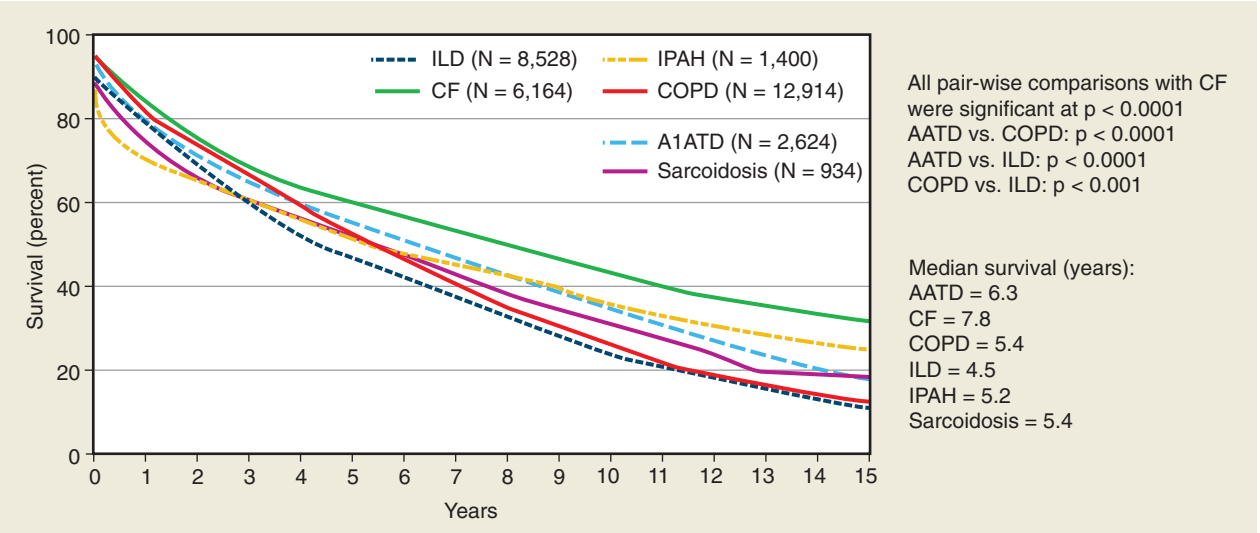

FIGURE 25-8 Adult recipient Kaplan-Meier survival by diagnosis (transplants: January 1990 to June 2011). The overall survival rate of patients with alpha-1 antitrypsin (AAT) deficiency is significantly higher than the survival rate of patients with chronic obstructive pulmonary disease (COPD) and interstitial lung disease (ILD), which includes idiopathic pulmonary fibrosis (IPF). Similarly, the overall survival rate of patients with COPD is higher than the survival rate of patients with idiopathic pulmonary fibrosis. *AATD,* alpha-1 antitrypsin deficiency associated COPD; *COPD,* non-AATD associated COPD; *CF,* cystic fibrosis; IPAH, idiopathic pulmonary arterial hypertension. (From Yusen RD, Christie JD, Edwards LB, et al: 30th official adult lung and heart-lung transplant report, 2013 in the Registry of the International Society for Heart and Lung Transplantation. http://www.ishlt.org. Accessed September 17, 2014.)

Trial, indicate that in selected subsets of patients with COPD (i.e., patients with heterogeneous emphysema that is upper lobe–predominant and who have low exercise capacity after pulmonary rehabilitation), LVRS can prolong survival, improve quality of life, and increase exercise capacity.[65,66] LVRS should not be considered in individuals with very severe COPD (i.e., characterized by FEV_1 <20% predicted with either a homogeneous pattern of emphysema or a diffusing capacity <20% predicted), because the mortality rate of LVRS is higher in such individuals than in medically treated patients.[67]

Given the positive results associated with LVRS in selected patients with COPD, nonsurgical bronchoscopic techniques have been developed in an attempt to reduce costs and expand treatment options for patients with high operative risk.[68] With the use of the bronchoscope, deployment of unidirectional endobronchial valves or coils into the airways results in collapse of the targeted lung parenchyma. Other techniques that have been studied include application of biodegradable gel to induce lung collapse or application of bronchial stents to create fenestrations and allow gas escape from hyperinflated areas of the lung. None of the aforementioned devices is currently approved by the U.S. Food and Drug Administration (FDA) for treatment of emphysema in the United States.[69]

Finally, for patients with AAT deficiency and established COPD, so-called *intravenous augmentation* with a purified preparation of AAT from human blood donors is recommended.[14] The best available evidence[70,71] suggests that for individuals with severe AAT deficiency and moderate degrees of airflow obstruction (i.e., FEV_1 35% to 60% predicted), weekly augmentation therapy may be associated with a slower rate of decline of lung function, a slower rate of loss of lung density on chest CT, and improved survival. Difficulties with intravenous augmentation therapy include the substantial expense (approximately $100,000 per year); the inconvenience of frequent intravenous infusions for life; and the infusion itself, which poses a theoretical risk for transmitting a blood-borne infection. Despite these drawbacks, the facts that augmentation therapy can slow the rate of FEV_1 decline, can possibly slow the rate of CT lung density loss, and is currently the only specific therapy for AAT deficiency have led to its endorsement in official guidelines from the ATS, the ERS, and the Canadian Thoracic Society.[14,72]

ASTHMA

Definition

Asthma is a clinical syndrome characterized by **airway obstruction,** which is partially or completely reversible either spontaneously or with treatment; **airway inflammation;** and **airway hyperresponsiveness** (AHR) to various stimuli.[73-75] Past definitions of asthma emphasized AHR and reversible obstruction; however, newer and more accurate definitions of asthma focus on asthma as a primary inflammatory disease of the airways, with clinical manifestations of increased airway hyperreactivity and airflow obstruction caused by the inflammation.

Incidence

Asthma is a chronic illness that has been increasing in prevalence in the United States since 1980. The number of people with asthma in the United States grew from 20 million in 2001 to 25 million in 2010 (8% of the U.S. population). According to data from the National Health Interview Survey performed by the Centers for Disease Control and Prevention in 2012, 18.7 million adults and 6.8 million children (9.3% of American children) reported having asthma. Asthma accounted for 1.8 million emergency room visits, or 25% of all emergency room visits. Asthma also accounted for 14.2 million outpatient visits, 439,000 hospitalizations, and, approximately 3400 deaths in 2010. Asthma costs in the United States grew from approximately $53 billion in 2002 to about $56 billion in 2007.[76,77]

Etiology and Pathogenesis

In the genetically susceptible host, allergens, respiratory infections, certain occupational and environmental exposures, and many unknown hosts or environmental stimuli can produce the full spectrum of asthma, with persistent airway inflammation, bronchial hyperreactivity, and subsequent airflow obstruction. When inflammation and bronchial hyperreactivity are present, asthma can be triggered by additional factors, including exercise; inhalation of cold, dry air; hyperventilation; cigarette smoke; physical or emotional stress; inhalation of irritants; and pharmacologic agents, such as methacholine and histamine.[78-80]

When a patient with asthma inhales an allergen to which he or she is sensitized, the antigen cross-links to specific immunoglobulin E (IgE) molecules attached to the surface of mast cells in the bronchial mucosa and submucosa. The mast cells degranulate rapidly (within 30 minutes), releasing multiple mediators including leukotrienes (previously known as *slow-reacting substance of anaphylaxis* [SRS-A]), histamine, prostaglandins, platelet-activating factor, and other mediators. These mediators lead to smooth muscle contraction, vascular congestion, and leakage resulting in airflow obstruction, which can be assessed clinically as a decline in FEV_1 or *peak expiratory flow rate* (PEFR) (Figures 25-9 and 10). This is the *early (acute) asthmatic response*, which is an immediate hypersensitivity reaction that usually subsides in approximately 30 to 60 minutes. In approximately 50% of asthmatic patients, however, airflow obstruction recurs in 3 to 8 hours.[80] This *late asthmatic response* is usually more severe and lasts longer than the early asthmatic response (see Figure 25-10).[81] The late asthmatic response is characterized by increasing influx and activation of inflammatory cells such as mast cells, eosinophils, and lymphocytes.[81,82]

Clinical Presentation and Diagnosis

The diagnosis of asthma requires a two-pronged approach of clinical assessment supported by laboratory evaluation. Because no single measurement can absolutely establish the diagnosis, and physical examination can be entirely normal between episodes, the history plays a key role in suggesting, and later establishing, the diagnosis of asthma. The classic symptoms of asthma are episodic wheezing, shortness of breath, chest

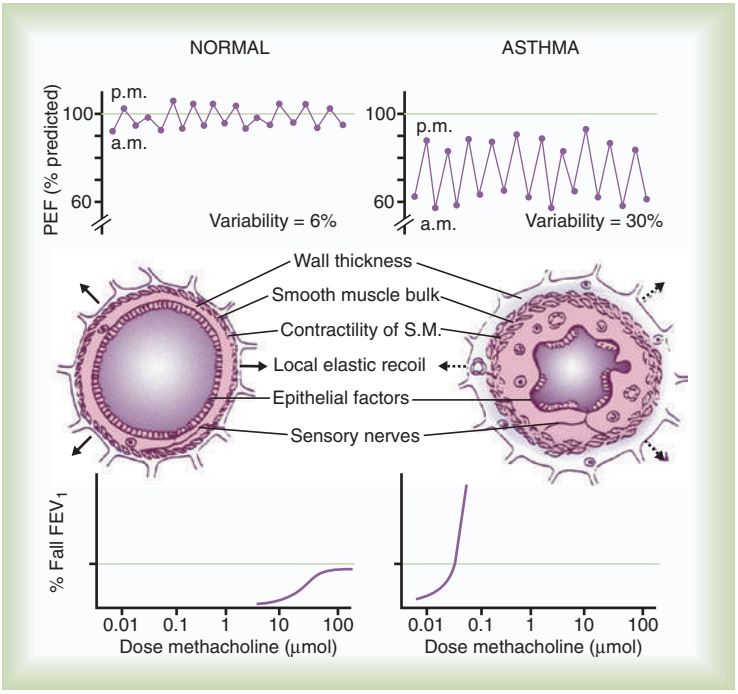

FIGURE 25-9 Inflammation in asthma. Cross sections of an airway from a healthy individual and a patient with asthma are shown. Multiple cells and multiple mediators are involved in asthma. Inflammatory cells, such as mast cells, eosinophils, lymphocytes, and macrophages, release a variety of chemical mediators, such as histamine, prostaglandins, and leukotrienes. These mediators result in increased wall thickness, airway smooth muscle hypertrophy and constriction, epithelial sloughing, mucus hypersecretion, mucosal edema, and stimulation of nerve endings. *Top,* Daily variability in peak airflow measurements. The normal increase in smooth muscle tone in the early morning, which causes airway narrowing in healthy individuals, is more exaggerated in asthmatics. *Bottom,* Dose-response curves to methacholine. (Modified from Woolcock AJ: Asthma. In: Murray JF, Nadel JA, editors: Textbook of respiratory medicine, Philadelphia, 1994, Saunders.)

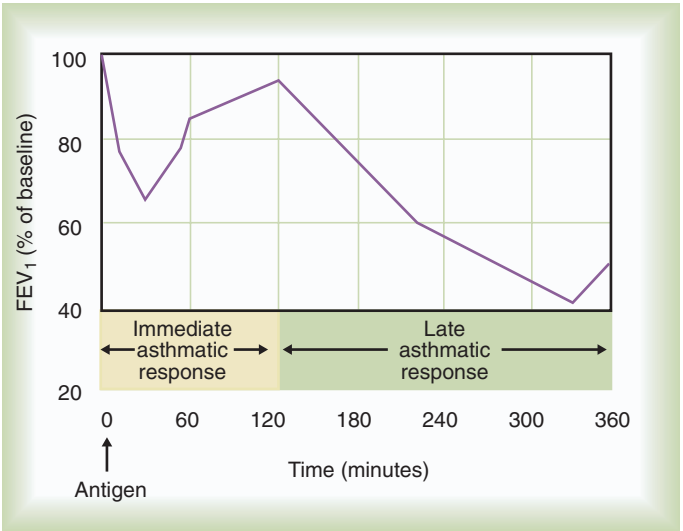

FIGURE 25-10 Early and late asthmatic responses. When a person with asthma is exposed to an allergen to which he or she is sensitized, the challenge results in a biphasic decline in respiratory function. An early asthmatic response occurs within minutes and usually subsides within 2 hours. In approximately half of asthmatic patients, a late asthmatic response occurs within 3 to 8 hours and may last for 24 hours or longer. (Modified from Wiedemann HP, Kavuru MS: Diagnosis and management of asthma, Caddo, OK, 1994, Professional Communications.)

tightness, and cough. The absence of wheezing does not exclude asthma, and sometimes a cough can be the only manifestation (cough-variant asthma). Not all wheezing is due to asthma, however. Obstruction of the upper airway by tumors, laryngospasm, aspirated foreign objects, tracheal stenosis, or functional laryngospasm (vocal cord dysfunction) can mimic the wheezing of asthma.

Confirmation of the diagnosis of asthma requires demonstration of reversible airflow obstruction. Pulmonary function tests may be normal in asymptomatic patients with asthma, but more commonly they reveal some degree of airway obstruction manifested by decreased FEV_1 and FEV_1/FVC ratio. By convention, improvement in the FEV_1 by at least 12% and 200 ml after administration of a bronchodilator is considered evidence of reversibility. Spontaneous variation in self-recorded PEFR by 15% or more also can provide evidence of reversibility of airway obstruction. Elevated values of exhaled nitric oxide also can be used to support the diagnosis of asthma when eosinophilic inflammation is present.[83]

Patients with asthma evaluated in a symptom-free period may have a normal chest x-ray examination and normal pulmonary function tests. Under these circumstances, provocative testing can be used to induce airway obstruction. Bronchoprovocation is a well-established method to detect and quantify

MINI CLINI

Recognizing Severity of Asthma

PROBLEM: A 20-year-old woman with a diagnosis of asthma is seen in the outpatient clinic for increased dyspnea with exertion requiring daily use of short-acting bronchodilators. The patient complains of difficulty attending classes in college and wakes up a couple of times a week feeling short of breath. She describes two visits to the emergency department in the last 12 months because of asthma, requiring use of corticosteroids for a short period. Physical examination shows normal breath sounds bilaterally without wheezing. Spirometry shows FEV_1 of 78% percent predicted with FEV_1/FVC of 75%. How do you describe the severity of her asthma?

SOLUTION: Classification of asthma severity is based on a combination of symptoms, medication requirements, and lung function. Although this patient has a spirometry consistent with mild airflow obstruction, her asthma is classified as moderately persistent because of the presence of daily symptoms, daily use of short-acting bronchodilators, frequent nighttime awakenings, limitation with normal activities, and history of exacerbations (see the following table).

Components of Severity		Classification of Asthma Severity (Youths ≤12 Years of Age and Adults)			
				Persistent	
		Intermittent	Mild	Moderate	Severe
Impairment	Symptoms	≤2 days/wk	>2 days/wk but not daily	Daily	Throughout the day
FEV_1/FVC:					
18-19 yr, 85%	Nighttime awakenings	≤2 ×/mo	3-4 ×/mo	>1 ×/wk but not nightly	Often 7 ×/wk
20-39 yr, 80%	Short-acting beta-2 agonist use for symptom control (not prevention of exercise-induced bronchospasm)	≤2 days/wk	>2 days/wk but not >1 time/day	Daily	Several times per day
40-59 yr, 75%					
60-80 yr, 60%					
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	Normal FEV_1 between exacerbations FEV_1 > 80% predicted FEV_1/FVC normal	FEV_1 ≥ 80% predicted FEV_1/FVC normal	FEV_1 ≥ 60% but < 80% predicted FEV_1/FVC reduced > 5%	FEV_1 ≥ 60% predicted FEV_1/FVC reduced > 5%
		0-1/yr	≥ 2/yr		
		Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time for patients in any severity category.			
Risk	Exacerbations requiring oral systemic corticosteroids	Relative annual risk for exacerbations may be related to FEV_1.			

AHR. Pharmacologic agents, including acetylcholine, methacholine, histamine, cysteinyl leukotrienes, and prostaglandins, and physical stimuli such as exercise and isocapnic hyperventilation with cold, dry air have been used to detect, quantify, and characterize nonspecific AHR in asthma.

The most commonly used stimulus for bronchoprovocation is methacholine. The generally accepted criterion for hyperresponsiveness is a decrease in FEV_1 by 20% or more below the baseline value after inhalation of methacholine.

The methacholine provocation test has few false-negative results (<5%), but a false-positive result may be found in 7% to 8% of the average population and patients with other obstructive lung diseases. Elevated IgE levels and eosinophilia may be present in patients with asthma, but their presence is not specific and their absence does not exclude asthma, making them less useful for the diagnosis.[73-75] Although ABG analysis is not helpful or necessary in diagnosing asthma, it can be helpful in assessing the severity of an acute asthma attack.

A patient experiencing an acute asthma attack usually has a low $PaCO_2$ as a result of hyperventilation. A normal $PaCO_2$ in such a situation is concerning because it indicates a severe attack and impending respiratory failure.

Management

The goal of asthma management is to maintain a high quality of life for the patient, uninterrupted by asthma symptoms, side effects from medications, or limitations on the job or during exercise. This goal can be accomplished by preventing acute exacerbations, with their potential mortality and morbidity, or by returning the patient to a stable baseline when exacerbations occur. Asthma management relies on the following four important components recommended by the National Asthma Education Program (NAEP) expert panel[73]:

1. Objective measurements and monitoring of lung function
2. Pharmacologic therapy
3. Environmental control
4. Patient education

Table 25-2 outlines the stepwise approach currently recommended for long-term management of asthma. This approach provides a framework for adjusting the dose of medication

TABLE 25-2

Stepwise Approach to Long-Term Management of Asthma Based on Severity

Severity*	Clinical Features Before Treatment†	PEFR or FEV_1	Long-Term Preventive Medications	Quick Relief Medications
Step 4				
Severe persistent	Continuous symptoms	≤60% predicted	Inhaled corticosteroids ≥800-2000 mcg/day	Inhaled beta-2 agonist as needed for symptoms
Red zone	Frequent exacerbations Nocturnal symptoms Symptoms limit activity	>30% variability	Long-acting bronchodilator‡ Oral corticosteroids	
Step 3				
Moderate persistent	Daily symptoms	>60%-<80% predicted	Inhaled corticosteroids ≥800-2000 mcg/day	Inhaled beta-2 agonist as needed for symptoms, not to exceed 3-4 times per day
Yellow zone	Exacerbations affect activity and sleep Nocturnal symptoms more than once per week Daily use of short-acting beta-2 agonist	>30% variability	Long-acting bronchodilator,‡ especially for nocturnal symptoms	
Step 2				
Mild persistent	Symptoms at least once per week but <1 time per day	≥80% predicted	Inhaled corticosteroid, 200-500 mg/day	Inhaled beta-2 agonist as needed for symptoms, not to exceed 3-4 times per day
Yellow zone	Exacerbations may affect activity or sleep Nocturnal symptoms more than twice per month	20%-30% variability	Long-acting bronchodilator‡ for nocturnal symptoms	
Step 1				
Intermittent	Intermittent symptoms less than once per week	≥80% predicted	None needed	Inhaled beta-2 agonist needed for symptoms but less than once per week
Green zone	Nocturnal symptoms not more than twice per month Asymptomatic with normal lung function between exacerbations	<20% variability		Inhaled beta-2 agonist or cromolyn before exercise or exposure to allergen

Modified from: Global Initiative for Asthma: Asthma management and prevention: a practical guide for public health officials and health care professionals, NIH publication no. 96-3659A, Bethesda, MD, 1995, National Institutes of Health, National Heart, Lung, and Blood Institute, and World Health Organization.
**Step-down:* Review treatment every 3 to 6 months. If control is sustained for at least 3 months, consider a gradual stepwise reduction in treatment. *Step-up:* If control is not achieved, consider step-up, but first review patient medication technique, compliance, and environmental control.
†The presence of one of the features of severity is sufficient to place a patient in that category.
‡Long-acting beta-2 agonist or sustained-release theophylline.

based on the severity of asthma in any patient at a particular time. This approach also takes into consideration the fact that asthma is a chronic and dynamic disease, which needs optimum control. Control of asthma is defined as minimal to no chronic diurnal or nocturnal symptoms, infrequent exacerbations, minimal to no need for beta-2 agonists, no limitation to exercise activity, PEFR or FEV_1 greater than 80% predicted with less than 20% diurnal variation, and minimal to no adverse effects of medication.[73-75]

Objective Measurement and Monitoring

Objective measurement of lung function is particularly important in asthma because subjective measures, such as patient reports of the degree of dyspnea and physical examination findings, often do not correlate with the variability and severity of airflow obstruction. It is recommended that spirometry be performed as part of the initial assessment of all patients being evaluated for asthma and periodically thereafter as needed.

Either spirometry or PEFR measurement can be used to assess response to therapy in the outpatient setting, emergency department, or hospital. NAEP guidelines also recommend that home PEFR measurement be used for patients with moderate to severe asthma.

When patients learn how to take PEFR measurements at home, the clinician is better able to recommend effective treatment. Daily monitoring of PEFR helps detect early stages of airway obstruction. All PEFR measurements are compared with the patient's personal best value, which can be established during a 2- to 3-week asymptomatic period when the patient is being treated optimally.[73-75]

MINI CLINI

Diagnosis of Wheezing

PROBLEM: You are asked to see a patient with a history of wheezing. The patient notes that the wheezing has been continuous, has been present for several months, and has been unresponsive to bronchodilator medications, including systemic corticosteroids and various inhaled bronchodilators.

SOLUTION: The patient has either refractory asthma or a condition mimicking asthma. The aphorism "all that wheezes is not asthma" applies here, and the clinician should suspect alternative diagnoses. Features that are atypical for asthma in this patient are the continuous nature of the wheezing and its complete refractoriness to medication. With this in mind, consideration of other "wheezy" disorders should include abnormalities of the upper airway. Specifically, tracheal stenosis or fixed upper airway obstruction (e.g., caused by tracheal tumors) could account for the patient's symptoms. Another condition that mimics asthma is vocal cord dysfunction. Characteristically, vocal cord dysfunction causes stridor with convergence of the vocal cords on inspiration (a paradoxical response). However, vocal cord dysfunction also can cause expiratory wheezing, with closure of the vocal cords on expiration. Further assessment of this patient might include a flow-volume loop or a flexible bronchoscopic examination of the upper airway, observing both the vocal cords and the trachea to the level of the main stem bronchi.

To help patients understand home PEFR monitoring, a zonal system corresponding to the traffic light system may be helpful (see Table 25-2). A PEFR measurement of 80% to 100% of the personal best is considered to be in the *green zone*. No asthma symptoms are present, and maintenance medications can be continued or tapered. A PEFR in the 60% to 80% range of the personal best is in the *yellow zone* and may indicate an acute exacerbation and requires a temporary step-up in treatment. A PEFR less than 60% of the personal best is in the *red zone* and signals a medical alert, requiring immediate medical attention if the patient does not return to the yellow zone or green zone with bronchodilator use.[75]

Pharmacotherapy

Pharmacotherapy for asthma reflects the basic understanding that asthma is a chronic inflammatory airway disease that requires long-term antiinflammatory therapy for adequate control.[73-82] Antiinflammatory agents such as corticosteroids suppress the primary disease process and its resultant airway hyperreactivity. Bronchodilators, such as beta-2–adrenergic agonists, anticholinergics, and theophylline, relieve asthma symptoms. Because asthma is a disease of the airways, inhalation therapy is preferred to oral or other systemic therapy. Inhaled therapy using metered dose inhalers or dry powder inhalers allows high concentration of the medication to be delivered directly to the airways, resulting in fewer systemic side effects. Spacer devices can be used to improve delivery of inhaled medication, but training and coordination are still required for patients using metered dose inhalers. Table 25-3 lists commonly used medications in the treatment of asthma.

Corticosteroids

Corticosteroids are the most effective medication currently available for the treatment of asthma. Although their mode of action is still unclear, corticosteroids probably act on various components of the inflammatory response in asthma.[84] Inhaled corticosteroids are effective locally, and regular use suppresses inflammation in the airways, decreases bronchial hyperreactivity and airflow obstruction, and reduces the symptoms of and mortality from asthma. Long-term, high-dose inhaled corticosteroids have far fewer side effects than oral corticosteroids. Side effects such as oropharyngeal candidiasis and dysphonia are controllable with spacer use and by rinsing the mouth after each treatment. Patients should be informed of other side effects of chronic inhaled corticosteroid use such as skin bruising and increased risks for glaucoma and cataracts.

Oral corticosteroids are effective for treating asthma, but the potential for devastating side effects during long-term use restricts their use to patients not responding to other forms of asthma therapy. Short-term, high-dose (0.5 to 1 mg/kg/day) oral corticosteroid therapy during exacerbation reduces the severity and duration, decreases the need for emergency department visits and hospitalization, and reduces mortality.[84]

Leukotriene Inhibitors

Leukotrienes are mediators of inflammation and bronchoconstriction and are thought to play a role in the pathogenesis of asthma. Three leukotriene antagonists are currently available for the treatment of asthma. Montelukast (Singulair; Merck, Whitehouse Station, NJ) and zafirlukast (Accolate; Astra Zeneca, London, UK) are leukotriene receptor antagonists, and zileuton (Zyflo; Abbott Laboratories, Chicago, IL) is a leukotriene synthesis inhibitor. These agents all are modestly effective for maintenance of mild to moderate asthma, but their exact role in asthma therapy remains to be determined. Inhaled steroids remain the preferred antiinflammatory drugs for treating asthma.[84,85]

Beta-2–Adrenergic Agonists

Inhaled beta-2–adrenergic agents are the most rapid and effective bronchodilators for treating asthma. They are the drugs of choice for all types of acute bronchospasm, and they provide protection from all bronchoconstrictor challenges when given prophylactically. However, they do not prevent the late asthmatic response. Beta-2 agonists are the drugs of choice for exercise-induced asthma. They exert their action by attaching to beta receptors on the cell to produce smooth muscle relaxation and by blocking mediator release from mast cells.

The effectiveness of beta-2 agonists as bronchodilators is not disputed, and they are the drug of choice for acute emergency management of asthma. However, there is concern that they may worsen asthma control if used regularly and that excessive

TABLE 25-3

Medications Commonly Used in the Treatment of Asthma or Chronic Obstructive Pulmonary Disease

Medication	Trade Names	Available Preparations	Usual Dosage	Comment
Inhaled Corticosteroids (Single Medication)				
Beclomethasone	Beclovent, QVAR	MDI 42 mcg/puff, 200 puffs/canister	2 puffs tid-qid, maximum 20 puffs/day	
Flunisolide	Aerobid	MDI 250 mg/puff, 100 puffs/canister	2 puffs bid, maximum 8 puffs/day	
Fluticasone	Flovent	MDI 44, 110, 220 mcg/puff	88-880 mcg/day	
Mometasone	Asmanex	DPI 220 mcg/spray	1-2 sprays daily-bid, maximum 4 puffs/day	
Budesonide	Pulmicort	DPI 90, 180 mcg/puff	360-720 mcg/day	
Inhaled Corticosteroids (Combined Medication)				
Fluticasone and salmeterol	Advair	DPI 100 mcg fluticasone/50 mcg salmeterol/puff, 250 mcg/50 mcg, 500 mcg/50 mcg/puff MDI HFA 45 mcg/21 mcg/puff, 115 mcg/21 mcg/puff, and 230 mcg/21 mcg/puff	400-2000 mcg/day (corticosteroid dose)	
Budesonide and formoterol	Symbicort	160 mcg budesonide/4.5 mcg formoterol/puff and 80 mcg/4.5 mcg/puff	160-640 mcg/day (corticosteroid dose)	
Fluticasone and vilanterol	Breo Ellipta	DPI 100 mcg fluticasone/25 mcg vilanterol/puff	100 mcg/day (corticosteroid dose)	Only approved for patients with COPD.
Systemic Corticosteroids				
Prednisone	Many	Tablets 1, 5, 20, 50 mg	5-50 mg/day	
Methylprednisolone	Medrol	Tablets 2, 4, 8, 16, 24, 32 mg	4-48 mg/day	
	Solu-Medrol	IV 40, 125, 500, 1000 mg	1-2 mg/kg q4-6h	
Hydrocortisone	Solu-Cortef	IV 100, 250, 500, 1000 mg	4 mg/kg q4-6h	
Beta-2 Agonists				
Albuterol	Proventil	MDI 90 mcg/puff, 200 puffs/canister	2-4 puffs q4-6h, maximum 20 puffs/day	
	Ventolin	Solution for nebulizer 0.083% and 0.5%	2.5-10 mg q6-8h	
		Tablets 2, 4 mg	2-4 mg q6-8h	
	Volmax	Sustained-release tablets 4, 8 mg	4-8 mg q12h	
Metaproterenol	Alupent	MDI 650 mcg/puff, 200 puffs/canister	2-3 puffs q3-4h, maximum 12 puffs/day	
	Metaprel	Solution 0.5%	2.5-10 mg q4-6h	
		Tablets 10, 20 mg	10 mg q6-8h	
Pirbuterol	Maxair	MDI 200 mcg/puff, 300 puffs/canister	1-2 puffs q4-6h, maximum 12 puffs/day	
Terbutaline	Breathaire	MDI 200 mcg/puff, 300 puffs/canister 1-2 puffs q4-6h		
	Bricanyl	Tablets 2.5, 5 mg	2.5-5 mg tid, maximum 15 mg/day	
		Solution 1 mg/ml	0.25 mg subcutaneously q15-30min	
Long-Acting Beta Agonists				
Salmeterol	Serevent	MDI 50 mcg/puff	2 puffs q12h	
Formoterol	Foradil	DPI 12 mcg/capsule	1 capsule inhaled q12h	
Indacaterol	Arcapta	DPI 75 mcg/capsule	75 mcg/day	Not indicated in patients with asthma.
Arformoterol	Brovana	Solution 15 mcg/ml	15 mcg inhaled bid	
Anticholinergics (Single Medication)				
Ipratropium bromide	Atrovent	MDI 18 mcg/puff, 200 puffs/canister Solution for nebulizer 0.02% 0.5 mg/2.5 ml vial, 0.5 mg qid	2-4 puffs q6h	
Tiotropium	Spiriva	DPI 18 mcg/capsule	1 capsule inhaled/day	
Aclinidium	Tudorza	DPI 400 mcg/actuation	800 mcg/day	M_2/M_3 muscarinic antagonist. Only approved for COPD.

TABLE 25-3

Medications Commonly Used in the Treatment of Asthma or Chronic Obstructive Pulmonary Disease—cont'd

Medication	Trade Names	Available Preparations	Usual Dosage	Comment
Anticholinergics (Combined Medication)				
Umeclidinium and vilanterol	Anoro Ellipta	DPI 62.5 mcg umeclidinium/25 mcg vilanterol/puff	62.5 mcg of umeclidinium/day	Umeclidinium is a muscarinic antagonist. Vilanterol is a long-acting bronchodilator. Not approved for patients with asthma.
Methylxanthines				
Aminophylline		IV	Load 5-6 mg/kg, maintenance	
		Tablets or capsules	0.5-0.9 mg/kg/hr	
Theophylline	Theo-Dur		300-1200 mg/day divided q6-8h	
	Slo-bid		for immediate and q12-24h	
	Theovent		for sustained	
	Uniphyl (immediate or sustained release)			
Leukotriene Inhibitors				
Zafirlukast	Accolate	Tablets 20 mg	20 mg bid	
Zileuton	Zyflo	Tablets 600 mg	600 mg qid	
Montelukast	Singulair	Tablets 10 mg	10 mg daily	
Other				
Roflumilast	Daliresp	Tablets 500 mcg	500 mcg/day	PDE-4 inhibitor. Primary use prevention of COPD exacerbations, not indicated for acute bronchospasm or asthma.
Azithromycin	Zithromax	Tablets 250 mg, 500 mg	250 mg/day	Macrolide antibiotic associated with reduction in number of COPD exacerbations.*
N-Acetylcysteine (NAC)	Mucomyst	Tablets 300 mg, 600 mg	1200 mg/day	High dose NAC is associated with decrease in exacerbation frequency in patients COPD.†
Omalizumab	Xolair	150 mg / 5 mL	150-375 mg subcutaneously every month	Anti-IgE therapy only approved for patients with moderate to severe asthma.

use may increase the risk for death from asthma, which makes the role of beta-2 agonists alone in long-term maintenance therapy questionable. It is clear that excessive beta-2 agonist use by asthmatics indicates an increased risk for death from asthma and indicates the need for more effective antiinflammatory therapy. Furthermore, because use of long-acting beta-2-agnosists in asthmatics has been associated with increased mortality, such agents should not be used in asthmatics but rather in combination with an anti-inflammatory drug such as an inhaled corticosteroid medication. Treatment with conventional doses of the short-acting beta-2 agonists available in the United States is felt to be safe for asthmatic patients.[82,84,86] The NAEP guidelines recommend that inhaled beta-2 agonists be used as needed. If a patient needs more than 3 or 4 puffs per day of a beta-2 agonist, additional antiinflammatory therapy should be considered.[84]

Longer acting (12 to 24 hours) beta-2 agonists, such as salmeterol and formoterol, are available in the United States. Their mechanism of action is different from that of the shorter acting beta-2 agonists discussed earlier. Long-acting beta-2 agonists have use in treating nocturnal asthma but again, should not be used alone in managing asthma.[73-75,86-88]

Inhaled corticosteroids remain the first choice of therapy in asthma.

Methylxanthines

The role of theophylline and similar drugs in the treatment of acute asthma is controversial. The NAEP expert panel did not recommend using theophylline routinely in the emergency treatment of asthma but did recommend its use orally or intravenously for patients admitted to the hospital for an acute asthma attack. Sustained-release theophylline drugs added to long-term asthma management therapy may be helpful in controlling nocturnal asthma symptoms because they maintain therapeutic plasma concentrations overnight. They also are helpful in soothing the symptoms of patients with labile asthma. However, the efficacy of theophylline is limited by its side effects of nausea, vomiting, headache, insomnia, seizures, and cardiac arrhythmias. Toxicity increases with blood levels greater than 15 mcg/ml, but levels of 8 to 10 mcg/ml are adequate for long-term therapy and are associated with fewer side effects.

Several factors affect the plasma levels of theophylline by increasing or decreasing hepatic metabolism of the drug. Conditions that tend to increase plasma concentrations include acute viral infections, cardiac failure, hepatic disease, and concomitant use of certain medications such as erythromycin or cimetidine. In these cases, the maintenance dose should be halved and the theophylline blood levels should be monitored. Conditions that tend to decrease plasma levels of theophylline include cigarette smoking and use of medications that increase hepatic clearance, such as phenobarbital.[73-75]

Anticholinergics

Inhaled anticholinergic agents, such as ipratropium bromide, are effective dilators of airway smooth muscles. Ipratropium produces bronchodilation by reduction of intrinsic vagal tone and blocking vagal reflex bronchospasm. However, ipratropium does not stabilize mast cells or prevent mediator release and is a less potent bronchodilator than beta-2 agonists. Ipratropium has few side effects, is safe because it is poorly absorbed, adds a bronchodilator effect to beta-2 agonists, and is useful for treating cough-variant asthma. Ipratropium also can be used in treating acute asthma when first-line bronchodilators are ineffective. The long-acting anticholinergic agent tiotropium has been shown to enhance asthma control (e.g., improved peak expiratory flow, increased FEV_1, and improved symptoms) when added to an inhaled corticosteroid compared with doubling the inhaled steroid dose.[89]

Anti–Immunoglobulin E Therapy

IgE plays a key role in the pathogenesis of asthma, and many asthmatic patients have elevated levels of IgE.[90] Corticosteroids do not inhibit synthesis of IgE by activated lymphocytes. Omalizumab, an antibody that binds IgE and blocks its biologic effects, has been approved by the FDA for patients with a history of allergy and with moderate to severe asthma that is poorly controlled with inhaled corticosteroids.[91] Studies have shown that treatment with omalizumab results in a reduction in the dose of inhaled glucocorticoids required to control symptoms and a reduction in the number of asthma exacerbation episodes.[92] For this reason, the NAEP asthma guidelines recommended that omalizumab should be considered as adjunctive therapy for patients with severe persistent asthma.[73]

Emergency Department and Hospital Management

Emergency management of acute asthma should include early and frequent administration of aerosolized beta-2 agonists and therapy with systemic corticosteroids. Frequent assessment for response with PEFR should be performed. The NAEP guidelines recommend that only selective beta-2 agonists (i.e., albuterol, levalbuterol, pirbuterol) should be used in high doses to avoid cardiotoxicity.[73]

Hospital and ICU care for patients with asthma should be aggressive. The goal is to decrease mortality and morbidity and to return the patient to preadmission stability and function as quickly as possible. Management includes O_2 supplementation, periodic administration of high doses of aerosolized beta-2 agonists (limited only by tachycardia or tremor), high-dose parenteral corticosteroids (>0.5 to 1 mg/kg/day), and antibiotics if there is evidence of infection. Sedatives and hypnotics should be avoided. Symptoms, PEFR, and ABGs should be monitored.

Patients with severe asthma and respiratory failure (hypoxemia, hypercapnia, increased work of breathing) need ventilatory support and present special challenges. Mortality rates for these patients can reach 22%, and complications are common, especially barotrauma. These complications can be minimized by limiting peak inspiratory pressure to less than 50 cm H_2O and by the use of small tidal volumes, allowing "permissive hypercapnia" if necessary. When asthma control is achieved, hospital discharge criteria include not needing supplemental O_2; having a PaO_2 greater than 60 mm Hg and a stable PEFR or FEV_1, with values close to the patient's best or greater than 70% of predicted; feeling that asthma symptoms are returning to preadmission levels and are not occurring at night; and 12- to 24-hour stability on discharge medications.[73-75]

RULE OF THUMB

In a patient presenting with an acute asthma attack, $PaCO_2$ is usually low because of hyperventilation. A normal $PaCO_2$ in this situation indicates a severe attack and impending respiratory failure.

Bronchial Thermoplasty

Bronchial thermoplasty is an approved addition to treatment options for adults whose asthma remains uncontrolled despite use of inhaled steroids and long-acting beta agonists.[93] Bronchial thermoplasty is a procedure in which a probe is introduced into the central airways through a bronchoscope and heat is applied (through radiofrequency waves) to airways of 3 to 10 mm diameter with the goal to reduce the airway smooth muscle mass, reducing the ability of the airways to constrict. Studies have shown that bronchial thermoplasty improves asthma-specific quality of life and reduces the number of severe

MINI CLINI

Assessing the Severity of an Acute Asthma Attack

PROBLEM: You have just obtained an ABG analysis on a patient who sought treatment at the emergency department for an acute attack of asthma. How would the ABG analysis help you assess the severity of the attack?

SOLUTION: In the early stages of an asthma attack, the ABG analysis shows a low $PaCO_2$ caused by hyperventilation. As the asthma attack progresses, and the FEV_1 decreases to less than 25% of predicted, the $PaCO_2$ returns to normal. When the FEV_1 decreases to less than 15% of predicted, carbon dioxide retention begins to occur. Changes in the pH reflect changes in the $PaCO_2$ level. The following table summarizes the ABG abnormalities based on the severity of an asthma attack:

Asthma Severity	Stage	PaO_2	$PaCO_2$	pH
Mild	I	Normal	Decreased	Increased
Moderate	II	Decreased	Decreased	Increased
Severe	III	Decreased	Normal	Normal
Very severe (respiratory failure)	IV	Decreased	Increased	Decreased

asthma exacerbation episodes and emergency department visits.[94,95] Moreover, there are now data suggesting that these effects are long-lasting (approximately 5 years) with regard to both asthma control (based on maintained reduction in severe exacerbations and emergency department visits for respiratory symptoms) and safety.[96] Although bronchial thermoplasty is a promising treatment for patients with asthma that is difficult to control, some controversy remains and more studies are needed before it can be recommended to all patients with poorly controlled asthma.[97]

Immunotherapy

Immunotherapy is based on the theoretical rationale that part of the immunologic response to an administered allergen is the production of IgG-specific antibody to the allergen injected. This newly generated IgG does not affix to most cells but can react with the allergen diffusing into the tissues and "neutralize" it. Although immunotherapy is acceptable in the treatment of allergic rhinitis, its use in the treatment of asthma is not standardized and remains controversial. However, a meta-analysis of 88 randomized controlled trials of injection allergen immunotherapy for asthma reported that immunotherapy is effective, with evidence of significant reductions in asthma medications and symptoms and a reduction in the degree of bronchial hyperreactivity.[98]

Environmental Control

The association between asthma and allergy has long been recognized. Among patients with asthma, 75% to 85% are reported to have positive immediate skin test reaction to common inhalant allergens. A thorough history is essential to diagnosing whether a patient's asthma has an allergic component and determining the relationship between exposure to an allergen and the occurrence of symptoms. Skin tests are more helpful for excluding an allergen as a cause of asthma symptoms because clinical sensitivity to an aeroallergen is rare in the absence of a positive skin test, whereas many positive skin tests do not have clinical relevance.

To prevent allergic reactions in patients with asthma, environmental control measures to reduce exposure to indoor and outdoor allergens and irritants are essential. Patients should be advised to avoid outdoor antigens, primarily ragweed, grass, pollens, and molds. Exposure to outdoor allergens is best reduced by staying indoors with the windows closed, in an air-conditioned environment, particularly during the midday and afternoon, when pollen and some mold counts are highest. Patients who are allergic to indoor allergens, primarily house-dust components and indoor molds, should take steps to eliminate these allergens from the home environment (e.g., single-room air purifier). All warm-blooded pets, including small rodents and birds, should be removed from the house because they produce dander, urine, and saliva that can cause allergic reactions. House-dust mites depend on atmospheric moisture and human dander for survival. Essential house-dust mite control measures include encasing mattresses and pillows in airtight covers, washing the bedding in water of 130° F weekly, avoiding sleeping on upholstered furniture, and removing carpets that are laid on concrete.

Additional helpful control measures include reducing the indoor humidity to less than 50%, removing carpets from the bedroom, and using chemical agents to kill mites. Indoor air-cleaning devices, especially high-efficiency particulate air/aerosol filters, may be useful, but they cannot substitute for controlling the allergen source. Humidifiers are potentially harmful because they can harbor and aerosolize mold spores, and the increased humidity they generate may encourage production of both mold and house-dust mites.[73-75]

Patient Education

With close back-up by the informed physician, respiratory therapist, or nurse, much of the day-to-day responsibility for managing asthma falls on the patient and the patient's family. Patient education is a powerful motivational tool, helping patients attain the skills and gain the confidence to control their asthma. Patient education involves helping patients understand asthma and learning and practicing the skills necessary to manage it. Patient education includes providing information; developing a partnership with the patient; involving the patient in decision-making; and demonstrating and observing asthma management practices such as the proper use of inhalers, nebulizers, and peak flowmeters.[86]

Special Considerations in Asthma Management

Exercise-Induced Asthma

Exercise-induced asthma is common in asthmatics, especially after participation in outdoor activities in cold weather. The

causes of exercise-induced asthma are not fully understood, but heat loss from the airways seems to be one of the causes.[81] Treatment consists of prophylactic inhalation of a beta-2 agonist.[99,100] Leukotriene inhibitors also may have a role in treatment of exercise-induced asthma.[73,74]

Occupational Asthma

An estimated 2% to 5% of all asthma episodes may be caused by exposure to a specific sensitizing agent in the workplace. Occupational asthma is the most common form of occupational lung disease in many industrialized countries. In an attempt to distinguish occupational from preexisting asthma, occupational asthma is defined as a disease characterized by a variable airflow limitation or AHR secondary to causes and conditions attributable to a particular working environment and not to stimuli encountered outside the workplace. Toluene diisocyanate is the most common cause of occupational asthma and is the best studied. Other causes of occupational asthma are listed in Table 25-4.

Generally, the treatment of occupational asthma is identical to treatment of other types of asthma. However, early diagnosis is important and in environmental control, in particular, cessation of exposure is key. Complete elimination of exposure is usually necessary because once sensitization has occurred, bronchoconstriction can be triggered by minimal subsequent exposure.[74,81]

Cough-Variant Asthma

Coughing may be the only complaint of patients with asthma. In such patients, the cough may be relieved by a bronchodilator or by avoiding inhaled allergens. If bronchospasm is not present at the time of examination and spirometry is normal (which is often the case), the diagnosis can be confirmed by showing reversible airway obstruction by a methacholine challenge test or suggested by elevated levels of exhaled NO.[83] Ipratropium bromide may be particularly helpful in the treatment of cough-variant asthma. Otherwise, the treatment is the same as for other types of asthma.

TABLE 25-4

Occupational Causes of Asthma

Occupation or Industry	Agent
Laboratory animal workers, veterinarians	Animals (dander, urine protein)
Food processing	Shellfish, egg proteins, pancreatic enzymes
Dairy farming	Storage mites
Poultry farming	Poultry mites, droppings, feathers
Detergent manufacturing	*Bacillus subtilis* enzymes
Baking	Flour
Sawmill workers, carpentry	Wood dust (western red cedar, oak, mahogany, zebrawood, redwood)
Nursing	Psyllium
Refining	Platinum salts
Plating	Nickel salts
Stainless steel welding	Chromium salts
Cosmetology	Persulfate
Refinery workers	Vanadium
Rubber processing	Formaldehyde, ethylenediamine
Plastics industry	Toluene diisocyanate, trimellitic anhydride

Nocturnal Asthma

Nocturnal asthma is a characteristic problem in poorly controlled asthma and is reported by more than two-thirds of patients who receive treatment that is less than ideal. It probably is due to the known physiologic decrease in the airway tone during sleep, which has been attributed to variation in catecholamine and cortisol secretion. Aspiration of gastric acid also may play a role in some patients with increased symptoms at night.

After ensuring adequate antiinflammatory therapy, medications for nocturnal asthma should be focused toward the night and especially the early morning hours, when the airway tone is lowest. Sustained-release theophylline and long-acting beta-2 agonists such as salmeterol are particularly helpful for controlling nocturnal asthma symptoms.[73] Addition of a proton pump inhibitor medication such as esomeprazole has not been shown to enhance asthma control.[101]

Aspirin Sensitivity

At least 5% of adults with asthma experience severe and even fatal exacerbation of asthma after taking aspirin or other nonsteroidal antiinflammatory drugs (NSAIDs). Many of these patients have nasal polyps, although the relationship is not causal. The presumed mechanism is the inhibition of the cyclooxygenase pathway by aspirin and NSAIDs, with subsequent shunting of all arachidonic acid into the 5-lipoxygenase pathway, causing overproduction of bronchoconstrictor leukotrienes. Individuals with asthma should avoid aspirin and NSAIDs and instead use alternatives such as acetaminophen (e.g., Tylenol). Patients should be informed that many over-the-counter medications contain aspirin and should be avoided as well.[73,81]

Gastroesophageal Reflux

The relationship between asthma and gastroesophageal reflux is controversial, although gastroesophageal reflux is nearly three times more prevalent in patients with asthma than in persons without asthma. Presumably, acid reflux into the esophagus causes vagal stimulation, resulting in a reflex increase in bronchial tone in patients with asthma. However, addition of a proton pump inhibitor to an asthma regimen has not been shown to enhance asthma control significantly.[101]

Asthma During Pregnancy

During pregnancy, one-third of patients have worse control of their asthma, one-third have better control of asthma, and one-third have asthma that is unchanged. The potential threat of adverse effects from asthma medications is far outweighed by the danger of uncontrolled asthma to the fetus and mother. Poorly controlled asthma during pregnancy can cause increased perinatal mortality, increased prematurity, and low birth weight.

Theophyllines, beta-2 agonists, or inhaled or oral corticosteroids can be used during pregnancy without significant risk for fetal abnormalities.[102]

Sinusitis

Acute sinusitis and chronic sinusitis have been related to exacerbations and poor control of asthma by causing postnasal drip and interfering with nasal patency. A limited CT scan of the sinuses should be obtained for patients with uncontrolled asthma. If sinusitis is present, therapy with antibiotics for 2 to 3 weeks, nasal decongestants, and nasal corticosteroid inhalers may help improve asthma control.[73,81]

Surgery

Patients with asthma are predisposed to respiratory complications after surgery, including respiratory arrest during induction of anesthesia, hypoxemia and possible hypercapnia, impaired effectiveness of cough, atelectasis, and respiratory infection. The likelihood of these complications depends on the severity of the patient's airway hyperreactivity, the degree of airflow obstruction, and the amount of excess airway secretions at the time of surgery. Optimizing the patient's lung function before surgery, including the administration of perioperative corticosteroids, is an important strategy for minimizing perioperative complications.[73,81]

BRONCHIECTASIS

Clinical Presentation

Bronchiectasis refers to the abnormal, irreversible dilation of the bronchi caused by destructive and inflammatory changes in the airway walls. Bronchiectasis has the following three major anatomic patterns[103]:

1. *Cylindrical bronchiectasis:* Airway wall is regularly and uniformly dilated
2. *Varicose bronchiectasis:* Irregular pattern, with alternating areas of constriction and dilation
3. *Cystic bronchiectasis:* Progressive, distal enlargement of the airways, resulting in saclike dilations

Bronchiectasis is thought to result from damage to the bronchial wall by chronic inflammation. Predisposing conditions are listed in Box 25-4.

Box 25-4 Causes of Bronchiectasis

LOCAL BRONCHIECTASIS

- Foreign body
- Benign airway tumor (e.g., adenoma)
- Bronchial compression by surrounding lymph nodes (e.g., middle lobe syndrome)

DIFFUSE BRONCHIECTASIS

- Cystic fibrosis
- Ciliary dyskinesia disorders (e.g., Kartagener syndrome, Young syndrome)
- Hypogammaglobulinemia
- Alpha-1 antitrypsin deficiency
- Allergic bronchopulmonary aspergillosis
- Rheumatoid arthritis
- Serious childhood lung infection (e.g., from whooping cough, measles, or influenza)

Evaluation

The hallmark of bronchiectasis is the chronic production of large quantities of purulent sputum. Dyspnea is variable and depends on the extent of involvement and the underlying disease. Hemoptysis occurs frequently and is usually mild, but severe hemoptysis can be seen. Radiographic studies confirm the diagnosis by showing airway dilation. A chest radiograph may show cystic spaces and tram tracks (thin parallel lines representing the airway walls). CT is the diagnostic standard; the diagnosis of bronchiectasis is established when the diameter of the bronchus exceeds the diameter of the adjacent pulmonary artery branch.[104] Because reversible airway changes consistent with bronchiectasis can follow pneumonia, CT should be deferred for 6 to 8 weeks after pneumonia resolves. Only then can a diagnosis of bronchiectasis be made.

Management

Antibiotics and bronchopulmonary hygiene are the mainstays of bronchiectasis management. Antibiotics can be given as needed or following a regularly scheduled regimen. Sputum cultures may be helpful in guiding antibiotic choice. Inhaled aminoglycosides may be a useful option for patients with chronic colonization by *P. aeruginosa*. Additionally, inhaled fluoroquinolones (ciprofloxacin) are currently being evaluated in patients with cystic fibrosis and noncystic fibrosis bronchiectasis.[105] Infection by *P. aeruginosa* in patients with bronchiectasis is a marker of severity but is not linked to accelerated decline in pulmonary function.[106] Secretions can be cleared by chest physiotherapy with postural drainage, cough maneuvers, and humidification. Inhaled bronchodilators may be helpful in some patients because accompanying airflow obstruction is common.[103] Inhaled hyperosmolar substances may be helpful in clearing secretion in patients with bronchiectasis. A Cochrane review concluded that dry powder mannitol improves tracheobronchial clearance in patients with bronchiectasis, patients with cystic fibrosis, those with asthma, and normal individuals.[107] Hypertonic saline has been studied to a limited extent in bronchiectasis and may be helpful. In cases that are complicated by massive hemoptysis, embolization of the bleeding bronchial artery may be helpful. Surgical resection should be reserved for patients with localized disease who develop massive hemoptysis or who are severely symptomatic despite appropriate medical therapy.[108-110]

ROLE OF THE RESPIRATORY THERAPIST IN OBSTRUCTIVE LUNG DISEASE

RTs play key roles in all aspects of managing patients with obstructive lung diseases; they are involved in diagnosis, acute

treatment, and follow-up and monitoring. In diagnosing obstructive lung diseases, RTs often perform the lung function testing that indicates the presence of airflow obstruction that is essential for diagnosis. Because of their close involvement with patients, RTs also play important roles in recognizing clinical features that may prompt physicians' appreciation of COPD variants, such as the presence of copious secretions, hemoptysis, or both that might lead to suspicion of bronchiectasis or the early onset or familial clustering of COPD that might prompt suspicion of AAT deficiency.[111] In the current environment of value-based care in which all health care providers must function at the "top of their license," RTs are increasingly at the front line of diagnosis and may be the first health care provider that patients see in evaluation for dyspnea.[112]

In acute management, hospital-based RTs often administer medications and therapies to patients with acute exacerbations of asthma or COPD. Examples include the delivery of bronchodilators in small-volume nebulizers, administration of chest physiotherapy in the management of bronchiectasis, and setup of supplemental O_2. For patients with severe exacerbations, ICU management of arterial lines, blood gases, and mechanical ventilation (with both noninvasive and conventional mechanical ventilation) usually involves RTs in key management roles. In managing patients with bronchiectasis, RTs are pivotal in administering chest physiotherapy and instructing in the use of flutter valves and percussive vests that may be critical parts of acute management.

Finally, in longitudinal follow-up of patients with obstructive lung diseases, RTs are involved in counseling (e.g., smoking cessation, medication management), administering pulmonary rehabilitation programs, and certifying and recertifying long-term O_2 therapy. RTs working in home care may conduct home visits to patients and set up and adjust equipment in the home. This description of activities of the RT in care of the patient with obstructive lung disease suggests that RTs are indispensable caregivers for patients with asthma, COPD, and bronchiectasis and that the care of patients with obstructive lung diseases constitutes a major component of RTs' activities.

SUMMARY CHECKLIST

- The spectrum of obstructive lung diseases includes chronic obstructive lung disease (consisting of emphysema and chronic bronchitis), asthma, and bronchiectasis. Airflow obstruction may be a feature of other lung diseases as well, such as sarcoidosis, lymphangioleiomyomatosis, and congestive heart failure.
- Chronic obstructive lung disease features persistent airflow obstruction despite therapy.
- Classically, asthma causes airway obstruction that is fully reversible with therapy and features symptoms such as episodic wheezing, shortness of breath, chest tightness, and cough.
- Bronchiectasis features permanent dilation of bronchi or bronchioles on chest imaging (often chest CT) and may result from various causes (e.g., childhood lung infection, cystic fibrosis, hypogammaglobulinemia, etc.).
- Major risk factors for COPD include cigarette smoking, chronic exposure to noxious fumes (e.g., cooking with biomass fuels in enclosed spaces), and genetic factors, the best characterized of which is AAT deficiency.
- The most common symptom of patients with COPD is dyspnea. Cough, chronic phlegm production, and wheezing also may be present.
- Goals in treating COPD are to improve airflow, maximize the patient's functional status, avoid exacerbations, and prolong the patient's survival as possible.
- Important treatments for COPD include inhaled bronchodilators, inhaled corticosteroids, supplemental O_2 when indicated, pulmonary rehabilitation, and preventive vaccinations (e.g., against influenza and pneumococcus). Lung transplantation and lung volume reduction surgery are also available for specific subsets of patients with advanced disease.
- The goal of stable asthma management is to maintain a high quality of life for the patient, uninterrupted by asthma symptoms, side effects from medications, or limitations on the job or during exercise. This goal can be accomplished by objective measurements and monitoring lung function, pharmacologic therapy, environmental control, and patient education.
- The goals of emergency management of acute asthma are to decrease mortality and morbidity and to return the patient to preadmission stability and function as quickly as possible. These goals are accomplished by O_2 supplementation and frequent administration of high doses of aerosolized beta-2 agonists, high-dose parenteral corticosteroids, and antibiotics if there is evidence of infection.
- The hallmark of bronchiectasis is the chronic production of large quantities of purulent sputum. Dyspnea is variable and depends on the extent of involvement and the underlying disease. Antibiotics and bronchopulmonary hygiene are important treatments.

CHAPTER 26

Interstitial Lung Disease

JEFFREY T. CHAPMAN AND JASON BORDELON

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Organize and distinguish among the interstitial lung diseases (ILDs).
- Interpret symptoms, examination signs, and pulmonary function test results in ILD.
- List causes, exposures, or pathologic characteristics associated with selected ILDs.
- Describe how to manage ILD in general and how some specific ILDs can be treated.

CHAPTER OUTLINE

KEY TERMS

asbestosis
connective tissue disease
corticosteroids
hypersensitivity pneumonitis
idiopathic pulmonary fibrosis
interstitial lung disease
lymphangioleiomyomatosis
occupational interstitial lung disease
organizing pneumonia
pulmonary Langerhans cell histiocytosis
sarcoidosis
silicosis

Interstitial lung disease (ILD) refers to a broad category of lung diseases rather than a specific disease process.[1,2] This category includes various illnesses affecting the lung parenchyma with many different causes, treatments, and prognoses. These disease processes are grouped together because of similarities in their clinical presentations, appearance on plain chest radiography, and physiologic features.

With over 100 separate disorders, it is essential to group ILDs based on cause, disease associations, or pathologic processes. An organizational scheme is presented in Figure 26-1. In evaluating patients with an ILD, diseases with known causes or associations, such as diseases related to specific exposures, diseases associated with systemic conditions, and diseases with a known genetic basis must be considered first. Most patients are classified with an ILD of unknown cause, the so-called *idiopathic interstitial diseases*. Their disorder is classified by pathologic pattern. These groups are divided into specific disease entities. Using this organizational scheme to guide a careful and complete history, one is able to understand the disease processes and work efficiently toward an accurate diagnosis and treatment.

As the name ILD implies, the histologic abnormalities that characterize ILD involve the pulmonary interstitium to a greater extent than the alveolar spaces or airways, although exceptions exist. Figure 26-2 illustrates the components of the normal pulmonary parenchyma. The interstitium is the area between the capillaries and the alveolar space. As Figure 26-2 shows, in the

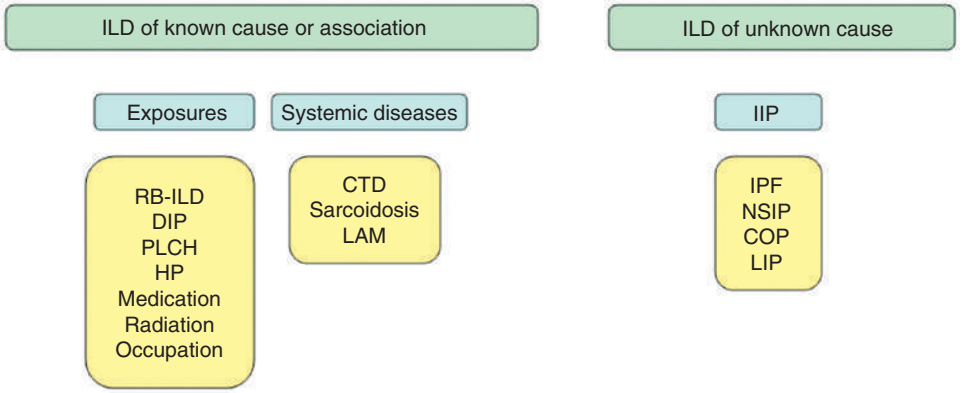

FIGURE 26-1 Current organization of interstitial lung disease (ILD). *COP,* Cryptogenic organizing pneumonia; *CTD,* connective tissue disease; *IBD,* inflammatory bowel disease; *IPF,* idiopathic pulmonary fibrosis; *LAM,* lymphangioleiomyomatosis; *LIP,* lymphocytic interstitial pneumonia; *NSIP,* nonspecific interstitial pneumonitis; *PAP,* pulmonary alveolar proteinosis; *PLCH,* pulmonary Langerhans cell histiocytosis.

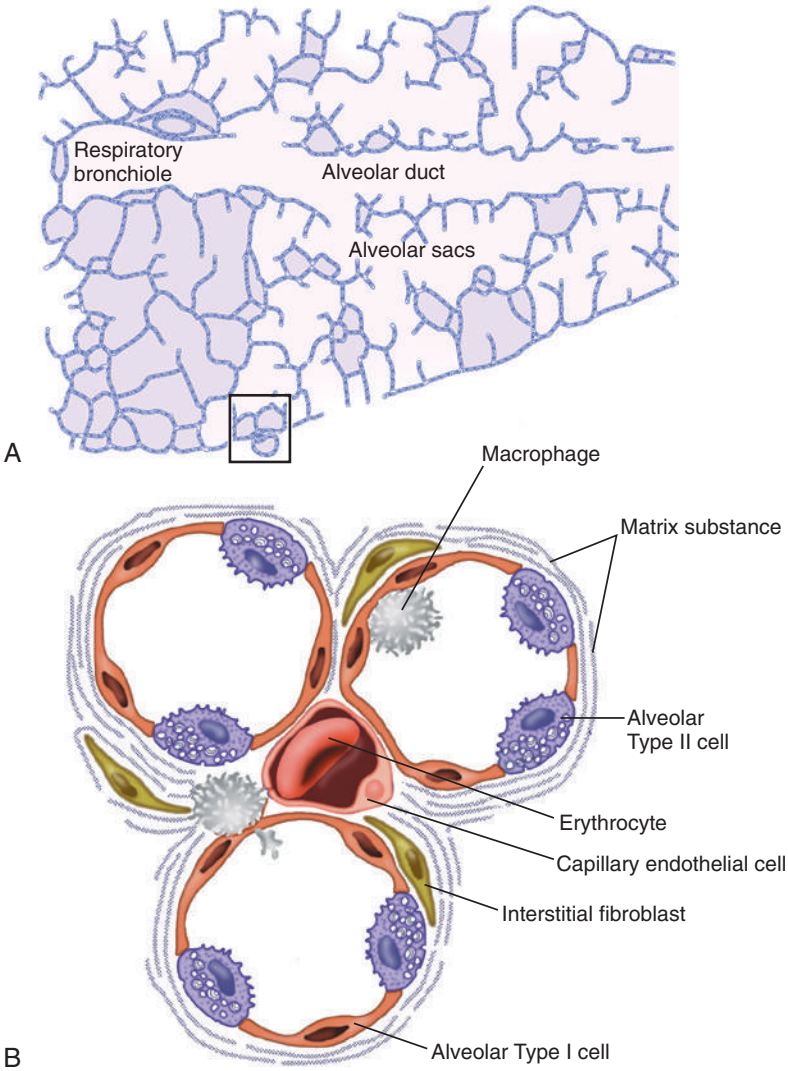

FIGURE 26-2 **A,** Diagram of the pulmonary parenchyma shows the respiratory bronchiole, alveolar duct, and alveolar sacs. **B,** The constituents of the interstitial space, including type I and type II alveolar epithelial cells, a capillary with vascular endothelial cells and erythrocytes in transit, resident macrophages, interstitial fibroblasts, and matrix substance.

normal state, this space allows close contact between gas and capillaries with minimal connective tissue matrix, fibroblasts, and inflammatory cells such as alveolar macrophages. The interstitium supports the delicate relationship between the alveoli and capillaries, allowing for efficient gas exchange. After an injury, the lung must respond to the damage and repair itself. If the exposure or injury persists or if the injury repair process is imperfect, the lung may be permanently damaged with increased interstitial tissue replacing the normal capillaries, alveoli, and healthy interstitium.

These pathologic abnormalities can lead to profound impairment in lung physiology and function. Gas exchange is impaired secondary to $\dot{V}/\dot{Q}$ mismatching, shunt, and decreased diffusion across the abnormal interstitium. The work of breathing in patients with interstitial lung disease (ILD) can be markedly increased because of decreased lung compliance. Together, these physiologic impairments lead to the exercise intolerance seen in all ILDs. If the injury that causes the ILD or the abnormal repair from injury is not halted, progressive tissue damage can occur, leading to worsening physiologic impairment and possibly death.

CHARACTERISTICS OF INTERSTITIAL LUNG DISEASE

Clinical Signs and Symptoms

Many ILDs have similar clinical features and are not easily distinguished based on history or examination. Symptoms are generally limited to the respiratory tract. However, extrapulmonary symptoms should not be ignored because they may point to an ILD associated with a systemic diagnosis. Exertional breathlessness (dyspnea) and a nonproductive cough are the most common reasons that patients with ILD seek medical attention. Other respiratory symptoms, such as sputum production, hemoptysis, pneumothorax, or wheezing, can occur and may suggest specific diseases (Table 26-1). If the patient also has prominent extrapulmonary symptoms, such as myalgia, arthralgia, sclerodactyly (tightening of the skin over the fingers), gastroesophageal reflux, or Raynaud phenomenon (discoloration of the digits, often initially with a white color because of spasm of the arteries that supply the digits), ILD resulting from underlying **connective tissue disease** may be present (Table 26-2).

TABLE 26-1
Unusual Pulmonary Findings and Likely Diagnosis

Pulmonary Findings	Disease	Frequency
Hemoptysis	LAM	Rare
Chyloptysis (coughing up chyle)	LAM	Rare
Pneumothorax	LAM, BHD	Common
Wheeze	Sarcoidosis, LAM	Common
Chylous pleural effusion	LAM	Common
Exudative pleural effusion	RA	Common

BHD, Birt-Hogg-Dubé syndrome; *RA,* rheumatoid arthritis.

Physical Examination

Most patients with ILD have bilateral fine inspiratory crackles, which usually are most prominent at the lung bases. However, some diseases, such as sarcoidosis and lymphangioleiomyomatosis (LAM), may have only decreased breath sounds without abnormal breath sounds despite a markedly abnormal chest radiograph. Expiratory wheezing is uncommon, and its presence suggests either airway involvement as part of the primary disease process (LAM, sarcoidosis, respiratory bronchiolitis–associated interstitial lung disease [RB-ILD], desquamative interstitial pneumonitis [DIP], pulmonary Langerhans cell histiocytosis [PLCH]) or concomitant airways disease, such as emphysema or asthma. Signs of pulmonary arterial hypertension with right ventricular dysfunction, such as lower extremity edema or jugular venous distention, may occur late in the course of any ILD and are not helpful in the diagnosis of a specific ILD. Examination also may show features of an underlying connective tissue disease, including synovitis, joint deformities, or skin rash.

Radiographic Features

ILDs manifest as abnormal lung parenchyma that casts abnormal radiographic shadows. For most ILDs, the chest radiograph

TABLE 26-2
Extrapulmonary Findings and Likely Diagnosis

Extrapulmonary Findings	Disease	Frequency
Raynaud phenomenon	All CTD	Common
Arthralgia	All CTD	Common
Myalgia	Polymyositis	Common
Large muscle weakness	Polymyositis	Common
Sclerodactyly	Scleroderma	Common
Rheumatoid skin nodules	RA	Rare
Fingertip fissures	Antisynthetase syndrome	Common
Dorsal hand rash	Dermatomyositis	Common
Facial rash	Dermatomyositis	Common
Exudative pleural effusion	RA	Common
Shawl distribution skin nodules	TSC	Common
“Pencil eraser” facial skin nodules	BHD	Common
Central nervous system benign cortical tuber	TSC	Common
Abdominal angiomyolipoma	LAM	Common
Renal cancer	BHD	Common
Cardiomyopathy	Sarcoidosis, polymyositis	Rare
Cardiac conduction block	Sarcoidosis	Rare
Violaceous facial skin nodules	Sarcoidosis	Common
Subcutaneous nodules	Sarcoidosis	Common
Cranial neuropathy	Sarcoidosis	Rare
Small fiber neuropathy	Sarcoidosis	Rare

BHD, Birt-Hogg-Dubé syndrome; *CTD,* connective tissue disease; *LAM,* lymphangioleiomyomatosis; *RA,* rheumatoid arthritis; *TSC,* tuberous sclerosis complex.

reveals reduced lung volumes with bilateral reticular or reticulonodular opacities. However, the chest radiograph has limited value because the three-dimensional abnormalities are summed into a two-dimensional image with loss of spatial information. High-resolution cross-sectional imaging via computed tomography (CT) provides detailed images representing pulmonary pathology.[3] High-resolution CT images allow noninvasive evaluation of ILDs and are a key element in making a confident diagnosis and managing ILD.[4]

Plain chest radiographs and high-resolution CT images of usual interstitial pneumonitis (UIP) show the typical fibrotic injury pattern. The chest radiograph (Figure 26-3, *A*) and high-resolution CT image (see Figure 26-3, *B*) in UIP typically reveal a bilateral, patchy, peripheral (subpleural), and basilar-predominant disease with reticulonodular infiltrates, often with honeycomb, cystic change. Honeycomb change refers to a pattern of scarring that looks like a bee's honeycomb, most characteristically at the lung bases in UIP. The lung architecture is distorted in patients with moderate or severe disease burden, with reduced lung volume and traction bronchiectasis, especially at the lung bases. Reticulogranular (ground-glass) abnormalities, increased attenuation of the lung tissue without distortion of the underlying blood vessels or bronchi, are absent or minimal in idiopathic pulmonary fibrosis (IPF). Pleural disease, air trapping, micronodules, and significant lymphadenopathy are not seen, although two-thirds of patients with UIP (also known as *IPF*) can have mild mediastinal adenopathy.[5]

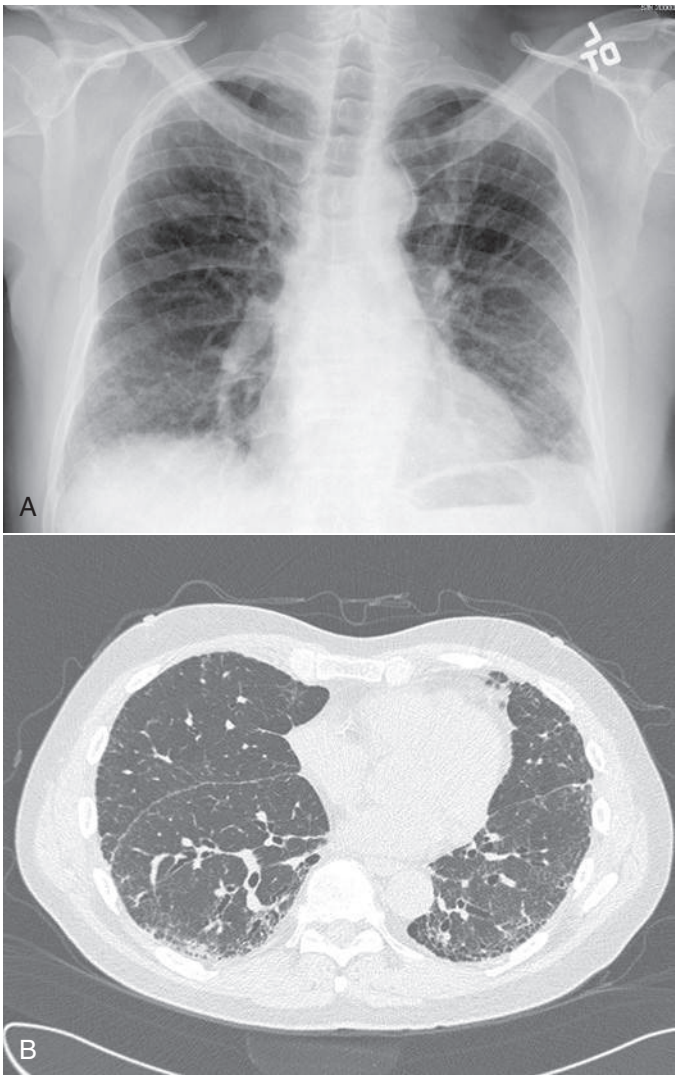

FIGURE 26-3 **A,** Posteroanterior chest radiograph showing the characteristic features of idiopathic pulmonary fibrosis, a common interstitial lung disease. Notice the bilateral lower zone reticulonodular infiltrates and the loss of lung volume in the lower lobes. **B,** Chest computed tomography image shows the peripheral nature of the fibrosis.

As the burden of disease increases, the chest radiograph may reveal multiple, tiny cysts in the most markedly involved regions. This cystic pattern, called *honeycombing,* reflects end-stage fibrosis and is a feature of many end-stage ILDs. These fibrotic cysts represent irreversible destruction of normal alveoli; therapies are aimed at preserving the remaining normal parenchyma and reducing symptoms.

RULE OF THUMB

In patients with spontaneous pneumothorax and interstitial infiltrates, LAM or PLCH should be considered.

In contrast to UIP, cellular nonspecific interstitial pneumonitis (NSIP) is a pattern of injury dominated by inflammation and has imaging findings distinct from those with UIP. Reticulogranular (ground-glass) attenuation predominates and is found centrally and peripherally in the middle and lower lung zones. If the inflammation can be reduced, these abnormalities may improve. A mixed pattern of injury with fibrotic nonspecific UIP also can be seen and is suggested by ground-glass attenuation in the presence of fibrotic changes. Ground-glass attenuation refers to a pattern of patchy infiltrates, with a fine texture like that of ground glass.

RULE OF THUMB

Calcification along the pleura on a chest radiograph suggests previous exposure to asbestos. Although such calcified areas (called *plaques*) do not cause symptoms or physiologic abnormality, they can provide a clue that the cause of ILD is asbestos exposure.

Physiologic Features

Similar to the radiographic findings, specific ILDs can vary considerably regarding the degree of physiologic abnormalities that occur. However, a restrictive physiologic impairment is the most common finding.[6] With this restrictive pattern, both forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) are diminished, and the FEV_1/FVC ratio is preserved or even above normal. Lung volumes are reduced, as is the diffusing capacity of the lung for carbon monoxide (DLCO).

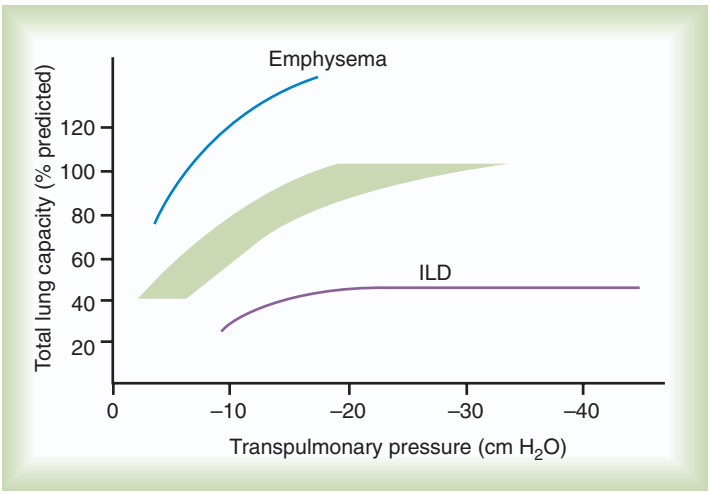

FIGURE 26-4 Static pressure-volume curve. The compliance characteristics of the lung are illustrated with a plot of lung volume against the corresponding transthoracic pressure measured during static (i.e., no flow) conditions. The *shaded area* represents the range of values expected with a normally compliant lung. The line labeled *ILD* represents an example of a patient with interstitial lung disease (ILD). At any particular lung volume, the transthoracic pressure is greater than expected. For comparison, the line labeled *Emphysema* shows the compliance characteristics of patients with emphysema.

This reduction in diffusing capacity reflects a pathologic disturbance of the alveolar-capillary interface, reflecting the abnormality in the interstitium of the lung.

Although not commonly evaluated under usual clinical circumstances, the compliance characteristics of the lungs can be evaluated with an esophageal balloon to measure intrathoracic pressure at various lung volumes. In almost all ILDs, the lungs have reduced compliance and require above normal transpleural pressures to ventilate (Figure 26-4). This lack of compliance results in small lung volumes and increased work of breathing.

Less frequently, a pattern of physiologic obstruction may be seen. This obstruction can be the result of the primary disease process (e.g., LAM, PLCH, or sarcoidosis in some patients) or concomitant emphysema or asthma.[7] If ILD develops in a patient with significant emphysema, the opposing physiologic effects of the two disease processes (i.e., restriction for the ILD and obstruction from the emphysema) may result in deceptively normal spirometry and lung volume measurements and apparently normally compliant lungs. For example, emphysema might cause lung volumes to increase whereas the restriction would be reflected by decreased lung volumes. The net effect of both processes in the same patient could be a normal lung volume. However, because both emphysema and ILD result in impaired gas exchange, DLCO is significantly decreased.

RULE OF THUMB

Among smokers with IPF, normal spirometry and lung volumes with reduced DLCO suggest the presence of coexisting emphysema.

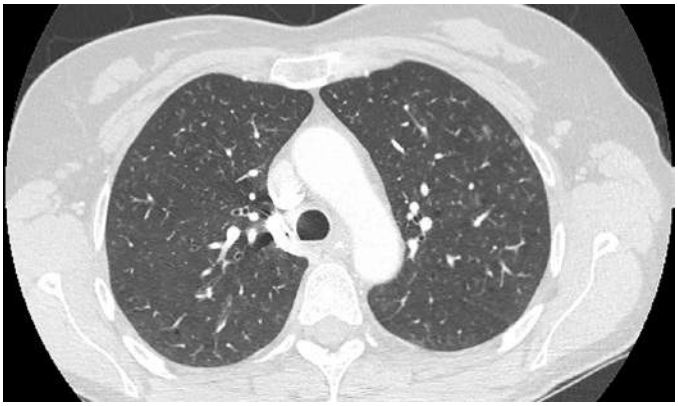

FIGURE 26-5 Respiratory bronchiolitis–associated interstitial lung disease (RB-ILD). There are numerous indistinct centrilobular nodules. Air trapping can be seen in RB-ILD but is not present in this case.

SELECTED SPECIFIC TYPES OF INTERSTITIAL LUNG DISEASE AND THERAPIES

Exposure-Related Disease

Tobacco-Associated Lung Disease

Although the association of first-hand tobacco smoke and obstructive lung disease is common and well known, tobacco smoke is also an avoidable cause of ILD. Although the association is rarer than with obstructive lung disease, first-hand tobacco smoke inhalation can lead to three types of ILD in susceptible individuals: RB-ILD, DIP, and PLCH. The first two disorders are related. Each disease consists of increased numbers of polyclonal activated macrophages. The diseases differ by the location of these overly abundant cells. In RB-ILD, macrophages accumulate in the respiratory bronchioles leading to bronchiolar remodeling and fibrosis of adjacent alveoli. As expected for a disease with combined airway and alveolar injury, pulmonary function testing reveals mixed restriction and obstruction with frequent air trapping. High-resolution CT images show this mixed pathologic location with indistinct centrilobular nodules (Figure 26-5). In DIP, the increased macrophages fill the alveoli, manifesting as restrictive impairment on pulmonary function testing and diffuse ground-glass attenuation on high-resolution CT imaging (Figure 26-6).

Pulmonary Langerhans cell histiocytosis (PLCH) is the third interstitial manifestation of tobacco smoke. Increased numbers of polyclonal macrophages play a prominent role. However, in PLCH, they are accompanied by fibroblasts and eosinophils in nodules concentrated around small airways. These nodules are star-shaped (or stellate) and destroy adjacent lung tissue, leading to the classic high-resolution CT image of stellate nodules associated with cysts, as seen in Figure 26-7. Although adult smoking-associated PLCH is pathologically similar to childhood Langerhans cell histiocytosis, the adult form does not involve bone and has not proved to respond to chemotherapy as the childhood form does. The relationship of these two disorders has yet to be defined.

FIGURE 26-6 Desquamative interstitial pneumonitis. Note the diffuse ground-glass attenuation.

FIGURE 26-7 Pulmonary Langerhans cell histiocytosis. Note the left upper lobe cysts and indistinct stellate-shaped nodule around an airway, which will become a cyst.

In each of these three diseases, the primary treatment is stopping smoking completely. With abstinence from smoking, most patients either minimally improve or remain stable,[8] but a few progressively worsen, sometimes to the point of needing lung transplantation. Active treatment with prednisone or other immunosuppressive medications is discouraged because few, if any, patients improve and the medications have significant side effects.[9]

Drug-Related and Radiation-Related Disease

Many drugs have been associated with pulmonary complications of various types, including interstitial inflammation and fibrosis, bronchospasm, pulmonary edema, and pleural effusions. Drugs from many different therapeutic classes can cause ILD, most commonly chemotherapeutic agents, antibiotics, antiarrhythmic drugs, and immunosuppressive agents (Box 26-1). There are no distinct physiologic, radiographic, or pathologic patterns of drug-induced ILD, and the diagnosis is usually made when a patient is exposed to a medication known to result in lung disease, the timing of the exposure is appropriate for the development of the disease, and other causes of ILD have been excluded. Treatment is avoidance of further exposure and systemic corticosteroids in markedly impaired or declining patients. In the specific instance of ILD related to exposure to the chemotherapeutic agent bleomycin, bleomycin injury is accentuated by exposure to increased fractional inspired oxygen (FiO_2), even months after last drug exposure. Thus, supplemental oxygen (O_2) should be used only if absolutely necessary patients with bleomycin-induced ILD.[10]

Box 26-1 Drugs Associated With the Development of Interstitial Lung Disease

ANTIBIOTICS
- Nitrofurantoin
- Sulfasalazine

ANTIINFLAMMATORY AGENTS
- Leflunomide
- Methotrexate
- Etanercept
- Infliximab

CARDIOVASCULAR AGENTS
- Amiodarone
- Tocainide

CHEMOTHERAPEUTIC AGENTS
- Bleomycin
- Mitomycin C
- Busulfan
- Cyclophosphamide
- Chlorambucil
- Melphalan
- Methotrexate
- Etoposide
- Vinblastine
- Imatinib

DRUGS USED IN AN ILLEGAL WAY
- Heroin
- Methadone
- Talc as an intravenous drug contaminant

Exposure to therapeutic radiation used to treat cancer may result in ILD. Patients presenting within 6 months of radiation therapy generally have ground-glass abnormalities thought to represent acute inflammation. The ground-glass abnormalities can occur in both radiation-exposed tissue and unexposed tissue. Short-term systemic corticosteroid treatment can improve lung function. In contrast, radiographic abnormalities that develop more than 6 months after therapy typically appear as densely fibrotic tissue within the radiation port. On CT scan, a straight line indicating the margin of radiation is frequently evident, as seen in Figure 26-8. These patients do not improve with corticosteroid therapy, and treatment is supportive.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (HP) is a cell-mediated immune reaction to inhaled antigens in susceptible persons.[11] Patients

FIGURE 26-8 High-resolution computed tomography slice shows dense fibrosis with a nonanatomic straight line boundary.

must be sensitized by an initial exposure, with subsequent reexposure leading to either an acute or chronic development of HP. Patients with acute HP present to medical attention with a history of a few days of shortness of breath, chest pain, fever, chills, malaise, and a cough that may be productive of purulent sputum. Patients who are chronically exposed to low levels of inhaled antigens may develop subtle interstitial inflammatory reactions in the lung that do not result in noticeable symptoms for months to years and can present with severe, impairing disease, which can be very difficult to distinguish from IPF.

Common organic antigens known to cause HP include bacteria and fungi, which may be found in moldy hay (farmer's lung) or in the home environment, in particular, in association with central humidification systems (humidifier lung), indoor hot tubs, and animal proteins (e.g., bird breeder's lung). Inorganic antigens from vaporized paints and plastics also can lead to HP. Numerous established antigens are listed in Table 26-3 along with the typical source of exposure and the associated syndrome.

Because the causal relationship between exposure and lung disease may not be obvious, a careful systematic occupational, environmental, and avocational history is crucial in evaluating patients with ILD. Elements that strongly suggest a diagnosis of HP are exposure to an appropriate antigen and the correct timing of symptom onset to the exposure. Blood samples may be obtained to determine whether there has been an antibody response to certain antigens associated with HP (serum precipitins). However, the presence of such antibodies is insufficient to establish the diagnosis of HP because many individuals develop antibodies in the absence of disease. Likewise, the absence of detectable antibodies does not rule out the diagnosis of HP because the culprit may be an antigen that is not included in the blood test panel that is analyzed.[12]

Specific therapies for HP are strict antigen avoidance and immunosuppression with corticosteroids in patients with symptomatic or physiologically impairing disease. In acute HP, corticosteroids seem to hasten recovery but do not improve ultimate lung function.[13] In chronic HP, patients with fibrosis on CT scan have a shorter survival and the benefits of long-term immunosuppression is unknown.[14]

TABLE 26-3

Causes of Hypersensitivity Pneumonitis

Antigen	Exposure	Syndrome
Bacteria		
Thermophilic Bacteria		
Saccharopolyspora rectivirgula	Moldy hay	Farmer's lung
Thermoactinomyces vulgaris	Moldy sugarcane	Bagassosis
Thermoactinomyces sacchari	Mushroom compost	Mushroom worker's lung
Thermoactinomyces candidus	Heated water reservoirs	Humidifier lung Air conditioner lung
Nonthermophilic Bacteria		
Bacillus subtilis, Bacillus cereus	Water, detergent	Humidifier lung Washing powder lung
Fungi		
Aspergillus species	Moldy hay	Farmer's lung
Aspergillus clavatus	Barley	Malt worker's lung
Penicillium casei, Penicillium roqueforti	Cheese	Cheese washer's lung
Alternaria species	Wood pulp	Woodworker's lung
Merulius lacrymans	Rotten wood	Dry rot lung
Penicillium frequentans	Cork dust	Suberosis
Aureobasidium pullulans	Water	Humidifier lung
Cladosporium species	Hot tub mists	Hot tub HP*
Trichosporon cutaneum	Damp wood and mats	Japanese summer-type HP*
Animal Proteins		
Avian proteins	Bird droppings, feathers	Bird-breeder's lung
Urine, serum, pelts	Rats, gerbils	Animal handler's lung
Chemicals		
Isocyanates, trimellitic anhydride	Paints, resins, plastics	Chemical worker's lung
Copper sulfate	Bordeaux mixture	Vineyard sprayer's lung
Phthalic anhydride	Heated epoxy resin	Epoxy resin lung

Occupational Disease

The three most common types of **occupational interstitial lung disease** are **asbestosis**, chronic **silicosis**, and coal workers' pneumoconiosis. Awareness of the associated risk and reduction in exposure has greatly reduced the incidence of these diseases in developed countries. However, they remain common in developing countries and among emigrants from these countries.

Predictable clinical and radiographic abnormalities occur in susceptible patients who have been exposed to asbestos.[15] These abnormalities include pleural changes (plaques, fibrosis, effusions, atelectasis, and mesothelioma) and parenchymal scarring

and lung cancer. Asbestos exposure alone increases the risk for lung cancer only minimally (1.5 to 3.0 times). However, asbestos exposure and cigarette smoking act synergistically to increase greatly the risk for cancer. Asbestos exposure also may result in benign asbestos pleural effusions or an entity known as *rounded atelectasis*. Benign asbestos pleural effusions may be asymptomatic or may be associated with acute chest pain, fever, and dyspnea. Benign asbestos pleural effusions usually resolve on their own, but may recur. Treatment is drainage to reduce symptoms. Rounded atelectasis typically manifests as a pleural-based parenchymal mass that may be mistaken for carcinoma. The characteristic CT features, such as local volume loss, pleural thickening, and the "comet tail" appearance of bronchi and vessels curving into the lesion, help distinguish rounded atelectasis from carcinoma.

The term *asbestos-related pulmonary disease* encompasses all of these entities, whereas *asbestosis* is reserved for patients who have evidence of parenchymal fibrosis. Most patients with asbestosis have had considerable airborne asbestos exposure many years before the lung disease becomes apparent. Exposure frequently is associated with occupations such as shipbuilding or insulation work. Patients report very slowly progressive dyspnea on exertion[16] and have crackles on lung examination. Physiologic testing shows restrictive impairment with a reduced DLCO. The chest radiograph reveals bilateral lower zone reticulonodular infiltrates similar to infiltrates seen in IPF. With an appropriate exposure history, the presence of radiographic pleural plaques or rounded atelectasis indicates asbestos as the likely cause of ILD, although neither history nor radiographic findings is required for establishing the diagnosis. Surgical lung biopsy with asbestos body determination can establish a definitive diagnosis, but this is infrequently performed owing to the age and debility of these patients. No medical therapy has been shown to improve or decrease progression of asbestosis. Severe impairment typically occurs 30 to 40 years after exposure, making almost all patients ineligible for lung transplantation because of advanced age. Management of asbestosis is supportive.

Chronic silicosis results from chronic exposure to inhaled silica particles. Occupations that commonly involve exposure to silica include mining, tunneling, sandblasting, and foundry work. The chest radiograph commonly shows upper lung zone–predominant abnormalities characterized by multiple small nodular opacities in the central lung tissue. These nodules (simple silicosis) are asymptomatic and may never progress or cause symptoms. However, in susceptible individuals, the nodules coalesce into large midlung zone masses known as *progressive massive fibrosis*. Some patients with abnormal chest radiographs report few, if any, symptoms and may have normal lung examination and pulmonary function testing. Many patients are impaired and have mixed restrictive and obstructive impairment with reduced diffusion capacity. The physiologic impairment may remain stable or, if progressive, massive fibrosis occurs, may progress even without continued exposure. Symptoms are typically exertional dyspnea and variable mucus production.

It is important to recognize the association of silicosis with lung cancer and active tuberculosis.[17] Patients with silicosis are at increased risk for lung cancer, and the risk is increased when combined with exposure to tobacco smoke, diesel exhaust, or radon gas. Patients with silicosis develop active tuberculosis 2 to 30 times more frequently than co-workers without silicosis. This association is especially important in societies with a high incidence of human immunodeficiency virus infection, which markedly increases the risk for silicosis-associated active tuberculosis.

Coal workers' pneumoconiosis develops as the result of chronic inhalation of coal dust. In the past, it was assumed that silica dust was responsible for the pulmonary disease seen among coal miners because the clinical and radiographic features are quite similar to those of chronic silicosis. However, it is now recognized that coal workers' pneumoconiosis and silicosis are the result of different exposures. Simple coal workers' pneumoconiosis, characterized by multiple small nodular opacities on the chest radiograph, is asymptomatic. Cough and shortness of breath do not develop unless the disease progresses to progressive massive fibrosis similar to that seen in silicosis.

There are no proved therapies for either silicosis or coal workers' pneumoconiosis other than eliminating future exposure. In patients with significant obstructive impairment or mucus production, inhaled bronchodilators and **corticosteroids** may relieve some symptoms. Exacerbations can be frequent and are treated with antibiotics and systemic corticosteroids.

Associated Systemic Disease

Connective Tissue Disease

ILD is a well-known complication of various connective tissue diseases.[18] The most commonly implicated disorders are scleroderma, rheumatoid arthritis, Sjögren syndrome, polymyositis/dermatomyositis, and systemic lupus erythematosus.

In any of these disorders, pulmonary involvement may remain undetected until significant impairment is present, because these patients may be inactive owing to the underlying connective tissue disease. In addition, there is generally poor correlation between the severity of the pulmonary and nonpulmonary manifestations of these diseases. In some instances, the lung disease may overshadow or may occur earlier than the other symptoms of the underlying disease. When symptoms develop, dyspnea and cough are common. On chest examination, crackles, wheezing, or a pleural rub may be heard because of the varied patterns of lung involvement in these disorders. The physiologic features are usually restrictive with decreased DLCO but may be obstructive depending on the anatomic location of the disease, especially with Sjögren syndrome (because the collections of lymphocytes that define this disease are most frequent in the bronchioles).

High-resolution CT findings are variable and range from normal lung architecture to ground-glass abnormalities to reticular and fibrotic changes.[19] The pathologic pattern of injury with these diseases is equally diverse and correlates with the high-resolution CT findings. Inflammatory injury patterns are

most commonly seen, such as NSIP and organizing pneumonia. The NSIP inflammatory injury pattern appears as ground-glass abnormalities on high-resolution CT scan, whereas organizing pneumonia is shown by patchy consolidated lung with air bronchograms. Both of these pathologic patterns can improve with aggressive immunosuppression. At the other end of the pathologic response spectrum is fibrotic injury, which manifests as UIP and shows reticular fibrotic opacities and honeycomb cystic changes on high-resolution CT scan. These abnormalities typically do not improve with immunosuppression, although long-term controlled studies are lacking.

Specific treatment of connective tissue disease–associated ILD must be individualized. Patients with evidence of extrapulmonary inflammation, an inflammatory pathologic pattern such as NSIP or organizing pneumonia on high-resolution CT or biopsy, or rapidly progressive symptoms, are usually treated with prolonged immunosuppressive agents such as cyclophosphamide, azathioprine, mycophenolate, or tacrolimus.[20,21]

More recent studies have begun to provide evidence-based therapy for these diverse patients. The Scleroderma Lung Study showed that 1 year of oral cyclophosphamide modestly improved lung function compared with modest decline in the control group.[20] However, after 1 year off immunosuppressive therapy, the patients treated with cyclophosphamide worsened and were indistinguishable from the untreated patients in the control group.[22] Many clinicians hypothesize that to preserve any lung function gained by cyclophosphamide, continued immunosuppression may be necessary, and mycophenolate is most often used.

Polymyositis-associated ILD is being increasingly recognized as a common disease entity. Patients usually present with "mechanic's hands" consisting of thickened skin and painful fingertip fissures, and 50% have Jo-1 antibodies on antinuclear antibody testing. Lung pathologic results typically show fibrotic NSIP or organizing pneumonia. As would be expected with these inflammatory patterns of injury, patients usually benefit from immunosuppression. Classic treatment is with cyclophosphamide, but tacrolimus and rituximab are emerging as salvage agents.

Sarcoidosis

Sarcoidosis is an idiopathic multisystem inflammatory disorder that commonly involves the lung.[23] It is the most common ILD in the United States. The tissue inflammation that occurs in sarcoidosis has a characteristic pattern in which the inflammatory cells collect in microscopic nodules called *granulomas*. In contrast to IPF, sarcoidosis is more common among young adults than among older adults. Sarcoidosis often follows a benign course of inflammation without symptoms or long-term consequences that spontaneously remits.

The most common manifestation of sarcoidosis is asymptomatic hilar adenopathy. Less frequently, the chest radiograph shows parenchymal opacities in the midlung zone that may be nodular, reticulonodular, or alveolar. When symptoms occur, cough, chest pain, dyspnea, and wheezing are most common. Pulmonary physiology may be normal, restrictive, obstructive, or mixed, all with reduced DLCO. Obstructive impairment may be related to endobronchial granulomatous inflammation or scarring.[24]

Corticosteroids are commonly used in the management of sarcoidosis, but treatment usually is reserved for patients with marked symptoms or physiologic impairment attributable to the disease.[25] Although corticosteroids almost always reduce active sarcoid inflammation, long-term side effects should limit the duration of steroid treatment. For patients requiring long-term immunosuppression, alternative immunosuppressive agents such as methotrexate, azathioprine, leflunomide, or tumor necrosis factor-alpha inhibitors such as infliximab should be used.[26] Involvement of other organs that may require corticosteroid therapy include cardiac involvement, uveitis, and peripheral or central nervous system involvement with cranial nerve abnormalities. Disease activity is difficult to detect in many patients. Serum angiotensin-converting enzyme levels and gallium scans are not well correlated with disease activity, and their routine use is discouraged.[27]

Lymphangioleiomyomatosis

Lymphangioleiomyomatosis (LAM) is a rare disorder of abnormal smooth muscle tissue proliferating around small airways and leading to severe obstruction and destruction of alveoli with resultant thin-walled cyst formation.[28] All patients are women, although both men and women with tuberous sclerosis complex can develop lung pathologic findings identical to those of LAM that is called *tuberous sclerosis complex LAM*. This peculiar pathologic process is caused by abnormalities in the *TSC-2* gene.[29]

Dyspnea on exertion and an obstructive ventilatory impairment with reduced DLCO is almost always present, except in very early disease. Disease progression is quite variable; some women having steadily worsening lung function during midlife, whereas some elderly women experience extremely slow decline over many years. Risk factors for worsening lung function include a significant bronchodilator response and possibly pregnancy. Other important disease manifestations include pneumothorax from a ruptured subpleural cyst. Unilateral or, less commonly, bilateral chylothorax is seen in about one-third of patients. This results from lymphatic obstruction by abnormal smooth muscle tissue. Treatment with a low-fat diet or blocking gut fat absorption is usually ineffective, and pleurodesis is required. Pleurodesis does not preclude subsequent lung transplantation.

Treatment is with inhaled bronchodilators and inhaled corticosteroids. Younger patients may ultimately require lung transplantation. Ongoing studies with rapamycin, which blocks the abnormal *TSC-2* gene and inhibits LAM cell proliferation, show promise for the first disease-specific therapy for an ILD.

Interstitial Lung Disease of Unknown Cause

Idiopathic Interstitial Pneumonias

Despite a careful history, physical examination, and high-resolution CT scan, most patients are not found to have an

exposure or systemic illness as a cause of ILD. These patients have a disorder isolated to the lung termed *idiopathic interstitial pneumonia (IIP)*. Prognosis and potential therapies are completely dependent on the type of pathologic pattern of IIP.

Idiopathic Pulmonary Fibrosis. **Idiopathic pulmonary fibrosis** (IPF) is the most common IIP and is a progressive fibrotic disease isolated to the lung.[30] Although the precise cause of IPF is unknown, studies have demonstrated that susceptible individuals have lung injury from diverse causes, such as metal dust, farming dust, tobacco smoke, subclinical gastric aspiration, and mechanical stress from abnormal surfactant proteins that lead to abnormal lung healing and progressive fibrosis.[31] Most patients are older than 60 years, and IPF is extremely unusual in persons younger than 40 years. Patients present with chronic cough and exertional dyspnea, and high-resolution CT suggests a fibrotic process.

The diagnosis of IPF is made by noting a lack of exposure or systemic disease known to cause ILD and determining UIP as the pathologic pattern of injury. The diagnosis of UIP is made when high-resolution CT shows bilateral and basilar-predominant peripheral reticular fibrosis and honeycomb cystic change with absence of significant ground-glass abnormalities, micronodules, and air trapping. Without these classic findings, a surgical lung biopsy is needed for diagnosis.[32,33] Patients who do not have IPF can have UIP on surgical lung biopsy (e.g., connective tissue disease), so this pattern of injury and repair is not unique to IPF.

Most patients die as a result of progressive fibrotic lung disease within 4 years of diagnosis. Data show that approximately half of patients die with gradually progressive disease over several years.[34] The other half experience stable lung function or minimal decline for months to years and then have sudden worsening over a few weeks or months, leading to death.[35] Baseline parameters that predict an increased risk for death include severity of dyspnea, severity of restrictive physiologic defect, reduced DLCO, presence of pulmonary arterial hypertension, degree of fibrosis on high-resolution CT, and SaO_2 desaturation on exertion.[36] Serial parameters that predict poor survival include worsening dyspnea, FVC, and DLCO.

Specific treatment for IPF is emerging after decades of IPF trials showing no benefit with aggressive immunosuppression,[37-39] interferon gamma,[40] etanercept,[41] bosentan, macitentan, ambrisentan, sildenafil,[42] imatinib,[43] warfarin, *N*-acetylcysteine,[44] and azathioprine in combination with both oral corticosteroids and *N*-acetylcysteine.[45] Pirfenidone and nintedanib, both molecules with multiple antifibrotic properties, have recently been shown to slow disease progression in selected patients with IPF. Perfenidone has been approved for use in Japan, Canada, and in several European countries at this writing,[46,47] and both perfenidone and nintendanib were approved for use in the United States by the U.S. Food and Drug Administration on October 15, 2014.

Studies have demonstrated concomitant pulmonary arterial hypertension in IPF leading to worse exercise intolerance and increased mortality.[48,49] Significant pulmonary arterial hypertension is suggested in patients with markedly impaired diffusion capacity but relatively preserved FVC. Medications that benefit pulmonary arterial hypertension such as bosentan and sildenafil generally have not proved beneficial for IPF either with or without pulmonary arterial hypertension.[50,51]

Nonspecific Interstitial Pneumonia. NSIP is an IIP with diffuse inflammation seen on surgical lung biopsy.[52] Patients are on average 7 to 10 years younger than patients with IPF, but considerable overlap exists. The degree of accompanying interstitial fibrosis is variable among patients. The most common presentation of NSIP is fibrotic NSIP. This type involves fibrosis and inflammation. Cellular NSIP is less common. Patients present with chronic or subacute cough and dyspnea. High-resolution CT shows predominant ground-glass abnormalities in cellular NSIP and both ground-glass abnormalities and fibrotic changes in fibrotic NSIP. Given that there is significant clinical and radiographic overlap between fibrotic NSIP and IPF, surgical lung biopsy is frequently required to distinguish these two entities, such as when elements of classic UIP are not present on high-resolution CT images.

The prognosis is much better for NSIP than IPF, with most patients surviving 7 to 10 years. Immunosuppression with oral corticosteroids and cytotoxic immunosuppressive agents is the primary therapy. Type and duration of therapy are guided by disease activity and degree of inflammation on biopsy and ground-glass abnormalities on high-resolution CT. Pathologic NSIP is found frequently as an IIP and is the most common pattern of injury seen in connective tissue disease–associated ILD. Owing to this frequent association, many authors consider NSIP a connective tissue disease isolated to the lung.[53,54]

Organizing Pneumonia. **Organizing pneumonia** (OP) is the revised term for *bronchiolitis obliterans organizing pneumonia*. The term *cryptogenic organizing pneumonia* is used when this pattern of injury occurs as an IIP, and it is termed *organizing pneumonia* when found in the setting of connective tissue disease. Patients with organizing pneumonia are typically younger than patients with IPF and present with acute or subacute dyspnea and cough. Approximately one-third describe a preceding viral illness. However, no other risk factors are known. High-resolution CT shows alveolar filling with air bronchograms mimicking acute pneumonia, and the patient with classic organizing pneumonia presents after having failed to improve despite several courses of antibiotics. Diagnosis usually requires surgical lung biopsy, especially if the clinical and radiographic features are uncertain because small areas of organizing pneumonia can be seen in various inflammatory and fibrotic disorders on transbronchial lung biopsy. Surgical lung biopsy specimens show young fibroblasts within the alveoli that are presumably recovering from an injury. The alveolar basement membrane is intact, allowing for significant recovery if the inflammation or injury can be suppressed.

Most patients improve with oral corticosteroids (0.5 to 1 mg/kg for 6 to 12 weeks). However, many patients have recurrence after corticosteroid withdrawal and require long-term immunosuppression with cytotoxic immunosuppressive agents. A few patients develop progressive fibrosis despite

aggressive immunosuppression and may be candidates for lung transplantation.

Lymphocytic Interstitial Pneumonia

Lymphocytic interstitial pneumonia is a rare disorder of polyclonal lymphocyte aggregates that accumulate diffusely in the interstitium.[55] The diagnosis almost always requires surgical lung biopsy. Patients are typically younger than patients with IPF and present with subacute dyspnea and cough. Pulmonary function testing may show a mixed picture, and high-resolution CT typically shows diffuse ground-glass attenuation with variable amounts of fibrosis. Most patients respond well to oral corticosteroids, with a few requiring long-term immunosuppression. Lymphocytic interstitial pneumonia is frequently associated with connective tissue diseases, especially Sjögren syndrome, and with immunodeficiency, and these possibilities should be investigated in all patients with lymphocytic interstitial pneumonia.

MINI CLINI

Clinical Deterioration in a Patient With Interstitial Lung Disease

PROBLEM: A 50-year-old man with fibrotic NSIP is being treated with oral corticosteroids and cyclophosphamide. After 6 months of therapy, he begins to report progressive breathlessness. Why is this occurring?

SOLUTION: Many ILDs follow a gradually progressive course to end-stage disease and death. The available treatments may result in temporary improvement or retard progression of the disease. These treatments seldom are curative, however. Progressive symptoms (exertional dyspnea or cough) in a patient being treated for ILD often, although not always, indicates disease progression.

The following possibilities must be considered and separated from progression of the disease:

1. *Superimposed infection:* Immunosuppressive agents used in the management of some ILDs increase the risk for infection in the lung and elsewhere. Common bacteria or uncommon opportunistic infections may be responsible. Pneumonia may be difficult to detect radiographically because of preexisting radiographic abnormalities, and bronchoscopy with bronchoalveolar lavage and transbronchial lung biopsy may be needed.
2. *Drug reaction:* Almost all medications used to treat ILD have been reported to be capable of causing an adverse pulmonary reaction. Some medications, such as methotrexate, have been described to result in pulmonary reactions in 5% to 10% of users. An adverse drug reaction should be considered in all patients with ILD who are being actively treated, particularly if there is a clear temporal relationship between starting the medication and the new or progressive respiratory symptoms.
3. *Steroid-related muscle weakness.* This is a less common complication of corticosteroid therapy and can cause exercise intolerance indistinguishable from progression of the underlying lung disease. Steroid-related muscle weakness (steroid myopathy) is difficult to diagnose because the weakness can result in worsening of the underlying restrictive physiologic defect. When proximal muscle weakness occurs in combination with progressive respiratory symptoms, the possibility of steroid myopathy should be considered. A greater than 20% drop in the FVC in the supine position compared with the sitting position suggests neuromuscular dysfunction.
4. *Pulmonary embolism:* Inactivity as a result of disease-related physiologic impairment and right ventricular dysfunction may be a risk factor for thromboembolic disease. A sudden decline in respiratory status, sometimes associated with pleuritic chest pain, should raise the possibility of acute pulmonary embolism.
5. *Lung carcinoma:* Patients with pulmonary fibrosis have an increased risk for lung cancer, and the development of lung cancer can contribute to clinical decline.
6. *Atherosclerotic vascular disease:* Many patients with ILD have independent risk factors for atherosclerotic vascular disease. They may have unrelated cardiac disease, such as coronary artery disease, left ventricular dysfunction, or valvular disease, which can be mistaken for a worsening of the pulmonary process.

Each of the possible explanations for the patient's breathlessness should be considered before ascribing it to progression of the ILD.

NONSPECIFIC THERAPIES

Oxygen Therapy

Because hypoxemia is common in ILD, supplemental O_2 therapy is frequently prescribed, although it has not been studied as extensively as in chronic obstructive pulmonary disease (COPD). Patients with ILD should have arterial O_2 saturation determined at rest and especially during exertion because many patients with only mild disease desaturate with exertion despite normal saturation at rest. Although studies are limited, supplemental O_2 delivered via nasal cannula can prevent resting hypoxemia and allow greater exertion before desaturation. These benefits may improve quality of life and potentially ward off development of pulmonary arterial hypertension, although further studies are needed.

We favor continuous rather than pulsed delivery of O_2 in patients with ILD because the desaturation with activity seen in most patients is not corrected with pulse therapy, and pulse units vary greatly in the amount of O_2 delivered.[56] For most patients, liquid O_2 is the best source to provide adequate flow rates. In motivated patients, transtracheal delivery of supplemental O_2 increases the efficiency of delivery and improves cosmetic appearance. However, patients must be chosen carefully because of the need for frequent care and risk for mucus drying, tracheal blockage by dried secretions, and rare bleeding.

MINI CLINI

Tobacco Use and Interstitial Lung Disease

PROBLEM: A 30-year-old woman has ILD and is a current smoker. She is concerned that quitting on her own is too difficult and comments that tobacco use is associated with emphysema, not with scarring. Should she be encouraged to quit smoking? Why or why not?

SOLUTION: Yes! Although the association between tobacco use and COPD is well known, the relationship with ILD is less well-appreciated. Smoking is a risk factor for the development of IPF but not the sole cause. However, the IIPs of DIP, RB-ILD, and PLCH have a strong association with cigarette smoking.

Approximately 90% of patients with DIP and RB-ILD are current or former tobacco smokers. More than 90% of patients with PLCH smoke, often quite heavily. As with other toxic exposures, complete avoidance of all smoke is important for these patients. In RB-ILD and PLCH, physiologic stabilization and occasionally even improvement can occur after stopping smoking. In DIP, the benefits of smoking cessation are unclear.

In addition to having concerns about these specific disease considerations, patients with ILD of any type cannot afford to risk the development of additional, smoking-related cardiorespiratory impairment. The patient should be strongly encouraged to stop smoking.

Pulmonary Rehabilitation and Exercise Therapy

Pulmonary rehabilitation, a very important part of treating obstructive lung disease, also has proved beneficial in the management of ILD. Pulmonary rehabilitation is important in building aerobic fitness, maintaining physical activity, and improving quality of life. When pulmonary rehabilitation is stopped, the benefits decrease over a few months.[57] We encourage all of our patients to enroll in outpatient pulmonary rehabilitation and to continue maintenance rehabilitation.

Vaccinations and Infection Avoidance

Because patients with ILD have increased consequences of respiratory infections, patients with ILD should receive a pneumococcal vaccine per U.S. Centers for Disease Control and Prevention guidelines and a yearly influenza virus vaccine. Additionally, we recommend that patients practice good hand hygiene (frequent handwashing). We do not recommend use of masks or special antibacterial products. Patients treated with prednisone in doses greater than 15 mg daily or with a steroid-sparing immunosuppressant should receive *Pneumocystis* prophylaxis (e.g., with oral trimethoprim-sulfamethoxazole, inhaled pentamidine, etc.).

Transplantation

The only therapy shown to prolong life in patients with end-stage, particularly fibrotic, ILD is lung transplantation.[58] Transplantation has been performed successfully in the management of most ILDs. A recommendation for lung transplantation must consider the significant risk for mortality at 1 year (10% to 25%) and 5 years (50% to 60%). Many patients with ILD are older than the upper age limit of "physiologic" age 65. Additionally, comorbidities such as gastroesophageal reflux disease, which is common in many ILDs, preclude lung transplantation because of the increased risk for chronic rejection and death.

Summary

The entities grouped as ILDs are a diverse group of illnesses of varied cause, treatment, and prognosis. These diseases generally manifest as chronic, progressive dyspnea on exertion and cough. Findings on examination are often limited to the chest in the form of fine, inspiratory crackles. The most common finding on chest radiograph is diffuse reticular or reticulonodular infiltrates with reduced lung volumes. Pulmonary function testing usually reveals restrictive physiology and decreased diffusion capacity; however, other patterns can be seen. Therapy depends on the underlying disease and may consist of immunosuppressive drugs and the avoidance of disease-inducing exposures.

ROLE OF THE RESPIRATORY THERAPIST

- The respiratory therapist (RT) sees patients with ILD in one of two settings. RTs assess and treat outpatients in several manners. In the role of pulmonary function technician, the RT assesses disease burden and serial changes in lung function. At the initial evaluation, the RT needs to provide accurate spirometry, lung volume, and DLCO, along with 6-minute walk distance and saturation, because these measures have important prognostic value. At subsequent visits, serial changes in these parameters are important to assess a patient's response to therapy or disease progression. Besides having important prognostic values, changes in lung function over time help determine whether to continue therapy or refer eligible patients for lung transplantation.
- RTs determine supplemental O_2 requirements at rest and with exertion and recommend the appropriate delivery amount, mode, and source of O_2. Also, RTs typically perform outpatient pulmonary rehabilitation, which can benefit many patients with ILD. RTs also may administer inhaled pentamidine, which is used to prevent *Pneumocystis jirovecii* infection in patients receiving immunosuppressive drugs for an ILD.
- The needs of patients with ILD change when admitted to the hospital. The RT plays a crucial role in assessing supplemental O_2 needs and delivering O_2 by the proper mode (nasal cannula, face mask, high-flow O_2 with nonrebreathing face mask, or intubation and mechanical ventilation). If obstructive impairment is suspected, the RT can recommend and deliver the appropriate bronchodilators or inhaled corticosteroids. Owing to the tenuous nature of these patients, careful monitoring by the RT of patients with ILD is required to prevent hypoxemia and its acute complications.

SUMMARY CHECKLIST

- ILDs are a diverse group of illnesses that can be organized into groups based on related causes.
- These diseases generally cause chronic, progressive dyspnea on exertion and cough.
- Findings on examination are often limited to the chest in the form of fine, inspiratory crackles.
- The most common chest radiograph finding is diffuse reticular or reticulonodular infiltrates with reduced lung volumes.
- Pulmonary function testing usually reveals restrictive physiology and decreased diffusion capacity; however, other patterns can be seen.
- Causes of the ILDs are diverse but are most frequently from exposure (tobacco, hypersensitivity pneumonitis antigens, silica, asbestos), autoimmune dysfunction (sarcoidosis, connective tissue disease associated), and abnormal injury healing (IPF).
- Nonspecific treatment may be considered in all ILD patients (e.g., supplemental O_2, pulmonary rehabilitation), but specific ILD treatment depends on the underlying disease and may consist of immunosuppressive drugs and avoidance of disease-inducing exposures.

CHAPTER 27

Pleural Diseases

CHARLIE STRANGE

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the anatomy and function of the visceral and parietal pleura.
- Describe how pleural effusions occur and the difference between transudative and exudative effusions.
- Identify common causes of transudative and exudative pleural effusions.
- Write definitions of chylothorax, hemothorax, and pneumothorax.
- Describe the impact of moderate to large pleural effusions on lung function.
- State the role of the chest radiograph in recognizing pleural effusions.
- State the purpose of thoracentesis and the potential complications.
- Identify the definitions of spontaneous, secondary, and tension pneumothorax.
- Describe the diagnosis and treatment of pneumothorax.

CHAPTER OUTLINE

KEY TERMS

alveolopleural fistula
bronchopleural fistula
chyle
chylothorax
empyema
exudative pleural effusion
hemothorax
parietal pleura
pleural effusion
pleurisy
pleurodesis
pneumothorax
primary spontaneous pneumothorax
reexpansion pulmonary edema
secondary spontaneous pneumothorax
stomata
tension pneumothorax
thoracentesis
transudative pleural effusion
visceral pleura

A spectrum of pleural diseases affects respiratory function. An understanding of pleural anatomy, physiology, and pathology is essential to delivering effective respiratory care. This chapter focuses on the two major diseases that occur in the pleural space: pleural effusion and pneumothorax.

THE PLEURAL SPACE

Each lung is covered by a thin membrane called the **visceral pleura** that adheres closely to the underlying lung (Figure 27-1). The visceral pleura dips into the fissures of the lung, allowing the surgeon easy access between the lung lobes and allowing

pleural fluid to travel freely between the lobes while remaining in the pleural space.

The ribs and connective tissue of the chest wall are covered on the inner surface by a similar membrane called the **parietal pleura.** The parietal pleura can be thought of as a sac that covers not only the rib surface (costal pleura) but also the diaphragm (diaphragmatic pleura) and the mediastinum (mediastinal pleura).

The blood vessels and airways that enter the lung connect to the mediastinum at the lung hilum. It is at this juncture that the visceral pleura meet the mediastinal parietal pleura to form a single, continuous pleural membrane (Figure 27-2).

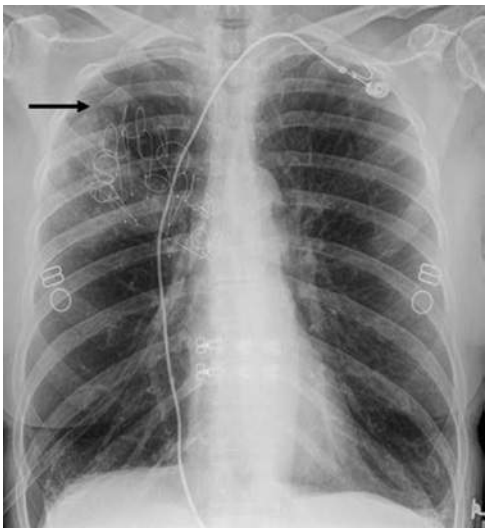

FIGURE 27-1 The presence of a pneumothorax is diagnosed by identification of a pleural line *(arrow),* in this case after bronchoscopic placement of lung volume reduction coils. A hydropneumothorax requires identification of both a pleural line *(arrow)* and the air-fluid interface of pleural fluid that causes a straight line in the chest. A high-quality monitor is needed to optimally detect the pleura.

Because the lung usually is completely inflated, it might be thought that the pleural membranes always touch. However, freeze-fracture imaging has demonstrated that there is a space between the visceral and parietal pleura that averages 10 to 20 mm in width and is filled with pleural fluid. This thin film of fluid allows the lung to slide over the ribs and a gliding movement that takes little energy and produces little friction.

The average person has approximately 8 ml of pleural fluid per hemithorax.[1] It is estimated that this pleural fluid has a total protein concentration similar to that of interstitial fluid elsewhere in the body: between 1.3 and 1.4 g/dl.[2]

In humans, the pleural spaces surrounding each lung are completely independent, being separated by the mediastinum. This is not the case in all other mammals. The slaughter of the American buffalo could occur with a single spear or rifle shot because the pleural spaces of the buffalo lung are connected. Consequently, air in the pleural space collapses both lungs. A similar situation can occur in any patient who has undergone median sternotomy, during which both pleural spaces were entered. Common operations resulting in this condition are lung volume reduction surgery and bilateral lung transplantation.

The pleural space is under negative pressure except during forced expiration. The intact thoracic rib cage provides elastic recoil pressure outward, whereas the intrinsic recoil pressure of the lung is inward toward the lung hilum. The diaphragm further decreases the intrapleural pressure below atmospheric pressure to allow inspiration to occur. In an upright person, the pressure is more negative at the top of the lung than at the bottom of the lung because of the weight of the lung and the effects of gravity. The net effect of the negatively pressurized pleural space is that fluid moves into the pleural space from adjacent sites when a communication is present. A patient with

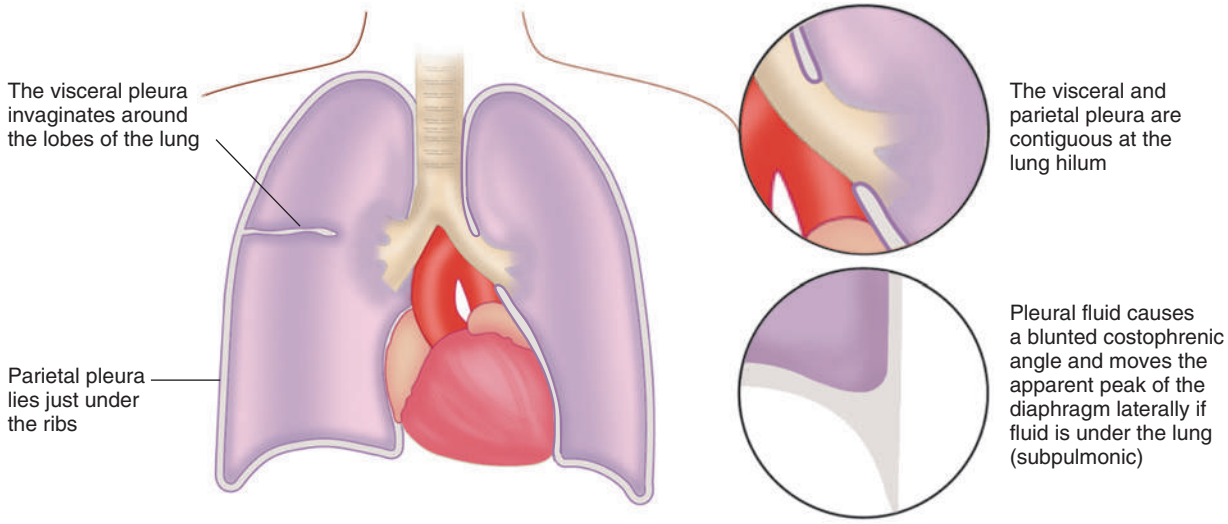

FIGURE 27-2 Anatomy of the pleura.

ascitic fluid and a hole in the diaphragm usually pulls fluid into the pleural space.

PLEURAL EFFUSIONS

Any abnormal amount of pleural fluid in the pleural space is called **pleural effusion.** The many causes of pleural effusion are categorized according to the factor that causes it and the content of the fluid.[3]

Pleural fluid enters the pleural space across both the visceral and the parietal pleura, particularly when the interstitial pressure within either the lung or the chest wall is increased. The main route for pleural fluid removal is small holes within the parietal pleura called **stomata** that are large enough to allow a red blood cell to enter and be cleared from the pleural space. The parietal pleural stomata connect with intercostal lymphatic vessels under the ribs that drain posteriorly into the mediastinum. In the mediastinum, these lymphatic vessels enter lymph nodes before draining into the thoracic duct, a large lymphatic channel within the chest, which empties into the left subclavian vein. Abnormalities of increased pleural fluid production or blockade of drainage can cause pleural fluid to accumulate.

Transudative Effusions

Any pleural effusion that forms when the pleural space is intact is called a **transudative pleural effusion.** A pleural fluid total protein concentration less than 50% of the serum total protein level and lactate dehydrogenase (LDH) values in the pleural fluid less than 60% of the serum value indicate the presence of a transudative pleural effusion. In the absence of serum values, an absolute pleural fluid LDH level less than two-thirds normal for serum suggests the presence of a transudate. These numbers were derived from large patient series in which pleural fluid and serum protein concentrations were measured while the cause of the effusion was being determined and corrected.[4]

The classification system listed in Box 27-1 is not perfect, and refinements continue to be proposed. For practical purposes, these numbers help narrow the possible causes of pleural fluid formation.

Transudative pleural effusions form when hydrostatic and oncotic pressures are abnormal[5] (Figure 27-3). The list of diseases that cause transudative pleural effusions is short. Therefore these diseases remain relatively easy to diagnose.

Box 27-1 Causes of Pleural Effusion

TRANSUDATIVE PLEURAL EFFUSION
- Congestive heart failure
- Cirrhosis
- Nephrotic syndrome
- Hypoalbuminemia
- Lymphatic obstruction
- Peritoneal dialysis
- Atelectasis
- Central venous catheter in pleural space
- Urinothorax

EXUDATIVE PLEURAL EFFUSION NEOPLASTIC DISEASE
- Carcinoma
- Lymphoma
- Mesothelioma

INFECTIOUS DISEASE
- Bacterial infection
- Tuberculosis
- Fungal infection
- Paragonimiasis
- Viral pleurisy

PULMONARY EMBOLISM AND GASTROINTESTINAL DISEASE
- Pancreatic disease
- Intraabdominal abscess
- Splenic infarction
- Esophageal perforation
- Abdominal surgery
- Endoscopic variceal sclerotherapy

COLLAGEN VASCULAR DISEASE
- Rheumatoid pleurisy
- Systemic lupus erythematosus
- Drug-induced lupus
- Immunoblastic lymphadenopathy
- Sjögren's syndrome
- Familial Mediterranean fever
- Churg-Strauss syndrome
- Granulomatosis with polyangiitis (formerly called *Wegener granulomatosis*)

DRUG-INDUCED PLEURAL DISEASE
- Nitrofurantoin
- Minoxidil
- Dantrolene
- Methysergide
- Bromocriptine
- Amiodarone
- Procarbazine, bleomycin, mitomycin
- Methotrexate

MISCELLANEOUS DISEASES AND CONDITIONS
- Benign asbestos pleural effusion
- Postcardiac injury syndrome (Dressler syndrome)
- Meigs syndrome
- Yellow nail syndrome
- Sarcoidosis
- Pericardial disease
- Fetal pleural effusion
- Uremic pleural effusion
- Trapped lung
- Radiation pleurisy
- Amyloidosis

ELECTRICAL BURNS
HEMOTHORAX
CHYLOTHORAX

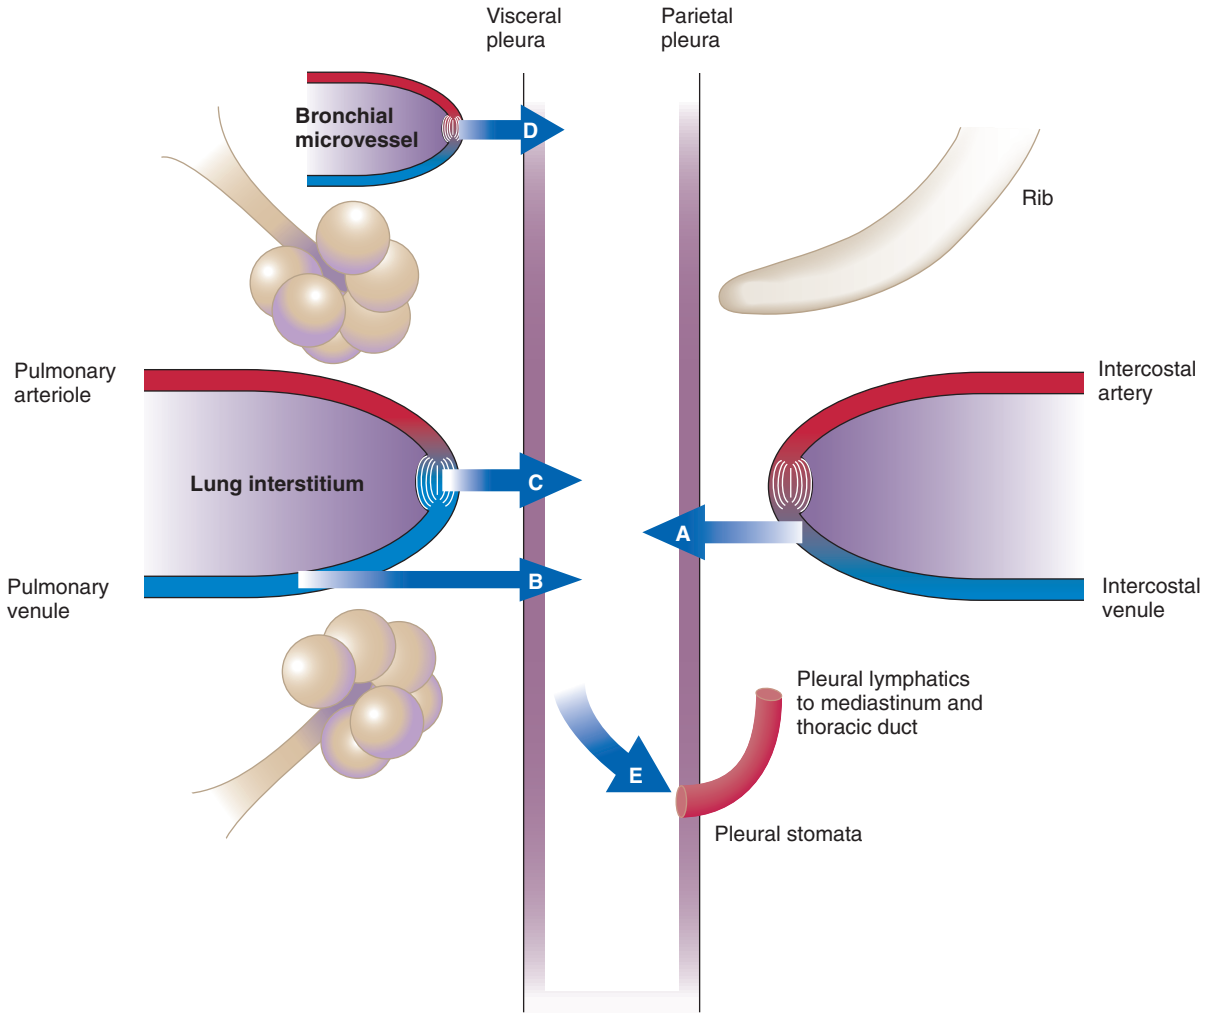

FIGURE 27-3 Pleural fluid formation requires both excess fluid formation and decreased elimination. In diseases such as pulmonary arterial hypertension, in which right-sided heart pressure is increased and systemic veins, such as the intercostal veins *(A),* are pressurized, pleural fluid does not form because pleural fluid formation is not increased and lymphatic drainage remains intact. However, when left ventricular failure causes pulmonary venule pressure *(B)* to increase, the addition of interstitial lung water overwhelms the drainage and produces a transudative pleural effusion. Injury to the capillaries *(C),* as in pneumonia or acute respiratory distress syndrome, causes fluid to leak into the lung interstitium and pleural space at increased rates. Under these conditions, fibrin can occlude the pleural lymphatic vessels *(E)* and cause fluid to accumulate. The bronchial microvessels *(D)* supply the pleura with blood and likely participate to some extent in production of pleural fluid.

Congestive Heart Failure

Elevation of pressure in the left atrium and pulmonary veins is the hallmark defining feature of *congestive heart failure* (CHF). Elevation of pulmonary venous pressure increases the amount of interstitial fluid in the lung. In severe cases, flooding of the alveoli causes pulmonary edema, but in less severe cases, interstitial lung water increases and decompresses into the pleural space. Because systemic venous pressure also is elevated, there is limited capability to remove pleural fluid through the intercostal veins. Therefore pleural fluid must be predominantly removed by the lymphatic vessels. Pleural effusions result when the capacity of pleural lymphatic drainage is overcome.[6]

CHF is the most common cause of pleural effusions in clinical practice. The effusions can be massive, filling the entire hemithorax and compressing the lung. More commonly, they are small and bilateral. The effusions are rarely drained because outcome is heavily influenced by successful management of the underlying CHF, which also clears the effusions.[7]

Nephrotic Syndrome

In *nephrotic syndrome* (also known as *nephrosis*), the kidneys leak more than 3 g of protein per day into the urine. Because patients become protein depleted, there is insufficient oncotic pressure within the blood to hold appropriate amounts of fluid within the blood vessels. These patients become edematous, and fluid leaks into the lung interstitium and pleural space. Pleural effusions are common but usually are small.

Patients with nephrosis are at increased risk for deep venous thrombosis and pulmonary embolism. In nephrosis, protein S, which keeps blood from clotting, becomes deficient from

leaking into the urine. The presence of large or asymmetric pleural effusions should raise the possibility that pulmonary emboli have occurred. Pleural effusions associated with pulmonary emboli usually are exudates and contain large numbers of red blood cells.

Hypoalbuminemia

Hypoalbuminemia is caused by a variety of debilitating diseases, such as acquired immunodeficiency syndrome and chronic liver disease. Pleural effusions rarely form until the serum albumin level is less than 1.8 g/dl. The mechanism of formation of pleural fluid is identical to that of nephrotic syndrome. Low protein levels in the blood allow fluid to leak into interstitial tissues and the pleural space. The effusions usually are small.

Liver Disease

End-stage liver disease causes transudative fluid to accumulate in the abdomen. This fluid is called *ascites.* Because the pleural space is under negative pressure during inspiration and because ascitic fluid often is under positive pressure, any small hole in the diaphragm can result in movement of ascitic fluid into the pleural space to form *hepatic hydrothorax.*

All ascitic fluid can end up in the chest because of the pressure gradient, and true ascites can be absent. This condition often is quite difficult to manage except with methods that limit ascites formation, such as sodium restriction and diuretics. Excessive pleural fluid is present in approximately 6% of patients with ascites, and 70% of these fluid collections are on the right side.[8]

Atelectasis

When segments of the lung collapse, intrapleural pressure becomes more negative and can produce small effusions. With relief of bronchial obstruction and postoperative pain, these effusions may go away.

Lymphatic Obstruction

Lymphatic obstruction within the mediastinum causes poor pleural fluid removal from the pleural space, although the pleural space is otherwise normal. The most common condition that causes this abnormality is cancer that metastasizes to the mediastinum. This condition should be differentiated from a true malignant pleural effusion, defined as cancer cells within the pleural space.

Rare Causes

There are other rare causes of transudative pleural effusions. Urinothorax occurs after rupture of the ureter causing a urine leak into the retroperitoneal space that refluxes into the chest. The pleural fluid has a low pH. A central venous line that is inappropriately placed into the pleural space can put large amounts of transudative fluid into the pleural space before this abnormality is recognized. The level of glucose in the pleural fluid can be very elevated, depending on the infusion. Peritoneal dialysate can migrate into the pleural cavity in patients undergoing continuous ambulatory peritoneal dialysis.

Exudative Effusions

An **exudative pleural effusion** is caused by inflammation in the lung or pleura. This type of pleural effusion has more protein and inflammatory cells present than does a transudative effusion. Because therapy for pleural effusion depends on the cause, **thoracentesis** often is performed to determine the specific biochemical and cellular characteristics of the pleural effusion. Box 27-1 lists the common causes of exudative pleural effusion. They account for approximately 70% of all pleural effusions.

Parapneumonic Effusion

Pleural effusions form in pneumonia because inflammation in the lung increases interstitial lung water and pleural fluid production. Most effusions are small and resolve with resolution of the bacterial pneumonia.[9] Complicated parapneumonic pleural effusion develops when the pleural fluid has a high enough protein content to clot. The clotting causes fibrin strands to span the visceral and parietal pleura. The net result is collection of pleural fluid into different pockets called *loculi* within the pleural cavity. These often cannot be drained by a single chest tube.

Progression to **empyema** is marked by the presence of bacteria within the pleural space, seen as pus or bacteria on Gram stain. Empyemas require drainage. Whether complicated parapneumonic effusions require drainage remains controversial, although most physicians perform drainage because some of these effusions can progress to empyema.[10]

Parapneumonic effusions are common causes of persistent fever among intensive care unit (ICU) patients with pneumonia. Sampling by thoracentesis is commonly performed to exclude empyema. Pleural fluid drainage can improve ventilation and dyspnea if the volume of fluid removed is large.[11]

Viral Pleurisy

Viral lung infections (**pleurisy**) can cause pleural inflammation, small pleural effusions, and pain. The effusions may be so small they may be overlooked on a routine chest radiograph, and even when they can be seen, the effusions often are too small to sample. Pleural pain, which is called *pleurodynia,* and which can be the result of many other pleural processes, often is difficult to manage. The typical patient with pleurodynia has shallow respirations; deeper breaths are limited by pain. The subsequent atelectasis can cause oxygenation difficulty caused by shunting.

Tuberculous Pleurisy

In many parts of the world, any lymphocyte-predominant exudative effusion is considered tuberculosis until proved otherwise. Tuberculous pleural effusions occur when a caseous granuloma in the lung ruptures through the visceral pleural surface causing an exudative inflammatory effusion. Experiments in which purified protein derivative (PPD) is placed into the pleural space of animals have shown that such effusions result from the body's immune reaction to tuberculin proteins.

Although these patients need respiratory isolation, only 25% of them have sputum that subsequently grows *Mycobacterium*

tuberculosis. The PPD skin test result is negative in 30% of patients when they come to medical attention but turns positive in 6 to 8 weeks in almost everyone.[12]

Malignant

Malignant disease is the most common cause of large unilateral pleural effusions among persons older than 60 years. Common cancers that form malignant pleural effusions include lung cancer and breast cancer, although any cancer can metastasize to the pleural surface. The effusions usually are lymphocyte predominant; malignant cells are found during cytologic examination of the pleural fluid.

Some malignant pleural effusions, such as those from lymphoma, respond to therapy for the malignant disease. However, most patients with symptomatic malignant pleural effusions need primary therapy with pleurodesis. **Pleurodesis** occurs when the visceral and parietal pleural membranes are fused by talc, other chemicals, or surgery to obliterate the pleural space.

Postoperative Effusion

A variety of operations involving the chest or upper abdomen produce pleural fluid.[13] Effusions after cardiac surgery usually are predominant on the left side and tend to be bloody. These effusions are particularly prevalent after a cutdown of the internal mammary artery for coronary artery bypass.

Small transudative pleural effusions are common when there is any atelectasis in the lung. Upper abdominal operations cause inflammation of the diaphragm. The resulting effusion has been termed a *sympathetic* effusion. Lung surgery in which the lung is unable to fill the thoracic cavity leaves a space under negative pressure, which fills with inflammatory pleural fluid. When the lung is unable to fill the space because of small postoperative size or visceral pleural fibrosis, the resulting pleural effusion can never be completely drained because of the "trapped lung."

Chylothorax

The thoracic duct is a lymphatic channel that runs from the abdomen through the mediastinum to enter the left subclavian vein. Disruption of the thoracic duct anywhere along its course can cause leakage of **chyle** into the mediastinum, which then may rupture into the pleural space and cause a **chylothorax.** The most common causes of rupture are malignancy (50%), surgery (20%), and trauma (5%).[14] The thoracic duct courses through the right side of the mediastinum in the lower thoracic cavity before crossing to the left side of the mediastinum at the level of T4 to T6. Rupture below this level causes right-sided pleural effusion, whereas rupture above this level causes left-sided pleural effusion.

In a patient who has eaten recently, the effusions are milky white as a result of the presence of chylomicrons (microscopic fat particles) absorbed by abdominal lymphatic vessels. In a fasting patient, these effusions usually are yellow. They may be bloody. A pleural fluid triglyceride concentration greater than 110 mg/dl confirms the diagnosis.[15] Computed tomography (CT) should be performed to evaluate the cause of the chylothorax.

Hemothorax

Hemothorax is the presence of blood in the pleural space. Hemothorax is arbitrarily defined as a pleural fluid hematocrit more than 50% of the serum value. Small amounts of blood in otherwise clear fluid can turn the fluid red, so measurement of the pleural fluid hematocrit is necessary to make this diagnosis.

Although hemothorax is seen most commonly after blunt or penetrating chest trauma, a number of medical conditions can give rise to blood in the pleural space. These should be considered in the absence of trauma. Any vein or artery in the thorax can bleed into the pleural space. A chest tube usually is inserted to monitor the rate of bleeding and determine whether the source is arterial or venous.[16]

Connective Tissue Diseases

Pleural effusions are found in a variety of connective tissue diseases, although the effusions usually are small. Effusions caused by inflammation of small blood vessels are the most common chest manifestation of systemic lupus erythematosus (SLE). Pleural effusions often accompany pericardial effusions in SLE and disappear with corticosteroid therapy.

Rheumatoid arthritis produces a characteristic effusion with a very low glucose content and low pH. These effusions can cause visceral pleural fibrosis and a trapped lung.

Uremic Effusion

Uremic pleurisy occurs under the same conditions as uremic pericarditis. The typical patient is undergoing dialysis that is inadequate in duration or frequency. Although the cause of pleural and pericardial inflammation in kidney failure remains unknown, the inflammatory process can take weeks to resolve.

Miscellaneous Causes

Discussion of the other causes of exudative effusions is beyond the scope of this chapter. Nevertheless, thoracentesis that yields findings compatible with any of those in the systemic diseases listed in Box 27-1 can narrow the differential diagnosis.

Physiologic Importance

Mechanics of Ventilation

Pleural effusions cause lung atelectasis because the capacity of the thorax is limited and fluid collapses the lung. Spirometry shows restriction. Studies correlating the volume of pleural fluid removed with improvement in forced vital capacity (FVC) show much variability from patient to patient.

Dyspnea is common with small pleural effusions, even when lung mechanics are relatively preserved. The mechanisms remain unknown but likely involve activation of stretch receptors or irritant receptors within the airways or nonadrenergic, noncholinergic C fibers in the chest wall or diaphragm. The net result is that dyspnea relief is variable after pleural fluid removal. Some patients have symptomatic relief after removal of small

RULE OF THUMB

The patient's vital capacity improves by approximately one-third of the pleural fluid volume removed. The remainder of the pleural fluid volume causes diaphragmatic compression and chest wall expansion. Some patients have a delay of 24 to 48 hours before the improvement can be seen as atelectasis resolves. Lack of any improvement suggests that lung consolidation or endobronchial obstruction is present. Improvement is less when the underlying disease is acute respiratory distress syndrome (ARDS).

pleural fluid volumes. Others can actually have more dyspnea if the fluid is removed in situations such as trapped lung, in which neural activation may increase with fluid withdrawal.

In rare instances, the pleurae thicken with a disease process sufficient to cause fibrothorax. Technically, fibrothorax is any process that causes fibrosis of the thoracic cage that affects pulmonary function. Fibrothorax can be caused by skin (e.g., fibrothorax that occurs, rarely, in scleroderma), soft tissue, bone (e.g., myositis ossificans, a disease in which muscles calcify), or pleura. The causes of pleural thickening significant enough to produce restriction include severe asbestos pleurisy, rheumatoid pleurisy, complicated trauma, cancer, and empyema. Treatment of fibrothorax from a pleural cause requires surgery, which is rarely performed because it is a very difficult operation.

Hypoxemia

Most patients with a pleural effusion have an increased alveolar-arterial (A-a) gradient resulting from the pathologic changes in the lung that are causing the effusion. Oxygenation can worsen after thoracentesis because changes in ventilation/perfusion ($\dot{V}/\dot{Q}$) matching are not instantaneous. Recovery to baseline PO_2 and subsequent improvement usually occurs a short time after thoracentesis.[16]

Diagnostic Tests

Chest Radiography

The chest radiograph is the most common method of detecting a pleural effusion. It is important that, if possible, the chest radiograph be obtained with the patient in an upright position to show a pleural fluid meniscus at the costophrenic angles. Many ICUs have rules that all radiographs are taken with patients sitting upright to optimize the value of the test. When the same patient undergoes radiography in the supine position, the effusion is distributed throughout the posterior part of the chest. The chest radiograph shows a generalized haze, which interferes with the detection of pulmonary infiltrates and quantifies the amount of fluid in the pleural effusion.

Lateral decubitus chest radiographs are performed by having patients lie on their side with the radiograph taken across the bed or table. This technique can show an effusion as small as 5 ml. This technique is used less often than other tests.

Ultrasonography and Computed Tomography

Pleural fluid and loculi can be detected easily with ultrasonography of the chest. The sensitivity of ultrasonography for pleural effusions is high, although ultrasonography is an operator-dependent study. Small portable ultrasound machines with high diagnostic accuracy have become available to localize the presence and location of pleural effusions. Most physicians use them routinely to optimize thoracentesis success.

CT scanning of the chest is the most sensitive study for identifying a pleural effusion. A contrast-enhanced scan is needed to delineate the pleural membrane and differentiate peripheral lung consolidation from pleural fluid. In addition to showing the size and location of a pleural effusion, the chest CT scan often gives information about the underlying lung parenchyma and the primary process causing the effusion.

Thoracentesis

In thoracentesis, pleural fluid is sampled percutaneously by means of inserting a needle into the pleural space (Figure 27-4). Administering an adequate local anesthetic ensures a painless procedure if care is taken to place lidocaine at the skin insertion site, along the periosteum of the involved rib, and at the parietal pleura, which is richly innervated with sensory nerve fibers. Diagnostic sampling of pleural fluid for cell counts, cultures, chemistries, and cytologic examination usually can be performed with a single syringe and a small needle. Samples for pleural pH should be kept from contact with room air. Pleural fluid drainage with lung reexpansion involves placing a larger catheter into the pleural space.

Thoracentesis involves the following three major risks: (1) intercostal artery laceration, (2) infection, and (3) pneumothorax.[17] Both an artery and a vein course under every rib, and the vessels become increasingly serpiginous with aging. Ensuring needle passage just over the rib margin makes bleeding during thoracentesis rare.

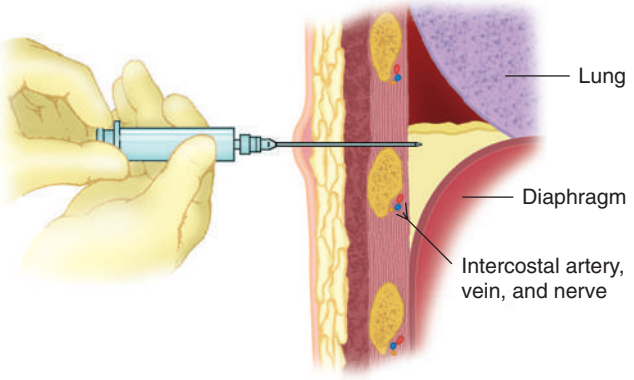

FIGURE 27-4 The technique of thoracentesis involves passage of a needle just superior to the rib. If the needle is placed too low on the chest, the diaphragm or organs below the diaphragm can be punctured. Diagnostic thoracentesis can be performed with small amounts of pleural fluid.

Because infection can be introduced into the pleural space, a totally sterile procedure is necessary. In some situations, the risk for infection is so high that thoracentesis rarely should be performed. When a lung is surgically removed, the space fills with sterile fluid. An infection introduced into this space usually necessitates open surgical drainage. Any trapped lung also carries a high risk for empyema because of the inability of the visceral and parietal pleura to meet and contain any infectious process. Needle puncture remains one of the most common causes of pneumothorax (see discussion of pneumothorax later in this chapter).

RULE OF THUMB

Chest tubes are usually removed when the volume of pleural fluid that comes out is less than 50 ml/24 hr. Chest tubes should not be kinked, to optimize pleural space drainage. Higher volumes suggest that the primary process has not been treated adequately. Daily monitoring of pleural fluid volume requires that the pleural fluid drainage system not be tipped over. Volumes should be recorded in the medical chart and marks made on the pleural drainage system to help determine the best time for chest tube removal.

Chest Thoracotomy Tubes

Chest tubes currently are manufactured in a variety of sizes and shapes, from 7F to 40F catheters. Catheter choice is frequently a matter of physician preference. Larger tubes are less likely to become obstructed and are capable of high airflow rates. Smaller tubes are easier to place over guidewire systems and cause less pain.

Intercostal placement is designed for the skin and soft tissue to approximate the tube and prevent air from entering the pleural space from the outside. The chest tube is then connected to a water-sealed chamber, which usually is contained within a commercially marketed three-bottle system that also regulates pleural pressure and is used to measure pleural fluid volume (Figure 27-5).

Thoracoscopy

The video-assisted thoracoscope is ideally designed for diagnostic and therapeutic work in the pleural space. Diagnostic thoracoscopy often is performed in a medical procedure room using local anesthesia and conscious sedation. The procedure involves placing the thoracoscope through an intercostal incision to visualize the lung surfaces, drain pleural fluid, perform biopsy under direct visualization, and perform pleurodesis if needed.

Pleurodesis

Pleurodesis is the process of fusing the parietal and visceral pleura with a fibrotic reaction that prevents further pleural fluid formation or seals the pleural space. Methods to produce pleurodesis include surgical abrasion and the application of intrapleural chemicals such as doxycycline, minocycline, and talc. Talc has been applied as a powder suspended in sterile saline solution and injected through the chest tube (talc slurry) or dusted through a thoracoscope (talc insufflation). The success rate of talc pleurodesis, approximately 90%, is higher than that of all alternatives except surgical abrasion.[18,19] Pleurodesis is used most commonly in managing symptomatic pleural effusions caused by cancer.

Although pleurodesis of benign effusions, such as those occurring with CHF, nephrotic syndrome, and idiopathic

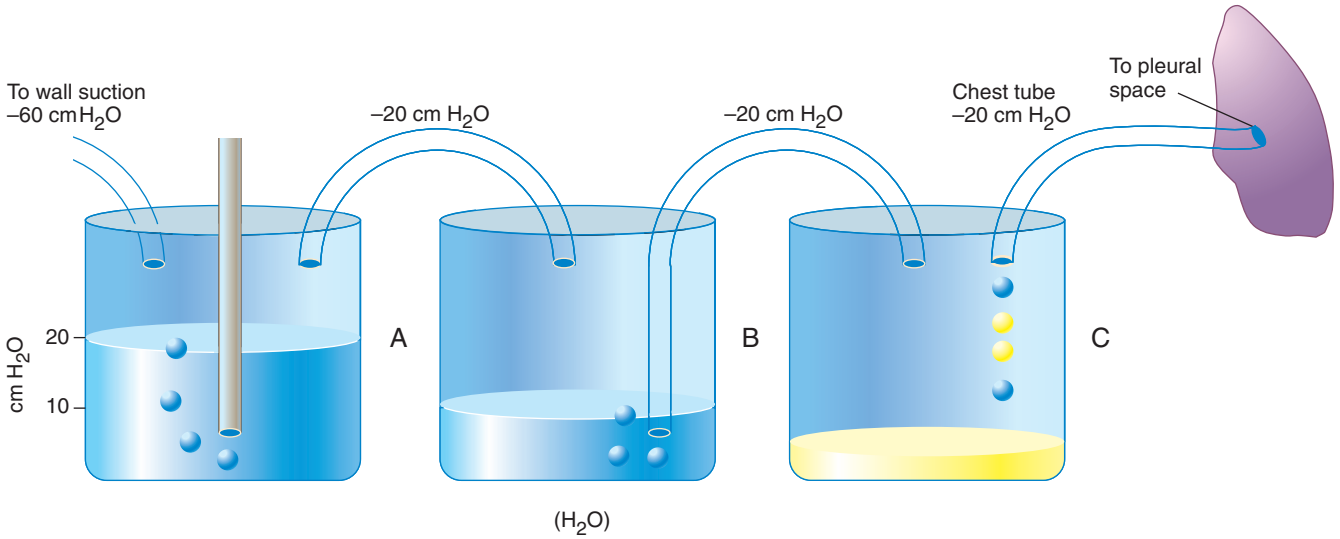

FIGURE 27-5 The standard three-bottle system is the basis for all commercial chest tube drainage systems. Pleural fluid and pleural air enter compartment **C,** which serves as a fluid collection trap so that the water-seal fluid volume will not rise (compartment **B**) and create resistance to air escaping the chest. Air cannot be inspired into the chest because of the water in compartment **B.** Open entrainment of room air through a submerged tube in compartment **A** buffers the amount of wall suction applied (–60 cm H_2O) to the height of the water column to standardize the pressure (–20 cm H_2O) transmitted to the chest.

chylothorax, has been performed successfully, the procedure is discouraged for pleural effusions that are not malignant. Most pleural effusions are best managed by controlling the underlying condition.[20]

Pleuroperitoneal Shunt and Indwelling Catheter

In refractory pleural effusions that cannot be treated adequately with pleurodesis, a small pump (PleurX, CareFusion, San Diego, CA) can be placed subcutaneously and tubes placed in the pleural and peritoneal spaces. The pleuroperitoneal connection has a one-way valve and a pumping mechanism to allow the patient to expel pleural fluid from the negatively pressurized chest to the positively pressurized peritoneum. The pleuroperitoneal shunt is placed as a last resort for refractory pleural effusions for which there is no other treatment.

More commonly, an indwelling catheter is placed into the pleural space and tunneled under the skin to prevent infections. This catheter then exits the skin and has an adapter that hangs outside of the body. The patient or family member then connects this catheter to vacuum bottles that fill with pleural fluid. Pleural fluid can be removed at home for recurrent effusions. If the pleural space is kept dry, a pleurodesis often results and the catheter can then be removed.[21]

PNEUMOTHORAX

Pneumothorax is air in the pleural space. Although air can enter the pleural space from outside the body, as occurs in sucking chest wounds, most cases of pneumothorax occur when disruption of the visceral pleura allows air from the lung to enter the pleural space. Pneumothorax is discussed according to the causative (etiologic) factor because traumatic pneumothorax is managed differently from spontaneous pneumothorax.

Chest pain, which is typically sharp and abrupt, occurs in nearly every patient with pneumothorax. Palpation of the chest wall does not worsen the pain, although respiratory efforts may be difficult. Dyspnea occurs in approximately two-thirds of patients when decreases in vital capacity and PO_2, probably as a result of airway closure at low lung volumes, cause $\dot{V}/\dot{Q}$ defects and shunting. When a spontaneous pneumothorax is evacuated, hypoxemia may persist in some patients.

The following sections describe the diseases that cause pneumothorax and the important treatment differences among them.

MINI CLINI

Indwelling Catheter Care

PROBLEM: A patient with a malignant pleural effusion has an indwelling PleurX catheter placed during his hospitalization and is now ready for hospital discharge. The nurse on the ward asks you to assist with discharge planning of the patient with this device.

SOLUTION: The care of an indwelling catheter at home requires the involvement of a dedicated caregiver who needs to be taught about proper catheter care, timing and technique of drainage, and vacuum bottle inventory. There is often one individual in a hospital that is most knowledgeable to provide this teaching. Often, this person is a respiratory therapist. Note that the brand name of PleurX is unique to the first company that advanced this technology and other catheter systems are available.

Teaching is facilitated by online resources from the catheter manufacturer that provide reading materials for home use. However, there is no substitute for hands-on training. If a PleurX catheter arrives on the hospital ward, dedicated time for teaching home care is best done a few days before hospital discharge. This allows the home care provider to have a better comfort level and causes fewer questions after the patient returns to home.

One major risk is infection. The risk for infection is sometimes worse than with other wounds because many of these patients have cancer and may be immune suppressed by chemotherapy or radiation. Infection can occur at the skin surface or by introducing an infection at the vacuum bottle adapter. The skin wound should be kept with a clean dressing, and signs of colored discharge or redness should prompt medical evaluation. A suture is left in place for some time after placement, and a suture abscess should prompt medical evaluation. To prevent introducing bacteria inside the catheter, the adapter should be cleaned before vacuum bottle attachment.

The number of vacuum bottles needed and the timing of drainage is determined by the volume of pleural fluid on previous drainage days. The goal of the catheter is to keep the pleural space dry enough to allow a natural pleurodesis by growth of cancer cells between the parietal and visceral pleura. The other goal is dyspnea relief. Vacuum bottle inventory and access is determined by local resources but should be preplanned.

Ultimately, the management of a PleurX catheter and whether it can be removed is a medical team decision best informed by a diary of pleural fluid volume removal and the patient's medical condition. Respiratory therapists should know about this device and its care.

Traumatic

Blunt and Penetrating Chest Trauma

Traumatic pneumothorax can be caused by either blunt or penetrating wounds of the thorax. The common causes of penetrating wounds include gunshots and knife punctures. In many cases, penetrating trauma to the chest can be managed conservatively with a chest tube. The clear indications for entering the chest surgically are uncontrolled bleeding from intercostal or pulmonary arteries and injury to the heart or great vessels. In these situations, the pneumothorax becomes secondary. The chest tube is multifunctional to allow measurement of the rate of bleeding, to allow the lung to be pulled to the parietal pleural surface to compress or tamponade bleeding, and to allow maximum ventilation.

In blunt trauma to the chest, pneumothorax can be the result of a rib fracture that enters the lung parenchyma and allows air to leak into the pleural space. For this type of injury, a chest

tube is placed and the rib fractures need no specific therapy. A more common injury is alveolar rupture, which breaks through the pleural membrane.

Two special injuries that produce pneumothorax are tracheal fracture and esophageal rupture. Tracheal fracture results from severe deceleration injury and often occurs along with fractures of the anterior aspect of the first through third ribs. In this case, urgent bronchoscopy is appropriate because tracheal fracture must be corrected surgically. Esophageal rupture produces an air fluid level in the pleural space. Pleural fluid amylase level is elevated from a salivary source.

Large-caliber chest tubes are placed for trauma-related pneumothoraces to allow exit of blood and blood clots, which can be difficult to remove through small-bore catheters. Air leaks from an injured lung can be large. When bleeding is a major component of pleural injury, two chest tubes are used: a posterior chest tube to drain blood that is gravity-dependent and an anterior and apical chest tube to drain air that moves to the lung apex in the absence of pleural disease.

Iatrogenic

Iatrogenic pneumothorax is the most common type of traumatic pneumothorax. Common causes are punctures of the lung from needle aspiration lung biopsy, thoracentesis, and central venous catheter placement. Unusual causes, such as feeding tube placement into the pleural space, also have been recorded. Because the pleural rupture is typically small in the absence of parenchymal lung disease, these lung punctures usually resolve within 24 hours and can be observed without chest tubes as long as serial radiographs are obtained.

Neonatal

In radiographic series, spontaneous pneumothorax occurs in 1% to 2% of all infants soon after birth.[22] The cause of pneumothorax is likely high transpulmonary pressure during birth coupled with transient bronchial blockade caused by meconium, mucus, or aspiration of blood that can produce transpulmonary pressure gradients as high as 100 cm H_2O.

Recognizing pneumothorax is difficult because breath sounds are transmitted widely through the chest of the neonate. A shift of the heart sounds away from the side of the pneumothorax may provide a clue. Transillumination of the chest with a high-intensity light is used in some centers. Almost all neonates with pneumothorax need a chest tube.

Spontaneous

Spontaneous pneumothorax is defined as any pneumothorax caused by the escape of air into the pleural space without an obvious cause. Spontaneous pneumothoraces are of two types: (1) **primary spontaneous pneumothorax,** in which there is no underlying lung disease, and (2) **secondary spontaneous pneumothorax,** in which lung disease is present.

Primary

Primary spontaneous pneumothorax occurs without underlying lung disease. In a way, this term is a misnomer because high-resolution CT scans have shown the presence of small subpleural blebs in more than 80% of patients.[23]

Primary spontaneous pneumothorax usually occurs in patients in their late teenage years or early 20s. Patients often are tall and slender, and the lungs and pleural membrane may not have grown at the same pace; the result is airspace enlargement and a thin pleural membrane.

Results of some studies suggest that cigarette smoking is a risk factor in more than 90% of cases of primary spontaneous pneumothorax.[24] The smoking history is typically short, and smoking cessation is recommended.

Secondary

Secondary spontaneous pneumothorax occurs in patients with underlying lung disease. In most cases, the underlying lung disease is chronic obstructive pulmonary disease with some component of emphysema. Pneumothorax also can occur with asthma and cystic fibrosis, usually during an exacerbation of disease.

Interstitial lung diseases in which lung volumes are spared, such as sarcoidosis, bronchiolitis obliterans with organizing pneumonia, Langerhans cell histiocytosis, and lymphangioleiomyomatosis, have a higher incidence than do diseases without any component of obstruction.

Depending on the extent of parenchymal lung disease, pneumothorax in this population can be devastating. A Veterans Affairs cooperative study included 185 patients with secondary spontaneous pneumothorax and monitored them for 5 years.[25] Although only 3 patients died of pneumothorax, the mortality rate was 43%.[1] Severe underlying lung disease caused most of these deaths. This finding suggested that most pneumothoraces occur in patients with severe lung dysfunction. The degree of dyspnea is disproportionate to the size of pneumothorax in this group of patients because pulmonary reserve is already diminished. Pneumothorax usually should be evacuated and not simply watched in this patient cohort.

Catamenial Pneumothorax

Catamenial pneumothorax occurs in association with menstruation and usually is recurrent and right-sided. The reason for the right-sided predominance is unclear. Many patients have endometriosis on the pleural surface, although it may be impossible to see because of hormonal involution during menses. Once the diagnosis is considered, catamenial pneumothorax is not difficult to manage in that most patients do not have a recurrence when ovulation is suppressed.

Complications

Tension Pneumothorax

Tension pneumothorax occurs when air in the pleural space exceeds atmospheric pressure. The radiographic appearance includes mediastinal shift to the contralateral side, diaphragmatic depression, and expansion of the ribs. The lung does not necessarily collapse completely if it is involved with a disease process such as ARDS.

MINI CLINI

Subcutaneous Emphysema

PROBLEM: A patient with ARDS experiences subcutaneous emphysema. How does the clinician determine where the air leak is occurring? Is a pneumothorax always present?

SOLUTION: Subcutaneous emphysema occurs when air enters the soft tissues. Although physical examination reveals subcutaneous bubbles, the patient's family needs to be reassured that the condition is rarely, if ever, physiologically significant. What is important to recognize, however, is that alveolar disruption has occurred, most commonly as the result of barotrauma.

Barotrauma disrupts alveoli and allows air to enter the interstitium of the lung. Rupture of the visceral pleura allows air to produce a pneumothorax, or the air can travel along the low-resistance tissue planes of the bronchovascular bundles and through the hilum of the lung to enter the mediastinum. From the mediastinum, air has easy access to the retroperitoneal space, including the scrotum and the neck. The presence of subcutaneous air does not necessarily mean that pneumothorax has occurred, although the risk factors for its development are present.

Air under pressure in the pleural space can enter the subcutaneous tissues through the intercostal incision made for chest tube placement. Subcutaneous air often is seen on a chest radiograph after chest tube placement, but the air rarely spreads unless the chest tube is occluded.

In the absence of pneumothorax, there is no way to determine which lung is causing subcutaneous emphysema. For any deterioration in gas exchange, radiographs should be repeated. Because air in the mediastinum can displace the mediastinal parietal pleura, it can be difficult to tell without chest CT whether a small pneumothorax is present. Because patients often are too unstable to be moved, a chest tube sometimes is placed because the potential benefits are greater than the risks.

Not all patients with radiographic tension have the physiologic changes commonly associated with tension pneumothorax. However, almost all pneumothoraces that occur during mechanical ventilation enlarge if not drained.

As pressure in the thorax increases and mediastinal shift places torsion on the inferior vena cava, venous return to the right side of the heart decreases. Cardiac output decreases, and hypotension with tachycardia results. Hypoxemia occurs as the lung continues to compress because of intrapulmonary shunting through the collapsed lung.

The respiratory therapist can make the diagnosis of tension pneumothorax. Treatment is emergency decompression of the chest. This procedure usually is done with an 18-gauge intravenous (e.g., Jelco, Smiths Medical, Dublin, OH) catheter inserted just over the second rib on the anterior aspect of the chest in the midclavicular line. Catheter placement should elicit a rush of air through the catheter, and this sign confirms the diagnosis. The blood pressure should recover rapidly, although resolution of hypoxemia depends on complete lung reexpansion and can be delayed. The soft intravenous catheter can be left in place while a more conventional chest tube is inserted.

RULE OF THUMB

Tension pneumothorax is a clinical diagnosis made at the bedside in more than 50% of cases. The clinical signs are diminished breath sounds, hyperresonance to percussion, tachycardia, and hypotension.

In one case series of 74 patients with tension pneumothorax, a clinical diagnosis was made for 45 patients; the associated mortality rate was 7%. In the other cases, the diagnosis was delayed from the onset of clinical signs by 30 minutes to 8 hours, resulting in a 31% mortality rate.[26]

Respiratory therapists are in the perfect position to make a timely diagnosis because ventilator alarms give early warnings.

Reexpansion Pulmonary Edema

Reexpansion pulmonary edema occurs in a lung that has been rapidly reinflated from low lung volumes, particularly when the pneumothorax has been long-standing or when the pressure gradient across the lung has become high, as might occur when there is endobronchial obstruction from cancer, mucus, or blood.

For many years, it was believed that alveolar edema occurs because intraalveolar pressure becomes negative and pulls fluid from the vasculature. However, the lung fluid has high protein content, a finding that suggests blood vessels have been injured as well.

One of the proposed mechanisms of vascular injury is a phenomenon of reperfusion injury caused by reactive oxygen (O_2) species. Support for this hypothesis has come from experimental studies that have shown administration of antioxidants before reexpansion decreases the amount of reexpansion pulmonary edema.

Regardless of the cause, lung reexpansion in nonemergency situations should proceed slowly and transpulmonary pressure should not become excessive. Most physicians who insert a chest tube for a large pneumothorax first place it to water seal without suction. If the lung is not completely inflated on the subsequent chest radiograph, the chest tube is placed to suction. Reexpansion pulmonary edema also occurs after drainage of pleural effusions. As a rule, thoracentesis should be limited to approximately 1000 ml, unless pleural pressures are monitored and not allowed to fall below −20 cm H_2O.

Diagnosis

The diagnosis of pneumothorax is established with chest radiography or ultrasound. The diagnosis requires a high-quality film to visualize a visceral pleural line. In the ICU, as many as 30% of cases of pneumothorax may be missed on a chest radiograph in retrospect. Impediments to diagnosis include a low-quality radiograph or using a computer monitor, supine position of the patient, concomitant presence of mediastinal air,

and subpulmonic or mediastinal position of the pneumothorax. Diagnosis is enhanced with additional upright radiographs or decubitus views.

The size of a pneumothorax is difficult to assess with a chest radiograph because a two-dimensional picture is being taken of a three-dimensional thorax. Size can be estimated with volume equations and can be confirmed with CT if needed.

RULE OF THUMB

The size of a pneumothorax on a chest radiograph can be estimated with the knowledge that the volume of the lung and thorax is proportional to the cube of their diameters.

For example, on a chest radiograph, the chest measures 8 cm from the spine to the lateral chest wall. A pneumothorax is measured 2 cm from the chest wall.

$$\text{Volume of the lung} = (6\text{ cm})^3 \approx 216\text{ cm}^3$$
$$\text{Volume of the hemithorax} = (8\text{ cm})^3 = 512\text{ cm}^3$$
$$\text{Lung size} = 216/512 = 42\%$$
$$\text{Pneumothorax size} \approx 58\%$$

The equation shows the large volume of lung that a pneumothorax can displace despite a "small" distance from the lung to the chest wall. Use of the equation is not as accurate as chest CT because many pneumothoraces collapse asymmetrically.

The diagnosis of pneumothorax by ultrasound occurs when the normal finding of lung sliding is lost. Ultrasound is not capable of judging the size of the pneumothorax because air in the pleural space does not transmit sound waves and the lung is not seen.

Therapy

Oxygen

O_2 should be administered to all patients who have a pneumothorax. Most of the air in a pneumothorax is nitrogen (N) because O_2 is readily absorbed. If an air leak is continuing, supplemental O_2 rather than N leaks into the pleural space. After an air leak has been stopped, administering O_2 decreases the blood and tissue partial pressure of N surrounding the pleural space. Pneumothorax resolution is normally 1.25% of the air per day. O_2 speeds recovery by increasing the gradient of N from the pleural space to the pleural tissues.

Observation

A 2001 consensus conference recommended observing patients in stable condition with primary spontaneous pneumothorax and also some patients with small secondary spontaneous pneumothorax before recurrence prevention is administered.[27] A small iatrogenic pneumothorax also should be managed with observation. Primary spontaneous pneumothorax often is observed for 4 hours in the emergency department (ED) before discharge to home follow-up care as long as the pneumothorax is not found to enlarge on serial chest radiographs. Discharged patients should have ready access to emergency care facilities and should be advised to return if they experience any worsened dyspnea or pain.

Patients with secondary spontaneous pneumothorax should be admitted to the hospital. During observation, it is important to record the respiratory rate and any signs of deteriorating respiratory function. A decrease in the patient's O_2 saturation can be an early warning of pneumothorax enlargement. Any deterioration indicates that the pneumothorax must be drained.

Simple Aspiration

Simple aspiration can be used in the ED when pneumothorax is first detected. A small catheter is placed into the pleural space, and air is sequentially evacuated with a three-way stopcock until no more air can be removed. If more than 4 L of air is aspirated and no resistance to further aspiration is felt, a chest tube is needed for continuing pleural air leak.

The goal of aspiration is to reexpand the lung. Many patients have a pneumothorax from air leak that subsequently heals between the time of onset and the time treatment is sought in the ED. Patients with primary spontaneous pneumothorax who undergo simple aspiration for lung reexpansion and who have a stable chest radiograph 4 hours after aspiration can go home without hospital admission.

Chest Tubes

Chest thoracostomy tubes (chest tubes) come in a variety of sizes, from 7F to 40F, and can be connected to a variety of one-way devices (e.g., Heimlich valves) that prevent entry of air into the pleural space from the outside environment. Regardless of chest tube size and the presence of a Heimlich valve or water seal, the effectiveness of chest tube placement for pneumothorax resolution depends more on lung surface healing than on the device used.

Small Bore. One simple device is a small-bore 7F catheter with a one-way valve apparatus (Heimlich valve) that prevents air movement back into the chest. Small-bore catheters can be placed with a small skin incision followed by either a guidewire and dilator technique or a trocar to get through the parietal pleura.

All chest tubes used to drain pneumothorax should be directed to the apex of the lung. Small-bore catheters can be placed in the second intercostal space anteriorly in the midclavicular line or laterally in the chest from the fifth through the seventh intercostal space.

It is difficult to determine whether a Heimlich valve has an ongoing leak unless it is placed to seal under water. This procedure can be done in the ED by placing the Heimlich valve into a cup of water or by placing it in line with a water-seal chamber to see whether an air leak is continuing after lung expansion.

Large Bore. Large-bore chest tubes usually are connected to a commercial equivalent of a three-bottle system to collect any pleural fluid present, determine whether an air leak is ongoing, and measure intrapleural pressure (Figure 27-6). Inserting large-bore catheters is done with local anesthetic and blunt dissection of soft tissue down to the parietal pleura.

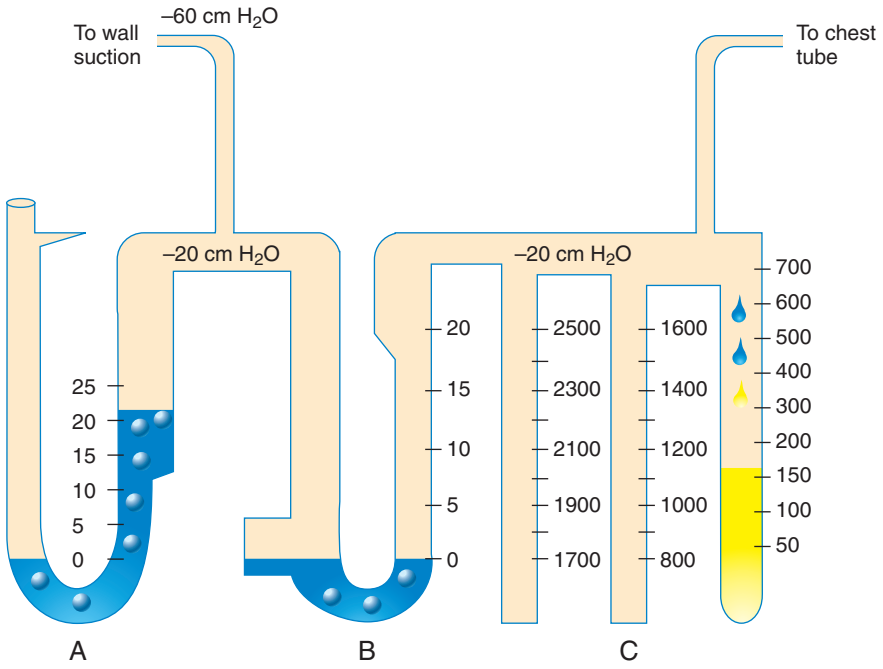

FIGURE 27-6 The Pleur-evac chest tube collection system collects fluid in compartment *C* so that it will not spill into the water-seal compartment *(B).* A patent chest tube should cause respiratory variation to be seen on the scale adjacent to compartment *B,* which measures intrapleural pressure. Compartment *B* also is the place to see bubbles if an air leak is present. The water level in compartment *A* controls intrapleural pressure and should be adjusted daily.

Dissection should be wide enough to allow insertion of a finger into the pleural space to ensure that no adhesions are holding the lung close to the insertion site and to allow unobstructed entrance of the tube into the pleural space, where it can be directed to the position of choice.

Chest tubes are secured with sutures. The insertion distance should be recorded and be checked on subsequent days to ensure that the chest tube does not migrate outward. Should the most proximal hole in the tube emerge from the skin, air will enter the tube and it will appear as if the lung is persistently leaking.

Another problem of apparent chest tube leak can occur when the insertion wound is large enough to allow air entry into the pleural space. This usually is accompanied by a sucking sound at the entrance, which can be occluded with petroleum gauze.

A chest radiograph is routinely obtained, although unless a lateral radiograph also is obtained, confirming the precise placement of the tube is often difficult. In addition, many chest tubes end up in the major fissure, where their function may be suboptimal.

Chest tube removal remains a highly variable practice. Removal of a chest tube as soon as an air leak visually ceases is associated with a 25% rate of recurrence of pneumothorax. The recurrence rate is near zero when chest tubes are removed 48 hours after the air leak no longer is seen in the water-seal chamber.[28] A common practice of clamping the chest tube, with chest radiographs before and after a 4-hour observation period, can be accompanied by the return of pneumothorax. If symptoms develop during chest tube clamping, the clamp should be removed immediately and the presence of air leak assessed.

Bronchopleural Fistula

Two terms are used for continuing air leaks from the lung through a chest tube. A **bronchopleural fistula** (BPF) is a large air leak that classically was described after surgery in which the airway was cut. Because some surgeons insist that BPF be reserved for this situation, the term **alveolopleural fistula** has been recently used for large air leaks that come from the lung tissue and that do not heal rapidly. Many patients with persistent air leaks are receiving mechanical ventilation, and positive airway pressures contribute to perpetuating the pleural air.

Because persistent air leaks can leak large quantities of air, more than one chest tube may be used to approximate the lung to the chest wall. This maneuver results in tamponade of the site of the air leak and allows pleural healing to occur.

Therapy for BPF involves meticulous monitoring of tidal volume, airway pressures, and positive end-expiratory pressure (PEEP); avoidance of auto-PEEP; and consideration of bronchoscopic closure or thoracoscopic surgery.[29]

Pleurodesis

Patients who have had one pneumothorax are more likely than the general population to have a second. The recurrence rate is greater than 30% among patients with primary spontaneous pneumothorax and approximately 40% among patients with secondary spontaneous pneumothorax. These high recurrence rates indicate that preventing a recurrent pneumothorax should be a priority, particularly for patients in whom pneumothorax

may be life-threatening. Preventing recurrence involves production of adhesions between the parietal and the visceral pleurae in the involved area and is termed *pleurodesis*.

The most noninvasive approaches to pleurodesis involve chemical sclerosis of the pleural space through the chest tube once the pleural air leak has stopped. The two most common preparations used for pleurodesis currently in the United States include 500 mg of doxycycline or 5 g of talc mixed into a 50-ml syringe of sterile saline solution. The agent is injected through the chest tube into the pleural space. Then the chest tube is clamped for 2 hours before drainage is allowed.

More invasive methods have included thoracoscopy with pleural poudrage (blowing talc onto the pleural surface under direct visualization), pleural abrasion through a thoracoscope, and thoracotomy with pleurectomy (removing the pleural surface to ensure lung adhesion). Recent recommendations are for pleurodesis to occur after the first secondary spontaneous pneumothorax with thoracoscopic bullae stapling and talc poudrage.[27]

MINI CLINI

Alveolopleural Fistula

PROBLEM: Pneumothorax develops in a patient undergoing ventilation for pneumonia. A 20F chest tube is placed and the lung fails to reexpand, although a large amount of air is passing through the water-seal chamber. The patient's minute ventilation is 20 L/min to keep gas exchange stable. What is the problem?

SOLUTION: The problem is an alveolopleural fistula caused by a large hole in the pleura that is difficult to manage. The lung surface of patients with underlying emphysema can contain large bullae that do not heal readily once ruptured. Large pleural holes also can develop in patients with necrotizing pneumonia and those who have undergone surgery on the lung.

The Fanning equation tells us that humidified airflow through a chest tube is proportional to the chest tube radius to the fifth power. Therefore the chest tube radius is the most important determinant of maximal airflow. Airflow through large air leaks has been measured as high as 16 L/min, a volume impossible to remove through a chest tube smaller than 24F, regardless of the amount of pressure applied.

This patient should receive a second, larger chest tube. The seal of the chest tube at the skin surface should be inspected to ensure that no air is entering the body from the outside. The position of both chest tubes should be confirmed either by x-ray examination or by hand to ensure the tubes are in the pleural space. Once the lung is expanded, the minute ventilation should decrease because effective alveolar ventilation will be improved.

Flow through stopcocks and chest tube collection devices is governed by the same considerations as chest tube size. The manufacturer of the chest tube collection device in your hospital will have the resistance figures necessary to ensure that 16 L/min of airflow can be accommodated.

Because the diseases that produce pneumothorax often involve both lungs, patients may experience sequential events in opposite lungs. In this situation, median sternotomy with bilateral abrasion or pleurectomy can be performed, particularly for patients at considerable risk for developing a pneumothorax, such as divers and aviators.

MINI CLINI

Measuring a Pleural Air Leak

PROBLEM: Pneumothorax develops in a patient with ARDS, and a chest tube is placed to reexpand the lung. Before the pneumothorax developed, the patient was ventilated easily at a rate of 16 breaths/min, which delivered a tidal volume (V_T) of 500 ml, and was exhaling 450 ml (a small difference caused by endotracheal cuff leak and tubing compliance). Since the pneumothorax developed, the patient needs a rate of 30 breaths at the same V_T to keep the $PaCO_2$ level the same. Exhaled V_T is 300 ml. What is the approximate size of this patient's air leak? What ventilation options are appropriate?

SOLUTION: Although research laboratories can measure airflow through a chest tube precisely with a pneumotachometer, clinical care can be provided by estimating the pleural air leak.

The following simple calculations suggest that the excess difference in returned V_T (450 to 300 ml or 150 ml) is due to air passing through the BPF:

30 breaths/min (150 ml differential = 4.5 L of pleural ventilation)

One other problem is that large amounts of carbon dioxide (CO_2) (up to 20%) may be removed through the chest tube.[30] Removal of CO_2 is beneficial because it allows lower V_T and respiratory rates for any given PCO_2. However, as the BPF closes, CO_2 will no longer be eliminated through the chest tube but only through the endotracheal tube, necessitating higher minute ventilation to maintain CO_2 clearance. This need for higher minute ventilation might falsely suggest that ARDS is worsening, when in reality the BPF is closing.

Nevertheless, when the air leak is measured with every ventilatory change, the mode of ventilation that minimizes air leak is the one most likely to allow pleural healing. Breath-by-breath analysis shows the difference between delivered V_T and exhaled V_T and approximates the volume of the pleural leak.

PEEP can be a major cause of large air leaks and should be turned off unless necessary for maintaining PO_2. Because there is no such thing as a true plateau pressure when air is exiting a BPF, V_T should be adjusted to produce the lowest peak airway pressure that can sustain ventilation and oxygenation. Position the patient so that the lung with the air leak is down (i.e., in the bed).[31]

Auto-PEEP can be impossible to measure if the fistula is large and decompressing the airways. Therefore, long expiratory times are preferred. Trials of pressure-controlled and high-frequency jet ventilation are appropriate. In a practical sense, these adjustments are the same ones made to prevent barotrauma in the first place and are limited by the severity of lung injury, which requires more support than would optimally close the air leak.

MINI CLINI

Management of a Bronchopleural Fistula

PROBLEM: A 40-year-old trauma patient with ARDS cannot be ventilated because of a large (16 L/min) BPF located entirely in the left lung. If surgery is not possible, what ventilatory options would be appropriate?

SOLUTION: Two ventilatory interventions have been attempted for large BPFs. The first is placement of a double-lumen endotracheal tube, which can carry most ventilation and PEEP on the right lung while underventilating the lung with the fistula to aid in its closure.[32] Long-term double-lumen ventilation is difficult because of tenuous tube position, the need for continuous paralysis, difficulty with secretion clearance, and high airway resistance through the small endotracheal tube lumens.

The second intervention is applying positive pressure to the chest tube. This back pressure increases resistance across the BPF and allows the remainder of the lung to better ventilate. One simple way to add chest tube resistance is to connect a PEEP valve to the expiratory port of the water-seal chamber.[33] PEEP usually is placed at the same level as the ventilator PEEP. Inspiratory pressures exceed PEEP, and air flows through the chest tube. However, as expiratory pressures equilibrate, PEEP can be held within the lung, allowing the beneficial effects on oxygenation.

Pressurizing the chest tube entails synchronous closure of the chest tube during inspiration[34] and requires specialized equipment that must be set up under controlled conditions. When used in combination with an in-line PEEP valve, BPF flow can be slowed during both inspiration and expiration.

These techniques usually increase the volume of intrapleural air. The net effect on oxygenation requires careful bedside observation because hypoxemia can worsen with any degree of lung collapse. Tension pneumothorax can occur so the patient must be monitored closely.

ROLE OF THE RESPIRATORY THERAPIST IN PLEURAL DISEASES

The respiratory therapist (RT) may play an important role in both the diagnosis and management of pleural disease. Diagnostically, the therapist's careful palpation and auscultation of the chest may show the dullness and decreased breath sounds that may prompt suspicion of a pleural effusion and lead the physician to order the imaging studies to confirm the presence of a pleural effusion. The RT who is managing the ventilator is often in the earliest position to appreciate a pneumothorax because the patient's ventilatory function would change when a pneumothorax develops. Furthermore, the RT may be called on to assist in performing a thoracentesis or placing a chest tube. Therapeutically, the RT may be called on to assist in setting up the fluid collection chamber after the chest tube is placed or in performing a talc pleurodesis. This broad spectrum of potential roles for the RT makes knowledge of the diagnosis and management of pleural disease essential for the capable RT.

SUMMARY CHECKLIST

- Pleural effusions form when excess pleural fluid is produced by the lung or chest wall in sufficient quantities to overcome the resorptive capacity of the pleural lymphatic vessels.
- Pleural fluid analysis is the key to understanding the specific cause of any pleural effusion.
- Transudates have a pleural fluid total protein level less than 0.5 and an LDH level less than 0.6 of the respective serum values. Common causes of a transudative effusion include CHF, nephrosis, and cirrhosis.
- Pleural fluid drainage returns approximately one-third of the lung volume as measured by FVC. The other two-thirds of fluid drainage allow the diaphragm to rise and the chest wall to normalize.
- Pneumothorax size is underestimated with a one-dimensional view of the chest. Measurement accuracy requires a three-dimensional perspective.
- The risk factors for pneumothorax and pneumomediastinum are the same. Air ruptures a pleural membrane in pneumothorax, and air passes through the lung hilum in pneumomediastinum.
- O_2 therapy speeds resolution of all pneumothoraces by improving N absorption.
- Chest tube flow depends on tube size, stopcock size, and collection system resistance.
- Breath-by-breath measurement of an air leak can be approximated by the difference between inspired and expired volumes (in the absence of endotracheal cuff leaks).
- The mode of ventilation that produces the least fistula airflow is the most likely to produce healing.
- Methods to decrease BPF airflow include lowering *tidal volume,* lowering respiratory rate, lowering PEEP, and avoiding auto-PEEP. In more severe cases, positioning the affected lung down, double-lumen tube ventilation, adding PEEP valves to the chest tube, inspiratory chest tube occlusion, or thoracic surgery should be considered.

CHAPTER 28

Pulmonary Vascular Disease

ADRIANO R. TONELLI AND RAED A. DWEIK

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- State how many patients develop venous thromboembolism each year.
- Describe how and where thromboemboli originate.
- Describe how pulmonary emboli alter lung and cardiac function.
- Identify the clinical features and electrocardiographic, chest radiograph, and arterial blood gas findings associated with pulmonary embolism.
- Describe how pulmonary embolism is diagnosed and managed.
- Describe the hemodynamic findings associated with pulmonary hypertension.
- Describe the possible mechanisms believed to be responsible for pulmonary arterial hypertension (PAH).
- State who is at risk for the development of PAH.
- Identify the clinical features associated with PAH.
- Describe the treatment used to care for patients with PAH.
- Describe the pathogenesis and management of PH associated with chronic obstructive pulmonary disease.

CHAPTER OUTLINE

KEY TERMS

deep venous thrombosis
pulmonary arterial hypertension
pulmonary embolism
pulmonary hypertension
venous thromboembolism

The vessels of the lung can be affected by many conditions, including clots and narrowing of the pulmonary arteries, conditions referred as **pulmonary embolism** (PE) and **pulmonary hypertension** (PH). PE occurs when a fragment of the thrombus in the venous system travels to the lung and pulmonary circulation. The thrombus usually originates in the deep veins of the lower extremities and therefore is called **deep venous thrombosis** (DVT). DVT and PE are grouped in the category named *venous thromboembolism* (VTE). *Pulmonary hypertension* is a term that defines an increase in the pressure in the pulmonary arteries that could result from a large number of conditions that affect the lung vessels, lung parenchyma, and/or the heart.

This chapter reviews disorders associated with the pulmonary vasculature. It predominantly focuses on venous thromboembolic disease and **pulmonary arterial hypertension** (PAH). PAH is a particular subgroup of patients with PH who have progressive narrowing of the pulmonary arteries that, if left untreated, leads to right heart failure (cor pulmonale) and death.[1]

VENOUS THROMBOEMBOLIC DISEASE

Venous thromboembolism (VTE) is a major national health problem with an estimated prevalence of 117 cases per 100,000 persons (i.e., DVT at 48 cases per 100,000 and PE at 69 cases per 100,000) and an incidence of 200,000 to 300,000 new cases per year in the United States.[2] VTE is treatable but requires prompt diagnosis and treatment to avert serious consequences, because one-third of deaths from PE occur within 1 hour of the onset of symptoms. In more than 70% of patients who die of PE, the diagnosis is not suspected.[3] In fact, the frequency of recognizable emboli in routine autopsies of adult patients varies from 1.5% to almost 30%.[4-6] In a population-based study of PE as a cause of death in New Mexico, only 34% of 812 documented cases of PE were diagnosed before death.[5] Similarly, another study[7] showed that only 28% of cases of massive or submassive PE were diagnosed before death, a finding that emphasizes the high rate of underrecognition of this disease.

Patients with undiagnosed PE have a higher mortality rate (approximately 30%[8]) compared to those in whom the condition was recognized and treated (mortality rate <8% with generally favorable long-term outcome).[9] A high index of suspicion to detect the disease is essential, particularly in patients at risk for VTE, such as those with multiple injuries, immobilization, bed rest, or intravascular catheters and the elderly (Table 28-1). Because clinical findings of VTE are frequently misleading,[10] objective tests are needed to confirm or exclude the diagnosis.

Pathogenesis

PE is a frequent complication of DVT[11]; however, the actual source of PE is found in only half of patients[7]. PE usually arises from detached portions of venous thrombi that form in deep veins of the lower extremities or pelvis (86%). A small percentage of PE arises from the right-sided heart cavities (3.15%) or from the superior vena cava (3%).[7]

Venous thrombosis can be due to heritable and/or acquired conditions, and in more than 80%, a risk factor can be identified. Conditions that favor thrombus formation include blood *stasis,* the presence of hypercoagulable states, and vessel wall abnormalities (factors known as the *Virchow triad*). Causes of blood stagnation include local pressure, venous obstruction, immobilization, congestive heart failure, shock and dehydration, varicose veins, and enlargement of the right heart chambers. Several conditions increase the intravascular coagulability of the blood and predispose to VTE disease[12] (Box 28-1). The most frequent causes of an inherited hypercoagulable state are the factor V Leiden mutation and prothrombin gene mutation, which together account for 50% to 60 % of cases.[13] Meanwhile, the major acquired conditions associated with an hypercoagulable state are recent major surgery, trauma, immobilization, antiphospholipid antibodies, malignancy, myeloproliferative disorders, pregnancy, and use of oral contraceptives.[14] Vessel wall abnormalities are found most often in patients who have sustained trauma or have undergone major surgery.

In general, more than one risk factor is responsible for VTE.[15] In the postoperative period, diminished blood flow favors the deposition of platelets and fibrin in the venous valve cups. Associated trauma and toxins can worsen endothelial damage and promote the release of mediators that encourage further adhesion, aggregation, and degranulation of platelets, which results in activation of the coagulation cascade and clot production.

TABLE 28-1

Frequency of Venous Thrombosis in Various Hospitalized Patient Groups

Group	Frequency (%)
Orthopedic (e.g., fractured hip)	54-67
Urologic (e.g., prostatectomy)	25
Surgical patients older than 40 yr	28
Gynecologic surgery	18
Cardiovascular surgery (e.g., acute myocardial infarction)	39
Obstetrics	3

Box 28-1 Conditions Predisposing to Venous Thrombosis and Pulmonary Thromboembolism

- Advanced age
- Postoperative status
- Previous venous thrombosis
- Trauma
- Oral contraceptive use
- Pregnancy
- Prolonged bed rest
- Long periods of travel
- Diagnosis of cancer
- Obesity
- Cerebrovascular accidents
- Thrombocytosis
- Erythrocytosis
- Hyperhomocysteinemia
- Mutation in gene coding for factor V (factor V Leiden)
- Mutation of prothrombin gene
- Antiphospholipid antibody
- Antithrombin deficiency
- Proteins C and S deficiency
- Abnormalities of fibrinogen
- Deficiency of plasminogen
- Sickle cell anemia
- Myeloproliferative disorder
- Paroxysmal nocturnal hemoglobinuria
- Heparin-induced thrombocytopenia

Modified from Arroliga AC, Matthay MA, Matthay RA: Pulmonary thromboembolism and other pulmonary vascular diseases. In George RB, editor: Chest medicine: essentials of pulmonary and critical care medicine, ed 3, Baltimore, 1995, Williams & Wilkins.

Pathology

PE is more frequently observed in the lower lobes and more commonly in the right rather than in the left lung, a phenomenon related to the pulmonary flow distribution that tends to favor the right side and the lower lobes.[4] Embolism to the pulmonary arteries produces pulmonary hemorrhage in the poorly perfused or infarcted lung in fewer than 10% of cases. Infarction secondary to thromboembolism is less common in the lung than in other tissues because the lung has two blood supplies, namely the pulmonary arterial and the bronchial circulations. At a capillary level, extensive connections exist between the pulmonary and bronchial circulations that prevent serious damage to lung tissue that is deprived of its pulmonary artery supply.[4] Cardiovascular diseases may affect bronchial circulation, which may lead to lung tissue necrosis when emboli occur. Pulmonary infarction is associated with thromboembolic obstruction of a medium-sized pulmonary artery and generally occurs at the lung bases, where it usually manifests as a wedge-shaped opacity on chest images. Microscopic examination of the lung in pulmonary infarction shows necrosis of alveolar walls, alveoli filled with red blood cells, and a mild inflammatory response in the periphery.[4]

RULE OF THUMB

PE is a complication of venous thrombosis. Patients with clots in the proximal venous system of the lower extremities and in the upper extremities are at high risk for developing PE.

Pathophysiology

The sudden obstruction of a pulmonary arterial branch causes a decrease or total cessation of blood flow to the distal area of the lung. This interruption of blood flow can cause respiratory and hemodynamic alterations.[16] The obstruction of the pulmonary artery by a clot increases the alveolar dead space (in which areas of the lung parenchyma are ventilated but not perfused), causes bronchoconstriction, and decreases the production of alveolar surfactant. As a compensatory mechanism, the body increases the total ventilation ($\dot{V}$), which in turn contributes to the sensation of dyspnea that accompanies PE and results in hypocapnia. Further ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatching may be caused by bronchoconstriction from hypocapnia, regional hypoxia, and the production of serotonin and histamine.[17]

Not all patients with PE have significant arterial hypoxemia, but the presence of a widened alveolar-arterial oxygen tension gradient and reduced arterial O_2 tension (PaO_2) are common.[18] Hypoxemia develops because of $\dot{V}/\dot{Q}$ mismatch, intrapulmonary shunt, and in some cases shock. Shock is caused by a large obstruction of the pulmonary vasculature or by numerous small emboli in the presence of cardiopulmonary disease. In this case, cardiac output decreases, peripheral O_2 extraction increases and the O_2 saturation of the venous blood markedly falls. In patients with elevated right heart pressures, an intracardiac right-to-left shunt may develop through a patent foramen ovale (present in one-third of the population).[16,17] Moreover, the depletion of pulmonary surfactant as a result of embolic occlusion can lead to atelectasis and intrapulmonary shunt, which also cause hypoxemia.[16]

The main consequence of PE is the increased resistance to blood flow caused by obstruction of the pulmonary arterial bed. The hemodynamic impact is determined by the extent of the pulmonary circulation involved (cross-sectional area), the underlying cardiopulmonary reserve, and the neurohumoral response to the embolism. PH occurs when approximately 50% or more of the pulmonary vascular bed has been occluded[16,17] and is made worse by pulmonary vasoconstriction resulting from hypoxemia and the release of vasoactive mediators such as serotonin and thromboxane A_2.[19,20] When PH occurs, the right ventricle must work harder to maintain the same flow given the higher pressure. This added strain results in dilation and dysfunction of the right ventricle. When the mean pulmonary arterial pressure increases to greater than 40 mm Hg during an acute first PE, the right ventricle fails and hemodynamic collapse and death occur.[21] Therefore a massive PE should be suspected any time there is unexplained hypotension accompanied by an elevated central venous pressure (jugular vein distention).[22] Death from massive PE is the result of cardiovascular collapse rather than of respiratory failure. Even massive emboli are likely to resolve within weeks, particularly in young individuals. Although the usual course of PE is to resolve rapidly (because the body dissolves the embolism with endogenous fibrinolytic agents), permanent residual emboli do occur.[23] Overall, fewer than 10% of patients have lung perfusion defects after 6 weeks and approximately 4% of patients with acute PE may develop long-standing PH.

Clinical Features

A high index of suspicion for VTE is crucial to make the diagnosis. Unfortunately, no specific signs or symptoms indicate the presence of VTE and a significant proportion of patients are asymptomatic (32%).[3,24] The physical findings of DVT in the lower extremities include erythema and warm skin in one-third of patients and swelling and tenderness in three-fourths of patients. In addition to the lack of sensitivity, the physical examination is not specific for diagnosing DVT. For instance, patients who have swelling above and below the knee, fever, and a history of immobility and cancer, the likelihood of finding DVT on a venogram is only 42%.[25]

The most frequent symptoms in patients with PE are dyspnea, followed by pleuritic chest pain (sharp pain predominantly during inhalation) and cough (Table 28-2).[26] The onset of dyspnea is usually rapid, within seconds (46%) or minutes (26%) of the PE.[26] Hemoptysis occurs in 13% to 20% of patients. The combination of dyspnea of sudden onset, fainting, and acute chest pain should raise suspicion of PE. In one study, this combination of symptoms was present in 96% of patients with confirmed PE compared with 59% of patients in whom PE was suspected but not confirmed.[27] In some patients, dyspnea lasts

TABLE 28-2

Clinical Characteristics in Patients With Pulmonary Embolism and No Cardiopulmonary Disease

Symptoms	Frequency (%)
Dyspnea at rest or with exercise	73
Pleuritic pain	44

Orthopnea	28
Wheezing	21
Signs	**Frequency (%)**
Tachypnea	54
Tachycardia	24
Rales	18
Decrease breath sounds	17
Loud P2	15
Jugular venous distension	14

From Stein PD, Beemath A, Matta F, et al. Clinical characteristics of patients with acute pulmonary embolism: data from PIOPED II. Am J Med 120:871–879, 2007.

only a few minutes, and this episode may be wrongly dismissed as being trivial.[16,18,27,28] There are no characteristic physical findings of PE. The most frequent physical findings include tachypnea, rales on chest examination, and tachycardia. These signs, like dyspnea, may be short-lived. Other common physical findings include an accentuated pulmonary component of the second heart sound (loud P_2) consistent with PH. Fever may be present in as many as 54% of patients.[18,27,28] Similar to what occurs in the diagnosis of DVT, fewer than 35% of patients in whom PE is clinically suspected actually have it.[3]

Because the clinical features lack specificity and treatment is anticoagulation (which carries risk for bleeding over time), confirming or excluding the diagnosis with appropriate testing is necessary, rather than committing the patients to long-term anticoagulation on the basis of clinical suspicion alone. At the same time, unless there is a contraindication (e.g., recent bleeding, head trauma, etc.), anticoagulation is begun when the diagnosis of PE is first suspected and continued until it is ruled out by tests. The rationale for this approach is based on the high mortality rate soon after the occurrence of PE.

Chest Radiograph

The chest radiograph cannot confirm or exclude the presence of PE but is helpful to rule out other potentially life-threatening conditions, such as pneumothorax or pneumonia, which can manifest in a similar way. In patients with dyspnea, a normal chest radiograph may be a clue to the presence of PE; however, the plain chest radiograph is abnormal in more than 80% of the patients who present with dyspnea.[29] Some of the abnormalities include enlargement of the right descending pulmonary artery (66%), elevation of the diaphragm (61%), cardiomegaly (55%), and a small pleural effusion (50%). Patchy radiographic opacities or round nodular lesions predominantly appearing next to the pleural surface are present in patients who have infarction or atelectasis. Other less common findings include the *Westermark sign,* in which there is pulmonary hyperlucency caused by a marked reduction in blood flow and the *Hampton hump,* a pleural-based opacity in the costophrenic angle that represents alveolar hemorrhage from a pulmonary infarction. These signs may be present in only 25% to 30% of patients with PE.[27,29,30]

Electrocardiogram

The electrocardiogram (ECG) is helpful to rule out other diagnoses, such as acute myocardial infarction and pericarditis. The ECG is frequently abnormal in patients with PE (87% of the time), but the ECG abnormalities are nonspecific in most cases (70% to 75%); tachycardia and ST-segment depression are most common.[27] Abnormalities such as depression of the ST segment and T-wave inversion in V_1 and V_2 may be present. An $S_1Q_3T_3$ pattern (S wave in lead D_I and Q wave with negative T wave in D_{III}) is associated with massive PE and is present in 19% of such patients.[25]

Arterial Blood Gases

Most patients with acute PE have hypoxemia and hypocapnia,[27] but many patients (15% to 25%) have a Pao_2 greater than 80 mm Hg.[18] Although a widened alveolar-arterial O_2 gradient is frequently present, a normal alveolar-arterial O_2 gradient may occur in approximately 20% of patients with angiographically documented PE.[18,27] Thus the ABGs can never establish the diagnosis of PE.

In intubated patients or those with chronic obstructive lung disease (COPD), a decrease in PaO_2 and an increase in $PaCO_2$ can accompany PE and should prompt suspicion. Massive PE with hypotension and respiratory collapse can result in hypercapnia and respiratory acidosis. Overall, the value of arterial blood gas (ABG) values in PE is to document hypoxemia, direct O_2 supplementation, or demonstrate hypercapnia in patients with limited cardiopulmonary reserve.

Diagnostic Modalities

The diagnosis of VTE disease relies on the diagnosis of DVT or PE. Importantly, the absence of one condition does not exclude the other.

By-Products of Thrombin and Plasmin

Clot formation is always associated with thrombin generation. Measurement of cross-linked fibrin split products (D-dimers) has been found sensitive for the diagnosis of acute VTE. D-dimer results have been particularly useful in the emergency department and outpatient area for the evaluation of patients with suspected DVT[31] and PE.[32] The D-dimer test has good sensitivity and negative predictive value but poor specificity and positive predictive value. The specificity of the test is only 39%, but a value less than the recommended cutoff for current quantitative enzyme-linked immunosorbent assay (ELISA) has been shown to rule out VTM in 98% of patients.[31-33] The negative predictive value of a negative D-dimer result with low pretest probability for DVT or PE is greater than 99%.[32,33]

Although there are several laboratory methods to measure D-dimer levels, tests using ELISAs are the most widely used and best-performing among the D-dimer assays regarding the sensitivity and negative likelihood ratio. For excluding PE or DVT, a negative result on quantitative rapid ELISA is as diagnostically useful as a normal lung scan or negative duplex ultrasonography finding. The D-dimer ELISA can be used to exclude PE in outpatients with a low to moderate suspicion without the need for further costly testing. In-patients, however, should undergo an imaging study as the initial test for PE because most will already have elevated D-dimer levels as a result of comorbid conditions.[32]

Testing for Lower-Extremity Deep Venous Thromboembolism

To evaluate the clinical pretest probability of DVT, the Wells score is frequently used. This score is calculated using the following clinical parameters: presence of cancer, immobilization, localized tenderness, swelling, edema, previous DVT, collateral superficial veins, and absence of an alternative diagnosis.[34] In cases in which there is a moderate to high pretest probability, several modalities could be used for diagnosing DVT, such as compression ultrasonography (most commonly used), impedance plethysmography (a noninvasive method that measures venous outflow by changes in impedance, which in turn estimates blood volume after rapid deflation of a cuff), and venography (involves the injection of contrast dye into a foot vein to allow venous visualization by x-rays). In patients with low pretest probability of DVT and a negative D-dimer, further testing may not be necessary.[31,35-37]

Compression ultrasonography has proved to be sensitive and specific for diagnosing symptomatic proximal DVT. This test is noninvasive, portable, and accurate and is the modality of choice for the diagnosing DVT. Compression ultrasonography combines B-mode scanning with a tightly focused pulse Doppler beam directed at the vessels of interest. DVT is diagnosed with the findings of venous noncompressibility, an echogenic filling defect, absence of Doppler flow, free-floating thrombus in the vein, and venous distention.[38] The most reliable sign of DVT is lack of compressibility of the vein, although a free-floating thrombus has the highest embolic potential (Figure 28-1). The sensitivity and specificity of compression ultrasound in symptomatic patients vary between 95% and 100% for detecting a proximal lower-extremity thrombus.[38,39]

Testing for Pulmonary Embolism

Noninvasive tests for the diagnosis of PE include the $\dot{V}/\dot{Q}$ scan and computed tomography angiography (CTA) scan of the chest. Either of these tests, depending on the resources available, may be the initial diagnostic examination if the presence of acute PE is clinically suspected.[40] Echocardiography can suggest the diagnosis (right ventricle dilation, dysfunction, or thrombus) and can provide prognostic information.[41] In certain cases when these noninvasive tests are nondiagnostic, pulmonary angiography may be needed to confirm or exclude the diagnosis of PE.

$\dot{V}/\dot{Q}$ scanning involves the inhalation of a radiolabeled gas (usually xenon-133 or technetium-99 m) and the intravenous injection of macroaggregated albumin tagged with a gamma-emitting radioisotope (^{99m}Tc-labeled macroaggregated albumin). The distribution of lung ventilation ($\dot{V}$) and lung perfusion ($\dot{Q}$) is studied, and areas of mismatch in which $\dot{Q}$ is less than $\dot{V}$ are sought. The presence of mismatches most often indicates embolic occlusion of the blood vessel, although other

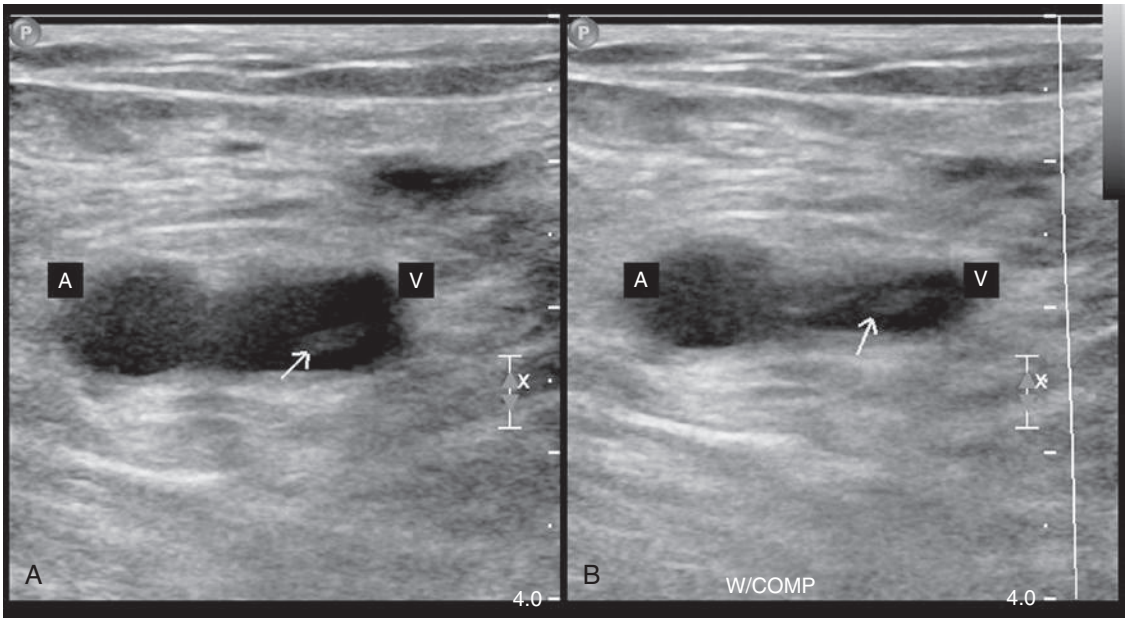

FIGURE 28-1 Deep vein thrombosis diagnosed by ultrasonography. **A,** An intraluminal thrombus is visible in the right common femoral vein *(arrow).* **B** Incomplete collapse of the femoral vein secondary to the presence of a clot. *A,* Femoral artey; *V,* femoral vein.

rare causes exist, such as extrinsic compression of the vessel by a mass, intraluminal obstruction by angiosarcoma, or obliteration of a vessel by vasculitis. The addition of a ventilation scan increases the specificity of the perfusion scan.[42] In general, with the presence of a parenchymal abnormality, the $\dot{V}$ defect coincides with the $\dot{Q}$ defect, and matched abnormalities are found. Normal results of a $\dot{V}/\dot{Q}$ scan exclude the presence of a clinically significant PE in the context of a low clinical probability of PE.[43] Abnormal $\dot{V}/\dot{Q}$ scan results can be classified as high probability, intermediate (or indeterminate) probability, and low probability for PE, according to the size of the defect and the degree of mismatch between the $\dot{V}$ and $\dot{Q}$.[42] Diagnostic accuracy is greatest when $\dot{V}/\dot{Q}$ scan results are combined with clinical probability[44] (Table 28-3). The presence of concomitant cardiopulmonary disease (e.g., chronic obstructive pulmonary disease), even if severe, does not diminish the diagnostic usefulness of $\dot{V}/\dot{Q}$ scans in the diagnosis of acute PE.[45-47]

Spiral (helical) CTA has been used extensively in the diagnostic evaluation of PE and has become the principal diagnostic imaging modality to evaluate suspected PE (Figure 28-2).[48,49] The reported sensitivity of CTA ranges from 53% to 100%, and the specificity ranges from 81% to 100%.[49] The variability is due to the experience of the radiologists and image quality.[50] Studies indicate that CTA scanning detects large PEs involving main and lobar emboli. However, this test is generally unable to detect smaller PEs. One potential advantage of helical CTA is its ability to identify alternative diagnoses in cases in which PE is not present (e.g., pneumonia, pleural disease, etc.). Multicenter trials suggest that helical CT scanning is safe to use for ruling out PE, at least in patients with a low or intermediate clinical probability of embolism. The Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) II trial evaluated the accuracy of multidetector CTA alone and combined with venous-phase imaging (CTA-CTV) for the diagnosis of acute PE. Excluding inconclusive studies (6%), the sensitivity of CTA was 83% and the specificity was 96%. The sensitivity of CTA-CTV for PE was 90%, and specificity was 95%. The predictive value of either CTA or CTA-CTV was high with a concordant clinical assessment, but additional testing was necessary when the clinical probability is inconsistent with the imaging results.[49,51] Several algorithms for diagnosing PE are available, but no approach has proved to be the best.[52-55] Figure 28-3 summarizes the diagnostic approach to pulmonary embolus using CTA.

For the patients who do not receive a definitive diagnosis on the basis of the results of noninvasive studies, *pulmonary angiography* is the test of choice. Pulmonary angiographic signs of acute PE include filling defects and cutoff of the pulmonary arteries. Other angiographic signs include absent, decreased, or delayed filling of pulmonary arteries; delayed venous emptying; pruning; and abnormal tapering. None of these findings is as specific as filling defects, particularly in the presence of other cardiopulmonary diseases. Table 28-4 presents the probability of finding PE with angiography on the basis of results of $\dot{V}/\dot{Q}$ scan and clinical probability.[56] A definite diagnosis can be established with noninvasive diagnostic tools in two-thirds of cases.[57]

Because of the history of surgery on the right hip, DVT and PE are the most likely diagnoses. The next examinations are duplex ultrasonography of the lower extremities followed by a $\dot{V}/\dot{Q}$ radionuclide study or a CTA scan of the chest. DVT should be sought in patients diagnosed with PE, to investigate the origin of the thrombus and assess prognosis, because individuals with PE and coexisting DVT are at increased risk for death.[58] The presence of a "normal" PaO_2 of 85 mm Hg in this patient

TABLE 28-3

Revised Prospective Investigation of Pulmonary Embolism Diagnosis Ventilation/Perfusion Scan Interpretation Criteria

High probability	Two or more large (>75% of a segment) segmental $\dot{Q}$ defects without corresponding $\dot{V}$ or abnormalities on chest radiograph
	One large segment $\dot{Q}$ defect and two or more moderate (25%-75% of a segment) segmental $\dot{Q}$ defects without corresponding $\dot{V}$ or abnormalities on chest radiograph
	Four or more moderate segmental $\dot{Q}$ defects without corresponding $\dot{V}$ or abnormalities on chest radiograph
Intermediate probability	One moderate or up to two large segmental $\dot{Q}$ defects without corresponding $\dot{V}$ defect or abnormalities on chest radiograph
	Corresponding $\dot{V}/\dot{Q}$ defects and parenchymal opacity in lower lung zone on chest radiograph
	Corresponding $\dot{V}/\dot{Q}$ defects and small pleural effusion
	Single moderate matched $\dot{V}/\dot{Q}$ defects with normal findings on chest radiograph
	Findings difficult to categorize as normal, low, or high probability
Low probability	Multiple matched $\dot{V}/\dot{Q}$ defects, regardless of size, with normal findings on chest radiograph
	Corresponding $\dot{V}/\dot{Q}$ defects and parenchymal opacity in upper or middle lung zone on chest radiograph
	Corresponding $\dot{V}/\dot{Q}$ defects and large pleural effusion
	Any $\dot{Q}$ defects with substantially larger abnormality on chest radiograph
	Defects surrounded by normally perfused lung (stripe sign)
	Single of multiple small (<25% of a segment) segmental $\dot{Q}$ defects with a normal chest radiograph
	Nonsegmental $\dot{Q}$ defects (cardiomegaly, aortic impression, enlarged hila)
Normal	No $\dot{Q}$ defects; $\dot{Q}$ outlines the shape of the lung on chest radiograph

MINI CLINI

Respiratory Distress After Hip Replacement

PROBLEM: You are asked to evaluate a 65-year-old man who has undergone right hip replacement. On the third day after surgery, the patient experienced dyspnea and pleuritic chest pain in the right hemithorax. On physical examination, his heart rate is 120 beats/min; respiratory rate, 25 breaths/min; and blood pressure, 120/85 mm Hg. The lungs are clear, and the heart examination does not show any gallops or murmurs. ABG measurements on room air show a pH of 7.49; $PaCO_2$, 30 mm Hg; and PO_2, 85 mm Hg. The chest radiograph is unremarkable. What is your differential diagnosis, and how should you treat this patient?

DISCUSSION: The differential diagnosis is extensive and should include an ischemic cardiac event such as myocardial infarction, as well as bacterial pneumonia. The type of chest pain is not typical of myocardial infarction. An ECG may be of value because in patients with myocardial infarction, elevation of the ST segments is prominent in the acute phase. Other laboratory data include elevation of the creatinine kinase and troponin levels, although these tests may become abnormal after several hours. The normal chest radiograph decreases the likelihood of the presence of pneumonia.

may be misleading. The wide alveolar-arterial gradient probably is caused by the presence of a pulmonary embolus. The patient should be anticoagulated.

Treatment

Prophylaxis

Prophylactic therapy reduces the risk for VTE in patients at risk. The frequency of proximal DVT varies from 2% to 4% among general surgical patients undergoing minor surgery to 40% to 80% among patients at the highest risk, such as those who have undergone hip or knee surgery.[59] Patients at moderate to high risk include those with acute spinal cord injury, myocardial infarction, ischemic stroke, or other medical conditions such as heart failure and pneumonia.[59] Patients admitted to medical intensive care units are another group at risk for DVT; indeed, DVT has been detected in 33% of these patients.[60] Unfortunately, compliance in the use of prophylaxis is variable.[59]

Pharmacologic choices for prophylaxis include low-dose subcutaneous heparin, low-molecular-weight heparin (LMWH; enoxaparin and dalteparin) and the factor Xa inhibitor (fondaparinux).[61-63] Mechanical measures to reduce venous stasis include early ambulation, wearing elastic stockings,

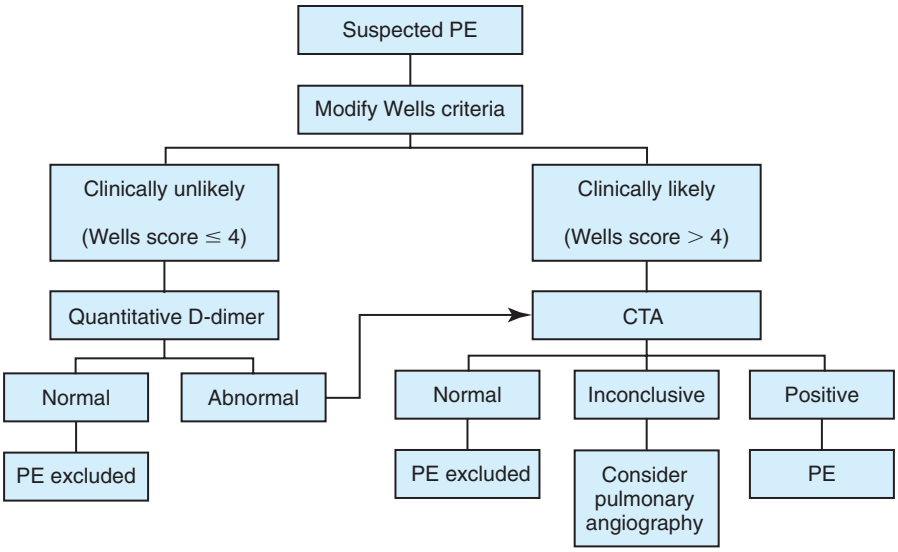

FIGURE 28-3 Strategy for diagnosis of pulmonary embolism using D-dimer and computed tomography angiography (CTA). Diagnosis is based on clinical suspicion (using the Wells modified criteria) and the results of CTA scan. The modified Wells criteria include the following: clinical symptoms of deep venous thrombosis (DVT) (3 points), other diagnoses less likely than pulmonary embolism (PE) (3 points), heart rate greater than 100 beats/min (1.5 points), immobilization 3 days or longer, surgery in the previous 4 weeks (1.5 points), previous DVT/PE (1.5 points), hemoptysis (1 point), or malignancy (1 point). (Modified from van Belle A, Buller HR, Huisman MV, et al. Effectiveness of managing suspected pulmonary embolism using an algorithm combining clinical probability, D-dimer testing, and computed tomography. JAMA 295:172–179, 2006.)

TABLE 28-5

Thromboembolism Risk and Recommended Thromboprophylaxis in Hospitalized Patients

Risk		DVT Risk Without Prophylaxis (%)	Suggested Option
Low	1. Minor surgery in mobile patient 2. Medical patients fully mobile	<10	1. No specific prophylaxis 2. Early and aggressive ambulation
Moderate	1. For general and abdominal-pelvic surgery 2. Medical patients, bed rest or sick 3. High bleeding risk	10-40	1. LMWH, unfractionated heparin, or fondaparinux 2. LMWH, unfractionated heparin or fondaparinux 3. Mechanical prophylaxis
High	1. Hip or knee arthroplasty, major trauma, hip fracture, and spinal cord injury 2. High bleeding risk	40-80	1. LMWH, fondaparinux, apixiban, dabigatran, rivaroxaban, unfractionated heparin, warfarin (Coumadin) (INR 2-3) for a minimum of 10-14 days 2. Mechanical prophylaxis

INR, International normalized ratio; *LMWH,* low molecular weight heparin. unfractionated.
NOTE: Mechanical prophylaxis includes graduated compression stockings or intermittent pneumatic compression. Recommendations suggest thromboprophylaxis in acutely ill hospitalized patients until they regain mobility.

pneumatic calf compression, and electrical stimulation of calf muscles. Mechanical methods are reserved for patients with contraindications to anticoagulant thromboprophylaxis.[64] Current prophylactic strategies for DVT and PE are summarized in Table 28-5. Most hospitalized patients who are immobile need prophylaxis for VTE.

RULE OF THUMB

Most hospitalized patients who are immobile need prophylaxis for VTE.

Management of Venous Thromboembolism: Anticoagulation

Management of Deep Venous Thrombosis. Unfractionated heparin is the time-honored drug treatment, but LMWH (e.g., enoxaparin, etc.) is widely used and has been endorsed in guidelines as first-line therapy.[65] Heparin has an immediate action and is relatively safe. Heparin is an indirect thrombin inhibitor that forms a complex with antithrombin, potentiating the cofactor potency to inactivate thrombin, factor Xa, and, to a lesser extent, factors XIIa, XIa, and IXa. Heparin does not lyse existing clots but prevents formation and propagation of new clots. Unfractionated heparin should is administered as a bolus

followed by a continuous infusion.[59] LMWH is administered subcutaneously, once or twice per day, and does not characteristically require blood test monitoring to ensure therapeutic benefit.[65] It is very important to achieve a therapeutic effect in the first 24 to 48 hours of starting anticoagulation therapy. The goal of unfractionated heparin therapy is to maintain an activated partial thromboplastin time greater than 1.5 times the control value.[66] The fastest way to achieve a therapeutic heparin effect is to follow an established normogram.[66-68] The complications of intravenous heparin administration include major bleeding (3.8%) and thrombocytopenia caused by immunoglobulin G antiheparin antibodies (2.5% to 3% of patients to whom heparin is given therapeutically, fewer than 0.5% of patients to whom it is given prophylactically). If thrombocytopenia or bleeding occurs, heparin should be discontinued promptly.

LMWH, once or twice per day given via the subcutaneous route, is the suggested therapy for proximal DVT if no contraindication exists.[69] This agent has been shown to be as effective and as safe as intravenous heparin therapy but less expensive. At the same time, in selected patients, LMWH can be administered at home in an efficacious and safe way that can potentially decrease the number of days of hospital admission for acute DVT.[66] The patients chosen for outpatient therapy should be in stable condition, should have a low risk for bleeding, and should not have renal insufficiency.

Several oral anticoagulants are approved by the U.S. Food and Drug Administration (FDA) for the treatment of VTE disease. These include vitamin K antagonists (warfarin) and the newer factor Xa (rivaroxaban,[70,71] apixaban,[72] and direct thrombin inhibitors (dabigatran[73]—unlabeled use). Warfarin should not be started before initiating heparin[69] because it also decreases production of proteins C and S, therefore causing a relative hypercoagulable state in the first 24 hours as a result of the depletion of these proteins. Factor Xa and direct thrombin inhibitors are fixed-dose oral treatments that do not require laboratory monitoring and reach their peak efficacy within 1 to 4 hours after ingestion, obviating the need for prolonged bridging. They have no readily available antidotes for bleeding events. These novel agents have similar efficacy as conventional anticoagulants for hemodynamically stable patients with VTE disease. Patients with the first episode of DVT generally need treatment with oral anticoagulants for at least 3 to 6 months.[66,74,75] Patients who need therapy for more than 6 months include those with idiopathic VTE, cancer, and/or recurrent DVTs.[66,76]

The role of thrombolytic therapy with streptokinase, urokinase, or tissue plasminogen activator is not well defined in the management of acute DVT. The administration of early thrombolytic therapy decreases the pain and the incidence of postthrombotic syndrome (characterized by persistent pain, swelling, skin discoloration, or venous ulceration), but the risks and benefits of this particular therapy are not well established.[66] A systematic review of the efficacy and the safety of the use of thrombolysis in the management of lower extremity DVT showed that this treatment increased the patency of the veins and reduced the incidence of postthrombotic syndrome at the expense of a small increase in the risk for bleeding.[77] Thrombolytic therapy may be indicated in patients with massive proximal DVT and high risk for limb gangrene.[69] Knowledge of the patient's values and preferences must be used to guide the best decision.[78]

Management of Pulmonary Embolism. The management of PE depends on the extent and status of the cardiopulmonary system. Therapy with heparin, whether unfractionated or low molecular weight, followed by warfarin (or newer anticoagulants) in a regimen similar to that for acute DVT is the treatment of choice. When the heparin effect is therapeutic within the first 24 hours, it will decrease the risk for recurrent PE, which is associated with higher mortality.[79] Patients with an acute PE need additional supportive measures. Supplemental O_2 should be administered to patients who have hypoxemia, and adequate analgesia should be prescribed for patients who have pain and anxiety. Resuscitation with fluids and vasopressor agents is necessary for patients who develop hypotension and shock. In the care of patients with severe hypoxemia, acute right heart failure,[80] or shock, thrombolytic therapy may be considered for lysis of the emboli. Persistent hypotension secondary to massive PE is the most commonly accepted indication for thrombolytic therapy; however, no major trial has conclusively demonstrated a mortality benefit of this intervention.[69,81,82]

Other options in the care of a patient with confirmed massive PE, in whom thrombolysis is either contraindicated or unsuccessful, include pulmonary embolectomy, catheter tip embolectomy (physical removal of the embolism), and catheter tip fragmentation. Because of associated risks, these techniques should be used in centers with appropriate experience.[40] For patients in whom anticoagulation is contraindicated (e.g., because of bleeding risk), placement of a filter into the inferior vena cava to prevent embolism of clot to the pulmonary arteries is a treatment option. Another reason for placing an inferior vena caval filter is that a recurrent embolism has occurred despite adequate anticoagulation or that the patient has experienced multiple past emboli and is considered not able to tolerate another PE. Filter placement reduces the risk for PE in the period immediately after insertion but is associated over the longer term with a higher incidence of recurrent DVT.

Prognosis

Factors associated with increased risk for death include right ventricular dysfunction,[41] right ventricular thrombus,[83] coexisting DVT,[58] higher serum brain natriuretic peptide (which is associated with right ventricular dysfunction)[84] and troponin levels (marker of myocardial injury),[85] low serum sodium (reflects neurohormonal activation),[86] and elevated lactic acid.[87] The prognostic model Simplified Pulmonary Embolism Severity Index (sPESI)[88] assigns a high risk for dying to those patients with any of the following factors: age older than 80, history of cancer, chronic cardiopulmonary disease, pulse 110/min or greater, systolic blood pressure less than 100 mm Hg, and arterial O_2 saturation less than 90%. Those with low risk (without risk factors) have a 30-day mortality of 1%; meanwhile, those

with high risk (at least one risk factor) have a 30-day mortality of 10.9%.[88]

If left untreated, PE has an overall mortality of 30%.[89] Early death is due to shock and/or a secondary embolic event. Long-term mortality is related to predisposing comorbidities and recurrent PE. Although the mortality from PE has decreased in recent years,[89] the death rate for the first episode of PE among hospitalized patients may be as high as 17.4% at 3 months.[90] Recurrent PE carries a much higher mortality rate, because only a quarter of patients will survive 3 months.[91]

PULMONARY HYPERTENSION

PH is defined by an elevation in mean pulmonary arterial pressure 25 mm Hg or greater at rest. PH is grouped in five categories, a classification that was updated in 2013 by the 5th World Symposium on Pulmonary Hypertension in Nice, France (Box 28-2).[92,93] The importance of the clinical system, besides allowing a better understanding of pathophysiology, is to give a framework for understanding important branch-points in the management and treatment of different conditions known to cause PH. The first category, PAH, is characterized by an elevation in pulmonary arterial pressure associated with high pulmonary vascular resistance (≥3 Wood units) and normal left ventricular filling pressures (pulmonary artery occlusion pressure ≤15 mm Hg).[94] PAH may be associated with several conditions, including collagen vascular disease, congenital heart disease, cirrhosis of the liver, human immunodeficiency virus (HIV) infection, and drugs and toxins (diet pills or anorexigens).[92,93] In patients in whom no underlying cause of PH can be identified, the disease is referred to as *idiopathic pulmonary arterial hypertension* (IPAH), previously known as *primary pulmonary hypertension* (PPH).[95-98]

PH also can develop as a consequence of PE, and this entity is known as *chronic thromboembolic PH*.[99] In addition, PH can be associated to heart or lung diseases or may result from a variety of other conditions grouped in PH with unclear or multifactorial mechanisms. PH resulting from lung diseases is further divided into several groups: PH associated with COPD, interstitial lung disease, other diseases with mixed obstructive and restrictive patterns, sleep breathing disorders, alveolar hypoventilation, chronic exposure to high altitude, and developmental abnormalities. A rare type of PH, pulmonary venoocclusive disease, is characterized by narrowing of the small pulmonary venules. Although challenging, recognizing pulmonary venoocclusive disease is important given that the response to PAH-specific treatment in this disease is limited and lung transplantation is frequently needed. These patients commonly develop pulmonary edema when treated with PH-specific therapies.

Box 28-2 Simplified Clinical Classification of Pulmonary Hypertension (Nice, 2013)

1. Pulmonary arterial hypertension
2. Pulmonary hypertension owing to left heart disease
3. Pulmonary hypertension owing to lung diseases and/or hypoxia
4. Chronic thromboembolic pulmonary hypertension
5. Pulmonary hypertension with unclear multifactorial mechanisms

Modified from Simonneau G, Gatzoulis MA, Adatia I, et al: Updated clinical classification of pulmonary hypertension. J Am Coll Cardiol 62(25 Suppl):D34–D41, 2013.

Pathogenesis

The initial event of PAH is probably an insult to the pulmonary endothelium (the cells that line the blood vessel) in patients with certain genetic predisposition.[100-102] This damage to the endothelium alters the balance between vasoconstrictive mediators (e.g., thromboxane and endothelin I) and vasodilators such as nitric oxide and prostacyclin, resulting in vasoconstriction. Vasoconstriction might not be the primary event, but it is an important component in the pathogenesis of PAH.[103-105] In addition to vasoconstriction, there is inflammation, thrombosis, cell proliferation, apoptosis and fibrosis, all of which can lead to pulmonary vascular remodeling and irreversible PAH.[106] Recent research suggests the presence of other potential pathways that contribute to PAH, including downregulation of potassium channels,[107] increased matrix metalloproteinases,[108] decreased vasoactive intestinal peptide,[109] disruption and progressive loss of endothelial caveolin-1 with enhanced expression in smooth muscle cells,[110] elevated serotonin,[111] and transforming growth factor-beta,[112] among others.[113] Potential new biomarkers and lines of therapies could result from these discoveries.[95-98,103-105,114]

Epidemiology and Clinical Findings

The true prevalence of PH is unknown. The prevalence of idiopathic and heritable PAH is estimated to be 5 to 15 cases per million adults.[115,116] Overall, PH affects all age groups as well as both genders. Idiopathic PAH is more common among women than among men, with a ratio of 3:1. Approximately 7% of all cases are heritable. Idiopathic PAH can occur at any age, although it is more common from ages 20 to 50 years.

On average, the diagnosis of PAH is delayed for 2 years after the onset of symptoms.[117] The condition frequently is misdiagnosed as asthma, anxiety, or depression because it is characterized by the onset of vague respiratory symptoms and hyperventilation. The most common initial symptom is dyspnea (60% of patients). Other common symptoms include chest pain (50% of patients), probably secondary to underperfusion of the right ventricle or stretching of the large pulmonary arteries, and syncope (passing out) (8% of patients) because of insufficient cardiac output, predominantly with activities. Less frequent symptoms include cough, hemoptysis, hoarseness, and Raynaud's phenomenon (blanching of the fingers on exposure to cold) in approximately 10% of patients.

Physical findings associated with PAH include a loud second heart sound and a right-sided third or fourth heart sound. Other common signs are a palpable right ventricular

heave and both pulmonary ejection and pulmonary tricuspid regurgitation murmurs. Signs of right ventricular failure are common. Cyanosis often is present as a result of low cardiac output or the presence of an intracardiac right-to-left shunt in patients with a patent foramen ovale or advanced stages of congenital heart diseases. Clubbing does not occur in PAH. The chest radiographic findings include enlargement of the main and hilar pulmonary arteries, "pruning" (or narrowing) of the peripheral arteries, enlargement of the right ventricle and atrium, and pleural effusion, although the chest radiograph may remain normal in 6% of patients.

Diagnosis

Before the diagnosis of PAH can be made, other underlying diseases associated with PAH must be excluded. Tests commonly ordered to establish the precise cause of PH include blood testing, ECG, pulmonary function testing, echocardiogram, $\dot{V}/\dot{Q}$ scan, CTA, and pulmonary artery catheterization.

Laboratory tests include a complete blood cell count, comprehensive metabolic panel, HIV test, rheumatologic panel, and liver function tests. These tests help identify conditions associated with PAH, such as systemic sclerosis, systemic lupus erythematosus, and mixed connective tissue diseases. Schistosomiasis, a parasitic disease and the most common cause of PH worldwide, must be ruled out in the appropriate setting. Electrocardiographic findings usually include right-axis deviation, right ventricular hypertrophy, and strain.[118] Pulmonary function tests are useful to rule out the presence of significant restrictive or obstructive airway disease. The most common abnormality on pulmonary function testing in patients with PAH is a low carbon monoxide diffusing capacity (DLCO), associated with relatively normal pulmonary mechanics.

The echocardiogram may show dilation of the right ventricle and right atrium, dysfunction of the right ventricle, and tricuspid regurgitation (Figure 28-4). One important noninvasive test for PAH is the $\dot{V}/\dot{Q}$ scan lung scan, which helps rule out the possibility of chronic thromboembolic PH, a mimic of PAH that has a different treatment, that is, possible thromboendarterectomy. In patients with PAH, the perfusion scan may be normal or show only patchy subsegmental defects. In patients with chronic thromboembolic PH, the $\dot{V}/\dot{Q}$ scan shows segmental defects; in these cases, confirmation of chronic thromboembolic PH requires pulmonary angiography. High-resolution CT is helpful to rule out associated causes such as interstitial lung disease, emphysema, or their co-occurrence.

Right heart catheterization is required to confirm the diagnosis and determine the degree of hemodynamic impairment, presence of vasoreactivity, and prognosis of patients with PAH (Figure 28-5). Patients with severe degrees of PH defined hemodynamically as high right atrial pressure and pulmonary vascular resistance, as well as low cardiac output, have a worse prognosis.[12,95-98]

Management

PAH can be life-threatening and carries a poor prognosis. Without therapy, only 33% of patients are alive 5 years after the onset of the disorder. During the past two decades, treatment has improved considerably.[119-124] Current treatment options include using calcium channel blockers, prostanoids, endothelin receptor antagonists, and phosphodiesterase-5 inhibitors.

Apical four-chamber view of the heart, revealing enlarged right atrium and ventricle compressing the left cardiac chambers **(A).** Doppler echocardiography showing tricuspid insufficiency jet *(arrow)* used to estimate the right ventricular systolic pressure, in this case 107 mm Hg. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

General Measures

Oral anticoagulation is recommended for patients with IPAH unless there is a contraindication to anticoagulation.[125,126] The recommended target international normalized ratio (INR) is 2 to 3. The role of anticoagulation in other forms of PAH is less clear and possibly not beneficial.[125] Supplemental O_2 should be used to maintain O_2 saturation greater than 90%, especially because hypoxemia is a major cause of pulmonary vasoconstriction. This is of particular importance in air travel or when staying at places with altitudes above 1000 m. Diuretics are indicated for right ventricular volume overload, and digoxin might be indicated for patients with refractory right ventricular

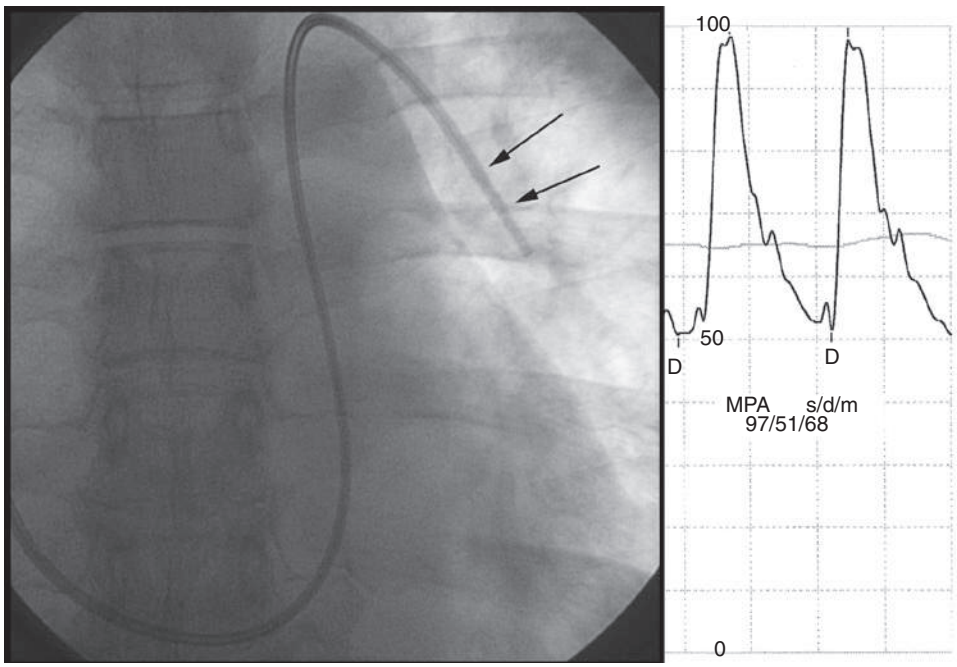

FIGURE 28-5 Right heart catheterization in pulmonary hypertension. On the *left panel* a pulmonary artery catheter is observed in the left pulmonary artery *(arrows).* On the *right panel* the corresponding pulmonary artery pressure tracing is shown, confirming the diagnosis of pulmonary hypertension. In this case the pulmonary artery, systolic, diastolic, and mean pressures were 97, 51, and 68 mm Hg, respectively.

failure and for rate control in atrial flutter or fibrillation.[123,124] Pregnancy is generally contraindicated in women with PH.

Calcium Channel Blockers

Patients with IPAH who respond to vasodilators in the short term have improved survival with long-term use of calcium channel blockers. Thus these agents should be considered only in IPAH patients who have significant and definite response to a short-acting vasodilator such as NO (others include intravenous epoprostenol or adenosine). Unfortunately, only a small fraction of IPAH patients qualify for and benefit from long-term therapy with oral calcium channel blockers.[123,124] Patients with other causes of PAH usually have negative acute vasodilator testing or, even if the testing was positive, they would not respond to long-term calcium channel blockers.[127]

NO is the preferred agent for pulmonary vasodilator testing because its half-life is very short, it does not affect cardiac output, and it enhances $\dot{V}/\dot{Q}$ matching.[127] NO is usually administered by mask at 10 to 40 parts per million for 2 to 5 minutes.[127] Protocols for using NO vary by institution. We use 40 ppm of NO delivered on room air (or the percentage of O_2 need to keep a pulse oximetry saturation ≥90%) for 5 minutes; others use 40 ppm of NO combined with 100% O_2.

Prostanoids

Several prostanoids are currently available for treating patients with severe PAH, including epoprostenol, treprostinil, and iloprost. Epoprostenol delivered via continuous intravenous infusion improves exercise capacity, hemodynamic variables, and survival in PAH patients.[128] Epoprostenol is unstable at room temperature and needs continuous intravenous infusion because of the short half-life of the drug. Common side effects include headache, flushing, jaw pain, diarrhea, nausea, skin rash, and musculoskeletal pain. Catheter-related complications include infection, sometimes serious (e.g., bacteremia), and thrombosis. By changing the buffer, a thermostable epoprostenol was developed and has been approved for clinical use by the FDA.

Another prostanoid, treprostinil, is a stable prostacyclin analogue with a longer half-life, allowing for subcutaneous,[129] intravenous,[130] inhaled,[131] or oral delivery. In addition to side effects seen with epoprostenol, patients receiving treprostinil subcutaneously may also experience pain at the infusion site. Inhaled teprostinil is administered by using the Tyvaso Inhalation System (ultrasonic, pulsed-delivery device; United Therapeutics, Research Triangle, NC). It is initially dosed at 3 inhalations, 4 times per day. If this dose is tolerated, it may be increased up to 9 inhalations, 4 times per day. Oral treprostinil has been approved by the FDA for the treatment of PAH. This mode of delivery is associated with gastrointestinal side effects and requires a slow titration. Iloprost is a stable prostacyclin analogue that can be delivered by inhalation and is an effective therapy for PAH.[132] Because of the relatively short duration of action of inhaled iloprost, it needs to be taken as 1 or 2 inhalations, 6 to 9 times per day. For its administration, the I-neb AAD System (Phillips Healthcare, Andover, MD) or Prodose AAD

System (Phillips Healthcare) should be used. Common side effects include cough, flushing, and headache. Inhaled iloprost may be useful as an adjunct to oral therapy.[119,120,123,124]

Endothelin-Receptor Antagonists

Endothelin antagonists represent another class of medications available for treating PAH. Bosentan, an orally administered nonselective endothelin-1 receptor antagonist, improves walking distance, hemodynamic variables, and functional class in patients with PAH.[133] The main side effect of bosentan is an asymptomatic increase in hepatic aminotransferase levels, which necessitates monitoring liver function at least monthly in all patients receiving bosentan. Ambrisentan, a selective type A endothelin-1 receptor antagonist, is also beneficial in patients with PAH. Its main side effect is peripheral edema.[134,135] Macitentan also has been approved by the FDA for treatment of PAH patients.[136] Macitentan blocks both endothelin type A and B receptors. Ambrisentan and macitentan are once-daily medications that do not need monthly hepatic aminotransferase determinations. All endothelin receptor antagonists are potent teratogens, and very careful contraception must be observed by patients receiving these medications.

Phosphodiesterase-5 Inhibitors

Sildenafil, a phosphodiesterase type 5 (PDE5) inhibitor, reduces pulmonary arterial pressure and is effective in treating PH.[121] By inhibiting PDE5, sildenafil stabilizes cyclic guanosine monophosphate (cGMP; the second messenger of NO), allowing a more sustained effect of endogenous NO, which is an indirect but effective and practical way of using the NO-cGMP pathway. Tadalafil, a long-acting PDE5 inhibitor, also improves outcomes in PAH and has some differences in acute effects when compared to sildenafil.[137,138] These medications are usually well tolerated; rarely, patients can have vision or hearing loss, priapism, and hypotension.

Soluble Guanylate Cyclase Stimulators

Riociguat has also been approved by the FDA for the treatment of PAH[139] and for patients with chronic thromboembolic PH who are not candidates for pulmonary thromboendarterectomy (i.e., surgery to remove clots from the pulmonary artery) or in whom the PH persists or recurs after thromboendarterectomy surgery.[140] This medication is associated with embryo-fetal toxicity; therefore patients need to follow strict recommendations to avoid pregnancy.

Surgical Therapy

Atrial Septostomy. The role of balloon atrial septostomy in treating patients with PAH is uncertain. Septostomy might be of benefit in the setting of severe disease with recurrent syncope and/or right heart failure despite maximal medical therapy. The procedure also can be used as a palliative bridge to lung transplantation. The rationale for its use is that the controlled creation of an atrial septal defect would allow right-to-left shunting, leading to increased systemic output and systemic O_2 transport despite the accompanying fall in systemic arterial O_2 saturation. The shunt at the atrial level would also allow decompression of the right atrium and right ventricle, alleviating signs and symptoms of right heart failure. Balloon atrial septostomy is a high-risk procedure and should be performed only in experienced centers to reduce the procedural risks.[123]

Lung Transplantation. Single or double lung transplantation has been used successfully in the treatment of patients with PAH. Patients who undergo lung transplantation have an immediate decrease in pulmonary artery pressure at the time of surgery and rapid improvement in right heart function despite severe preoperative cor pulmonale.[123] This option is reserved for special cases not responsive to medical treatment who have indicators of poor prognosis (syncope, refractory right heart failure, function class III/IV, or severe hypoxemia).[141] Perioperative mortality for transplantation is higher in PAH, but after the immediate postoperative period, some patients have an excellent response with dramatic improvements in symptoms and quality of life.[142] Although lung transplantation is an alternative for treating patients with PAH, the disadvantages of transplantation are the need for lifelong immunosuppression and the morbidity and mortality, which increase over time. The survival rate 3 years after lung transplantation is approximately 60%. Unfortunately, by the time PAH patients are considered for transplantation, they are usually poor candidates for transplantation because of the multiple organ system failures that may accompany PAH.

RULE OF THUMB

In patients with shortness of breath who have an unremarkable physical examination, the presence of a low DLCO and normal pulmonary mechanics suggests a pulmonary vascular cause (e.g., PH) as a cause of the shortness of breath.

Pulmonary Hypertension in Chronic Lung Disease

PH is a frequent complication of COPD (see Chapter 25). Approximately 50% of elderly patients with COPD have PH with significant reduction in survival and quality of life. The PH associated with COPD is multifactorial. Alveolar hypoxia, because of its potent pulmonary vasoconstrictive effect, is probably the most important factor contributing to PH in patients with COPD. Sustained alveolar hypoxia causes pulmonary vasoconstriction and eventually medial hypertrophy, fibrosis of the intima, and narrowing of the lumen of the pulmonary blood vessels. Other factors include the loss of vascular surface caused by destruction of lung parenchyma, compression of the vascular bed as a result of hyperinflation, hyperviscosity of the blood as a result of polycythemia, and left ventricular diastolic dysfunction. The presence of PH in patients with COPD correlates with the severity of the disease. Patients with severe hypoxemia (PaO_2 <55 mm Hg) may have more elevated pulmonary artery pressures, although the mean pulmonary artery pressure resulting from COPD alone rarely exceeds 35 to

40 mm Hg.[143-146] Patients with mean pulmonary artery pressure higher than 35 to 40 mm Hg have a poor prognosis.[147]

MINI CLINI

Dyspnea and Near-Syncope

PROBLEM: A 35-year-old woman has shortness of breath. She had an episode of near-syncope approximately 6 months ago; a diagnostic evaluation was done, and the results were negative. The physical examination shows a loud second heart sound. A chest radiograph shows questionable cardiomegaly. The forced vital capacity and forced expiratory volume in 1 second are normal, but the DLCO is only 40% of the predicted value. What is the cause of the dyspnea and the low DLCO?

DISCUSSION: This patient could have PH of unknown cause, that is, IPAH. She has physical findings consistent with high pressure in the right side of the heart (a loud second heart sound), and she has symptoms that are common in this disorder, such as dyspnea and near-syncope or syncope. The differential diagnosis is broad, but a low D_{LCO} in the presence of normal lung mechanics could indicate an abnormality of the pulmonary vasculature.

An echocardiogram is usually the first test of choice to assess for the presence of PH. If the echocardiogram is consistent with the diagnosis, pulmonary artery (also known as *right heart*) catheterization is needed to confirm the diagnosis, determine the severity, and exclude left heart disease. For the diagnosis of IPAH, other underlying diseases that can be associated with PAH must be excluded. A $\dot{V}/\dot{Q}$ scan and/or pulmonary angiogram can exclude chronic thromboembolic disease, a CT scan of the chest and pulmonary function tests can help determine the presence of parenchymal lung disease, and blood serologic tests can be used to evaluate for connective tissue disease. A 6-minute walk test may help in determining the functional capacity of the patient and assess her response to treatment. Several treatment options are currently available for patients with PH. The best option depends on the underlying cause of the PH and the severity of the disease.

O_2 therapy is the main treatment that improves survival among patients with COPD and PH, although smoking cessation and lung volume reduction (in selected individuals) may also offer survival benefits in patients with COPD. Vasodilator agents used for PAH are sometimes used in these patients, but the results of large clinical trials are not yet available.[145,147,148]

ROLE OF THE RESPIRATORY THERAPIST IN PULMONARY VASCULAR DISEASE

Respiratory therapists (RTs) can play a key role in diagnosing and managing individuals with pulmonary vascular disease. Diagnostically, the astute RT may help diagnose VTE and PH by recognizing the signs and symptoms of DVT/PE and PH (e.g., acute onset of dyspnea, pleuritic pain, pedal edema). Communication with the managing physician to point out these findings and suggest a workup may prove lifesaving.

Therapists also may play an important role in both preventing and managing pulmonary vascular disease. Ensuring patients' compliance with vascular compression stockings can help prevent PE. Therapists may also be members of teams that care for patients with PH, as in administering NO during pulmonary vasodilator challenge and managing inhaled therapies that are used to treat PAH (e.g., inhaled iloprost and treprostinil).

SUMMARY CHECKLIST

- VTE (DVT and PE) is an important cause of morbidity and mortality among hospitalized patients.
- Early recognition and treatment are essential and can be lifesaving. One-third of the deaths caused by PE occur within 1 hour of the symptom onset. The mortality rate in the group of patients with PE that goes undiagnosed is 30%; if the venous thrombosis is recognized and managed, the mortality rate is less than 8%.
- The point of origin of PE is DVT of the lower extremities or pelvis in 86% of cases.
- Most of the time, the clinical presentation of PE and DVT is nonspecific. A high index of suspicion is important to make the diagnosis in patients at risk.
- Prophylactic therapy reduces the risk for VTE in patients at risk, but, unfortunately, prophylactic therapy is underused.
- Pharmacologic choices for prophylaxis include low-dose subcutaneous heparin, warfarin, LMWH, and dextran. Mechanical measures include early ambulation, wearing elastic stockings, pneumatic calf compression, and electric stimulation of calf muscles.
- Management of VTE includes anticoagulation therapy (heparin and warfarin).
- IPAH is a rare disease that mainly affects young adults. In IPAH, damage to the endothelium of the pulmonary artery alters the balance between vasoconstrictors and vasodilators, favoring vasoconstriction. Thrombosis and cellular proliferation are contributors to PH.
- Management of IPAH includes anticoagulation and the administration of vasodilators (calcium channel blockers, prostanoids, endothelin receptor antagonists, PDE5 inhibitors, and soluble guanylate cyclase stimulators). Lung transplantation is an option for refractory cases.

CHAPTER 29

Acute Respiratory Distress Syndrome

MATTHEW C. EXLINE, EDUARDO MIRELES-CABODEVILA, AND R. DUNCAN HITE

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Diagnose patients with acute respiratory distress syndrome (ARDS) using currently recommended criteria (Berlin criteria).
- Differentiate normal lung function that prevents pulmonary edema versus common disease mechanisms that lead to pulmonary edema, including nonhydrostatic edema (e.g., ARDS) and hydrostatic pulmonary edema (e.g., congestive heart failure).
- Describe the effect pulmonary edema has on lung function, including gas exchange and lung compliance.
- Identify the histopathologic findings associated with the exudative phase and the fibroproliferative phase of ARDS.
- Describe the common risk factors associated with the onset of ARDS.
- Quantify the impact of ARDS on individual patients (e.g., mortality and morbidity), hospitals, and health care systems.
- State the approaches to managing ARDS, including therapies that directly target improving lung function and care designed to support and protect other vital organs.
- Describe how ventilator settings (e.g., mode, tidal volume, positive end expiratory pressure, inspiratory flow rate) should be adjusted for patients with ARDS.
- Describe how mechanical ventilation can cause lung injury and how ventilator-induced lung injury can be avoided.
- Describe the use of innovative and alternative strategies for assisting ventilation in ARDS, including modes of mechanical ventilation, prone positioning, neuromuscular blockade (paralytics), extracorporeal support, and other interventions.
- Describe the current status of evidence to support the use of pharmacologic therapies (e.g., nitric oxide, surfactant, corticosteroids) in treating patients with ARDS.

CHAPTER OUTLINE

KEY TERMS

acute hypoxemic respiratory failure
acute lung injury
acute respiratory distress syndrome
airway pressure release ventilation
barotrauma
congestive heart failure
conservative fluid management
extracorporeal carbon dioxide removal
extracorporeal membrane oxygenation
high-frequency oscillatory ventilation
hydrostatic pulmonary edema
inspiratory-to-expiratory ratio
nonhydrostatic pulmonary edema
lung protective ventilation
multiple organ dysfunction syndrome
positive end-expiratory pressure
prone positioning
pulmonary edema
ventilator–induced lung injury
volutrauma

Acute hypoxemic respiratory failure (AHRF) may develop in many clinical settings and is a common reason for admission to the intensive care unit (ICU). There are a wide variety of causes for AHRF, including infection (e.g., bacterial or viral pneumonia), pulmonary embolus, airway obstruction (e.g., tumor, mucous plug), and more. Two common causes of AHRF are the abnormal leakage of fluid from inside the vascular space (i.e., alveolar capillary) into the alveoli, which is commonly referred to as pulmonary edema. This chapter will focus on understanding the diseases that cause pulmonary edema formation by highlighting one common source of pulmonary edema known as the **acute respiratory distress syndrome** (ARDS).[1] In addition, the chapter will explore the clinical syndrome of ARDS, including current management strategies, and the vital role of the respiratory therapist (RT) in helping manage ARDS.

PHYSIOLOGY OF PULMONARY EDEMA

Liquid and Solute Transport in the Lungs

In addition to maintaining gas exchange and lung perfusion, as detailed in other chapters, a key component of normal lung function is to maintain a net flux of fluid through the lung parenchyma without causing lung edema or alveolar consolidation. For maximal gas exchange, the entire cardiac output must pass through the extensive capillary network that surrounds the total surface area of the alveolar airspaces. As a feature of the anatomy of the alveolus, the walls of the alveolus are separated from the capillary walls by the very thin lung interstitium (Figure 29-1). This close approximation of the alveolus to the

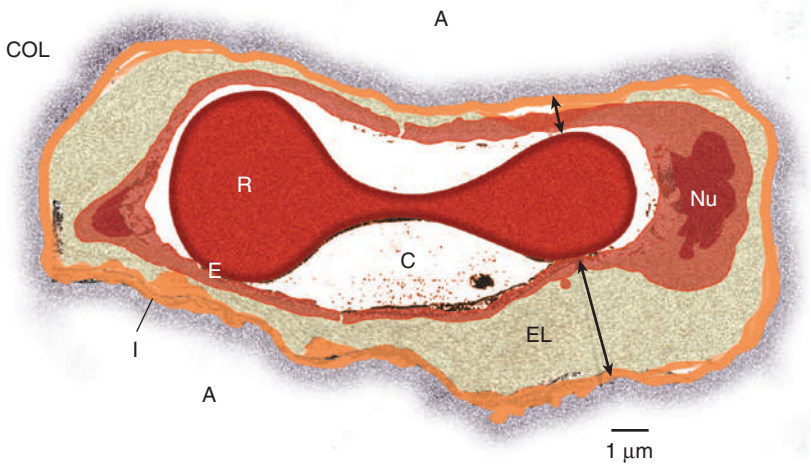

FIGURE 29-1 Cross section of an alveolar wall shows the path for O_2 and CO_2 diffusion. The thin side of the alveolar wall barrier *(short double arrow)* consists of type I epithelium *(I),* interstitium formed by the fused basal laminae of the epithelial and endothelial cells, capillary endothelium *(E),* plasma in the alveolar capillary *(C),* and the cytoplasm of the red blood cell (RBC) *(R).* The thick side of the gas-exchange barrier *(long double arrow)* has an accumulation of elastin *(EL),* collagen *(COL),* and matrix that separates the alveolar epithelium from the alveolar capillary endothelium. As long as the RBCs are flowing, O_2 and CO_2 diffusion probably occur across both sides of the air-blood barrier. *A,* Alveolus; *Nu,* nucleus of the capillary endothelial cell. (Human lung surgical specimen, transmission electron photomicrograph.)

capillary walls minimizes the distance for gases (i.e., O_2 and carbon dioxide [CO_2]) to diffuse between the airspace and blood. However, this small barrier also serves as a conduit for leakage of fluid out of the lumen of the capillary into the lung interstitium and alveolar airspace. Under normal conditions, the vascular and lung compartments work synergistically to maintain a physiologic amount of fluid leakage. Under normal circumstances, the alveoli contain air and are without fluid. In pathologic disease states involving either the capillaries or the alveoli, the rate of leakage of fluid into the lung can exceed the lung's capacity to clear the fluid (i.e., through the lymphatic drainage of the lung), thereby leading to excessive fluid accumulation in the airspace (called *pulmonary edema*) and abnormal lung function and gas exchange.

On average, the entire blood volume of the body circulates through the lungs in 1 minute or less. This incredible feat is achieved through an ingenious design that begins at the outflow tract of the right ventricle and passes through the thick-walled branches of the pulmonary artery, which successively divide into bronchial and bronchiolar branches. Beyond the terminal bronchioles, the pulmonary vasculature divides further to form a fine capillary meshwork that surrounds the alveoli. The large surface area of the capillary network provides for a low–hydrostatic pressure (5 to 12 mm Hg), high-volume system wherein large volumes of blood come into immediate contact with alveolar gases. At the capillary level, the vessel walls are composed solely of endothelial cells bound to basal lamina.

The interstitial space of the lung is separated into two compartments: (1) the alveolar side, which is the space between the capillaries and epithelial lining of the alveolus, and (2) the nonalveolar side. The alveolar interstitium is composed of several structural proteins (collagens and elastin) and proteoglycans, which form a relatively stiff, noncompliant basement membrane between the membranes of the vascular endothelium and the alveolar epithelium. All combined, this structure is very thin (<0.5 μm) and facilitates gas exchange (see Figure 29-1). In contrast, the interstitium on the nonalveolar side of the capillaries is composed of collagen, elastin proteins, and mucopolysaccharides in a hyaluronic acid gel that is more compliant and serves to interconnect membranes of the airway epithelium, vascular endothelium, and fibroblasts.

Under normal conditions, the physical properties of the interstitium allow absorption of water by these tissues with no leakage of fluid into the alveoli and no impact on pulmonary gas exchange. This interstitial fluid content leads to an interstitial pressure that keeps fluid in the interstitial space, thereby serving as a hydrostatic pressure that is similar to but opposes the hydrostatic pressure in the vascular space. Overall, the interstitium, particularly the nonalveolar component, is highly compliant and able to accommodate relatively large increases in fluid volume in the interstitium without significant change in interstitial hydrostatic pressure or leakage of fluid into the alveolar airspace.

The alveolar capillaries contain pores (pumps and channels) that selectively permit the leakage of protein and allow movement of electrolytes and nutrients between the intravascular space and the interstitium of the lungs.[2] The net exchange of fluids between the intravascular space (i.e., within the capillaries) and the interstitium of the lungs is determined by the combined influences of hydrostatic and osmotic forces within the blood and interstitium. Osmotic forces reflect the effects of dissolved proteins to retain fluid within the interstitial space. Under normal conditions, the capillary hydrostatic force and interstitial osmotic force influencing the movement of fluid out of the bloodstream into the interstitium are slightly greater than the capillary osmotic force and interstitial hydrostatic forces opposing this movement. This balance is governed by the Starling forces. As a result of the normal balance of these forces, a small fraction of the cardiac output (approximately 0.01%) normally filters from the capillaries into the interstitial space of the lungs.[3] This filtration process plays a role in the immune defenses of the lung and is a major determinant of total lung fluid content.

The lung protects itself from excessive fluid accumulation by several mechanisms. The lung *lymphatic drainage system* is the primary system for removing filtered fluid and protein from the lungs. Fluid and solutes enter the lymphatic drainage channels from small lymphatic capillaries located around the respiratory bronchioles. This process is assisted by the presence of a modest pressure gradient within the lungs. Higher pressure near the dense alveolar interstitium forces fluid away from the alveolar surface toward the lower pressured nonalveolar interstitium and terminal lymphatic vessels. Drainage is enhanced further by intrathoracic pressure alterations that occur with respiration, and retrograde (backward) flow is prevented by the presence of one-way lymphatic valves. Ultimately, lymphatic fluid drains out of the lung into the superior vena cava through the thoracic duct.[4]

When the rate of fluid leakage into the interstitium exceeds the capacity for drainage through the pulmonary lymphatic vessels, backup mechanisms exist for storing additional fluid and protecting against alveolar flooding. Loose connective tissue surrounding the bronchioles and bronchi is capable of storing twice the normal fluid content of the lungs.[4] Also, fluid can fill the interlobular septal spaces or cuffs; when this happens, the fluid-filled septal spaces can be seen on a chest radiograph as linear interstitial infiltrates (known as *Kerley lines*) at the lung periphery (Figure 29-2). As total lung fluid accumulates, the capacity of the gel-like matrix in the nonalveolar lung interstitium to accommodate fluid is maximized. Once this capacity is maximized and the rate of fluid accumulation exceeds the rate of lymphatic drainage, fluid will start to accumulate within the alveoli; the alveoli then become flooded.

Hydrostatic Versus Nonhydrostatic Edema

Despite these extensive protective mechanisms to protect the alveolus from excess fluid leakage, common disease states can result in fluid flux that exceeds the lung's capacity to remove or store the fluid. Under such circumstances, small increases in lung fluid content produce large increases in interstitial hydrostatic pressure, accumulation of intraalveolar fluid, and the

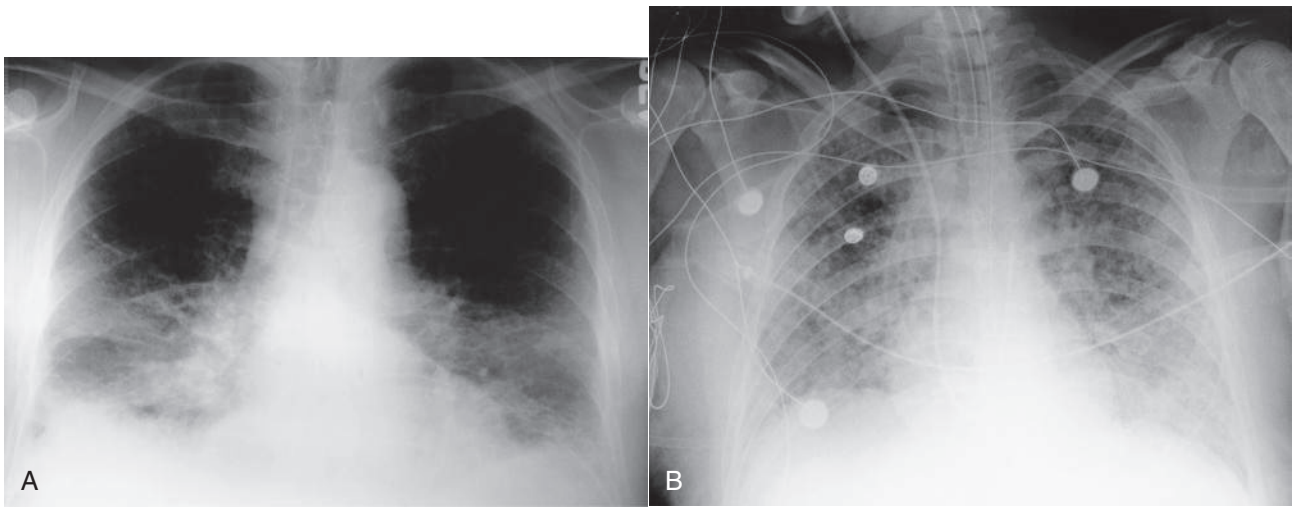

FIGURE 29-2 Chest radiographs show typical radiographic features of congestive heart failure (CHF) and acute respiratory distress syndrome (ARDS). **A,** CHF is characterized by cardiomegaly, interstitial infiltrates, bilateral perihilar and basilar alveolar infiltrates, and bilateral pleural effusions, which cause blunting of the costophrenic angles. **B,** ARDS is commonly associated with normal cardiac size, diffuse peripheral alveolar infiltrates, and minimal or absent pleural effusions.

clinical entity called **pulmonary edema.** The diseases that cause pulmonary edema are typically categorized as either hydrostatic or nonhydrostatic edema. To clarify the distinction between hydrostatic and nonhydrostatic edema, a simple analogy is to consider the intravascular hydrostatic force within the capillary as a body of water and the alveolar barrier as an impermeable dam with pumps that help regulate the water levels behind the dam (Figure 29-3). Hydrostatic pulmonary edema occurs when the pressure or volume of water exceeds the capacity of the dam's pumps to maintain the water levels. Water then floods the land below the dam (the alveolus in this metaphor). Nonhydrostatic pulmonary edema occurs when the dam is cracked or damaged and the water leaks through it onto the land below the dam. It should also be noted that the type or color of water is different in nonhydrostatic edema because the cracks in the dam permit leakage of more sediment (equivalent of protein and cells in patients with ARDS).

Hydrostatic Pulmonary Edema

Hydrostatic pulmonary edema is often also called *cardiogenic pulmonary edema* because of its close association with abnormalities in intravascular hydrostatic pressures that cause edema. Whereas increased hydrostatic pressures in the pulmonary arteries lead to pulmonary arterial hypertension and problems with right heart failure, increased hydrostatic pressures in the pulmonary veins lead to increased hydrostatic pressures in the alveolar capillaries that increase fluid leakage out of the capillary. In most patients, elevation of pulmonary venous pressures are caused by increased pressures in left-sided heart pressures (left atrial or left ventricular end-diastolic pressure), which are key characteristics of left-sided congestive heart failure, both diastolic and systolic (Box 29-1). The elevated hydrostatic pressures within the capillary ultimately lead to elevated interstitial fluid pressure and alveolar flooding through leakage of fluid from the respiratory epithelium.[5] In the setting of increased hydrostatic pressure, the endothelial and epithelial barriers remain intact and impermeable to large proteins and molecules. As a result, the fluid that accumulates within the alveoli, when measured from bronchoalveolar lavage (BAL) fluid samples, has characteristics identical to those of interstitial fluid, that is, with low protein levels similar to those of transudative fluid collections sampled from the pleural and peritoneal spaces in the same disease states.[4]

Box 29-1 Common Causes of Hydrostatic Pulmonary Edema

CARDIAC
- Left ventricular failure
  - Systolic (e.g., myocardial infarction, myocarditis)
  - Diastolic (e.g., left ventricular hypertrophy)
- Valvular heart disease (e.g., aortic, mitral)

VOLUME OVERLOAD
- Excessive fluid administration
- Renal failure
- Hepatic failure
- Hypoalbuminemia (e.g., malnutrition)

Nonhydrostatic Pulmonary Edema

Nonhydrostatic pulmonary edema, also called *noncardiogenic pulmonary edema*, results from injury to the vascular endothelium and/or alveolar epithelium. This injury creates a loss of integrity in the barrier between the vascular and alveolar spaces (like cracks in a dam; see Figure 29-3). In contrast to hydrostatic pulmonary edema, nonhydrostatic pulmonary edema is associated with increased total lung water despite normal microvascular hydrostatic pressure. Although many seemingly unrelated

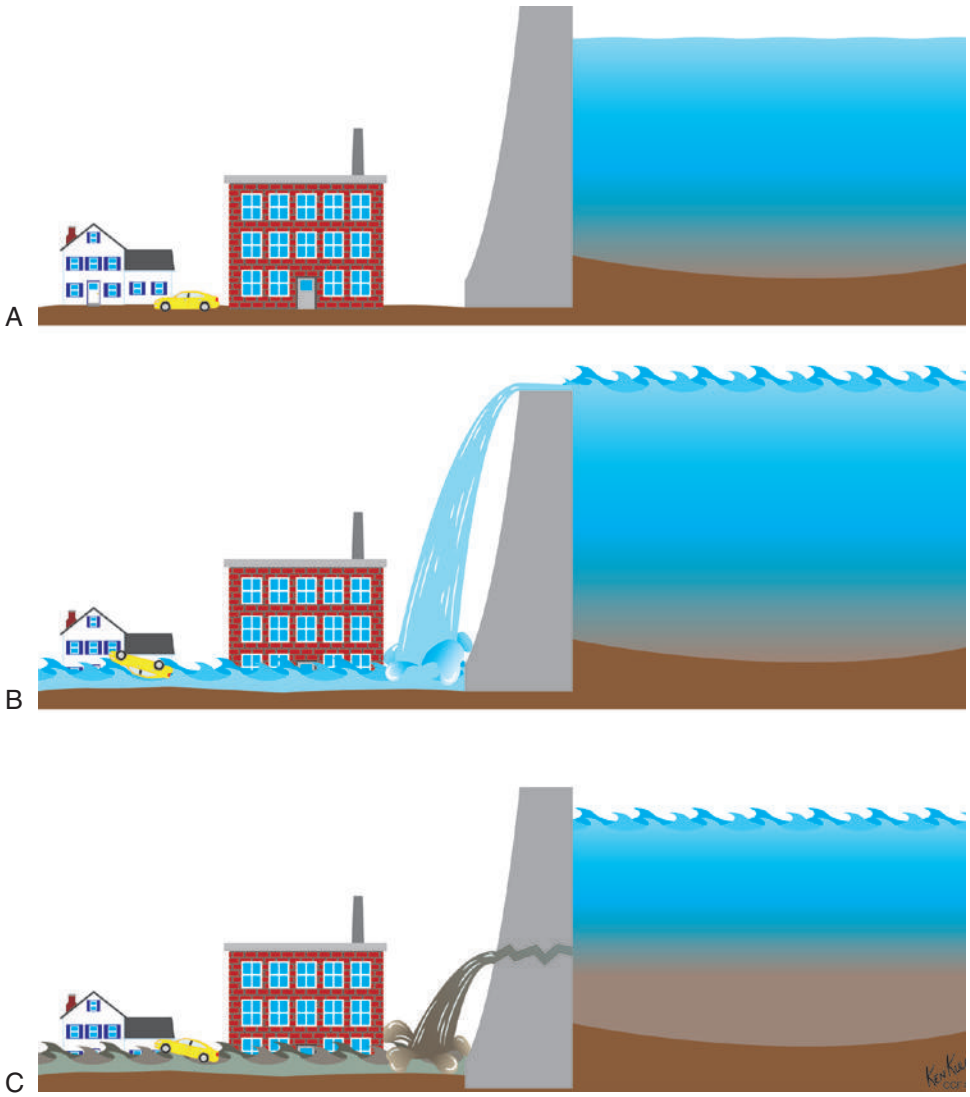

FIGURE 29-3 The intact dam **(A)** represents the normal condition in which oncotic and hydrostatic forces (Starling forces) are balanced, keeping the town dry (where the town represents the alveolar space). In **B,** the dam remains intact but the water level has risen, overwhelming the dam (i.e., exceeding the forces that resist alveolar flooding) and flooding the town representing the alveoli. This condition resembles hydrostatic pulmonary edema. In **C,** a crack in the dam (simulating the alveolar-capillary interface) allows water through the dam, flooding the town. Note that the water flooding the town is darker because it contains more sediment and mud from the lake. The condition in **C** simulates the damage to the alveolar-capillary interface that accompanies inflammation in acute respiratory distress syndrome, causing nonhydrostatic pulmonary edema. The muddier water flooding the town (representing the alveolar space) in **C** than in **B** represents the more proteinaceous, inflammatory nature of the fluid that floods the alveoli in nonhydrostatic pulmonary edema.

risk factors for ARDS have been identified, all causes of ARDS feature disruption of endothelial and epithelial barriers and typically occur under conditions associated with widespread microvascular injury to the lungs. Vascular endothelial injury in the lungs causes increased microvascular permeability and allows fluid to pass from the capillaries into the interstitial space. As protein-rich fluid enters the pulmonary interstitium from the vasculature, the osmotic gradient between the capillary and the lung approaches zero and no longer opposes the hydrostatic forces that favor fluid movement from the capillary into the lung. This process is likely facilitated both by damage to the normally impermeable alveolar epithelial barrier, which is a key feature of ARDS,[6] and by impaired alveolar fluid clearance in ARDS.[7]

Many acute illnesses can lead to the development of ARDS (Box 29-2), but a common mechanism was proposed by Weiland and colleagues.[8] Regardless of the cause, ARDS is typically associated with an influx of polymorphonuclear neutrophils (PMNs), which release inflammatory by-products, such as proteases, phospholipases, and oxygen radicals into the lung.[2,9] These inflammatory by-products degrade the endothelial and epithelial barriers and recruit additional PMNs to continue the

Box 29-2 Clinical Features of Congestive Heart Failure and Acute Respiratory Distress Syndrome

FEATURES COMMON TO BOTH CONGESTIVE HEART FAILURE AND ACUTE RESPIRATORY DISTRESS SYNDROME

- Symptoms of anxiety, dyspnea, tachypnea
- Decreased compliance and reduced lung volumes
- Hypoxemia (mild to severe), often requiring ventilator assistance
- Chest radiograph shows diffuse alveolar and interstitial infiltrates

FEATURES FAVORING CONGESTIVE HEART FAILURE

- Clinical history suggestive of CHF (see Box 29-1)
- Symmetric pulmonary infiltrates, cardiomegaly, or pleural effusions on chest radiograph (see Figure 29-2)
- Elevated pulmonary artery catheter wedge pressure (18 to 30 mm Hg)
- Bronchoalveolar lavage fluid: Low protein and minimally increased cellularity
- Prompt (<12 to 24 hours) and lasting response to diuretics and CHF therapy

FEATURES FAVORING ACUTE RESPIRATORY DISTRESS SYNDROME

- Clinical history of a risk factor for ARDS (see Box 29-3)
- Asymmetric, peripheral infiltrates on chest radiograph (see Figure 29-3)
- Bronchoalveolar lavage fluid: Very high protein level and marked cellular influx
- Transient improvement with CHF therapy, but uncommon to significantly improve during initial 12 to 36 hours

CHF, congestive heart failure.

inflammatory cascade. In contrast to hydrostatic pulmonary edema, the fluid that accumulates in ARDS, when sampled using BAL, typically demonstrates very high levels of protein, neutrophils, and total cells (Figure 29-4).[1]

Although PMNs play a central role in the development of ARDS, multiple pathways lead to the inflammatory cascade in the lung and subsequent loss of alveolar membrane integrity. Other chemical insults (e.g., gastric aspiration), inhalational injury (e.g., of noxious gas such as chlorine), or immunologic pathways (e.g., tumor necrosis factor [TNF] or interleukin-8 [IL8]) all contribute to the hemodynamic and inflammatory events characteristic of ARDS.[10] Sepsis, one of the most common causes of ARDS, features activation of many of these inflammatory pathways. The relative contributions and exact roles of these proinflammatory mediators in the pathogenesis of ARDS are not known.[1,11] Attempts to control the inflammatory response in sepsis and ARDS by blocking specific mediators (e.g., steroids and antibodies to TNF and IL-1) unfortunately have not proved beneficial and are not currently used.

It is important to note that acute illnesses associated with the development of ARDS also can lead to widespread systemic organ injury (e.g., renal failure, encephalopathy), which is caused by similar inflammatory pathways leading to injury and fluid leak in those organs.[12,13] This syndrome of diffuse organ impairment is frequently referred to as the **multiple organ dysfunction syndrome** (MODS). ARDS is the pulmonary manifestation of MODS, and MODS is a common cause of death in ICUs. In contrast to ARDS, illnesses that lead to hydrostatic pulmonary edema typically do not cause MODS.

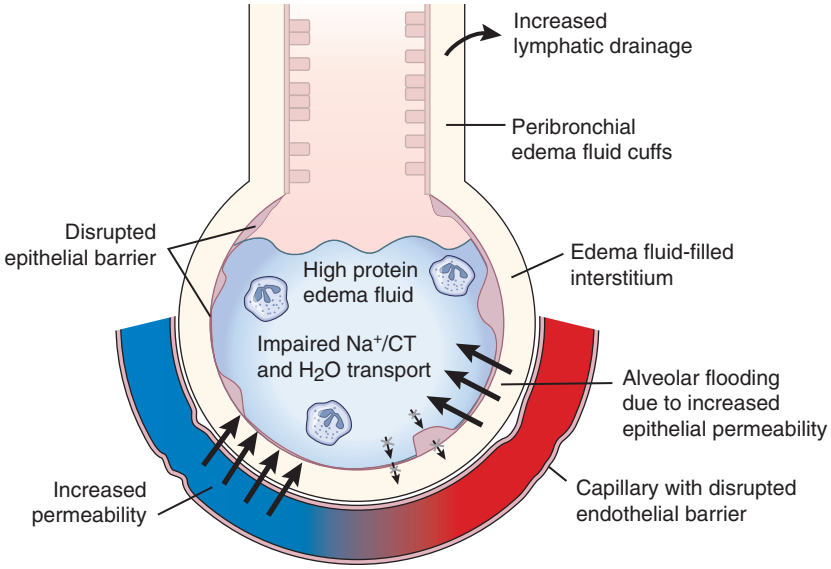

FIGURE 29-4 In this cartoon, the anatomy of the normal alveolus is on the left side of the figure including the alveolar epithelium (type I and type II cells), pulmonary capillary with its endothelium, surfactant layer, and alveolar macrophages. In the normal alveolus, little or no excess fluid is present. The right side of the picture represents the changes associated with acute respiratory distress syndrome, including injury and leak of the capillary endothelium and alveolar epithelium, damage and depletion of surfactant, influx of inflammatory cells (neutrophils) and cytokines, and leak of fluid with high protein levels. (Modified with permission from Matthay MA, Zimmerman GA: Acute lung injury and the acute respiratory distress syndrome: four decades of inquiry into pathogenesis and rational management. Am J Respir Cell Mol Biol 33:319–327, 2005.)

Gas Exchange and Lung Mechanics in Pulmonary Edema

Hydrostatic pulmonary edema and ARDS are both associated with restrictive physiology, reduced lung compliance, and refractory hypoxemia, which are largely the result of the accumulation of interstitial and alveolar fluid. In addition, impaired gas exchange that results from pulmonary edema is complicated further by an increase in the work of breathing. The increased work of breathing is caused by dramatic reductions in lung compliance that in turn result from alveolar collapse and interstitial fluid accumulation. This scenario commonly causes acute respiratory failure and the need for ventilatory assistance (invasive or noninvasive). In most cases, the severity of lung dysfunction and hypoxemia is worse and more prolonged in ARDS compared to the hydrostatic pulmonary edema of **congestive heart failure** (CHF). The inflammatory nature of the intraalveolar fluid in ARDS also impairs surfactant synthesis, secretion, and function. The resulting surfactant abnormalities further impair pulmonary gas exchange (i.e., related to atelectasis and impaired compliance). The negative effects of alveolar consolidation and atelectasis on pulmonary gas exchange are further worsened by a loss of the normal vascular response to alveolar hypoxemia. Normally, pulmonary arteries in areas of alveolar hypoxia will constrict as a physiologic response to preserve ventilation/perfusion ($\dot{V}/\dot{Q}$) matching. However, in ARDS, this normal vasoconstrictive response is impaired. Because the body is unable to shunt blood away from the diseased alveoli, these nonaerated alveoli receive excessive blood flow, which contributes to severe $\dot{V}/\dot{Q}$ mismatching and an intrapulmonary right-to-left shunting of blood flow, which causes hypoxemia.

In summary, pulmonary edema may arise from acute illnesses associated with increased pulmonary venous pressure (hydrostatic pulmonary edema or CHF) or may result from conditions associated with acute injury to the lung, in which the normal barriers to fluid movement within the lungs are disrupted, as in the nonhydrostatic pulmonary edema of ARDS. Although CHF and ARDS are distinct disease processes that require different management strategies, differentiating these two forms of pulmonary edema in patients is frequently challenging because signs and symptoms of both are often very similar. The remainder of this chapter will focus on the distinct characteristics and management approaches for ARDS. In so doing, the reader should gain further ability to understand which characteristics and management approaches are both similar and distinct to CHF.

DEFINITION AND DIAGNOSIS

Early in the 20th century, the clinical problem of respiratory distress shortly after birth was identified in premature infants. By the 1950s, the mechanism for the respiratory distress syndrome (RDS) of neonates was identified as a primary deficiency of pulmonary surfactant caused by birth at a stage of gestation (typically ≤32 weeks) before fetal lung maturation.[14] The first formal report of RDS in adults was published in the late 1960s, and the entity of adult respiratory distress syndrome (ARDS) was created.[15] Over the next 25 years, extensive research was focused on this highly lethal condition (i.e., initially with an associated mortality rate of 60% to 70%), but outcomes did not improve significantly during this period.[16] Progress was challenged by a lack of consensus in the definition of the syndrome and by variation in approaches to clinical management.[17] A key component of the challenge of defining ARDS is the close similarity to other disease entities, including CHF, pneumonia, and lung contusion. In the absence of a key distinguishing feature that easily separates ARDS from these other common disease conditions; the definition of ARDS must include several features, which in combination form a syndrome.

In response to these challenges, a consensus definition for acute (no longer called *adult*) respiratory distress syndrome (ARDS) was created in 1994 with input from key thought leaders from both Europe and the United States and is commonly referred to as the American-European Consensus Conference (AECC) definition (Table 29-1).[17] Because the syndrome of ARDS in children (older than newborns) is not significantly

TABLE 29-1

Recommended Definitions for the Acute Respiratory Distress Syndrome

	AECC Criteria (1994)	Berlin Criteria (2012)
Timing of onset	Acute onset (no definition)	Within 1 week of known risk factor (trigger)
Risk factor	Not included	If no risk factor identified, hydrostatic edema must be formally excluded
Exclusion of hydrostatic edema	Right heart catheterization with wedge pressure ≤18 mm Hg *or* no clinical evidence of left atrial hypertension	Requirement for wedge pressure measurement removed. Clinical vignettes using history, clinical signs/symptoms, and echocardiography provided
Hypoxemia	ALI: P/F ratio ≤300 ARDS: P/F ≤200 (regardless of PEEP level)	Three categories of ARDS (no ALI): *Mild:* P/F ratio = 201-300 *Moderate:* P/F = 101-200 *Severe:* P/F ≤100 (must have PEEP or CPAP ≥5 cm H_2O)
Chest imaging	Bilateral infiltrates seen on frontal chest radiograph (no specific criteria)	Bilateral infiltrates not explained by effusions, collapse, or nodules

Modified from Acute Respiratory Distress Syndrome Task Force; Ranieri VM, Rubenfeld GD, Thompson BT, et al: Acute respiratory distress syndrome: the Berlin definition. JAMA 307:2526–2533, 2012.

different from that in adults, the AECC definition discontinued using the term *adult* in favor of *acute* for the syndrome's title. The AECC definition includes five central components: (1) reduced lung compliance, (2) hypoxemia (ratio of PaO_2/FiO_2 [P/F] <200), (3) bilateral infiltrates on chest radiograph, (4) an acute illness associated with the development of ARDS that can trigger the onset of ARDS, and (5) no evidence of CHF (based on measurements from a pulmonary artery catheter or other means to estimate elevated pressures on the left side of the heart). The AECC definition includes a condition known as **acute lung injury** (ALI) which shares all characteristics of ARDS except hypoxemia that is less severe (i.e., P/F ratio of <300 compared to <200 to qualify as ARDS). Since 1994, The AECC definition has served as the gold standard for identifying and enrolling patients with ARDS into clinical trials. The combination of this consistent definition and enhanced collaboration between investigators around the world has led to dramatic discoveries and marked improvements in the outcomes of patients.

In 2012, the AECC definition of ARDS was updated by a new international consensus group that met in Berlin, Germany in 2011. These updates were made in response to limitations of the AECC that had been identified over the ensuing two decades. This new definition is commonly referred to as the Berlin definition or Berlin criteria (see Table 29-1).[18] The key new features of the Berlin definition include the following:

1. Replacement of the distinction between ALI and ARDS with three categories of ARDS severity (mild, moderate, and severe) based on ranges of P/F ratio and levels of **positive end expiratory pressure** (PEEP)
2. Inclusion of noninvasive techniques to estimate left heart pressures, including echocardiography
3. Enhanced specificity for interpretation of chest radiographs when trying to determine the presence of bilateral infiltrates or opacities
4. Enhanced specificity regarding the timeframe referred to as "acute" (i.e., occurring within 1 week of the triggering condition)

With the introduction of the Berlin definition, it is anticipated that use of the term *acute lung injury* will diminish because it has become clear that ALI and ARDS are not distinct conditions and only represent differences in severity of the same condition. Although no major clinical trials have yet been completed using the Berlin definition, it is expected that the Berlin definition will become the basis for future trials and for communication among clinicians caring for patients with ARDS.

Distinguishing Acute Respiratory Distress Syndrome from Nonhydrostatic Pulmonary Edema in Clinical Practice

Despite the strength of these definitions for ARDS and nonhydrostatic pulmonary edema, differentiating ARDS from **hydrostatic pulmonary edema** (CHF) based on the AECC or Berlin definition can remain challenging, even for experienced clinicians. In Box 29-2, clinical features that are common to both CHF and ARDS and those that can distinguish each are outlined. CHF is more common than ARDS and should be considered whenever the history or physical examination findings suggest one of the causes of CHF listed in Box 29-3. A clinical history of infection, recent trauma, or risk factors for aspiration may be present in either patient group, but the presence of these risk factors (triggers) favors a diagnosis of ARDS. To underscore the difficulty in distinguishing the cause of pulmonary edema, many patients with ARDS are older and have preexisting illnesses that also place them at risk for CHF.

It is difficult to distinguish between CHF and ARDS based on the radiographic findings alone. Both CHF and ARDS are characterized by diffuse alveolar infiltrates that especially occur in dependent lung zones (see Box 29-2). CHF is more often associated with cardiomegaly, perihilar infiltrates, and pleural effusions, whereas ARDS is more often associated with the presence

RULE OF THUMB

The severity of hypoxemia can be measured in many ways with the most complex method, known as the *alveolar-arterial (A-a) gradient*. Calculation of the A-a gradient is cumbersome; therefore many clinicians choose to use methods that are simple and quick and that provide useful estimates for trending the response of a patient to therapy. The P/F ratio is calculated using the PaO_2 obtained from an arterial blood gas (ABG) analysis and the fraction of inspired oxygen (FiO_2) at the time the ABG value was obtained. When calculating P/F ratios, it is important to remember the difference between a fraction and a percent. In other words, a patient who is receiving 40% supplemental O_2 has a FiO_2 of 0.40 (not 40). As an example, the P/F ratio of a patient on 50% O_2 whose PaO_2 is 100 mm Hg calculates to be 200. Assuming the patient met the other points of the Berlin criteria to have ARDS, the P/F ratio would indicate the patient has moderate ARDS.

Box 29-3 Risk Factors for Acute Lung Injury and Acute Respiratory Distress Syndrome

DIRECT INJURY
- Pneumonia (viral, bacterial, fungal)
- Gastric aspiration
- Toxic inhalation (phosgene, cocaine, smoke, high concentration of oxygen)
- Near drowning
- Lung contusion

INDIRECT INJURY
- Sepsis and prolonged shock
- Burn injury (chemical or heat-induced)
- Multiple trauma
- Transfusions (transfusion-related acute lung injury [TRALI])
- Pancreatitis
- Gynecologic causes (abruptio placentae, amniotic embolism, eclampsia)
- Drug effect (e.g., *trans*-retinoic acid for acute leukemia)
- Sickle cell crisis

of peripheral alveolar infiltrates, air bronchograms, sparing of the costophrenic angles, and normal cardiac size. However, cardiac size and pleural effusions may be difficult to interpret on portable chest x-ray studies with patients lying supine in the ICU. Consequently, differentiating between CHF and ARDS on the basis of the chest radiograph is often difficult.

Pulmonary edema of any cause is associated with impaired gas exchange and abnormal lung mechanics. Both CHF and early ARDS (especially in the exudative phase; see below later discussion) are associated with interstitial and alveolar accumulation of fluid. As a result of $\dot{V}/\dot{Q}$ mismatching and shunt accompanying this fluid accumulation, arterial hypoxemia develops. Because of associated reduced lung compliance and increased ventilator rates, patients with interstitial and alveolar edema of any cause use a higher fraction (25% to 50%) of their total metabolic output to support their increased work of breathing.

Intuitively, invasive measurement of hemodynamic variables using a pulmonary artery (Swan-Ganz) catheter would seem to offer a definitive way to differentiate hydrostatic and nonhydrostatic edema. However, in practice, the measurement of the cardiac output or pulmonary arterial pressure either invasively or noninvasively has not been shown to be essential for diagnosis of ARDS or beneficial in the daily management of ARDS patients.[19] The increasing availability and accuracy of noninvasive assessment of cardiac function by means of echocardiography, when combined with other physical examination features (capillary refill and mottling), can provide reliable information that can effectively guide clinical decision making.[20]

A potential method of separating CHF from ARDS is based on differences in the characteristics of the edema fluid. As previously discussed, ARDS is associated with inflammatory injury to the pulmonary microvasculature, which allows the influx of inflammatory cells and proteinaceous fluid into the interstitium and alveolar spaces. The inflammatory nature of this exudative fluid is reflected by the presence of large quantities of inflammatory cells (predominantly neutrophils) in BAL fluid (BALF). The BALF findings also can provide diagnostic insights regarding respiratory infections that may be present, and potentially the primary source for ARDS. In contrast, the alveolar edema fluid in CHF is typically noninflammatory, and the protein content is much lower than the protein content of normal BALF.[21] Despite its potential value, performing BAL and analyzing BALF is not currently a standard clinical practice in managing patients with acute respiratory failure caused by pulmonary edema.

Histopathologic Findings

During the early years of understanding RDS and ARDS, pathologists were critically important in helping characterize and understand the primary abnormalities in the lung tissue by examining lung biopsies and autopsies.[14] Although biopsy of the lung can provide specific information that can reliably distinguish ARDS from nonhydrostatic forms of pulmonary edema, lung biopsy is typically not required for managing patients with ARDS. The changes in the lung tissue in ARDS are typically separated into two phases based on the overall duration of the disease process: (1) the exudative phase (1 to 7 days) and (2) the fibroproliferative phase (3 days to weeks).

MINI CLINI

A careful history and evaluation of the overall clinical presentation often are the most useful means by which CHF and ARDS can be initially differentiated in a patient who has refractory hypoxemia and bilateral infiltrates on the chest radiograph. For example, a patient presents to the emergency department with complaints of increased cough and shortness of breath and a low-grade fever (38.2° C). His medical history includes a long history of systolic congestive heart failure (ejection fraction of 20% to 25% on recent echocardiogram). On examination, he has rales noted in both bases, engorged neck veins, bilateral lower extremity edema and bilateral infiltrates with cardiomegaly on chest radiograph. His P/F ratio on ABG analysis and 50% FiO_2 are 175. His white blood cell count is within normal range, and he has no other signs of systemic inflammatory response syndrome (SIRS) or other organ failure (e.g., renal, hepatic, central nervous system). Based on this manifesting information, the patient is more likely to have CHF as a cause of his pulmonary edema than ARDS, despite his fever and a P/F less than 200. Low-grade fever can be commonly seen in exacerbations of CHF. It would be typical for this patient to improve quickly with diuretic therapy and other measures to lower afterload.

The exudative phase is characterized by diffuse damage to alveoli and blood vessels and the influx of proteinaceous fluid and inflammatory cells into the interstitium and alveolar spaces. Also, many of the alveolar spaces are filled with *hyaline membranes,* which are composed of cellular debris and condensed plasma proteins (Figure 29-5). As a result of these characteristic changes, an early name for ARDS was hyaline membrane disease. Pathologically, there is destruction of the alveolar wall, which includes type I pneumocytes (the predominant structure cells lining the alveoli) and type II pneumocytes (which make and secrete surfactant).[22,23] The pathologic findings of ARDS also include cellular injury to the lining (endothelium) of the pulmonary capillaries. When the primary condition that triggered the onset of ARDS is quickly identified and treated, the exudative phase is typically short, lasting only a few days and is fully reversible, leaving no significant chronic signs of injury to the lung.

After the cause of lung injury is established and the initiating events are controlled, a process of lung repair begins. On pathologic examination, this appears as an overabundance of alveolar type II pneumocytes and infiltration or proliferation by fibroblasts within the alveolar basement membrane and intraalveolar spaces. Fibroblasts drive intraalveolar and interstitial fibrosis.[23] The extent of fibrosis determines the degree of pulmonary disability in patients who survive ARDS. The exact mechanisms controlling lung remodeling in ARDS are not well established but very likely involve by-products of inflammatory cells (e.g., proteases, antiproteases, IL-6) and

FIGURE 29-5 Light microscopic image of an alveolus in acute respiratory distress syndrome (ARDS) with injury to the alveolar epithelium, interstitial edema, and the development of hyaline membranes *(arrow).* Hyaline membranes form as the coalescence of cells and serum proteins, particularly clotting factors. These membranes were an early hallmark of findings in premature newborns with RDS and led many to refer to RDS as hyaline membrane disease. (Modified with permission from Tomashefski JF, Jr: Pulmonary pathology of adult respiratory distress syndrome. Clin Chest Med 11;593–619, 1990.)

various growth factors (transforming growth factor [TGF]-alpha, TGF-beta).[24,25] However, the remodeling process after ARDS is quite variable. Typically, patients have nearly complete normalization of lung compliance and oxygenation 6 to 12 months after the illness, with a persistent slight impairment of the diffusing capacity. However, in a small percentage (5% to 10%) of patients the architecture of the lung does not fully return to normal and patients can experience chronic respiratory disability related to irreversible pulmonary fibrosis and obliteration of the pulmonary vasculature. The extent of recovery depends on the severity and duration of the initial trigger that led to ARDS and the influence of potential secondary forms of injury that may develop over the patient's complete hospital course. Secondary forms of lung injury include nosocomial infection, O_2 toxicity, and forms of **ventilator-induced lung injury** (VILI), which will be reviewed in detail in the following section.

KEY FEATURES

Risk Factors (Triggers) and Host Susceptibility

Whether using the AECC or the Berlin definition for ARDS, an essential component of ARDS is that the patient must have an associated illness that stimulates an acute inflammatory response that leads to lung injury. These acute illnesses are typically referred to as risk factors or triggers for ARDS. It has been proposed that the risk factors for ARDS should be categorized into problems that lead to either direct injury or indirect injury to the lung (see Box 29-3).[17] In this concept, direct injury occurs as the result of triggers that begin in the lung (e.g., pneumonia and aspiration) and create an acute inflammatory reaction within the lung that ultimately leads to the alveolar injury characteristic of ARDS. Conversely, indirect injury is caused by acute illnesses that trigger an acute inflammatory reaction that begins outside of the lung (e.g., pyelonephritis or massive hemorrhage) and spreads to the lung by the SIRS, thereby leading to the alveolar injury of ARDS. Some studies have suggested that the response of patients to treatment in ARDS may differ depending on whether the initial injury is direct versus indirect. However, thus far, this distinction has not proved to predict response to treatment or other important clinical outcomes.[26] This lack of distinction is most likely explained by the fact that all risk factors share the ability to initiate SIRS, which when severe enough, leads to ARDS.

It is important to recognize that only a minority of patients with risk factors for ARDS ultimately develop the full clinical syndrome. The key factors that determine which patients will develop ARDS are the severity and duration of the risk factor, and variables that lead some patients to be more susceptible. In all patients with ARDS, sepsis is the most common risk factor, but even among all patients with sepsis; fewer than 20% will develop ARDS. As the severity of sepsis increases to include severe sepsis and/or septic shock, the likelihood of ARDS developing increases dramatically and can exceed 50%. Among direct insults that lead to ARDS, pneumonia is the most common. Pneumonia caused by influenza infection is believed to carry an especially high risk for developing ARDS and a higher severity of ARDS once it develops.[27] Similarly, patients who are likely to have recurrent problems with a known risk factor, such as aspiration, are more likely to develop ARDS after multiple aspirations than after a single aspiration. Transfusion-related acute lung injury (TRALI), which occurs particularly after transfusions of platelets or plasma (less likely from packed red blood cells) from female donors, has become an increasingly recognized trigger for ARDS, but only carries a risk of less than 5%. The risk of TRALI increases with the number of transfusions.[28] Furthermore, patients can have more than one risk factor for ARDS, which also increases the risk for developing ARDS.[29] As for the susceptibility of the host to develop ARDS after any risk factor, important variables are increased age (i.e., age >50 years), prior liver disease, alcoholism, and genetic polymorphisms related to inflammatory mediators (e.g., IL-1, TNF, and surfactant).[30] Evidence suggests that cigarette smoking may also increase susceptibility to ARDS.[31]

Epidemiology and Outcomes

The exact incidence of ARDS (including ALI) varies depending on the population, but most recent estimates in the United

States suggest that each year there are 75 to 90 cases per population of 100,000, which represents almost 200,000 cases for the entire country.[32] ARDS may account for up to 16% of mechanically ventilated patients on admission to the ICU in big tertiary care centers.[33] Although there are more common conditions that require ICU care and mechanical ventilation, the high severity of illness associated with ARDS creates a substantial burden on providers and the health care system. Recent estimates indicate that ARDS patients in the ICU use over 2 million days in the ICU and almost 4 million days in the hospital, with total costs measured in billions of dollars. These burdens address the impact of the illness only on society and health care system. As for the impact on the individual patients with ARDS, the associated mortality and morbidity is even more substantial.

The early mortality rates associated with ARDS between the late 1960s and the early 1990s were very high, that is, 60% to 80%. Given our ability to maintain respiratory function in ARDS using mechanical ventilation, only a small minority (10% to 15%) of patients with ARDS die from respiratory failure. The most common cause of death in patients with ARDS relates to the original risk factor that triggered ARDS and from the MODS that develops in patients whose original risk factor is more severe or prolonged. Fortunately, the mortality rate over the past 20- to 25 years has declined dramatically, with most recent mortality rates typically reported between 20% to 40% and some experience as low as 20%.[34-36] The reasons for this improved survival is likely multifactorial and include advances in supportive care, early detection, effective management of comorbid diseases such as nosocomial infection, and the broad application of approaches to mechanical ventilation that limit VILI.

Beyond a risk for death, many important morbidities affect survivors of ARDS, including a long period on mechanical ventilation, time in the ICU and hospital, and slow recovery of lung function. Lessening these morbidities has increasingly become the primary target for recent, large ARDS clinical trials. In the early 1990s, patients with ARDS required an average of more than 21 days on mechanical ventilation, whereas more recent clinical trials have reported that most patients require mechanical ventilation for less than 10 days.[37] As the duration of the time spent on mechanical ventilation has declined, so has the number of days in the ICU and hospital. However, the recent increasing use of long-term acute care facilities has made these comparisons with early experience more complicated. Recovery of lung function as assessed by pulmonary function tests such as spirometry, diffusion capacity (DLCO), and 6 minute walk test (6MWT) demonstrates that ARDS survivors typically recover more than 80% of lung function over 3 to 12 months.[38] The rate of recovery depends on several variables, including ARDS severity, the original risk factor, patient age, and more. Recovery of vital capacity, expiratory volume, and total lung capacity typically occur earliest, whereas recovery of DLCO and 6MWT is more prolonged. This difference is likely explained by the slower pace of recovery for the vascular (capillary) component of the lung after ARDS.

In addition to outcomes primarily linked with lung function, morbidities are associated with the other aspects of ICU care that are needed in managing ARDS patients (e.g., sedation, delirium, and immobility) that have long-term impact on other organ function, such as muscle strength and cognition.[38] Using a variety of techniques to assess muscular and cognitive function, survivors of ARDS consistently demonstrate prolonged impairments in both for at least 6 to 12 months; however, in some patients the changes may never reverse. Consequently, increasing attention and urgency has been placed on identifying and using supportive care strategies to minimize these morbidities and accelerate recovery.

RULE OF THUMB

Although ARDS was once considered a diagnosis that carried a high likelihood for death (≥70%), current rates of survival in patients with ARDS are much higher, with far more than 50% surviving. As a result of our ability to provide mechanical ventilation that does not cause harm, very few patients with ARDS die from respiratory failure. Consequently, short-term periods of hypoxemia in patients with ARDS do not significantly increase the likelihood for death. Patients with more severe disease (more hypoxemia) that persists do have higher mortality rates. Most patients who die from mechanical ventilation die from the disease that triggered the ARDS. Accurate early diagnosis and treatment of the risk factor is a key factor to increase the patient's chance for survival. For the RT, this means that patients with severe hypoxemia may need to undergo diagnostic tests that require transportation to radiology (e.g., CT scans) or that might disrupt their ventilation (e.g., bronchoscopy). Until the triggering risk factor has been clearly established, these risks must generally be taken.

THERAPEUTIC APPROACH

Once the diagnosis of ARDS is made, one of the most important steps for managing and determining the outcome of patients with ARDS is to establish the triggering risk factor. Identifying and controlling the cause of ARDS is an important step to stop progression of the lung injury. After diagnosis, the care focuses on preventing further injury (lung and other organs) and supporting the body while it recovers. This section presents an overview of the current approach to supportive care (ventilator and overall), rescue interventions, and potential therapies for ARDS (Box 29-4). Furthermore, Table 29-2 provides a summary of the recommendations regarding specific interventions that are reviewed and that are currently considered and used by clinicians.

As previously mentioned, efforts to improve outcomes in ARDS up until and through much of the 1990s were largely unsuccessful.[16] A key factor contributing to the lack of success was the large variation in research and management approaches across investigators and institutions. The results of early efforts

Box 29-4 Key Points in the Care of Patients With Acute Respiratory Distress Syndrome

1. Diagnose ARDS (use screening and current Berlin definition):
   a. Diagnose the cause of ARDS
   b. Treat the cause of ARDS
2. Organ support: Key points in ARDS
   a. Minimize delirium
      i. Treat anxiety and pain
      ii. Promote patient awareness, ability to interact, and orientation
   b. Support lung function
      i. Maintain effective gas exchange
      ii. Balance the benefits of PEEP in oxygenation and recruitment with the increased intrathoracic pressure and its potential negative impact on hemodynamics
   c. Fluid balance
      i. Once patient has achieved hemodynamic stability, initiate protocolized conservative fluid management
      ii. Maintain perfusion pressures
3. Prevent further lung injury:
   a. Avoid barotrauma and volutrauma (to avoid further lung injury)
      i. Set V_T according to height
      ii. Keep tidal volume as low as possible, ideally 4 to 6 ml/kg ideal body weight
      iii. Keep plateau pressure below 30 cm H_2O
      iv. Tolerate hypercapnia
   b. Avoid O_2 toxicity (avoid biotrauma)
      i. Titrate FiO_2 and PEEP to a SpO_2 of 88% to 95%
   c. Avoid aspiration (to avoid pneumonia)
      ii. Keep head of bed elevated at 30 degrees
      iii. Subglottic suctioning
   d. Liberate from mechanical ventilation as soon as possible
      i. Daily assessment of spontaneous breathing
      ii. Minimize sedation (give sedation holidays), use a protocol for sedation
      iii. Encourage mobility and alertness

PEEP, positive end expiratory pressure.

were often conflicting, which made interpretation and application of study findings to patients very difficult. In response to this challenge, the National Institutes of Health launched a multicenter network of investigators and institutions to specifically collaborate on clinical treatment strategies for ARDS, a group that has since been known as the *ARDS Network* (ARDSNet).[39] Not by coincidence, the launch of ARDSNet was in 1994 at the same time that the AECC ARDS definition was created. Several landmark clinical trials by ARDSNet have demonstrated improvements in patient outcomes, including increased survival. The ARDSNet remains active, has been renamed the *Prevention and Early Treatment of Acute Lung Injury* (PETAL) Network, and is now expanding its focus to include ARDS prevention.[40] Similar networks of ARDS investigators have successfully formed outside the United States, including in Canada, France, Australia, and New Zealand, and have provided important contributions.

Mechanical Ventilation and Other Respiratory Supportive Care

Mechanical ventilation is the cornerstone of supportive care for patients with ARDS. In general, the three goals of mechanical ventilation are safety, comfort, and liberation from mechanical ventilation. Safety encompasses two main clinical objectives: ensuring gas exchange and preventing further lung injury caused by mechanical ventilation or ventilator-induced lung injury (VILI). Comfort focuses on ensuring synchrony with the ventilator and balancing the work of breathing distribution. Keeping in mind these goals and clinical objectives of ventilation, one can see that some are more important at different stages of ARDS. In the early exudative phase of ARDS, the main goal is to ensure gas exchange and prevent further lung injury. As the disease process resolves and the patient-ventilator interaction and awareness is more important, comfort and liberation become the main goals. This does not mean that each goal is

TABLE 29-2

Summary of Current Treatment Strategies in Acute Respiratory Distress Syndrome

Treatment	LEVEL OF RECOMMENDATION		
	Recommended	Not Recommended	Alternative/Rescue Therapy
Lung protective (low tidal volume—6 ml/kg ideal body weight) ventilation	X (all patients)		
Conservative fluid management	X (all patients)		
Prone positioning (with or without neuromuscular blockade)	X (P/F < 150)		
Inhaled vasodilators		X	
Beta-2 agonists		X	
Supplemental nutrition		X	
Corticosteroids			X
Surfactant replacement therapy		X	
Inverse-ratio ventilation		X	
Airway pressure release ventilation			X
High-frequency ventilation			X
Extracorporeal support			X

mutually exclusive, but it does help explain choices about which mode of ventilation to apply to a given patient at a given time.

Setting Tidal Volume

Although mechanical ventilation provides lifesaving support to patients with ARDS and other forms of acute respiratory failure, mechanical ventilation can be dangerous and can cause further lung injury, which is often referred to as ventilator-induced lung injury (VILI). Although there are multiple forms of VILI, the most important and well-established forms of VILI are volutrauma and barotrauma. **Barotrauma** is the rupture of alveolar structures that results in gross leak of air outside of the lung parenchyma into adjacent tissue spaces (e.g., pleura and mediastinum). Pneumothorax and pneumomediastinum are the common clinical manifestations of barotrauma, and although not certain, these complications are thought to be most closely related to excess airway pressures on mechanical ventilation. **Volutrauma** is similarly a form of injury to the alveolar structure but that does not lead to a macroscopic rupture of the wall with clinically recognizable leak of air, but instead leads to an overstretching and subsequent microscopic cellular injury to the alveolar and capillary walls, causing them to become leaky. This cellular injury then becomes the trigger for an inflammatory cascade that may cause further nonhydrostatic pulmonary edema. A critically important point for every RT is that the volutrauma related to mechanical ventilation must be included on the list of potential risk factors and triggers for ARDS. The strategy of using V_Ts that avoid volutrauma is commonly referred to as low tidal volume ventilation (LTVV) or **lung protective ventilation** (LPV).

The first highly successful trial completed by the ARDSNet in 2000 using LPV demonstrated a 22% reduction in mortality in patients with ARDS managed with a "low stretch" or low V_T approach. The study compared a strategy of low V_T (of 6 ml/kg ideal body weight [IBW]) versus a larger V_T of 12 ml/kg IBW. Until this trial, the standard of practice for mechanical ventilation for several decades had been to use a V_T of 12 to 15 ml/kg.[41] The results of this trial showing a significant survival benefit associated with low V_T transformed the standards for care of patients with ARDS and is considered one of the most important reasons for the dramatic improvements in mortality and morbidity associated with ARDS over the past 10 to 15 years. More recent trials of mechanical ventilation in patients without ARDS have suggested that VILI may happen in many more patients than just those with ARDS and that LPV may be a preferred approach for choosing a V_T in other clinical settings (e.g., chronic obstructive pulmonary disease [COPD], etc.). These trials include even patients requiring only brief exposures to mechanical ventilation during elective abdominal surgical procedures.[42]

To deliver LPV to patients effectively, two important points must be understood. First, the target of 6 ml/kg (range 4 to 7 ml/kg) is based on a patient's IBW not the actual weight. During growth and maturation of the lung parenchyma during childhood and early adult life, the length/height of the patient will be the variable that most determines the size and capacity of the lungs. Gender also plays a small role, with males having slightly larger lung capacity than females of similar height. Changes in weight associated with obesity, edema, or loss of an extremity from amputation do not affect the IBW. Also, surgical removal of a lung (pneumonectomy) or portion of a lung (lobectomy) should be considered, with a relative reduction in target V_T based on the percent of total lung that has been removed. There are many sources online and in print providing calculators or tables to assist bedside providers with a patient's IBW once the patient's height has been measured.

MINI CLINI

Tidal Volume

V_T in mechanical ventilation should be kept within a safe range to prevent volutrauma or VILI. The recommended size of V_T is 6 ml/kg of IBW (not actual body weight). IBW is determined by knowing a patient's gender, weight, and height, and tables with formulas for calculating IBW are readily available. It is important for the RT to accurately calculate each patient's IBW when starting mechanical ventilation and throughout the patient's course of mechanical ventilation.

For example, a 50-year-old male who is 6 feet and 0 inches tall and weighs 224 lb (100 kg) has an ideal body weight of only 70 to 75 kg. Using his IBW and the V_T target of 6 ml/kg, the ventilator should be set for a V_T of 420 to 450 ml. If his actual body weight were incorrectly used, a V_T of 600 ml would have been selected and would be too large and could lead to VILI and increased mortality. The RT should also consider whether the patient has any history of surgical lung resection. For example, if the same patient had undergone a left-sided pneumonectomy, leaving only the right lung for function, the selected V_T should be reduced by approximately 50% to 200 to 250 ml.

The second point is that the use of a lower V_T in LPV often will result in worsened gas exchange, with patients demonstrating worsening oxygenation and ventilation, including lower P/F ratios and higher levels of $PaCO_2$. These seemingly adverse effects of LPV on ABGs often create confusion and concern for families and care providers, including RTs. However, these changes are not associated with worse overall patient outcomes (e.g., as measured by mortality or time on mechanical ventilation). Quite the contrary, by keeping a V_T lower, the patient's outcomes will be dramatically improved.

Selecting the Mode of Mechanical Ventilation

For decades, the discussion of which mode of mechanical ventilation is best for ARDS has caused vigorous debate with many strong and divergent opinions. In practice, the clinician may use any mode of mechanical ventilation to deliver the recommended V_T. At this time, there is no definitive evidence that one mode is better than the other in delivering LPV. To simplify this issue, the mode of ventilation should principally serve the goals

of safety (i.e., ensuring and limiting the inhaled V_T) while also ensuring minute ventilation/gas exchange. More complete details outlining mechanical ventilation and the available associated modes are provided in Chapter 45.

The mode that most directly achieves the goal of controlling V_T is volume control, which includes continuous mandatory ventilation (also known as *volume control* or *assist/control*). In this traditional mode, which is still present on most ventilators, the clinician sets the V_T (6 ml/kg of IBW) and the ventilator delivers the target V_T on every breath, whether patient-initiated or not. However, there are several potential shortcomings to this mode, of which the most important are patient-ventilator dysynchrony, requiring heavier patient sedation, and double triggering, in which the patient's actual inspiratory time exceeds the set inspiratory time on the ventilator, thereby triggering a second mechanical breath during the same inspiratory cycle and causing delivery of a V_T twice the targeted size. In response to this limitation, many ventilator manufacturers have refined their volume control modes to use other targeting schemes. For example, on the Maquet Servo-I (Rastatt, Germany), volume control has a dual targeting scheme, which turns into a pressure-controlled breath when the patient initiates a sufficient inspiration. On the Drager Evita XL (Lubeck, Germany), when the autoflow feature is activated, volume control converts to a pressure control mode with an adaptive targeting scheme.[43,44]

In pressure control modes, the V_T depends on the set inspiratory pressure above PEEP, inspiratory time, patient effort, airway resistance, and lung compliance. In practice, this means that to consistently achieve the target V_T, the set inspiratory pressure and inspiratory time need to be adjusted manually or automatically by the ventilator. The same variation in patient respiratory effort that creates challenges for volume control modes also creates problems in these modes by limiting the ability to maintain targeted V_T and minute ventilation and less ability to prevent excessive V_T, which can lead to VILI. In response to this challenge, some newer ventilators include technologic features that may improve the ability to maintain LPV, including adaptive or intelligent targeting schemes[45] in which the inspiratory pressure is automatically adjusted to achieve a target V_T. Whether these technologic advances lead to advantages that provide improved clinical care for patients remains unproved currently.

In the volume control and pressure control modes, variation in patient effort is a challenge. This challenge can be addressed with sedation, analgesia, and/or neuromuscular blockade to blunt patient respiratory effort. However, the adverse effects of these pharmacologic interventions must be considered (discussed further later) and are increasingly recognized as affecting the long-term outcome of ARDS survivors.

Positive End Expiratory Pressure

The use of PEEP in patients with ARDS was first reported in 1967,[15] and by the mid-1970s, the effects of PEEP on lung compliance, oxygenation, and cardiac output (Figure 29-6) had been well characterized.[46] Of interest, since that time, even after much debate and research, there is no standardized method to set PEEP in ARDS.[47-49]

The rationale for using PEEP requires understanding the pressure-volume (P-V) curve of the lung. The P-V relationship can be established for a given patient by measuring lung volume during step increases in airway pressure. The classic P-V curve has an S, or sigmoid, shape (Figure 29-7). The initial limb has large changes in pressure for each step increase in volume, the middle limb has the "best" change in pressure per volume, and the final limb again has large pressure changes for each step increase in volume. From the resulting curve, we can obtain a

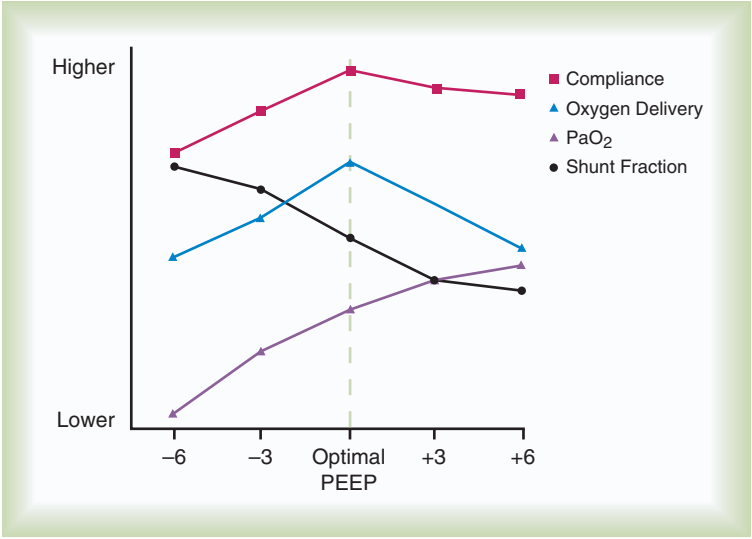

FIGURE 29-6 Determination of optimal PEEP from simultaneous measurements of hemodynamic (DO_2), gas exchange (shunt fraction and arterial oxygenation [PaO_2]), and physiologic values. Optimal PEEP does not correspond to PEEP associated with optimal pulmonary gas exchange. When adjusting PEEP, the clinician should consider its effects on systemic DO_2 and lung compliance such that systemic organ injury and lung injury are minimized.

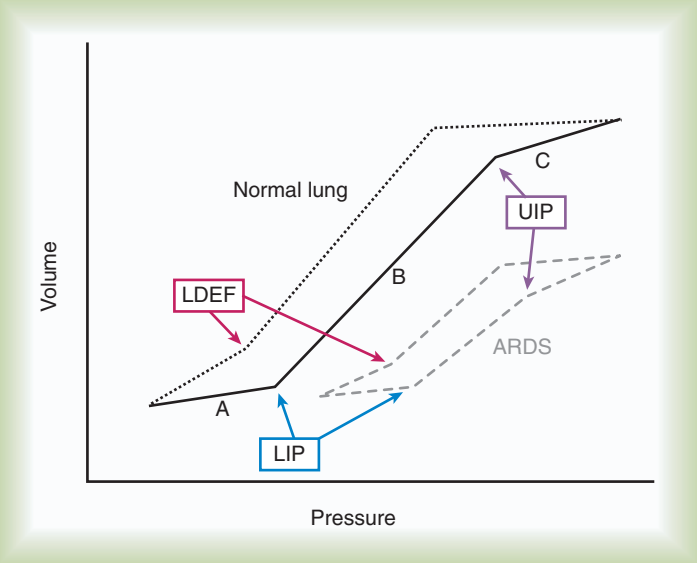

FIGURE 29-7 Typical pressure-volume relationships during normal conditions and during acute respiratory distress syndrome (ARDS). At low lung volume, inspiratory pressure increases faster than lung volume *(line A)* owing to high alveolar surface tension. As alveoli open, surface tension decreases, and the pressure required to increase lung volume further decreases *(line B)*. The lower inflection point *(LIP)* occurs between *lines A* and *B* and represents the volume above which most alveolar units are open. The upper inflection point *(UIP)* occurs at near-maximal lung volume and corresponds to the point at which further increases in pressure result in minimal increases in lung volume *(line C)*. Pressure applied above the *UIP* is associated with alveolar distention. During the expiratory phase of the respiratory cycle *(dotted line)*, the lower deflection point *(LDEF)* is the point below which lung volumes slowly decrease (alveolar units collapse). During ARDS *(gray dashed curve)*, pressure-volume relationships change such that higher pressure is needed to maintain alveolar patency, and alveolar distention occurs at lower V_T levels. Near-maximal lung volumes are typically achieved at an inspiratory pressure of approximately 35 cm H_2O in normal conditions and during *ARDS*. Attempts to increase inspiratory pressure to more than 35 cm H_2O provide little additional ventilation and substantially increase the risk for injury to the lungs. During *ARDS*, the *LIP* often occurs at a pressure of 5 to 15 cm H_2O. PEEP at levels greater than *LIP* may prevent end-expiratory alveolar collapse and reduce lung injury secondary to alveolar shear stress.

lower inflection point (LIP), which is where the initial and middle limbs meet, and an upper inflection point (UIP), which is where the middle and upper limbs meet. The LIP represents the point in the P-V curve at which recruitment (i.e., opening) of a significant number of alveolar units begins. The LIP is typically the same point below which the alveolar units will close (atelectasis) if no airway pressure is applied. The UIP represents the point beyond which alveolar units are generally unable to expand or distend further, so the pressure rises above the UIP. Imaging studies have shown evidence that recruitment and overdistention occurs throughout the P-V curve, which may be interpreted as showing that there is no absolute point at which safety can be guaranteed.[50] From the physiologic standpoint, PEEP increases the functional residual capacity (residual volume + expiratory reserve volume) and decreases the amount of unaerated lung (atelectasis), leading to improved gas exchange and lung compliance.

RULE OF THUMB

Changes in physiologic markers (oxygenation, compliance) take time after changing the level of PEEP. When decreasing PEEP, the changes in physiology becomes evident early, usually within 5 minutes. On the other hand, when increasing PEEP, the changes in physiology make take at least 60 minutes to become fully evident and may continue to change with time.[51]

During mechanical ventilation, the goal is to maintain the PEEP above the LIP to avoid repeated cycles of alveolar collapse and recruitment (also known as *cyclic recruitment* or *atelectrauma*) and keep the V_T below the UIP to avoid cyclic overdistention. Although creating P-V curves on patients receiving mechanical ventilation can be done so that the LIP and UIP can be actually quantified, measuring P-V curves is both technically challenging (requiring patient to be heavily sedated and off PEEP) and time-consuming. Because the actual LIP and UIP are not typically measured and available to the providers, titration of PEEP is typically performed using best estimates from the more commonly available pressure and volume data collected daily during mechanical ventilation. Thus identifying the level of PEEP that allows the patient to remain within the middle limb of the P-V curve during daily practice in the ICU can be challenging.

In ARDS, the challenge to estimate the P-V relationships to determine the "optimal" or "best" PEEP settings is even greater. The P-V curves are flatter and more deviated to the right (Figure 29-6), which creates a smaller window for the settings to maximize benefits while avoiding overdistention. Furthermore, these patients' need for PEEP during mechanical ventilation is typically greater, making them less tolerant to a formal assessment of the P-V curve (which requires a brief period with PEEP set to 0 cm H_2O). It must also be noted that in ARDS, the P-V relationships are highly dynamic and depend on the patient's overall condition. For example, administering or removing additional fluids can result in worsening or improvement that can require adjustment of PEEP to maintain the patient in the middle portion of the P-V curve. Finally, the use of PEEP is further complicated by the potential adverse hemodynamic effect of PEEP to decrease venous return to the right heart. Despite these challenges, careful titration of PEEP and maintaining low V_T are equally important components of LPV to prevent VILI.[52]

The search for a reliable method to accurately set PEEP in ARDS is ongoing. There are methods focused on oxygenation, others on lung compliance, and still others using CT imaging to determine best PEEP.[53] In a recent study, a comparison of methods based on lung mechanics versus using a table based on oxygenation (like the one used in the ARDSNet trials) favored the table approach.[53] Overall, trials assessing different

levels of PEEP in ARDS do not demonstrate a difference in mortality; however, higher levels of PEEP in more severe disease (P/F ratio <150) may lead to decreased mortality and less use of rescue strategies.[49,54] Taking all of this into account, it is reasonable to use a table to set the PEEP (see http://www.ARDSNet.org) and FiO_2 and in severe ARDS a higher PEEP may be better.

MINI CLINI

Avoiding Ventilator-Induced Lung Injury

PROBLEM: How can VILI be minimized in patients with ARDS through adjustments of PEEP and V_T?

DISCUSSION: Alveolar shear stress occurs when alveoli collapse during expiration and are reopened as the next V_T is delivered. Patients with ARDS are prone to developing this form of lung injury because surface tension increases as a result of impaired surfactant synthesis and function and decreased lung compliance. Alveolar collapse at end-expiration (the LIP of the P-V curve) can be avoided with PEEP, which reduces alveolar shear stress by preventing the cyclic opening and closing of the alveoli during each ventilatory cycle. Because partially patent alveoli require less pressure to inflate than collapsed alveoli, PEEP also improves lung compliance. Improved compliance is reflected by an increase in the slope of the P-V curve (see Figure 29-7).

The clinician can gauge the effects of PEEP on the basis of calculated changes in lung compliance (see Figure 29-6). In the clinical setting, changes in lung compliance are estimated from the compliance of the entire respiratory system, which includes the combined influences of lung compliance, chest wall compliance, and abdominal pressure:

$$\text{Compliance of the respiratory system} = \text{Tidal volume}/-(\text{Plateau pressure} - \text{Total PEEP})$$

As PEEP increases, risk also increases for alveolar overdistention and volutrauma. This is identified as a decrease of compliance as the PEEP increases. Just as alveolar collapse during end-expiration is associated with decreased lung compliance; alveolar overinflation during end-inspiration is reflected by decreasing compliance and corresponds to the UIP of the P-V curve (see Figure 29-7).

RULE OF THUMB

In most patients with ARDS, PEEP levels below 20 cm H_2O are generally preferred. Levels of PEEP greater than 20 cm H_2O should *not* be routinely used unless the benefits of higher levels of PEEP are supported by objective end points, such as improved lung compliance (see Figure 29-6) or optimal alveolar recruitment (see Figure 29-7).

Respiratory Rate and Inspiratory Time

ARDS is associated with alveolar consolidation and $\dot{V}/\dot{Q}$ mismatching, causing increased physiologic shunt and dead space ventilation. Also, critically ill patients typically have elevated rates of metabolism rates and CO_2 production, explaining why patients with ARDS require much higher minute ventilation to maintain $PaCO_2$ in the normal range. The challenge is that we use low V_Ts to prevent lung injury in ARDS, resulting in the need to increase the ventilator rate to achieve adequate $PaCO_2$ levels. In conventional practice and most large ARDS trials, the respiratory frequency is kept below 35 breaths/min. The concern with faster ventilator rates is that these faster rates will cause auto-PEEP and impaired perfusion.[55-57] Thus, in managing patients with ARDS, the clinician must resist the urge to correct the $PaCO_2$ value to normal. Instead, in the absence of a contraindication to hypercapnia (e.g., elevated intracranial pressure), we allow hypercapnia ("permissive hypercapnia") with a goal to maintain the arterial pH at no less than 7.15 to 7.20. Even when $PaCO_2$ rises to a point during which pH may become dangerously low (e.g., <pH 7.15), the absolute need to keep the V_T at 6 ml/kg IBW remains. In this circumstance, the pH can be corrected by other means, for example, either through normal physiologic retention of bicarbonate by the kidneys over time, pharmacologic supplementation (intravenous or oral) of bicarbonate, or, in rare instances, use of extracorporeal removal of CO_2.[58] Animal models and human studies have confirmed the safety of controlled hypoventilation or "permissive hypercapnia."[59]

In conventional modes of mechanical ventilation, the respiratory cycle is characterized by an **inspiratory-to-expiratory ratio** (I/E) exceeding 1:2 (i.e., the time for expiration is at least two times that of the time for inspiration). Patients with obstructive lung diseases (COPD and asthma), typically benefit from I/E rates with even longer expiratory times (i.e., I/E ratios of 1:3 to 1:4) to allow full lung emptying. However, in patients with ARDS, the impact of pulmonary and interstitial edema is to create a stiffer lung, which characteristically does not require as much time for exhalation. As a result, using I/E ratios of 1:1 are generally recommended in managing patients with ARDS. An I/E ratio of 1:1 can be achieved by using slower inspiratory flow rates, which also can help minimize airway pressures during inspiration (i.e., lower the peak inspiratory pressure). More extreme reductions in inspiratory time (i.e., I/E ratios = 1.5:1 to 2:1), a technique known as *inverse-ratio ventilation (IRV),* also have also been used in ARDS, but inverting the I/E ratio is generally not recommended and is considered an alternative ventilatory approach.

RULE OF THUMB

Administering high levels of supplemental O_2 can cause lung injury as a result of O_2 toxicity. O_2 toxicity is considered to be time-dependent and dose-dependent; that is, the longer the exposure and the higher the FiO_2, the worse the injury will be. The RT must continuously titrate the FiO_2 and PEEP to keep the target SpO_2 in the range of 88% to 95%.

Nonventilatory Supportive Care

Supportive care in the ICU, including patients with ARDS, focuses on maintaining function of key organs and minimizing the complications associated with critical illnesses and spending several days in an ICU. These points of management do not directly treat the primary risk factor that triggered ARDS, but are nonetheless critically important to optimize patient outcomes both during and after their time in the ICU. Supportive care measures apply to many (if not most) patients on mechanical ventilation in the ICU and can be very general (e.g., prophylaxis against deep vein thrombosis, gastric acid suppression, and prevention of nosocomial infections), but many first have been tested and most are well proved for patients with ARDS (e.g., LPV). Ventilatory support of the lungs with mechanical ventilation is a key component, but it is not the only supportive measure that has benefit on lung function (e.g., conservative fluid management). This section will briefly review a few key aspects of supportive care related to both the lungs and other key organs.

Conservative Fluid Management. In managing the critically ill patient, blood pressure, cardiac output, and oxygenation must be preserved to ensure perfusion of vital organs (e.g., kidney, brain). Fluids are given both intravenously and orally to critically ill patients to preserve perfusion and hydration. The amount of fluids taken in by critically ill patients invariably exceeds the amount of fluids that the patient loses, and patients often gain approximately 1 L of fluid per day. Such fluid retention was widely accepted in ARDS management until the ARDSNet Fluids and Catheters Treatment Trial (FACTT), which was completed in 2006 and changed the approach to fluid management in ARDS. In this study, a new, protocol-driven **conservative fluid management** strategy was compared to a so-called *liberal strategy* that was typical of standard practice before the beginning of the study. The two strategies (conservative vs. liberal) were applied for the first 7 days of ARDS treatment in patients who were no longer in shock. The key finding of the FACTT study was that a conservative strategy led to improved gas exchange (oxygenation), shorter duration of mechanical ventilation and ICU length of stay for survivors, and no increased frequency of other organ failures, including renal failure.[60]

In practice, once patients with ARDS are hemodynamically stable (i.e., not needing fluid boluses or vasopressors to maintain blood pressure for at least 12 hours), a conservative fluid management should begin. This approach includes reducing all unnecessary maintenance fluids and aggressively giving diuretics to reduce total body fluid, while closely monitoring for negative effects of diuresis on tissue perfusion and responding promptly to electrolyte changes caused by diuretics (e.g., hypokalemia, hypernatremia, and alkalosis). Using a conservative fluid approach, the total amount of nonhydrostatic pulmonary edema can be more actively and promptly reduced than with a liberal approach, in which normal alveolar processes are expected to slowly clear alveolar flooding. At the bedside, a common clue that diuresis may be appropriate is the presence of significant edema in the patient's face, hands and feet and/or persistent evidence of pulmonary edema and pleural effusions on the chest radiograph.

MINI CLINI

Managing Hydrostatic Pressure in Patients With Acute Respiratory Distress Syndrome

PROBLEM: Critically ill patients requiring mechanical ventilation for acute respiratory failure often receive large volumes of fluid in the form of intravenous medications, maintenance fluids, and nutrition (enteral or parenteral). Excessive or nonessential fluid administration should be avoided in patients with ARDS because they have "leaky capillaries" and are remarkably sensitive to changes in pulmonary vascular hydrostatic pressure. How can iatrogenic pulmonary edema be avoided in these patients so they can be liberated from mechanical ventilator sooner?

DISCUSSION: Noninvasive estimates of total body water, such as daily weights and total fluid intake and output measurements, are helpful tools but often are not accurate. The inaccuracy of noninvasive estimates of total body fluid content are tolerable as long as the patient's overall clinical status is improving and the patient is hemodynamically stable (i.e., with acceptable blood pressure and tissue perfusion). The use of a protocol to guide fluid management leads to faster liberation of mechanical ventilation. In the conservative fluid management strategy used in the FACTT trial,[60] the approach combined clinical and invasive monitoring to guide fluid therapy. While patients are in shock (requiring fluid boluses and/or vasopressors to maintain a mean arterial pressure ≥60 mm Hg), fluid conservative management is not attempted. Once patients are no longer in shock for 12 hours (a much shorter timeframe than previously considered safe), the protocol uses clinical signs of effective circulation (capillary refill), urine output, and central venous pressure (CVP) measured by a central venous catheter to determine when diuretics should be given. These parameters are reassessed every 4 hours, and diuretic therapy is given when patients meet the appropriate criteria. The target level for CVP was less than 4 mm Hg, which is the range for CVP under normal conditions. The use of the conservative fluid protocol (compared to liberal or usual fluid management) caused patients to have significantly reduced fluid accumulation during their ICU course and to be liberated from mechanical ventilation an average of 2 or 3 days sooner.

Sedation and Analgesia

Over the past 10 to 15 years, the approach to managing sedation and analgesia in critically ill patients has changed dramatically. Protocolized sedation and scheduled daily interruptions of sedation (awakenings) lead to shorter times on mechanical ventilation and decreased length of ICU stay.[61,62] Furthermore, evidence from survivors of ARDS has demonstrated that many experience persistent problems with memory and cognition and that these changes relate to the types of sedation that

patients receive during their care in the ICU. In particular, using benzodiazepines (e.g., lorazepam or midazolam) seems to carry the greatest risk for these adverse neurocognitive effects. One of the earliest neurocognitive warning signs in the ICU is the development of ICU-associated *delirium*, which can be caused by several common environmental challenges in the ICU, including lack of sleep, noise, use of restraints, and immobility. The use of benzodiazepines also has been strongly linked to the development and progression of delirium in the ICU.

Given these concerns related to the acute and long-term adverse effects of ICU sedation, current strategies for sedation aim to minimize the exposure to all sedatives, in particular benzodiazepines.[63] Preferred agents to treat patient agitation (including ventilator dyssynchrony) are analgesic (e.g., narcotics) and antipsychotic drugs, which are more likely to directly address delirium. This recent emphasis on reducing the level of sedation for patients on mechanical ventilation poses a challenge for the RT, who along with the nursing staff, must manage patients who are more awake and who breathe spontaneously while receiving lung protective ventilation. We can no longer assume that a heavy sedation to optimize a patient's synchrony with mechanical ventilation is the best and safest approach for the patient. An approach that balances the short-term risks of mechanical ventilation with the longer term risks of sedation is recommended, and the goals of care should be discussed daily among all caregivers to ensure success.

Nutrition

Malnutrition in the ICU leads to poor outcomes, but so does overfeeding. Further, the type of alimentation may affect how the body reacts to disease. Although the literature on nutritional management of patients with ARDS is rather scant, two recent studies deserve comment. The ARDSNet EDEN trial studied whether using trophic feeds (a small amount of enteral nutrition just to keep the gut working) was better than full enteral nutrition for the first 6 days of care of patients with ARDS. The results of the study showed no benefit for the full nutritional approach either during the ICU stay or 1 year later.[64]

Although an early small trial suggested benefit from supplementing nutrition with omega-3 fatty acids, another recent ARDSNet trial, the OMEGA trial,[65] in which omega-3 fatty acids, along with γ-linolenic acid and antioxidants (given to help modulate the inflammatory response in ARDS), were compared to placebo. Again, no differences were observed between the treatment and placebo groups. A recent meta-analysis of seven trials examining omega-3 fatty acids also found no effect from nutritional supplements in patients with ARDS.[66] Currently, there is no specific recommendation regarding nutrition in patients with ARDS. Guidelines recommend the same nutritional management as for any critically ill patient.

Mobility

It has long been recognized that the prolonged period patients spend lying in bed on mechanical ventilation has an adverse effect on the mass and function of muscles for patients in the ICU, including those with ARDS.[67,68] As mentioned previously, profound weakness is a commonly reported symptom in ARDS survivors, and can persist for 6 to 12 months or more. This adverse consequence of ICU care is related to both drugs (e.g., steroids, neuromuscular blocking paralytic agents) and just the simple lack of mobility (immobility). Mobilizing a small, select group of patients receiving mechanical ventilation in ICUs has been done for decades, but this has been typically limited to patients after tracheostomy, after several weeks of immobility. Over the past decade, numerous clinical trials from the United States and Europe have demonstrated that early mobilization of patients on mechanical ventilation, including ARDS patients with severe hypoxemia, is both highly beneficial and safe. In these studies, early mobilization typically refers to allowing capable patients to sit on the side of the bed, stand, and/or walk within 48 to 72 hours of ARDS onset, even while they are still endotracheally intubated. The benefits of early mobility include reducing the length of time ARDS survivors spend in the ICU and hospital and accelerating the recovery and return to their baseline functional status after hospital discharge, including return to work. This important element of supportive care has not yet become the standard of care in many ICUs because of apprehension by caregivers (physicians, nurses, and RTs) about the safety of mobilizing critically ill patients. Also, the costs associated with increased commitment of physical therapists and RTs to the ICU have often been considered prohibitive. However, when all costs of patient care (ICU, hospital, and posthospital discharge) are considered, the cost of mobilizing patients is no higher or is actually reduced.[69]

Adjunctive Strategies to Improve Lung Function

Prone Positioning

In view of the heterogeneous distribution of lung injury in patients with ARDS, it has been proposed that changing the position of the patient could result in improved $\dot{V}/\dot{Q}$ matching within the lungs. In this regard, it is known that alveolar consolidation in ARDS tends to be most pronounced in the dependent lung zones (posterior regions when patient is lying supine), where blood flow is greatest.[70] These observations led investigators to experiment with positioning the patient so that aerated lung fields (nondependent lung zones) become dependent by positioning of the patient in the prone position (i.e., placing chest and face down). So-called *proning* the patient recalls the old adage to "put the good lung down."

The mechanisms by which **prone positioning** improves oxygenation is the subject of debate. Some proposed mechanisms include improved matching of ventilation with perfusion, increased functional residual capacity, increased cardiac output, more effective drainage of upper and lower airway secretions, and improved diaphragmatic excursion. Investigations using animal models of ARDS have shown that ventilation in the supine position causes compressive forces on the dorsal airspaces, resulting in derecruitment of lung units. This phenomenon is reversed by ventilation in the prone position.[71,72]

In 1977, Douglas and colleagues[73] were the first to describe improved oxygenation with prone positioning of patients with

ARDS. However, because of concerns over the logistics and safety of proning patients, prone ventilation strategy remained unpopular. This concern prevailed even in the face of studies that had demonstrated a beneficial effect of prone ventilation.[74] Recently, a large multicenter, randomized clinical trial demonstrated that using prone positioning for more than 16 hours per day improved survival when started within the first 36 hours of onset of mechanical ventilation[75] for patients with moderate to severe hypoxemia (P/F ratio <150 mm Hg). These new studies have again demonstrated the advantages of prone ventilation, including improved oxygenation and improved long-term survival over supine ventilation without the need for expensive pharmacologic interventions or new ventilator modalities. Despite these advantages, prone positioning of patients with ARDS requires an experienced and committed staff (nursing and RT) and may require special equipment to facilitate turning, especially for obese patients. Some patients may not tolerate prone ventilation or may have a relative contraindication to proning, such as open surgical wounds or late trimester pregnancy. However, as more centers gain comfort with the logistics of rotating patients, prone position ventilation has emerged as one of the first-line adjunctive therapies available to assist in oxygenating the patient with severe ARDS and is considered by many to now be the standard of care for patients with sustained severe ARDS (P/F ratio <150 for more than 12 to 24 hours on stable ventilator settings).

Neuromuscular Blockade

Neuromuscular blocking paralytic agents have been used for decades to enhance compliance with mechanical ventilation in patients with ARDS, especially when the ventilatory mode has involved low-volume ventilation or inverse-ratio ventilation. Furthermore, with severe dyspnea and/or ventilator dyssynchrony, a substantial portion of the patient's arterial O_2 content can be consumed by accessory respiratory muscles. Therefore, in patients who continue to remain hypoxemic despite maximal ventilator settings and adequate sedation, a trial of neuromuscular blockade is usually warranted.

Although earlier studies showed improved oxygenation with neuromuscular blockade for the first 48 hours, they did not address whether neuromuscular blockade conferred any survival advantage. A multicenter randomized trial considered 90-day in-hospital mortality as the outcome measure after treatment with a bolus of the paralytic drug cisatracurium followed by a 48-hour infusion. The cisatracurium group showed improved adjusted 90-day survival, more days off the ventilator, and a lower incidence of barotrauma complications. In a post hoc analysis of the study, the benefit of neuromuscular blockade was most evident in patients with more severe disease as defined by a P/F ratio less than 120. Although problems with muscle weakness related to neuromuscular blocker use were thought to be more likely in the intervention group, no such effect was seen, perhaps related to the short duration of paralysis in the study.[76] Despite the promising nature of these results, many clinicians remain concerned about the adverse neuromuscular effects of neuromuscular blockers in ARDS, particularly in patients with only mild to moderate ARDS who are oxygenating adequately on conventional ventilation.

Inhaled Vasodilators

The potential role of inhaled vasodilators in ARDS is based on the idea that vasodilators that enter via the airways (as compared to intravenously) are preferentially distributed to well-ventilated portions of the lung, where the vasodilator can cause local vasodilation. In this way, well-ventilated areas of the lung receive a greater portion of the total pulmonary blood flow, which results in improved oxygenation by reducing $\dot{V}/\dot{Q}$ mismatch (Figure 29-8).

Nitric oxide (NO) and prostacyclin are naturally occurring potent vasodilators that play a critical role regulating blood flow within the normal lungs. NO is soluble in liquids and gases and diffuses readily through various tissues. When NO diffuses from the alveolus into the capillary, it is bound by hemoglobin. As a result, the vasodilatory effects of NO are short-lived (few minutes) and are localized to the area of tissue where the NO is released.

Prostacylin is a prostaglandin byproduct of arachadonic acid metabolism and several analogues have been pharmacologically developed (e.g., epoprostenol [Flolan]) and revolutionized the treatment of pulmonary hypertension over the past 20 years.[77] Although not gaseous, epoprostenol and other prostacyclin analogues can be nebulized and provide a similar effect as inhaled NO.

When given clinically, the beneficial effects of NO can be achieved at low concentrations of inhaled NO (5 to 10 ppm) and are typically not improved with higher doses. Because of its profound effects on pulmonary hemodynamics, discontinuing inhaled NO or other pulmonary vasodilators may be associated with severe rebound pulmonary vasoconstriction and

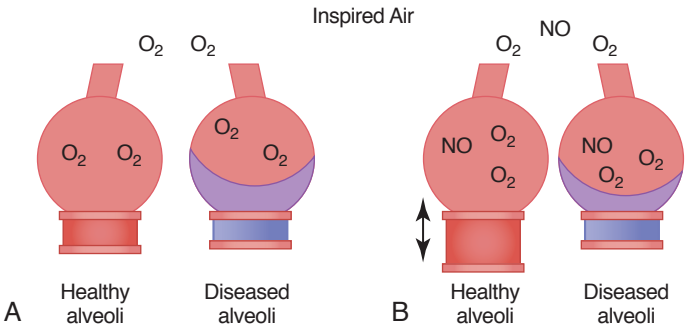

FIGURE 29-8 The damage of acute lung injury and acute respiratory distress syndrome is heterogeneous. **A,** Despite autoregulatory changes that favor vasodilation of well-oxygenated alveoli, perfusion goes to both the healthy, unaffected alveoli and the diseased alveoli that are unable to oxygenate blood. This results in $\dot{V}/\dot{Q}$ mismatch or a shuntlike state resulting in deoxygenated blood returning from the lung and hypoxemia. **B,** The addition of inhaled NO to the inspired gas results in vasodilation of the capillaries adjacent to healthy alveoli promoting increased blood flow to the "good" alveoli and diminishing the percentage of blood going to diseased alveoli, resulting in improved $\dot{V}/\dot{Q}$ match and improved oxygenation.

hypoxemia. A large multicenter randomized trial involving more than 300 patients reported that NO at a dose of 5 ppm provided a short-term benefit in oxygenation, but was ineffective in altering mortality or duration of ventilator support.[78] No large clinical trials of nebulized prostacyclin analogues have been completed in ARDS, but the current consensus is that the results of those trials would likely resemble those for inhaled NO.

Beyond the lack of proved outcome benefit for pulmonary vasodilators, other adverse consequences that should be considered include potential toxicities and cost. There are breakdown products of NO that are potentially toxic, including reactive free radicals (e.g., peroxynitrite and methemoglobin). As a result, use of inhaled NO during mechanical ventilation must involve close monitoring and special exhaust systems to prevent exposure of health care personnel. The cost of NO and its patented delivery system (INOmax, Ikaria, Perryville, IL) is substantial, causing many institutions to limit its use until new evidence supporting a more significant improvement in patient outcomes is available. Nebulized epoprostenol serves as a less expensive alternative to NO at many centers.[79]

The apparent discrepancy in the effects of inhaled vasodilators—with improvements on oxygenation without a favorable effect on survival or time on mechanical ventilation—further emphasizes that enhancing oxygenation alone is insufficient to establish the efficacy of a treatment.[78,80] In the case of pulmonary vasodilators, oxygenation has improved but the patient's overall chances for survival and time on mechanical ventilation have not changed while being exposed to potential risks and unnecessary costs. Given these limitations and adverse consequences, use of inhaled vasodilators should be limited to patients with refractory, severe ARDS (P/F < 80) to prevent the need for and/or use as a bridge to more invasive adjunctive therapies (e.g., extracorporeal support). If inhaled vasodilators are started, clinicians should reassess the need for continuing their use within 24 hours of starting, and daily thereafter.

MINI CLINI

In the management of a patient with ARDS, oxygenation (PaO_2 or SpO_2) is a readily available measure that often attracts the attention of bedside providers. In an attempt to improve oxygenation, providers are often faced with decisions as to whether they should increase V_T or PEEP, change ventilator mode, or use additional therapies such as pulmonary vasodilators (e.g., inhaled NO). In all instances, the severity of the patient's hypoxemia is typically not closely linked with likelihood of survival, so that these changes or additions are not likely to positively affect the patient. Increasing V_T or PEEP can have very harmful effects by increasing VILI, and inhaled vasodilators add to the cost and complexity of the patient's care. These maneuvers should be reserved for patients with persistent and severe hypoxemia and should not be pursued without close consultation with the patient's intensivist.

Corticosteroids

Although most patients who survive ARDS have minimal residual pulmonary impairment, a small but significant number of patients require prolonged mechanical ventilatory support because of abundant fibroproliferation in the lung during recovery from ARDS. The high mortality rate among these patients seems to relate to the extent and severity of pulmonary fibrosis.[81] High-dose corticosteroids have been used to manage uncomplicated pulmonary fibrosis following ARDS. In small studies from single institutions,[82] patients treated with corticosteroids for ARDS-related pulmonary fibrosis have demonstrated improved gas exchange and low mortality (24%). In a larger, multicenter ARDSNet trial, corticosteroids were used for patients with late fibroproliferative ARDS (>7 days' duration) and did not demonstrate a survival benefit.[83] Importantly, patients given steroids after 14 days from ARDS onset experienced a higher mortality rate than control patients. Currently, the routine use of corticosteroids for the treatment of established ARDS cannot be recommended and should be avoided after 14 days from ARDS onset.[84]

Use of steroids in the earliest stages of ARDS has been evaluated, but they have not yet proved to provide a significant outcome benefit. It should be noted that many patients who meet the syndrome definition of ARDS can have other pulmonary disease processes that mimic ARDS (e.g., alveolar hemorrhage, interstitial lung disease, organizing pneumonia). Many of these conditions can respond to steroid therapy. In patients in whom the triggering risk factor cannot be easily identified and/or the course of illness is atypical or prolonged, clinicians often will consider these conditions and perform an open lung biopsy before starting steroid therapy. Potential adverse consequences of high-dose steroid therapy are numerous, including hyperglycemia, altered mental status, and muscular weakness. Thus routine use of systemic steroids in patients with ARDS is not advised at this time.

Beta-2 Agonists

In addition to their effects as bronchodilators, high doses of beta-2 agonists (e.g., albuterol, salbutamol) have been shown to accelerate clearance of alveolar edema by the epithelium of the alveolar wall.[85] Although beta-2 agonists are often used in patients with ARDS, their therapeutic benefits were not formally studied in ARDS until recently. Two recently completed trials in both the United States (ARDSNet) and Europe did not demonstrate a clinically significant benefit in patients with ARDS when using either aerosolized albuterol or intravenous salbutamol.[86,87] Demonstrated effects of beta-2 agonists have included reduced lung water using a surrogate measurement and improved lung function (lower plateau pressures), but no change in oxygenation (i.e., P/F ratio) has been observed.[86] In the ARDSNet trial, which is the largest to date, the trial was terminated early because of potential concern for increased mortality in the patients receiving beta-2 agonists, although the difference did not achieve statistical significance.[87] At this time, beta-2 agonist therapy cannot be recommended for use in ARDS.

Exogenous Surfactant Administration

Surfactant dysfunction and deficiency is a well-established component of RDS in premature infants as well as in children and adults with ARDS. Surfactant abnormalities contribute to the development of ARDS by promoting instability of the alveolar units (airway shear trauma, atelectasis, and right-to-left shunt) and by allowing inflammatory injury to alveoli to continue unchecked. Delivery of exogenous surfactants via direct intratracheal administration has become a cornerstone of therapy in RDS since the early 1990s.[88,89] Multiple surfactant preparations are commercially available, including natural surfactants (harvested from lungs of animals used in the meat industry) and synthetic surfactants, which are created artificially.[90]

Unfortunately, the pathogenesis of surfactant deficiency in the ARDS of children and adults is more challenging. The depletion of surfactant in premature newborns is related to the lack of lung maturation and surfactant production. In contrast, the surfactant depletion of ARDS is caused by inflammation of the alveolus and subsequent degradation of the endogenous surfactant (i.e., that normally produced by the patient's lungs). Numerous clinical trials have demonstrated improvement in oxygenation with intratracheal surfactant administration, including both natural and synthetic preparations.[91,92] However, the improvements in gas exchange have typically proven to be short-lived (24 to 72 hours) and have not demonstrated significant impact on clinical outcomes such as mortality or duration of mechanical ventilation in survivors.[34,93] These negative results in ARDS (in contrast to clear benefit in neonatal RDS) are thought to largely be explained by the degradation of the exogenously administered surfactant via the same inflammatory mechanisms that depleted the patient's native surfactant. Future studies of surfactant therapy are likely to include a combined approach that includes specific (e.g., monoclonal antibodies) or nonspecific (e.g., steroids) antiinflammatory agents. Despite the strong scientific rationale that surfactant replacement therapy may still prove beneficial for ARDS in the future, its cost is substantial and it is not considered a part of current ARDS management.

Alternative and Rescue Ventilation Strategies

In addition to the LPV approach of mechanical ventilation in ARDS (discussed previously), other ventilatory strategies are available and may prove beneficial in selected patients, but are less well-studied. These alternative approaches should be considered for patients who have failed LPV and the other components of "routine care." As such, these therapies are often considered primarily in patients with refractory severe ARDS and are often referred to as "rescue" or "salvage" therapies. In research trials and at some medical centers, the threshold for using such rescue approaches is defined by markers of unsafe ventilation, such as high plateau pressures (i.e., >30 cm H_2O) or high O_2 requirements (e.g., FiO_2 > 60%). Because the level of evidence regarding these alternative modes of ventilation is lower, variation in practice is greater and the choice of which ventilator strategy to use depends on the patient's clinical condition, the hospital's expertise (especially among intensivists, RTs, and nurses), and the availability of the necessary equipment.

Inverse-Ratio Ventilation

Inverse-ratio ventilation (IRV) is a form of pressure control (most often) or volume control ventilation with either a continuous mandatory or intermittent mandatory breath scheme. In conventional modes of mechanical ventilation, the respiratory cycle is characterized by I/E ratios exceeding 1:2; that is, the amount of time in the respiratory cycle in which expiration occurs is at least twice as long as the time for inspiration. During IRV, the inspiratory time on the ventilator is prolonged so that the I/E ratio is reversed (i.e., inspiratory time now exceeds expiratory time) and the I/E ratio characteristically ranges between 2:1 and 4:1. The clinical goal of IRV is to elevate the mean airway pressure to recruit alveolar units through prolongation of the inspiratory phase, hopefully improving oxygenation. The increase in mean airway pressure primarily results from incomplete lung emptying during a shortened exhalation time, causing air trapping and the development of additional PEEP, referred to as either *auto-PEEP* or *intrinsic PEEP*. Initial reports using IRV suggested significant improvement in oxygenation in patients with ARDS,[94] but subsequent studies that controlled for the level of PEEP did not demonstrate an advantage.[95] The IRV approach can lead to increased patient discomfort and ventilator dysynchrony, which often requires more sedation or even paralysis. As a result, use of IRV has declined significantly in recent years.

Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) was described by Stock and colleagues[96] in 1987 as a mode to allow unrestricted spontaneous breathing (e.g., IMV) in the setting of lung injury. The mode is a form of pressure control intermittent mandatory ventilation with IRV (the I/E ratio may exceed 4:1). The clinical aim of APRV is to increase the mean airway pressure to allow recruitment of alveoli while allowing the patient to spontaneously breathe. Ventilator manufacturers vary in how they implement APRV, but this mode generally features two levels of PEEP: a high PEEP (also named P_{high}), often set to approximately 25 to 30 cm H_2O, and a low PEEP (also known as P_{low}) that is usually set to zero. In APRV, patients can spontaneously breathe, which should make APRV more comfortable than traditional IRV. After a period at the high PEEP level, there are brief, approximately 0.5-second, decreases in airway pressure to the low PEEP level, allowing volume release and generating a mandatory V_T. Owing to the prolonged inspiratory times, APRV is associated with an increase in mean airway pressure and intrinsic PEEP. Indeed the literature demonstrates increases in oxygenation when APRV is used; however, the clinician is cautioned in using APRV because of technical issues with its application (e.g., no protocol has been tested and proved) and because there is a risk for injuriously large V_T and transpulmonary pressures.[97] Regarding the use of APRV as a routine mode

for management of ARDS, the evidence so far is not conclusive, with no large randomized control trial comparing APRV to conventional ventilation.[98] However, some centers use APRV routinely.[99] In terms of using APRV as a rescue therapy, there is scant literature; the H1NI influenza pandemic generated as few case reports.[100] Taken together, we suggest that APRV remains as an alternative to manage patients with severe hypoxemia when conventional ventilation has failed and the clinician must exercise caution based on the concerns mentioned previously.

High-Frequency Ventilation

High-frequency ventilation (HFV) was initially devised as a method to minimize the hemodynamic effects of conventional mechanical ventilation (i.e., the large inflating pressures and volumes).[101] It soon became evident that HFV had theoretical advantages for managing ARDS. HFV is different from any of the conventional modes of ventilation because it uses a rapidly moving piston to create movement of air through a circuit. The device allows setting a mean airway pressure over which oscillations happen. V_Ts generated by HFV are very small (i.e., characteristically smaller than the patient's dead space), and higher mean airway pressures are provided to maintain alveolar patency, thereby theoretically preventing VILI. HFV has been successfully used in ventilating neonates with RDS and has been used both as routine therapy and rescue therapy.[102,103] Use of HFV in ARDS has been the subject of considerable debate as available trials have shown widely differing results.

To date, four randomized control trials have assessed the use of HFV versus conventional ventilation for the routine care of patients with severe ARDS. The first two of these trials[104,105] were conducted before later studies proved the benefits of using lower V_Ts in ARDS; both of these studies showed that using HFV was feasible and could support gas exchange without hemodynamic compromise.[106] Until the H1N1 influenza pandemic of 2009, few centers in the world used HFV routinely because no protocol had been proved, few devices were available (i.e., only a single device was available in the United States), and their use required specific training. With the H1N1 influenza outbreak in 2009 and the frequent development of ARDS among affected patients, a resurgence of interest in HFV occurred. After this renewed interest, two additional trials—OSCILLATE[107] (which assessed the efficacy of HFV; i.e., under conditions of ideal use, can HFV provide benefit?) and OSCAR[108] (testing effectiveness; i.e., how does HFV work under conditions of usual care?)—evaluated the routine use of HFV versus conventional lung protective ventilation in managing patients with early ARDS.—The OSCILLATE trial showed an increased mortality rate in patients treated with HFV and had to be stopped early.[107] In contrast, the OSCAR trial showed no difference between HFV and conventional modes of mechanical ventilation in treating ARDS.[108] At the current time, we do not recommend HFV in routine ARDS management, and, when being considered, its use should be reserved to referral centers with established experience.

Regarding the use of HFV as a rescue strategy for patients with severe hypoxemia from ARDS, there is less definitive information but a larger clinical experience. Anecdotal evidence, as well as published case series, suggests that HFV can have a role as a rescue strategy.[109,110] For example, in the CESAR trial[111] using HFV as part of a protocol prevented the need for extracorporeal membrane oxygenation in patients with severe ARDS. Thus, in some centers, **high-frequency oscillatory ventilation** is used as a rescue therapy for patients with severe ARDS.[112] The RT must remember that patients on HFV will be exposed to high mean airway pressures and also to high levels of PEEP, which may reduce cardiac output and overall O_2 delivery despite elevated arterial oxygenation.

Extracorporeal Support

Extracorporeal membrane oxygenation (ECMO) was first introduced in 1972 as a form of respiratory support for patients with severe AHRF. ECMO involves establishing a circuit for diverting a large proportion of the cardiac output through an artificial gas-exchange device, or "artificial lung," to facilitate the exchange of CO_2 and O_2. There are two types of ECMO, which differ according to which vessels are cannulated for the circuit: venoarterial and venovenous ECMO. In the case of a venoarterial circuit, both gas exchange and hemodynamic support can be offered through the ECMO circuit. However, venoarterial ECMO carries the risk associated with having a large indwelling arterial catheter in the patient (e.g., clots, bleeding, accidental withdrawal of the catheter). For pure respiratory failure, a venovenous circuit allows for gas exchange without hemodynamic support and can now be offered through a single venous cannula with fewer potential risks than venoarterial ECMO.

After an initial flurry of interest during the 1970s, a clinical trial comparing ECMO to conventional mechanical ventilation in ARDS showed no survival benefit with ECMO and enthusiasm subsided.[113] However, with continued improvements in equipment and delivery methods along with anecdotal cases with favorable results, more recent studies have been performed and suggest improved outcomes including survival[114] and less severe disability at 6 months.[111] These promising results and the experience gained during the 2009 H1N1 influenza pandemic led many institutions to use ECMO as rescue therapy for patients with ARDS who cannot be managed with conventional ventilatory modes.[114] The role of ECMO in the routine management in ARDS remains an area of intense debate and conflicting opinions. Overall, we consider ECMO to be a reasonable alternative to conventional ventilation strategies when the ARDS patient experiences refractory hypoxemia despite conventional management.[115] Unfortunately, this debate may never be fully resolved, because a rigorous randomized trial for patients with severe disease will require that the control group not be offered the therapy, which many clinicians and families are unwilling to support.

Similar to ECMO, **extracorporeal carbon dioxide removal** ($ECCO_2R$) entails the use of artificial membranes to supplement the gas-exchange deficiencies of damaged lungs. $ECCO_2R$ has a venovenous circuit that diverts a fraction of the cardiac output (approximately 20%) through a membrane lung. $ECCO_2R$ is primarily designed to remove CO_2 and does not

directly influence oxygenation though oxygenation is indirectly facilitated through the removal of CO_2, which would otherwise compete with O_2 exchange within the alveoli. By this mechanism, $ECCO_2R$ allows the clinician to maintain the same level of oxygenation at lower ventilatory rates and reduce the risk for lung injury related to mechanical ventilation. A small clinical trial (with 40 adults) compared $ECCO_2R$ with conventional mechanical ventilation and found improved gas exchange, lower peak airway pressure, lower ventilatory rates, and reduced thoracic volumes (i.e., less overinflation of the lungs).[116] However, there was no survival benefit with $ECCO_2R$ at 30 days in that trial.[117]

Not all patients are good candidates for extracorporeal support, especially those with multisystem organ failure as opposed to primary respiratory failure. In considering ECMO or $ECCO_2R$, we favor early assessment and avoiding barotrauma and lung injury induced by prior prolonged mechanical ventilation. In conclusion, severely hypoxemic patients who do not respond to conventional ventilation, with or without some of the adjunctive therapies discussed previously, should be considered for early referral to centers that specialize in ECMO use.

THE ROLE OF THE RESPIRATORY THERAPIST IN ACUTE RESPIRATORY DISTRESS SYNDROME

The RT is essential as the expert in mechanical ventilation and respiratory support for the ICU team. Patients with ARDS represent some of the most challenging patients to manage on mechanical ventilation and require the greatest experience and expertise. The pivotal roles that RTs play in caring for patients with ARDS include ventilator setup, monitoring and frequent adjustments, equipment checks, drawing ABGs, placing arterial lines or performing hemodynamic assessments, and monitoring pulse oximetry and/or exhaled CO_2 monitors.

In treating patients with ARDS, RTs are essential members of the ICU team. In multiple randomized trials, RT-driven ventilator management protocols have outperformed usual care protocols in management of ARDS, including using the most advanced techniques (e.g., ECMO) and achieving liberation from the ventilator.[61,118] The assistance of RTs in ventilator management—offering advice concerning ventilatory strategies, reinforcing the value of low stretch approaches to all members of the team, and performing key technical tasks—is invaluable.

More specific to the management of patients with ARDS, the RT must learn and consistently apply the following key general aspects of supportive care:

1. ARDS is a diffuse injury of the lungs, but is not homogenous. Despite the presence of widespread pulmonary injury on radiographs and altered gas exchange in ARDS, there are areas of the lung with near-normal mechanical characteristics.
2. Better oxygenation (in terms of PaO_2 or SpO_2) is not always linked to better survival. This is an essential concept, because at the bedside we sometimes confuse improvement in oxygenation with success.
3. Mechanical ventilation can lead to VILI, which when not addressed can worsen ARDS and increase mortality secondary to MODS. The RT must always remember that it is the volume, not the pressure, that causes VILI.[119]
4. Initiation and maintenance of LPV, including $V_T = 6$ ml/kg of IBW and sufficient PEEP to exceed the lower inflection point, should become the priority and focus of daily care. The RT should take an active role in making sure that an accurate estimate of the patient's height has been obtained so an accurate IBW can be calculated.
5. Modes of mechanical ventilation that emphasize control of the V_T should be preferred. Although many modes are capable of maintaining V_T and no single mode has been proved to be superior, respiratory therapists should become familiar with how to manage each mode in a manner that prioritizes control of the V_T. Unnecessary transitions to multiple modes of mechanical ventilation in patients with ARDS are typically not helpful and further complicate interpretation of the patient's response to therapy.[120-122]
6. Inspiratory time can be prolonged in ARDS patients to target I/E ratios as low as 1 : 1. Hypercapnia can and should be tolerated (permissive hypercapnia) as long as pH remains above 7.15 to 7.20.
7. Adjunctive therapies, including prone positioning and neuromuscular blockade, may benefit respiratory function and be warranted in patients with severe ARDS.
8. Other nonrespiratory measures of supportive care are now proved to improve the outcomes of patients with ARDS, and RTs should be familiar with these approaches and should support and encourage their consistent application to all ARDS patients.
9. Pharmacologic therapies (e.g., inhaled NO, surfactant) are available and can enhance oxygenation in patients with ARDS but are expensive and do not change patient outcomes. Their routine use in ARDS is not recommended, and should be discouraged.
10. A small percent of patients with ARDS will develop refractory, severe hypoxemia in which the conventional approaches fail. Alternative or "rescue" therapies are as yet unproved but are available at large referral centers. Transfer of patients with refractory hypoxemia should be considered early in the course of disease within the initial 24 to 72 hours.

SUMMARY CHECKLIST

- Pulmonary edema from both hydrostatic (e.g., CHF) and nonhydrostatic (e.g., ARDS) causes may give rise to acute respiratory failure and are often difficult to differentiate on initial clinical evaluation.
- Pulmonary edema leads to bilateral alveolar infiltrates on the chest radiograph, restriction in lung volumes, and significant decline in gas exchange, particularly oxygenation.

- The pathologic findings of ARDS are characterized early by acute alveolar inflammation and injury with neutrophils and cytokines, which can rapidly reverse. In severe and/or persistent ARDS, a fibrotic phase can develop and can lead to a more prolonged course of recovery.
- The clinical definition and diagnosis of ARDS is based on the presence of a syndrome of characteristics that include abnormalities on the chest radiograph, hypoxemia, and a known risk factor or trigger that generates acute inflammation. There are well-established consensus definitions for ARDS that should be used by all caregivers.
- Although ARDS is a common critical illness with high associated mortality and morbidity, recent improvements in the care of patients with ARDS have substantially improved the likelihood of survival and have reduced recovery time for survivors.
- Although the physical examination and chest radiograph frequently do not provide sufficient information to distinguish CHF from ARDS, the clinical history and noninvasive methods to evaluate cardiac function (e.g., echocardiography) often provide key insights that can assist with accurately differentiating the cause of pulmonary edema. Alternative diagnostic techniques such as bronchoscopy or pulmonary artery catheterization can be helpful but are typically not required.
- The management of ARDS focuses on identification and treatment of the triggering risk factor and comprehensive supportive care of vital organs, particularly optimization of gas exchange and avoidance of VILI.
- Currently recommended ventilatory strategies for patients with ARDS are designed to minimize VILI using LPV that emphasizes low V_TS and sufficient levels of PEEP. Multiple modes of mechanical ventilation can be used to achieve LPV, but providers must prioritize avoiding VILI and be willing to tolerate reduced gas exchange, including lower oxygenation and higher $PaCO_2$.
- Adjunctive strategies beyond mechanical ventilation, such as prone positioning and neuromuscular blockade, have recently demonstrated benefit in patients with severe ARDS.
- Other nonventilatory supportive care measures (e.g., conservative fluid management, reduced sedation, early mobility) have been shown to improve outcomes in ARDS and should be encouraged and supported by RTs when possible.
- Alternative ventilation strategies, such as APRV, HFV, and ECMO still lack definitive proof of efficacy, but are available for patients who fail conventional LPV as suggested by severe, refractory hypoxemia. Using these rescue strategies should be considered early in the disease course, because their potential benefits lessen with more prolonged disease.

CHAPTER 30

Respiratory Management of Trauma, Obesity, Near Drowning, and Burns

LORENZO BERRA

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the clinical presentation and the differences in approach to the assessment of patients with life-threatening trauma, pulmonary and body surface burns, obesity, and near drowning.
- Discuss the specific pathophysiology that would guide the application of respiratory care to the management of patients with life-threatening trauma, pulmonary and body surface burns, obesity, and near drowning.
- List the factors affecting gas exchange in each of these patient types.
- Discuss indications for oxygen therapy, noninvasive ventilation, and invasive mechanical ventilation.
- Describe concerns associated with the application of mechanical ventilation to patients with life-threatening trauma, pulmonary and body surface burns, obesity, and near drowning.
- Discuss the application of lung protective ventilation to patients with life-threatening trauma, pulmonary and body surface burns, obesity, and near drowning.
- Discuss the use of positive end expiratory pressure, lung recruitment maneuvers, and prone positioning in patients with life-threatening trauma, pulmonary and body surface burns, obesity, and near drowning.
- Discuss the process of ventilator discontinuation in patients with life-threatening trauma, pulmonary and body surface burns, obesity, and near drowning.

CHAPTER OUTLINE

KEY TERMS

% total body surface area
blunt trauma
carbon monoxide poisoning
cold shock cardiac-respiratory reflexes
cyanide toxicity
cyanocobalamin
cytochrome oxidase
decremental PEEP trial

dry drowning
exudates
fasciotomy
fluvial or brackish water
Glasgow Coma Scale
glomerular filtration rate
hydrophilic drugs
lipophilic drugs
morbid obesity
obesity hypoventilation syndrome
obstructive sleep apnea
penetrating trauma
pulmonary contusion
recruitment maneuvers
severe obesity
super obesity
tension pneumothorax
thiosulfate
thoracic flap (flail chest)
transudates
wet drowning

LIFE-THREATENING TRAUMA

Epidemiology

Trauma is the third overall cause of death in the United States and the primary cause of death for Americans between 1 and 44 years of age.[1] Each year, trauma accounts for 41 million admissions to emergency departments (EDs) and 2 million hospital admissions. Each year, more than 190,000 Americans lose their lives to trauma. But what exactly is trauma? In the most basic sense, trauma is an injury to the body that threatens life and limb integrity. The injury is caused by a physical agent (a force, heat, radiations, etc.) acting on one or more regions of the human body. As a result, trauma patients can have vastly different presentations and clinical manifestations and can require different levels of care. Not every trauma that involves the thorax requires intensive care and respiratory support, just as some traumas that do not involve the chest might require intensive care and respiratory support (e.g., in the setting of transfusion-related acute lung injury or head trauma). Additionally, patients who suffer from trauma and require invasive mechanical ventilation (for trauma that directly involves the thorax, because of the need for an artificial airway, or as a result of massive transfusion) are at higher risk for ventilator-associated pneumonia (VAP), thus complicating these patients' clinical courses. Among patients admitted to the intensive care unit (ICU) after trauma, it has been shown that the presence of traumatic brain injury (TBI) and a poor **Glasgow Coma Scale** score (GCS, Table 30-1) (GCS < 8) on admission are the main determinants of patient outcome, measured as post-ICU disability and quality of life.[2] Neurologic damage appears to be pivotal in determining patient mortality and disability; therefore the respiratory therapist must pay special attention to maintaining adequate oxygenation without compromising perfusion and hemodynamics. Because of the heterogeneous presentation of trauma, there is no overarching rule of thumb regarding patient respiratory management, and the respiratory therapist plays a key role in identifying life-threatening problems and tailoring the support of respiratory function.

Clinical Assessment and Specific Pathophysiologic Concerns

During the first evaluation of a trauma patient, the respiratory therapist, together with the medical team, should focus on the airway and breathing. If blunt injury is present, cervical spine injury always should be suspected and immobilization of the cervical spine must be instituted immediately.[3]

Assessment of a victim of major trauma should start with a GCS evaluation. If a patient is fully awake, responsive (GCS = 15), and able to maintain a patent airway, close respiratory and neurologic monitoring should be instituted until the medical team completes surveillance. If a patient's GCS range is between 14 and 9, the respiratory therapist should pay extra attention to the status of the patient because the clinical condition might quickly deteriorate, requiring endotracheal intubation and invasive ventilation. A GCS lower than 8 always mandates securing the airway by endotracheal intubation and further diagnostic evaluation.

RULE OF THUMB

Trauma victims with TBI and a GCS scores of less than 8 require endotracheal intubation and generally have poorer postinjury quality of life and greater disability.

TABLE 30-1
Glasgow Coma Score

Response	Score
Best Eye Response (E)	
Spontaneously	4
To speech	3
To pain	2
No response	1
Best Verbal Response (V)	
Oriented to time, place, and person	5
Confused	4
Inappropriate words	3
Incomprehensible sounds	2
No response	1
Best Motor Response (M)	
Obeys commands	6
Moves to localized pain	5
Flexion withdrawal from pain	4
Abnormal flexion (decorticate)	3
Abnormal extension (decerebrate)	2
No response	1
Total Score	**15**
Change in Mental Status	
Close monitoring is required.	14-9
Comatose. Securing the airway is required.	≤8
Totally unresponsive	3

Head, Neck, and Upper Airway Injuries

The presence of external injuries to the head should raise the suspicion of TBI. These patients are at risk for rapid neurologic deterioration as a result of an array of alterations in mental status, ranging from confusion to seizures to coma. The respiratory function of these patients can be compromised by upper airway obstruction because of loss of muscular tone or, as with seizures, to excessive muscular tone that requires immediate sedation, paralysis, and endotracheal intubation. Endotracheal intubation might be challenging because of the mandatory immobilization of the cervical spine (Figure 30-1). Management of the upper airways is complicated by anatomic alterations of the rhino-oropharynx caused by the traumatic injury. Severe maxillofacial injuries or destructive trauma of the upper airway prompts tracheal access for definitive airway management.[4] The presence of blood, gastric contents, oral secretions, and foreign material complicate artificial airway placement and management.

Lower Respiratory Injuries

Chest trauma is usually classified either as **penetrating trauma** (i.e., high force applied to a small surface area of the body, such as with a gunshot) or **blunt trauma** (i.e., high force applied over a larger body surface, such as the case of a head-on-end motor vehicle accident).[5] However, most chest injuries do not fall into one of these two categories but instead represent a mix of the two. Depending on the depth of the penetrating lesions, patients can present different clinical features. A lesion that breaches the chest wall violating the pleural space without injuring the lung causes a decoupling of the chest wall/lung relationship. During spontaneous breathing the chest wall tends to expand while the lung tends to collapse. This results in a physiologically negative pleural pressure. When the pleural space is exposed to atmospheric pressure, as in the case of a penetrating trauma injury, the negative pleural pressure causes air to enter the pleural space. At this point the chest wall expands and the lung collapses, resulting in a pneumothorax. If the penetrating injury violates both the pleural space and the lung, air can enter the pleural cavity from both the chest wall and the lung. Patients with this particular injury are at high risk for developing a **tension pneumothorax**. A tension pneumothorax develops when the pleural lesion acts as a one-way valve allowing the entrance of air into the pleural space and progressively trapping air in the expanding pleural cavity. With every breath, the volume of air increases in the pleural cavity. As volume increases, pressure increases, resulting in a force directed toward the opposite pleural cavity. The high unilateral pressure causes a shift of mediastinal structures, resulting in distortion and eventual collapse of the main vascular structures, specifically the vena cava. This phenomenon leads to rapid hemodynamic deterioration that, if unrecognized, results in cardiovascular collapse and death. Penetrating traumas may involve one or more bronchial structures.

Bronchial injuries cause large volumes of air to rapidly enter the pleural cavity as well as the mediastinum, depending on the location of the injury.[6] The presence of bronchial injury should be suspected when, after the placement of a chest tube for pleural drainage, large amounts of air continue to exit the chest tube in a synchronized pattern with positive pressure ventilation. Tracheal lesions can be life-threatening and require prompt surgical evaluation and appropriate airway management. The chosen artificial airway should be capable of bypassing the tracheal lesion to provide adequate pressurization and mechanical ventilation to both lungs. Mechanical ventilation through a tracheal disruption leads to pneumomediastinum, hemodynamic instability, and mediastinal infection.

Esophageal rupture may result in a communicating lesion with the respiratory tract or with the mediastinum. In the first case, the main clinical features are gas leakage during mechanical ventilation and aspiration of gastric material, which can result in chemical pneumonia or full-blown acute respiratory distress syndrome (ARDS). It is vital to recognize and treat these lesions as soon as possible.[7]

Blunt trauma is the other main mechanism that can cause physical injury to the human body. The main sign that a significant blunt trauma has affected the thoracic region is the presence of rib fractures.[8] Rib fractures can be unifocal (one point of fracture per rib) or multifocal (two or more points of fracture in a single rib). This difference is fundamental in understanding the effects of rib fractures on respiratory function. Unifocal fractures can be either nondisplaced or displaced. Nondisplaced rib fractures do not usually require particular attention if the number of fractured ribs is low. However, multiple fractured ribs can be extremely painful and impair proper inspiration, leading to shallow breathing and fatigue. These patients benefit from pain medication and, eventually, pneumatic stabilization of the chest wall through CPAP.[9]

RULE OF THUMB

The presence of bronchial injury should be suspected when, after the placement of a chest tube for pleural drainage, large amounts of air continue to exit the chest tube in a synchronized pattern with positive pressure ventilation.

Displaced rib fractures are even more painful, and sharp bone edges can cause pneumothorax through laceration of the visceral pleura. Pain control and pneumatic stabilization are encouraged. These patients should be routinely monitored because they can develop internal pleural bleeding, especially in the setting of anticoagulant therapy. The presence of blood in the pleural cavity (hemothorax) requires pleural drainage and close monitoring of the bleeding (total amount of blood lost and presence of active bleeding). Surgical evaluation is mandatory. Multifocal fractures of one or more ribs create a **thoracic flap (flail chest)** that is extremely painful and impairs normal respiratory mechanics. During inspiration, when pleural pressure becomes negative, the free flap will be pushed inward, whereas during exhalation, when pleural pressure is positive, it will be pushed outward. This causes extreme pain because the edges of the ribs will be subjected to continuous friction. Based

FIGURE 30-1 **A,** In trauma cervical stabilization is generally obtained by a rigid collar that encircles the neck and supports the chin and the back of the head. The goal of cervical collars is to restrict a certain motion in flexion and extension, while supporting the chin and the occiput. When rigid cervical collar are applied venous outflow at the neck should always be maintained, to avoid increased intracranial pressure. **B,** During intubation, it is tolerated to undo the anterior part of the cervical collar while an assistant maintains in-line stabilization with the occiput held firmly in neutral position (hands are placed along the side of the head with fingertips on the mastoid holding the occiput down). When possible, another assistant applies cricoid pressure. This orientation might limit visualization of the vocal cords for the operator; however, reduction of atlantooccipital motion should be the priority. Awake or asleep fiberoptic intubation or newer airway management instrumentation should be planed before intubation of a patient with unstable cervical spine.

on the extent of the lesion, flail chest can impair normal ventilation. The current therapeutic approach is based on pain management and continuous positive airway pressure (CPAP). Needless to say, the presence of flail chest is associated with a high risk for pneumohemothorax.

Blunt trauma also can cause **pulmonary contusions**. This injury is characterized by acute inflammation and exudation of plasma and blood components into the alveolar space. Even though these lesions resolve spontaneously, they are at high risk for bacterial or viral infection, leading to pneumonia.[10] These inflammatory processes are usually located in the regions of the lung that were subject to the traumatic force.

The application of a traumatic blunt force on the abdomen causes a rapid increase of intraabdominal pressure. This could lead to diaphragmatic rupture. A rupture of the diaphragm impairs normal respiratory function and represents a medical and surgical emergency. If positive pressure ventilation is not applied, the negative intrathoracic pressure during inspiration literally sucks visceral organs into the pleura, causing massive lung collapse, acute bowel obstruction, and possibly splanchnic ischemia.

RULE OF THUMB

All patients with chest trauma, regardless of whether the injury is penetrating or blunt, require careful assessment for pneumothorax, airway injuries, disruption of thoracic vessels, and chest contusion leading to ARDS.

Special Considerations in Patients With Chest Trauma

All bedridden patients are at increased risk for atelectasis secondary to decreased tidal volume and residual volume. Mucus clearance is impaired by inadequate mobilization and excessive or inadequate pain control. Secretion retention might aggravate atelectasis by creating thick mucus plugs in the distal bronchial tree. This phenomenon exposes the bedridden patient to hospital-acquired pneumonia. Secretion retention is a major issue in patients with chest trauma. The pain associated with the trauma (i.e., rib fractures) further impairs the cough reflex. In addition, direct chest trauma might be complicated by lung contusion. The presence of edema and blood in the lung parenchyma represents a perfect growth medium for pathogenic bacteria. The role of the respiratory therapist is crucial in the prevention of potentially life-threatening respiratory complications. There are four interventions on which the respiratory therapist should focus (Box 30-1):

1. *Mobilization*. The patient should be assisted in changing positions periodically to help with mucus drainage and prevention of atelectasis. If tolerated, patient should be helped to move out of bed and to spend some time in a chair.[11]
2. *Humidification of the airways.* Regardless of mechanical ventilation, bedridden patients should receive optimal humidification of the airways to prevent the accumulation of dry secretions.

Box 30-1 Basic Respiratory Interventions in the Bedridden Trauma Patients

- Mobilization
- Humidification
- Pain control
- Incentive spirometry
- Noninvasive continuous positive airway pressure and bilevel positive airway pressure

3. *Pain control.* Control of pain in the trauma patient is one of the most challenging tasks of the critical care team. Inadequate pain control generally results in minimal chest expansion as a reflex response to minimize pain associated with breathing. Excessive use of pain medications (i.e., opioids) also will decrease chest expansion and cough reflex because of sedative effects. Both scenarios exacerbates the pathophysiologic sequence of events described earlier, leading to pneumonia.[12]
4. *Incentive spirometry and noninvasive ventilation (NIV).* Patients should be encouraged as soon as possible to take advantage of incentive spirometry. Incentive spirometry consists of regular breathing exercises performed with the aid of a dedicated device. Regular exercise has shown this prevents formation of atelectasis and reduces secretion retention. The use of such devices requires the full collaboration and dedication of the patient. Secretions clearance can be aided by gentle external chest percussion (i.e., chest physiotherapy), avoiding sites of injury, if tolerated. Should these interventions fail, the respiratory therapist should consider the use of intermittent NIV (CPAP or bilevel positive airway pressure) to reexpand the residual volume and assist tidal ventilation. Recruitment maneuvers should be carefully performed in patients with chest trauma. The presence of silent lesions could cause hypertensive pneumothorax under elevated airways pressures.[13]

Respiratory Management

Every trauma patient represents a case by itself, and the respiratory management of trauma patients should focus on the mechanism of chest injury. Supplemental oxygen is generally administered immediately after the trauma to prevent secondary hypoxic injury. However, any sign of pending respiratory failure should prompt endotracheal intubation and initiation of mechanical ventilation (Box 30-2). Upper airway disruption might require emergent tracheostomy. Advanced airways management such as a double-lumen endotracheal tube (ETT) may be required for injury of the trachea or for selective lung ventilation for bronchial injuries. Injury to the lung parenchyma always should be suspected after major trauma. Extensive lung injury frequently evolves into traumatic ARDS requiring protective lung ventilation strategies (see Chapters 29 and 52). In addition, trauma patients are at higher risk for developing lung injury resulting from the large volume of blood components that these patients may require (i.e., transfusion-related lung injury and/or transfusion-associated circulatory overload).

Box 30-2 Mechanical Ventilation of the Trauma Patient

- Mode: Pressure or volume ventilation
- Tidal volume: 6 to 8 ml/kg predicted body weight
- Inspiratory time 0.6 to 1.0 second
- Plateau pressure: Less than 28 cm H_2O
- Driving pressure of 15 cm H_2O or less
- Rate only limited by the development of auto-PEEP
- Minute volume to maintain normal $PaCO_2$
- PEEP 5 to 10 cm H_20
- FiO_2 set to maintain target PaO_2
- If ARDS, manage as any other ARDS patient

Bronchoscopy plays a major role in the respiratory care of trauma patients. It first allows removal of foreign bodies and drainage of blood clots and provides an excellent method for removal of tenacious mucus plugs. Moreover, it is the gold standard for diagnosis of proximal and distal major airway lesions and is capable of providing a first-line treatment. Trauma patients are at high risk for VAP, and preventive clinical bundles should be applied as soon as possible (see Chapter 24). Recent reports outlined beneficial effects of these bundles (i.e., decreased sedation, early mobilization, and improved secretion clearance) compared to early tracheostomy for patients requiring prolonged mechanical ventilation. However, it is still difficult to predict the time for weaning from mechanical ventilation. A number of factors play a role in liberation from mechanical ventilation, such as neurologic status, muscular strength, adequate pain management, proper healing of major injury, and hemodynamic instability.

OBESITY

Epidemiology

Obesity is defined by an excess of weight in relation to a person's height. It is mainly measured through the body mass index (BMI), which is the ratio of an individual's weight (kg) divided by the square of the individual's height (m):

$$\text{BMI} = (\text{weight})/(\text{height})^2 = \text{kg}/\text{m}^2$$

A normal BMI range for a healthy individual is between 20 and 25 kg/m^2, and a BMI over 30 kg/m^2 is defined as obesity. Among the different excesses of BMI, a BMI greater than 40 kg/m^2 is defined as **severe obesity**, a BMI greater than 45 kg/m^2 is defined as **morbid obesity**, and a BMI greater than 50 kg/m^2 is defined as **super obesity**. In the last decade, the prevalence of obesity progressively has increased in the U.S. population, reaching a plateau of almost a third of the total population. There are differences in obesity prevalence among different ethnic groups, with non-Hispanic Asians having a lower prevalence compared to non-Hispanic whites, non-Hispanic African Americans, and Hispanic groups. Obesity is connected to a plethora of adverse health conditions and imposes considerable burdens on the U.S. health care system.

MINI CLINI

Trauma: Recognizing Common Life-Threatening Acute Respiratory Complications in Trauma Patients

PROBLEM: A water-skier was sent by medical flight to the hospital after collision with a boat following a 30-feet acrobatic jump. The unknown young man was intubated with a 7.0-mm ETT at the scene for hypoxemia and GCS 6 with no lower limb movements. Vital signs at admission in the ED were heart rate 40 beats/min, blood pressure 80/40 mm Hg, O_2 saturation 99%, and body temperature 35° C. He weighs 160 lb and is 6 ft tall. The ventilator settings are as follows: volume-controlled ventilation mode, tidal volume (V_T) 500 ml, respiratory rate 14 breaths/min, and positive end expiratory pressure (PEEP) 5 cm H_2O. During central line placement, the RT notices that the peak airway pressure increased from 18 cm H_2O to 35 cm H_2O, activating the high pressure alarm, and SaO_2 declined rapidly from 99% to 90%. What are the next steps the RT should take?

SOLUTIONS:

1. Immediately inform the medical team regarding the alarming acute increased peak pressure and decreased SaO_2.
2. Verify that the ETT did not migrate into the right main stem bronchus during neck positioning for central line placement by confirming tube positioning.
3. Pass a suctioning catheter to verify absence of ETT kinking or occlusion resulting from secretions or blood.
4. Visually inspect that the inspiratory and expiratory ventilator circuit is not kinked and that the water trap is not filled.
5. Auscultate breath sounds on all lung fields and inspect tracheal deviation or asymmetry in chest movements during ventilation. Tension pneumothorax should be suspected when breath sounds are absent on the affected part of the thorax and the trachea deviates away from the affected side. The thorax may also be hyperresonant with jugular venous distention. Increased intrathoracic pressure might cause hypotensive and hypoxemia. If not recognized, tension pneumothorax leads to cardiovascular collapse and death.
6. Immediate chest radiograph and arterial blood gas (ABG) analysis should be requested to confirm hypoxemia and rule out acute changes (i.e., pneumothorax, acute pleural effusion, hemothorax, bronchial mucus plug causing large lobar or entire lung collapse).
7. Until a pneumothorax is ruled out, V_T should be decreased and respiratory rate increased ideally by use of a manual ventilator. This is to ensure that limited pressure is applied to minimize the volume of gas extending the possible pneumothorax.
8. Regardless of the final diagnosis, the respiratory therapist has a key role in the care of the trauma patient in the acute settings. Common tasks of the RT are titration of the ventilator after acute changes in the patient's condition, travel to a computed tomography (CT) scan or other emergent hospital location (i.e., operating room or ICU), and assistance with procedures such as bronchoscopy, chest tube placements, or intracranial pressure monitoring.

Obesity is associated with increased morbidity and mortality in the context of both acute and chronic medical problems, including diabetes mellitus and related complications, hypertension, dyslipidemia, cardiovascular disease, gallstones, cholecystitis, and certain forms of cancer. Although there is now a considerable amount of data available on the impact of obesity on ICU outcomes, there are still contradictory conclusions concerning the nature of this impact, possibly because obese ICU patients on average are younger and are affected with less severe diseases compared to nonobese ICU patients; however, obese ICU patients require the same level of intensive care.

Among people with a BMI within the range of severe obesity, the distribution of adipose tissue plays a major role in determining the risks for chronic diseases. Current guidelines concerned with the clinical care of the obese recommend measurement of waist circumference in people with a BMI greater than 25 kg/m^2 and propose that waist circumferences of 102 cm in men and 88 cm in women define abdominal adiposity. Most studies examining the association between fat distribution and mortality have shown that abdominal adiposity is an important predictor of mortality. In particular, waist circumference has been associated with mortality even in people with a normal BMI, indicating that BMI might be of limited use in assessing the severity of a person's obesity and that fat tissue distribution plays a major role in the pathophysiology of obesity.[14]

RULE OF THUMB

Patients who are obese have a greater likelihood of mortality in the ICU if their waist circumstance is greater 102 cm in men and 88 cm in women.

Specific Pathophysiologic Concerns

Adipose tissue is a potent source of proinflammatory molecules that induce a chronic inflammatory state mimicking critical illness and diminishing immune and metabolic reserves (Box 30-3). Moreover, an increased BMI requires additional cardiovascular, respiratory, and metabolic work, further diminishing an individual's physiologic reserves.[15]

Obesity is a risk factor for cardiovascular disease independent of diabetes mellitus and hypertension. The mechanism of obesity-related cardiovascular disease involves an increase in both preload and afterload. Adipose tissue is perfused on average by 3 ml of blood per each 100 g of tissue. The resulting expansion of blood volume increases venous return (preload), cardiac output, and cardiac work. Afterload is increased by secretion of steroids and catecholamines and through the renin-angiotensin endocrine axis. Myocardial hypertrophy and diastolic dysfunction are the results of these alterations, eventually leading to heart failure, arrhythmias, or sudden cardiac arrest. Myocardial hypertrophy and the consequently reduced heart-wall compliance, as well as reduced heart chamber volumes, are responsible for poor tolerance of intravenous fluids in these patients. Additionally, the presence of diabetes mellitus and hypertension in this setting exponentially increases the risk for myocardial infarction. Moreover, the presence of diabetes mellitus increases the risk for a silent myocardial infarction being present at the time of admission or happening as a complication of critical illness. This risk is especially pertinent to the extreme range of obese patients, whose physical activity is very limited and who may not manifest symptoms of myocardial ischemia or show signs of congestive heart failure before ICU admission.

Box 30-3 Physiologic Concerns Associated With Obesity

- Cardiovascular disease
- Venous thrombosis and pulmonary embolism
- Chronic renal failure
- Obstructive sleep apnea
- Obesity hypoventilation syndrome
- Reduced lung volumes
- Expiratory flow resistance
- Air-trapping and auto-PEEP

The presence of a proinflammatory/procoagulatory state induced by adipose tissue and associated with a sedentary lifestyle and venous stasis puts these patients at high risk for venous thrombosis and pulmonary embolism. The increased cardiac output of obese patients is responsible for an increased glomerular filtration rate in patients whose obesity-related complications have not yet compromised kidney function. However, diabetes mellitus and hypertension can be responsible for chronic kidney failure. Thus an evaluation of kidney function is mandatory in this patient population. Abnormal glomerular filtration and excess adipose tissue alter the clearance and the volume distribution of most drugs that are administered to obese patents.

Dosing of **lipophilic drugs** should be based on the actual body weight of the patient, whereas for **hydrophilic drugs** dosage is best determined using the ideal body weight (IBW) or predicted body weight (PBW) of the patient and corrected for higher renal clearance if an abnormally high **glomerular filtration rate** is present. Because of altered clearance, distribution, and accumulation of drugs, obese patients are particularly prone to underdosage and overdosage of hypnotic medications. Because most of these drugs are lipophilic, allowing them to cross the blood-brain barrier, the accumulation of drugs in excess adipose tissue can occur and result in a slowed release into the bloodstream. Frequent spontaneous awakening trials are necessary to assess the accumulation of drugs in the adipose tissue and to determine the ability of the patient to promptly recover from sedation to avoid delaying liberation from mechanical ventilation.[16]

RULE OF THUMB

Over two-thirds of obese patients have sleep apnea. All obese patients on admission should be evaluated for sleep apnea if not already being treated for it.

More than two-thirds of obese people have **obstructive sleep apnea** (OSA). However, the factors that lead to a higher incidence of OSA in obese patients are still poorly understood. It has been argued that obesity can act in different ways on the respiratory system, that it narrows the upper airway, causes upper airway collapsibility, and disrupts the normal physiologic respiratory drive. Specifically, it has been shown that obesity is associated with the deposition of peripharyngeal fat, which may increase pharyngeal collapsibility. In addition to this, it has been shown that the proinflammatory state associated with obesity alters the pharyngeal-patency control mechanisms, resulting in additional airway occlusion. Neuromuscular control of pharyngeal patency is of the utmost importance in these patients. Any increase in a proinflammatory state or loss of active neuromuscular control (e.g., because of a neurologic condition or sedation) further aggravates upper airway occlusion.

Lung volumes progressively decrease as BMI increases. Total lung capacity and residual volume decrease linearly as BMI increases, while functional residual capacity is exponentially reduced at higher BMI values, especially in patients with a central fat distribution (high waist circumference). Furthermore, forced vital capacity, forced expiratory volume in 1 second, maximum voluntary ventilation and forced mid-expiratory flow are significantly reduced in obese persons, with airway closure occurring during tidal breathing in the extreme range of obesity. Low functional residual capacity increases the risk for expiratory flow limitation and airway closure. This is thought to be due to an increase in pleural pressure caused by the transmission of the gravitational weight of the abdomen. The weight of the abdomen displaces the diaphragm in a cephalad position, causing passive atelectasis in the most gravity-dependent regions of the lung. The collapsed lung tissue exerts less elastic recoil on adjacent structures, particularly on the smaller airways, reducing their diameter. The increase in pleural pressure further aggravates airway collapse. The ensuing expiratory flow limitation can lead to incomplete exhalation with air trapping, resulting in dynamic hyperinflation. Dynamic hyperinflation (auto-PEEP) is one of the most common sources of increased work of breathing and patient-ventilator asynchrony in mechanically ventilated patients.

Trapped end-expiratory gas causes auto-PEEP. This trapping of gas behind collapsed airways acts as a recoil pressure that needs to be released at the beginning of inspiration before the generation of a V_T, resulting in wasted work of breathing.[17,18] It has been observed that the sitting position can increase functional residual capacity, reverse expiratory flow limitation, improve respiratory mechanics and gas exchange, and lower the PEEP required to restore functional residual capacity to a normal physiologic level—another indication of the pathophysiologic role of abdominal weight in obesity.[19] The presence of expiratory flow limitation and atelectasis in the dependent zones of the lung is pivotal in the development of ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch and hypoxemia. To supplement the increased rates of O_2 consumption and carbon dioxide (CO_2) production in the setting of impaired gas exchange, obese patients increase their respiratory drive and minute ventilation, maintaining adequate alveolar ventilation at the expense of higher dead space ventilation. However, the most severely obese patients acquire a reduced chemosensitivity, impairing their ventilatory response to hypoxemia and hypercapnia (**obesity hypoventilation syndrome** [OHS]). These patients tend to slowly progress to hypoventilation with hypercapnic respiratory failure. It has been shown that noninvasive nocturnal ventilation is effective in restoring a more normal physiologic chemosensitivity and compensatory respiratory drive.[20]

RULE OF THUMB

The majority of patients with severe obesity develop flow limitation, air trapping, and auto-PEEP, especially when ventilated in the supine position.

Clinical Assessment

Given an unstable respiratory/cardiovascular equilibrium, obese patients are particularly prone to acute respiratory failure in the setting of disease. Particular attention must be paid to gas exchange and signs of increased work of breathing (labored breathing, high respiratory rates, use of accessory muscles), because any deterioration in their clinical status can quickly precipitate respiratory failure requiring mechanical ventilation.

BMI, body fat distribution, and history of snoring, sleepiness, and headaches should be determined or collected on admission. The degree of self-mobilization and physical daily activity should be investigated, and the risk for deep venous thrombosis or pulmonary embolism should be assessed. A plan for airway management and intubation should be discussed before the onset of respiratory failure, especially if the patient shows signs of a particularly difficult airway for intubation. The past use of, and settings for, home nocturnal CPAP or NIV should be investigated, and their continued use should be encouraged. In the presence of a history suggestive of OSA/OHS, intermittent/nocturnal noninvasive bilevel positive airway pressure/CPAP should be started regardless of the patient's respiratory status.

Respiratory Management

See Box 30-4.

Box 30-4 Respiratory Management of Obesity

- Oxygen therapy for management of hypoxemia
- Inhalational bronchodilators for management of asthma symptoms
- Noninvasive CPAP for management of sleep apnea
- NIV for obesity hypoventilation syndrome and hypercarbic respiratory failure
- Invasive mechanical ventilation for management of hypoxemic and hypercarbic respiratory unresponsive to NIV

CPAP, Continuous positive expiratory pressure; *NIV,* noninvasive ventilation.

Oxygen Therapy

Hypoxemia is the most common gas-exchange abnormality in obese patients. It can be mild and easily corrected by O_2 supplementation, or it can be severe enough to require mechanical ventilation. However, a mild, progressive hypoxemia should prompt close monitoring of gas exchange, work of breathing, and mental status, because it might be a sign of impending respiratory failure. A sudden onset of hypoxemic respiratory failure should raise the suspicion for pulmonary embolism. If the patient's response to O_2 supplementation is inadequate but the patient has sufficient mental status, NIV should be initiated.

Aerosolized Pharmacology

Obese patients have a higher incidence and severity of asthma, and they frequently require inhalation therapy. For a detailed discussion, see Chapter 35.

Noninvasive Ventilation

NIV should be attempted when the patient's neurologic status is sufficient but O_2 therapy alone is ineffective at correcting hypoxemia or when hypercapnia complicates the respiratory failure. By the time NIV is attempted, a plan for airway management and intubation already should have been made. NIV should be instituted immediately in the setting of hypercapnic respiratory failure. If qualified staff is available, noninvasive mechanical ventilation can be set up and begun in EDs or respiratory wards. An alert and cooperative mental status, proper mask-fitting, ability to clear secretions, and relative hemodynamic stability are essential factors that contribute to the success of NIV. Pressure-support ventilation with adequate PEEP is the preferred mode of ventilation. Vital signs, level of consciousness, respiratory pattern, oxygenation, delivered V_T, gas exchange, and circuit leaks should be frequently assessed to guarantee proper ventilatory therapy.[21]

Approach to Noninvasive Ventilation

The approach to noninvasive ventilation is as follows.

1. Explain the indications of NIV and the possible outcomes (requirement of intubation or prolonged use of NIV) to the patient. Explain to the patient that he or she is not allowed to drink or eat anything by mouth until able to avoid the risk for aspiration during NIV.
2. Perform an ABG analysis to assess baseline gas exchange.
3. Fit the mask appropriately. If more than one model is available, quickly check with the patient which one is most comfortable.
4. Suggested initial settings are 10 cm H_2O of pressure support and 10 cm H_2O of PEEP.
5. Monitor vital signs, gas exchange, respiratory rate, V_T, and comfort of the patient.
6. Gradually increase PEEP in 2–cm H_2O increments to improve airway patency and oxygenation (SpO_2 > 90%). Check hemodynamics carefully.
7. Gradually increase pressure support in 2–cm H_2O increments to improve V_T (until 6 to 8 ml/kg of IBW), reduce the respiratory rate (<25 breaths/min), reduce ventilatory distress, and improve CO_2 clearance.
8. Check gas exchange at 60 minutes. If noticeable improvement has been observed and there is no clinical deterioration, NIV can be continued. If NIV did not improve oxygenation or hypercapnia, the patient should be intubated and mechanically ventilated.

RULE OF THUMB

If the first hour of NIV does not at least partially correct the patient's clinical presentation, hypoxemia, and hypercarbia, endotracheal intubation should be immediately considered.

Invasive Mechanical Ventilation

Intubation. Airway management in obese patients can be challenging because of the anatomic and physiologic alterations described earlier that make this population prone to airway obstruction and severe hypoxemia. BMI is a predictor of mask ventilation difficulties because of reduced upper airway space, difficulty fitting the mask, increased pressure required for V_T generation, and reduced diaphragmatic excursion. Intubation is difficult as well; however, BMI is not an effective predictor of intubation difficulty, but neck circumference above 40 cm is associated with difficult intubation. There is no common agreement on which approach to intubation should be used in obese patients. A possible strategy is awake intubation through the use of fiberoptics, although this technique requires coordination, proper anesthesia of the upper airways, and complete collaboration of the patient, with this final factor being particularly important for success, although particularly difficult in the critically ill obese patient. The advent of video-laryngoscopy has significantly reduced the amount of difficulty clinicians face in airway management, and the use of a video-laryngoscope should be strongly considered in any intubation plan for the critically ill obese patient. A kit for rapid airway access should be present at the bedside or within reach until the airway is secured. Regardless of the device or technique adopted—which should be based on patient evaluation and personal expertise—optimal positioning is mandatory to increase the chance of securing the airways. The "ramped position" consists of elevating the upper body and head of the patient to align the sternum and ear horizontally. This positioning technique results in a significantly improved laryngoscopic view. In addition, the elevated head of bed positioning typical of the ramped position improves respiratory mechanics and lung volumes during preoxygenation, increasing the time to desaturation. The use of CPAP during preoxygenation can additionally increase the nonhypoxemic apnea time by 50%.

Tidal Volume, Minute Volume, and Respiratory Rate. Pressure control ventilation or volume control ventilation can be equally effectively used to mechanically ventilate the obese patient (Box 30-5). However, regardless of mode of ventilation, V_T settings *must not be calculated* based on actual body weight,

Box 30-5 Mechanical Ventilation of the Obese Patient

- Mode: Pressure or volume ventilation
- Tidal volume: Average 6 ml/kg PBW, range 4 to 8 ml/kg PBW
- Inspiratory time 0.6 to 1.0 second
- Plateau pressure: Less than 28 cm H_2O, unless TPP measured then TPP less than 20 cm H_2O
- Driving pressure equal to or less than 15 cm H_2O
- Rate only limited by the development of auto-PEEP
- Minute volume generally 10 L/min or greater
- Lung recruitment maneuver with decremental PEEP trial to set PEEP
- FiO_2 set to maintain target PaO_2
- Position head of the bed to 30 degrees or greater elevation
- Noninvasive ventilation for 24 to 48 hours after extubation

PBW, predicted body weight; *TTP,* transpulmonary pressure.

but on PBW or IBW, because an increased BMI does not reflect increased lung size. The best current evidence and practice stresses the importance of lung protective ventilation with a V_T target of 6 ml/kg PBW (range, 4 to 8 ml/kg PBW) in all critically ill patients. There are different equations and formulas to calculate the predicted or IBW, and there could be significant differences in the calculations. The most widely recommended formulas are listed below. These are the formulas used by the NIH/NHLBI ARDS Network in their landmark study:

$$PBW_{MEN} = 50.0 + 0.905^{*}([\text{Height in cm}] - 152.4)$$
$$PBW_{WOMEN} = 45.5 + 0.905^{*}([\text{Height in cm}] - 152.4)$$

Minute ventilation and respiratory rate should be adjusted to ensure an adequate clearance of CO_2. Because of the increased metabolic rate, minute ventilation is commonly greater than 10 L/min. In assisted partial ventilatory support, respiratory rate and volumes should be carefully monitored, especially in the setting of OHS, as central desensitization to CO_2 might result in depressed respiratory drive in the setting of normal oxygenation. It is reasonable in this context to have a lower oxygenation target (SpO_2 88% to 92%).

RULE OF THUMB

V_T in obese patients always should be determined based on PBW, *not* actual body weight because lung size is not based on weight, it is based on height and gender.

Lung Recruitment. It has been demonstrated in intraoperative settings that **recruitment maneuvers** in obese, mechanically ventilated patients are effective at improving respiratory system compliance and oxygenation without affecting hemodynamics. This effect is due to the reversal of atelectasis that forms during induction and persists without adequate levels of PEEP during mechanical ventilation. It is advisable to perform a recruitment maneuver whenever PEEP is increased or after temporary PEEP discontinuation (e.g., disconnection of the patient from the ventilator circuit in the setting of high PEEP).[22] A recruitment maneuver during volume or pressure control ventilation can be performed as follows:

1. Assess hemodynamic stability of the patient.
2. Switch to pressure control ventilation with the following settings:
   Pressure control: +15 cm H_2O
   PEEP: +10 cm H_2O
   Respiratory rate: 10 breaths/min
   I/E ratio: 1 : 1
3. If patient is stable, after 30 seconds increase PEEP by 5 cm H_2O (PEEP: +15 cm H_2O).
4. Check oxygenation and hemodynamics.
5. If patient is stable, after 30 seconds increase PEEP by 5 cm H_2O (PEEP: +20 cm H_2O).
6. Check oxygenation and hemodynamics.
7. If patient is stable, after 30 seconds increase PEEP by 5 cm H_2O (PEEP: +25 cm H_2O).
8. Check oxygenation and hemodynamics.
9. Switch to volume control and perform a **decremental PEEP trial**. Set ventilator setting similar to that before recruitment maneuvers (RM) but keep PEEP at 25 cm H_2O and FiO_2 at 1.0. Measure total respiratory system compliance (Crs) after 3 to 5 minutes.
10. Decrease PEEP to 21 cm H_2O after 3 to 5 minutes and measure Crs.
11. Decrease PEEP to 19 cm H_2O after 3 to 5 minutes and measure Crs.
12. Decrease PEEP to 17 cm H_2O after 3 to 5 minutes and measure Crs.
13. Continue this process until the best Crs PEEP can be identified.
14. Recruit the lung again and then set PEEP at the best Crs PEEP plus 2 cm H_2O.
15. Decrease the FiO_2 to the lowest level maintaining PaO_2 in the target range.

This approach to setting PEEP works well in morbidly obese patients and results in improved lung mechanics compared to the routine use of 8 to 12 cm H_2O PEEP in these patients. In patients with less severe obesity PEEP in the range of 10 to 15 cm H_2O generally stabilizes the lung and avoids atelectasis.[23]

Positioning. It has been shown that elevation of the head of the bed is effective at improving respiratory system compliance and oxygenation, reducing expiratory flow limitation, and reducing PEEP requirements for optimal ventilation in obese patients. This phenomenon is related to the gravitational effects of the abdomen on the diaphragm. When obese patients lie in the supine position, the abdominal content pushes against the diaphragm and displaces it in a cranial direction, resulting in increased pleural pressure and passive atelectasis in the dependent zones of the lung (see the section on pathophysiology). The adoption of a sitting position changes the vector of the gravitational forces of the abdomen, partially releasing the diaphragm from abdominal pressure. Changes in bed position in morbidly obese patients (e.g., from sitting to supine, and back

to sitting) should be followed by a recruitment maneuver in order to reexpand the regions of the lungs that collapsed during the transient increase in pleural pressure. In general, unless contraindicated, obese patients should be managed with the head of the bed elevated above 30 degrees.

RULE OF THUMB

FiO_2 and pressure support level should always be weaned before PEEP level is decreased. When FiO_2 is approximately 0.40 and pressure support is 10 cm H_2O or less, PEEP can be decreased.

Ventilator Discontinuation. One of the most challenging aspects of ventilatory management of obese patients is liberation from mechanical ventilation. Expiratory flow limitation, low respiratory system compliance, atelectasis, and impaired neurologic respiratory drive play an important role in determining increased work of breathing in morbidly obese patients. As critical illness resolves, catabolic muscular wasting and post–critical illness muscular weakness aggravate the patient's respiratory condition. There is still no consensus or scientific data on what might be the best approach for ventilatory weaning in these patients. Requiring a longer time on mechanical ventilation and more prone to fail liberation from mechanical ventilation, these patients more often require tracheostomy and transfer to long-term respiratory care facilities. However, it has been shown that morbidly obese patients who undergo tracheostomy have a higher morbidity and mortality and are more prone to tracheostomy-related complications. As the beneficial effects of PEEP and positioning in this population become more clear, especially in partially reversing the phenomena that lead to increased work of breathing, it is advisable that PEEP should be carefully reduced only after the FiO_2 has stabilized at approximately 0.40. In addition, it is preferable to gradually reduce the level of pressure support while keeping the PEEP level stable, and eventually test a careful reduction of PEEP down to 8 to 10 cm H_2O, if feasible. It would be best to extubate these patients while they are on PEEP and start noninvasive CPAP or bilevel positive airway pressure immediately after extubation. Noninvasive mechanical ventilation then can be gradually adjusted and weaned in the following 48 to 72 hours.

MINI CLINI

Obesity: The Role of Postoperative Noninvasive Ventilation

PROBLEM: A 550-lb patient is recovering in the postoperative care unit after a laparoscopic cholecystectomy. The procedure was uneventful. The nurse called you because the SpO_2 decreased from 95% to 88% over the past hour despite a nonrebreather facemask at 12 L/min. You see the patient; she is calm, resting in no pain, and breathing regularly at 8 breaths/min. Other vital signs are heart rate 66 beats/min, blood pressure 128/70 mm Hg and body temperature 36.5°C. After reviewing the nursing notes, you notice that patient required 4 mg of midazolam before surgery for anxiety, 4 mg of hydromorphone during surgery, and additionally 10 mg of morphine in the recovery room.

SOLUTIONS: Inform the medical/surgical team of the increased hypoxemia in this high-risk obese postsurgical patient. Suggest the medical/surgical team perform an ABG analysis to confirm hypoxemia and determine PCO_2 to rule out pharmacologic narcosis and request a chest radiograph to rule out postoperative atelectasis. In agreement with the medical/surgical team, this patient should receive NIV and be monitored for 24 hours by telemetry.

In this patient, NIV instead of CPAP is required because not only is there most likely marked atelectasis but this patient's ventilatory drive has been depressed by sedatives and narcotics, requiring ventilatory support. NIV may be required for only 24 hours, but considering the size of the patient and the likelihood that the patient has sleep apnea, the use of CPAP during sleep should be considered on an ongoing basis and the patient evaluated for sleep apnea once recovered from the acute episode.

NEAR DROWNING

Epidemiology

Drowning is one of the major causes of accidental pediatric death and is more common in low-income and middle-income countries. In adults, drowning is generally associated with alcohol and drug abuse. From 2005 to 2009 in the United States, there were approximately 4000 deaths resulting from drowning, of which almost 1000 were children younger than 14 years of age. It has been calculated that for each drowning casualty there are at least five times as many near-drowning–related admissions to EDs, of which half require hospitalization.

The essential feature of drowning and the primary cause of death is asphyxia leading to cardiopulmonary collapse. Permanent injuries include a spectrum of brain damage, starting with minor memory problems, to severe learning disabilities, including a permanent vegetative state.[24-26]

Specific Pathophysiologic Concerns

The pathophysiologic mechanisms of drowning comprise the following two reflexes:

1. Inhalation of fluid causes irritation and cough response, resulting in fluid being either swallowed or inhaled. Laryngospasm with closure of the glottis prevents aspiration of large amounts of fluid in the lungs (**"dry drowning"**), diverting these fluids to the stomach. Generally, the laryngospasm lessens with unconsciousness, leading to **"wet drowning"**—the aspiration of fluid, which is a more common occurrence.
2. **Cold shock cardiac-respiratory reflexes** occur with sudden immersion in water cooler than 25°C. The breathing pattern is characterized by gasping followed by hyperventilation and

shallow breathing at almost total lung capacity. At lower water temperatures, sudden peripheral vasoconstriction can acutely increase systemic vascular resistance, leading to sudden cardiovascular collapse if the heart is unable to overcome the acute increase in preload and afterload.[27]

During "wet drowning," specific respiratory and blood chemistry dysfunction depend on whether fresh or seawater has been inhaled.

1. Inhalation of fresh water.[28]
   a. *Inhalation of fresh water and its effects on the respiratory system*. Inhalation of fresh water rapidly depletes alveolar surfactant, leading to $\dot{V}/\dot{Q}$ mismatch. Inhaled water is quickly absorbed into the vascular system from the alveolar space by osmosis, causing alveolar collapse and worsening shunt and hypoxia. Additionally, in the setting of inhaled fresh water, acute neurogenic pulmonary edema secondary to cerebral hypoxia has been shown to worsen alveolar flooding. However, if hypoxia is reversed, normal pulmonary function can be quickly restored.
   b. *The effects of inhalation of fresh water on other organs*. If a large volume of fresh water is inhaled, it is rapidly absorbed into the circulation, leading to electrolyte imbalance. Hyponatremia can lead to seizures, especially in pediatric patients. Additionally, diluted plasma causes water to rapidly enter into erythrocytes by osmosis, causing hemolysis. The resulting hyperkalemia and hyponatremia can cause ventricular fibrillation, and the liberation of hemoglobin into the plasma can precipitate acute renal failure.
2. Inhalation of salt water.[29]
   a. *Inhalation of salt water and its effects on the respiratory system*. Seawater has a three-fold higher osmolarity than blood. Hypertonic fluid inhalation therefore causes water to move from the circulation into the lungs. In experimental studies in animals, inhaled seawater accounted for less than 50% of the volume of water retrieved from the lungs at autopsy. In contrast with the inhalation of fresh water, this phenomenon explains the sustained edema and prolonged shunt after the inhalation of salt water. Additionally, salt water causes direct damage to the alveolar-capillary membrane, enhancing lung injury.
   b. *The effects of inhalation of salt water on other organs*. If a large volume of salt water is inhaled, the rapid loss of circulating volume into the alveolar space across the injured alveolar capillary membrane may cause hemoconcentration, hypernatremia, and hypoalbuminemia. This phenomenon, if not recognized and rapidly reversed, leads to vascular collapse and hypovolemic shock.

Despite the pathophysiologic differences and the obvious circumstantial differences between drowning in salt water versus fresh water, at autopsy a definitive diagnosis cannot be made.[30-32]

Respiratory Management

Immediate management of patients who present with drowning or near-drowning events must follow the classic airway-breathing-circulation approach, and cardiopulmonary resuscitation should be started immediately, if needed (Box 30-6). If possible, prone positioning of the patient is preferable, because it allows optimal clearance of water from the tracheobronchial tree, especially in the case of salt water drowning. Temperature monitoring and active body temperature control should be initiated as soon as possible because submersion and inhalation of water drastically reduces body temperature.

Box 30-6 Respiratory Management of Near Drowning

- Basic cardiopulmonary
- Airway clearance
  - Bronchoscopy
  - Lavage
  - Prone positioning
- Mechanical ventilation as in all ARDS patients

RULE OF THUMB

Near-drowning victims almost always develop ARDS and should be managed from a mechanical ventilation perspective like any other ARDS patient.

Airway Clearance Therapy

The aspiration of foreign matter occurs relatively commonly in drowning or near-drowning events, particularly events involving drowning in shallow water. The most common aspirated material is sand, mud, or dirt. This can be easily recognized if solid material is found in the upper airways or in the stomach. It has been reported that a CT scan can show distinct hyperdense "sand bronchograms" in cases of sand aspiration. The inhalation of foreign material in the setting of drowning or near drowning is particularly harmful, because the material is usually solid, is nonsoluble, has a high density, and tends to consolidate and clog distal airways. This further worsens the onset of ARDS that follows drowning by enhancing the inflammatory response and by mechanically sealing the airways. Upper airway clearance should be performed as soon as possible. Foreign material in the distal airways can be washed after intubation through repeated bronchoscopy and bronchoalveolar lavages.[33,34]

Mechanical Ventilation

Almost every patients who experiences drowning or near-drowning events will develop ARDS. Ventilatory management of these patients should follow ARDS ventilation guidelines as outlined in Chapter 27 and 48 (Box 30-7). Frequently, these patients develop bronchospasm as a result of the irritant effects of water in the airways. Laryngospasm and persistent upper airway closure are usually resolved on the administration of paralysis at intubation, but severe bronchospasm might persist, requiring antibronchospasm inhalatory or intravenous therapy (see Chapter 35). Drowning in **fluvial or brackish water** or

Box 30-7 Mechanical Ventilation of the Near-Drowning Patient

- Mode: Pressure or volume ventilation
- Tidal volume: Average 6 to 8 ml/kg PBW
- Inspiratory time 0.6 to 1.0 sec
- Plateau pressure: less than 28 cm H_2O
- Driving pressure equal to or less than 15 cm H_2O
- Rate only limited by the development of auto-PEEP
- Minute volume to maintain $PaCO_2$
- PEEP 5 to 10 cm H_2O
- FiO_2 set to maintain target PaO_2
- Prone position
- If ARDS, manage as normal for ARDS patients

seawater is usually complicated by pneumonia caused by opportunistic pathogens inhaled at the moment of drowning. However, these bacteria usually do not show antibiotic resistance and prompt antibiotic prophylaxis should be able to prevent pneumonia.

Positioning

Whenever feasible, prone positioning is preferable immediately after cardiovascular stabilization, especially in the case of brackish water or saltwater drowning, in which the osmotic activity of the inhaled salt causes continuous refilling of the lungs with water. The prone position allows clearance of salt-containing fluids from the lungs and might prove useful in the setting of severe ARDS.

RULE OF THUMB

Once stabilized, salt-water near-drowning victims generally benefit from prone positioning, which allows better clearance of inhaled fluids from the lungs.

BURNS

Epidemiology

In the United States, each year approximately 450,000 people receive medical treatment for burn injuries; of these patients, 40,000 are hospitalized. Over 60% of the estimated U.S. acute hospitalizations related to burn injury were admitted to 127 burn centers. Each year 3400 patients die as a result of burn and smoke inhalation. In a selected case series from 2003 to 2012 the reason for admission was 43% fire, 34% scald, 9% contact, 4% electrical, 3% chemical, and 7% other burn injuries.[35] The main feature characterizing the natural history of serious burns is burn shock. Burn shock can lead to death within the first hours after injury. The most important cause of mortality, among those who survive burn shock is wound sepsis (Box 30-8). After recovery from the acute inflammatory phase, postburn deformities delay full functional recovery. Improved survival has been associated with early resuscitation, prevention of

Box 30-8 Survival in Burn Patients

Survival in burn patients has been associated with:

- Early fluid resuscitation
- Prevention of post burn sepsis
- Aggressive surgical treatment
- Improved perioperative care
- Development of multidisciplinary teams

MINI CLINI

Near Drowning: Recognizing Life-Threatening Acute Respiratory Complications

PROBLEM: An unresponsive 3-year-old boy is brought into the ED by his parents after he was rescued from their swimming pool. The parents were hosting a midsummer barbecue when they heard screaming kids and found their son face-down in the swimming pool. Vital signs at admission to the ED were heart rate 40 beats/min, blood pressure 50/20 mm Hg, $SatO_2$ 88%, and body temperature 33° C. What are the next steps and how should the RT respond?

SOLUTIONS: This is an emergency, and the team should be prepared for impending cardiac arrest because of near drowning. Advance Cardiac Life Support (ACLS) should be started right away without delay. While the medical team supports the circulation, the RT should be prepared for emergent and possibly difficult intubation because of aspiration, oral/pharyngeal/tracheobronchial fluids, and edema. A few pediatric ETT sizes, a pediatric intubation kit, and a difficult airway cart with an emergent tracheostomy kit should be at the bedside.

Wall suctioning should be readily available, and a pediatric fiberoptic bronchoscope for deep suctioning and/or foreign body retrieval should be at the bedside.

In summary, a pediatric near drowning should be treated as an emergency with standard pediatric ACLS. However, immediately after recovery, the RT should focus on pulmonary toilette by body positioning, suctioning, and titration of the ventilator in anticipation of impending respiratory complications; refractory hypoxemia; and ARDS.

postburn sepsis, aggressive surgical treatment, improved perioperative care, and the development of multidisciplinary treatment teams. The first phase of the care of patients with serious burn injury is challenging in both respiratory care and hemodynamic management. Intensivists and respiratory therapists during the initial management period must work cooperatively in the management of these critically ill patients.[36]

Clinical Assessment

During the clinical assessment of burn patients the airway is the first priority. Burn patients always should be considered trauma patients; airways evaluation and management should follow what is described in the previous section on airways management of the trauma patient. Airways of burn patients should be

monitored closely because exposure to hot gases, flames, and toxic gases causes airways obstruction as a result of acute edema. Early intubation in these patients is essential, and early initiation of mechanical ventilation is required. Signs for early intubation include gradual but progressive compromise of respiratory mechanics and gas exchange and the presence of facial burns or any direct or indirect evidence of upper airways involvement.

Respiratory assessment of burn patients should focus on the following[37]:

1. Extension (**total body surface area**, [TBSA]) and depth of external burns
2. Degree of involvement of lung tissue
3. Inhalation of toxic gases (carbon monoxide and cyanide)

The surface area of external burns can be easily quantified by the rule of nines, which estimates the total amount of the body surface area involved by the burns (%TBSA). The evaluation of external burns with the rule of nines is crucial to the medical team to guide fluid management during the first hours of treatment (Table 30-2). An adult patient of approximately 80 kg and with burns of 50% of TBSA would require 16 L of fluids in the first 24 hours, of which 8 L is given within the first 8 hours (1 L/hr of fluid infusion). It is imperative for the RT to know the rate of fluid resuscitation and the hemodynamic response during the first critical hours after major burn. The severity of the burn depth is classified based on the anatomic planes progressively involved in the injury (Table 30-3). A first-degree burn is a superficial injury that involves only the epidermis. The second-degree involves the dermis. Third-degree injury is characterized by the destruction of both the epidermis and dermis above the fascia. Fourth-degree involves the muscles and the bones. Surgical intervention with debridement and grafting should be considered starting from second-degree burns.

Extensive chest-wall burns commonly lead to worsening gas exchange and work of breathing. The accumulation of edema in the chest wall and upper abdomen lowers chest wall compliance. The deterioration of respiratory mechanics can be so severe to require early **fasciotomy**.

Lung injury frequently results from inhalation of hot gases and smoke. ARDS is the typical presentation of heat-related lung injury. Fluid overload and systemic inflammatory response usually complicates the respiratory status and respiratory management of burn patients. Direct visualization of the tracheobronchial tree by fiberoptic bronchoscopy can be extremely helpful in revealing mucosal alterations and disruptions characterized by inflammation, erythema, carbonaceous debris, and ulcerations.

Carbon monoxide poisoning and **cyanide toxicity** are common findings in patients who have fire-related burns. The respiratory therapist should be aware that CO and cyanide poisoning do not cause cyanosis. SaO_2 in blood should be measured by ABG analyses because most SpO_2 sensors are unable to distinguish SO_2Hb from methemoglobin (MetHb) and carboxyhemoglobin (COHb). This phenomenon results in false 100 SpO_2 readings even when the patient is lethally hypoxemic. In the absence of blood gas analyses, a cooximeter can measure concentration of MetHb and COHb. CO has an affinity for hemoglobin a hundred times greater than that for O_2, and this can shift the oxyhemoglobin dissociation curve to the left. Patients become symptomatic when COHb levels are higher than 15%; levels greater than 50% are lethal. In these patients, 100% O_2 should be administered as soon as possible because it reduces the half-life of COHb to 40 to 60 minutes. When feasible, hyperbaric O_2 should be considered to prevent serious neurologic sequelae.[38,39] Inhalation of cyanide-containing gas during combustion of nitrogenous materials is characterized by

TABLE 30-2

TABLE 30-3

Severity of Burn Depth

Degree of Burn	Depth of Injury	Level of Pain
First degree	Superficial, only involving the epidermis	Tender and sore
Second degree	Involves the dermis	Very painful
Third degree	Destruction of the epidermis and dermis above the fascia	Very little to no pain
Fourth degree	Full-thickness burns involving the fascia, muscles, and bones	Painless

Box 30-9 Early Clinical Features of Carbon Monoxide and Cyanide Poisoning

- Anxiety
- Tachycardia
- Arrhythmias
- Tachypnoea
- Hypertension followed by:
  - Headache
  - Confusion
- Dyspnea
- Hypotention
- Bradycardia followed by:
  - Neurologic system symptoms (seizures, reduced consciousness)
  - Respiratory failure with pulmonary edema
  - Coma
  - Death

the presence of an adequate O_2 delivery and metabolic acidosis with anion gap. Cyanide compounds work by interfering with mitochondrial O_2 usage, blocking the final step of the oxidative phosphorylation cascade. The O_2 use impairment, despite a normal O_2 delivery, is confirmed by a high mixed venous O_2 saturation. Concentration of cyanide higher than 20 parts per million (ppm) is considered dangerous, and 100 ppm is lethal. **Thiosulfate** and **cyanocobalamin** are administered as soon as possible to reduce the half-life of this toxic compound. For both CO and cyanide poisoning, early clinical features are anxiety, tachycardia and/or arrhythmia, tachypnea, and hypertension, followed by headache, confusion, dyspnea, hypotension, and bradycardia leading to neurologic symptoms, such as seizures and reduced consciousness, respiratory failure with pulmonary edema, coma, and death (Box 30-9).[40]

RULE OF THUMB

CO and cyanide poisoning do not cause cyanosis. SaO_2 in blood should be measured by ABG analyses, because most SpO_2 sensors are unable to distinguish SO_2Hb from MetHb and COHb. This phenomenon results in false normal SpO_2 readings (100%) even when the patient is lethally hypoxemic.

Pathophysiology of Burn Patients

Burn injury can cause extensive tissue destruction, leading to a vast inflammatory process, which starts with the release of inflammatory cytokines. To simplify, there is a local burn effect at the site of the burn and a systemic effect mediated by inflammatory mediators that are released. However, these two effects are interlinked and difficult to separate from each other.

It is generally better to divide burn patients according to the systemic response over time: a severe systemic response that lasts up to the first 48 hours followed by a late response starting at 48 hours, and ending at approximately 72 hours after the burn accident.[37]

1. Commonly, if TBSA exceeds 25%, a systemic inflammatory process becomes evident and fluids from the intravascular space enter the extravascular space and develop a generalized edema. Edema expands quickly within the first hours after the injury. If patients are not sufficiently hydrated, this fluid shift rapidly leads into an impairment of local and systemic perfusion with tissue and organ damage causing ischemia, metabolic acidosis, and mixed venous desaturation, as a result of hypovolemic and distributive shock. The hematocrit gradually increases secondary to hemoconcentration. At the same time, the massive systemic inflammation commonly leads to cardiovascular instability followed by myocardial depression if not treated.
2. The first few hours after injury are characterized by a hyperdynamic state with high metabolic requirements with elevated CO_2 production and O_2 consumption. Massive vasodilation increases pulmonary shunt fraction, worsening hypoxemia that can develop into full pulmonary edema. However, this phase is short-lived and progresses to a catabolic state. At this stage, patients are at high risk for developing infections, with pneumonia being the most common.
3. The effects of the inhalation injury on the tracheobronchial tree and the lungs lead to edema, bronchospasm, and buildup of secretions. Different degrees of ARDS usually follow lung burn injury. When the burn circumferentially surrounds the chest, a mechanical constriction can develop worsening chest and respiratory system compliance.

Specific Concerns

Burn-injured patients with an inhalation injury have a significantly increased risk for morbidity and mortality. Inhalation injury can complicate 20% of burn patients, and these patients often present with facial burns. Patients presenting with facial burns, burnt nasal hairs, soot in the oral and nasal pharynx, and any signs of upper airway burns should be immediately intubated because of the probability of serious airway obstruction developing over time is nearly 100%. At admission it is difficult to identify characteristic radiographic features of inhalation injury. The effects become evident over time only when secondary complications such as inflammation, infection, or atelectasis develop. For this reason, the respiratory status and the airway patency of burn victims should be continuously monitored for the high risk for developing airway obstruction if an artificial airway is not already in place. Securing the airways as soon as possible should be the priority before catastrophic, irreversible airways obstruction occurs. One of the challenges in the respiratory care for severely injured burn patients is the clearance of copious and tenacious secretions. Secretions are accumulating throughout the tracheobronchial tree as a result of increased mucus secretion, buildup of toxic debris and necrotic cells, and peribronchial inflammatory **exudates** and **transudates**. In addition, mucociliary transport is severely impaired by disrupted tracheal-bronchial epithelium causing small airways plugs, worsening alveolar collapse, and predisposing to pulmonary infections. Optimization of airway humidification, careful endotracheal tube suctioning, and bronchoscope toilette are

milestones of daily respiratory care of these particular vulnerable patients.[41-43]

RULE OF THUMB

Burn-injured patients with an inhalation injury have a significantly increased risk for morbidity and mortality.

Respiratory Management

Respiratory care of burn patients is complex. Hemodynamics, fluid resuscitation, %TBSA involvement and related injuries, time from the injury, and upper and lower respiratory conditions are some of the key elements that the RT needs to know while caring for these patients.

Oxygen Therapy

The SaO_2 of burn patients has to be monitored continuously. Until proved otherwise, all victims rescued from a fire should be treated with O_2 for suspected cyanide and CO poisoning. In the presence of cyanide and CO poisoning and to monitor response to treatment, noninvasive portable cooximetry or ABG analysis allows measurements of SaO_2, COHb, and MetHb levels. Cyanide poisoning is treated pharmacologically. The RT should monitor continuously the level of MetHb in the blood, especially if cyanide is treated with nitrite donors. Methylene blue should be administered if levels of MetHb become symptomatic. CO poisoning treatment is focused on dislodging CO from the hemoglobin. High concentration of inspired O_2 via nonrebreathing mask is mandatory in these patients, because O_2 shortens the half-life of CO. When available, a hyperbaric chamber is used in the treatment of the most severely CO poisoned burn patients; CO is quickly dissociated from hemoglobin and **cytochrome oxidase**. Hyperbaric O_2 at three times atmospheric pressure reduces the half-life of CO to approximately 3 minutes, compared to 80 minutes for regular 100% O_2 via nonrebreather mask. It also may reduce the brain (and other organs) tissue ischemia by increasing O_2 transport in plasma to the brain.[44,45]

RULE OF THUMB

Patients presenting with facial burns, burnt nasal hairs, soot in the oral and nasal pharynx, and any signs of upper airway burns should be immediately intubated because the probability of serious airway obstruction developing over time is nearly 100%.

Early Endotracheal Intubation

In these patients early endotracheal intubation is generally recommended for four reasons: (1) Protection of the airways from the risk for occlusion secondary to mucosal and interstitial edema, (2) the need for extensive pulmonary toilette by multiple bronchoscopies, (3) delivery of high fraction of inspired O_2 during CO poisoning, and (4) initiation of early lung protected ventilation in patients at high risk for developing ARDS.

Fiberoptic Bronchoscopy

Fiberoptic bronchoscopy is often used in these patients for diagnostic and treatment purposes. Bronchoscopy is used in acute settings for clearance of foreign bodies from the airways, disrupted mucosa, and mucous debris that might precipitate hypoxemia by alveolar obstruction, collapse, and atelectasis. The copious and tenacious secretions and necrotic tissue often require multiple fiberoptic bronchoscopies over time. Clearance of the tracheobronchial tree has three purposes: (1) Improving ventilation while avoiding $\dot{V}/\dot{Q}$ mismatch, (2) preventing bacterial overgrowth within the bloody-necrotic secretions and pneumonia, and (3) enhancing nebulized drug delivery that is commonly used in these patients (e.g., bronchodilators, antioxidants, and pulmonary vasodilator). Other use of bronchoscopy in these patients includes inspection of injury and monitoring over time of major lesions and distal bronchoalveolar lavage for a microbiologic sample if pneumonia is clinically suspected.[46]

RULE OF THUMB

Hyperbaric O_2 at three times atmospheric pressure reduces the half-life of CO to approximately 3 minutes, compared to 80 minutes for regular 100% O_2 via nonrebreather mask.

Active Humidification

Active humidification with heated humidifiers supplied by heated wire circuit should be used when possible. The aim of using continuous heated well-humidified ventilation is avoidance of mucus plugs in the distal airways and endotracheal tube while preventing body temperature loss.

Mechanical Ventilation

Mechanical ventilation should be titrated according to the underlying major respiratory condition of the patient (i.e., upper airway edema, lower airway injury, intoxication, ARDS, or pulmonary edema). In addition, the respiratory therapist should be prepared to change ventilation management according to the rapid cardiovascular and respiratory changes of the patient's clinical course during hospitalization. A typical early pulmonary scenario is a combination of pulmonary edema resulting from the high rate of fluid infusion and distal atelectasis secondary to secretions and mucus accumulation. Often ARDS develops, complicating the multifactorial respiratory failure and worsening lung compliance and hypoxemia. An early protective lung ventilation approach with low V_T and high PEEP is especially advantageous in these patients. Neuromuscular-blocking drugs are often beneficial to optimize low V_T ventilation (Box 30-10). In refractory hypoxemia, prone positioning and the use of inhaled pulmonary vasodilators might be considered an adjunct to respiratory treatment when

Box 30-10 Mechanical Ventilation of Patients With Smoke Inhalation and Pulmonary Burns

- Mode: Pressure or volume ventilation
- Tidal volume: 4 to 8 ml/kg PBW
- Inspiratory time 0.6 to 1.0 sec
- Plateau pressure: less than 28 cm H_2O unless chest wall compliance decreased
- If compliance decreased, plateau pressure can exceed 28 cm H_2O
- Measure end inspiratory transpulmonary pressure to determine acceptable plateau pressure, \
- Driving pressure equal to or less than 15 cm H_2O
- Rate only limited by the development of auto-PEEP
- Minute volume to maintain normal $PaCO_2$
- PEEP 5 to 10 cm H_2O, unless ARDS
- FIO_2 1.0 initially because of concern for CO poisoning
- If ARDS, manage as any other ARDS patient

feasible. The use of venovenous extracorporeal membrane oxygenation remains highly controversial in patients with extensive burn because of the risk for exsanguination. Early tracheostomy is often advocated because it improves secretion management by cough and suctioning, patient recovery by weaning from anesthetic medications, and wound care by patient collaboration.[47,48]

SUMMARY CHECKLIST

- In trauma patients, careful assessment for injuries of the head, neck, upper airway, and chest should occur immediately on presentation.
- Obese patient are at significant risk for cardiovascular disease. In addition, lung volumes are generally decreased, with atelectasis and airflow limitation that can result in air trapping and auto-PEEP. High levels of PEEP are frequently required.
- Near-drowning victims frequently have aspirated foreign material and present with significant pulmonary edema and electrolyte imbalances.
- Patients with smoke inhalation and pulmonary burns require careful assessment of their airways. Any clinical signs of upper airway injury generally require immediate intubation and mechanical ventilation.
- Chest trauma frequently results in injuries that cause disruption of major vessels and the development of tension hemothorax or pneumothorax.
- All obese patients should be assessed for sleep apnea and obesity hypoventilation syndrome.
- Fresh water drowning frequently results in hyponatremia, hemolysis, hyperkalemia, and ventricular fibrillation. Salt water drowning frequently results in marked pulmonary edema, hemoconcentration, hypernatremia, and hypoalbuminemia.
- Respiratory assessment of burn patients should focus on percent of TBSA, degree of tissue involvement, and inhalation of toxic gases.

MINI CLINI

Burn: Recognizing Hypoxemia in Patients After a Fire and Titrating Ventilation

PROBLEM: A 55-year-old firefighter presents at the hospital with 60% TBSA second- and third-degree burns after the successful rescue of an entire family from their burning house. The patient is 6 feet, 2 inches and 240 lb. During transport to the hospital he was intubated with an 8.0-mm ETT for increased shortness of breath and changes in mental status. Breath sounds are audible bilaterally. Ventilator settings are pressure support ventilation 15, PEEP 5 cm H_2O, and FiO_2 0.5. The patient's vital signs are heart rate 110 beats/min, blood pressure 90/50 mm Hg, respiratory rate 30 breaths/min, and SpO_2 98%. Endotracheal suctioning shows moderate dark/black secretions. The medical team started fluid resuscitation at a rate of 1 L/hr of normal saline. An arterial line was placed in his right radial artery, and the medical team has been struggling for the past half hour in the emergency room to place a central line. His SpO_2 has declined to 92%, but the other vital signs are unchanged. What should the RT do?

SOLUTIONS: Immediately confirm ETT positioning by auscultation of bilateral breath sounds and suggest a chest radiograph to the medical team if it was not requested already. Confirm by ETT suctioning the dark/black secretions in the airways, which imply a severe inhalation burn and cyanide poisoning.

Obtain a blood gas sample as soon as possible to rule out CO poisoning and evaluate metabolic acidosis. It is imperative to perform a blood gas analysis as soon as possible in any burn patient with a TBSA greater than 25% admitted to the ED even when SaO_2 is 99% to 100%. It might be a falsely high reading because of MetHb and COHb. The blood gas analysis should include PaO_2, MetHb, COHb, $PaCO_2$, pH, anion gap, lactate, and base excess. If available, noninvasive continuous monitoring for MetHb and COHb should be applied to trend MetHb and COHb values and evaluate response to treatment.

This is a critically ill patient with extensive and severe burns (TBSA 60%, second- and third-degree burn) and inhalation injury with an ongoing massive fluid resuscitation requirement. Ventilator settings should be titrated according to the clinical scenario; however, the following should be recommended: (1) increase FiO_2 up to 100% until the presence of CO and cyanide poisoning has been ruled out; (2) increase minute volume ventilation, avoiding increased V_T and mean airway pressure, to minimize effects of metabolic acidosis; (3) titrate PEEP by performing best PEEP trial. This patient most likely will develop pulmonary edema secondary to inflammation and fluid resuscitation and ARDS secondary to inhalation injury.

- Generally, gas-exchange abnormalities in trauma victims are a result of disruption of the chest wall and pulmonary contusion.
- Generally, gas-exchange abnormalities in obesity are a result of low lung volumes and the development of atelectasis.
- Generally, gas-exchange abnormalities in near drowning are a result of fluid shifts and the activation of inflammatory mediators.
- Generally, gas-exchange abnormalities in burns are a result of burns to the lung parenchyma and inhalation of foreign materials and toxic gases, specifically CO and cyanide.
- O_2 therapy is immediately indicated in the management of near drowning and pulmonary burns. Obese patients and trauma victims require O_2 therapy based on the severity of the patient's clinical presentation.
- Noninvasive ventilation is primarily indicated in the management of patients with sleep apnea, patients with OHS, and trauma patients with unstable chest walls.
- Invasive mechanical ventilation can be indicated in all four settings based on the severity of the injury.
- The primary concern during mechanical ventilation to trauma patients is the presence of a tension pneumothorax and hemodynamic instability.
- The primary concern with the application of mechanical ventilation to obese patients is the appropriate selection of V_T (based on PBW) and the appropriate application of PEEP.
- Near-drowning victims and pulmonary burn patients frequently and rapidly develop ARDS.
- In all four categories of patients, lung protective mechanical ventilation should be used from the onset of mechanical ventilation.
- PEEP and lung recruitment maneuvers should be applied to the markedly obese patient and any patient who develops ARDS. Prone positioning should be considered early in near-drowning patients and any patient with refractory hypoxemia unresponsive to the lung recruitment maneuvers and the setting of PEEP by decremental trial.
- Spontaneous breathing trials are the primary approach to weaning from ventilatory support for all of these patients.

CHAPTER 31

Lung Cancer

PETER J. MAZZONE AND HILARY PETERSEN

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the epidemiology of lung cancer in the United States, particularly current trends.
- Identify risk factors for lung cancer.
- State the classification of lung cancer types and the cellular features of the four common types of lung cancer.
- Describe our current understanding of the pathophysiology of lung cancer.
- Identify the clinical features of the common types of lung cancer.
- Describe the diagnostic approach to lung cancer.
- State the importance of proper staging for lung cancer.
- Describe the treatment and outcomes for the common types of lung cancer by stage.
- State the role of the respiratory therapist in managing patients with lung cancer.

CHAPTER OUTLINE

KEY TERMS

adenocarcinoma
chemotherapy
computed tomography
flexible bronchoscopy
large cell carcinoma
magnetic resonance imaging
mass
nodule
non–small cell carcinoma
Pancoast syndrome
paraneoplastic syndrome
positron emission tomography
radiotherapy
screening
small cell carcinoma
squamous cell carcinoma
staging system
surgical resection
tumor, node, metastasis (TNM) staging
transbronchial needle aspiration
transthoracic needle biopsy

Lung cancer is a major public health problem. In the United States, approximately 28% of cancer deaths are due to lung cancer.[1] Most of these deaths could be avoided if people did not smoke tobacco-related products. Worldwide tobacco consumption has not been declining, however, suggesting lung cancer will remain an epidemic for years to come. Advances in early detection and treatment have been slow, but steady. The overall prognosis remains poor, with just over one in eight lung cancer patients still living 5 years after diagnosis. This chapter provides an overview of lung cancer for the respiratory therapist (RT).

EPIDEMIOLOGY

New Cases

In 2014 an estimated 224,210 new cases of lung cancer were diagnosed in the United States.[1] Lung cancer is the second most

frequently diagnosed cancer in men and women. The incidence of lung cancer peaked in men in 1984 and has since been declining. In women, however, the incidence increased during the 1990s, with a leveling off toward the end of the decade. These trends parallel the smoking patterns of men and women.[1] The World Health Organization estimates that there are 2 million cases of lung cancer worldwide each year.

Deaths

Lung cancer is the number one cause of cancer-related death in men and women; it surpassed colon cancer in the early 1950s in men and breast cancer in the late 1980s in women. There are more deaths from lung cancer than breast, colon, and prostate cancer combined. Mortality rates in men declined significantly in the 1990s, whereas a slow increase occurred in women. These rates parallel the smoking patterns of men and women (Figures 31-1). In 2014 in the United States, an estimated 159,260 deaths were due to lung cancer. In men, lung cancer is the leading cause of cancer-related deaths from age 40 years to end of life. In women, lung cancer surpasses breast cancer in the age group of 60 and older.[1]

Tobacco-Related Products

Direct exposure to tobacco has occurred in 85% to 90% of individuals with lung cancer. Many tobacco-related carcinogens have been identified. The age at which smoking began, the number of cigarettes smoked per day, and the duration of smoking all influence the likelihood of developing lung cancer. Also, the intensity of smoking, the depth of inhalation, and the composition of the cigarette influence the risk. All types (see later) of lung cancer are associated with smoking. The strongest associations are with two of the cell types: *small cell* and *squamous cell carcinoma*. The risk for developing lung cancer decreases over time after smoking cessation, although it never reaches that of a lifelong nonsmoker.

There is evidence that *nicotine,* a chemical in tobacco, is highly addictive.[2] Approximately one-fifth of all adults in the United States smoke cigarettes. Progress had been made in the fight against cigarette use; in the decades from 1970 to 1990, the percentage of women who smoked declined from 33% to 25% and the rate of smoking among men decreased from 43% to 28%. The annual decline that had occurred since the early 1970s began to slow through the 1990s despite mounting evidence associating smoking with disease and death.[3] In addition, a decrease in smoking has not been observed among adults 18 to 24 years old. Cigarette smoking among young people remains a major public health concern. Of young adults (18 to 24 years), 33% have been reported to be current users of tobacco,[4] and 3000 teenagers begin smoking each day.[5] Approximately 13% of middle school children and 28% of high school students use tobacco products. In the context that a person who has not started smoking as a teenager is unlikely ever to become a

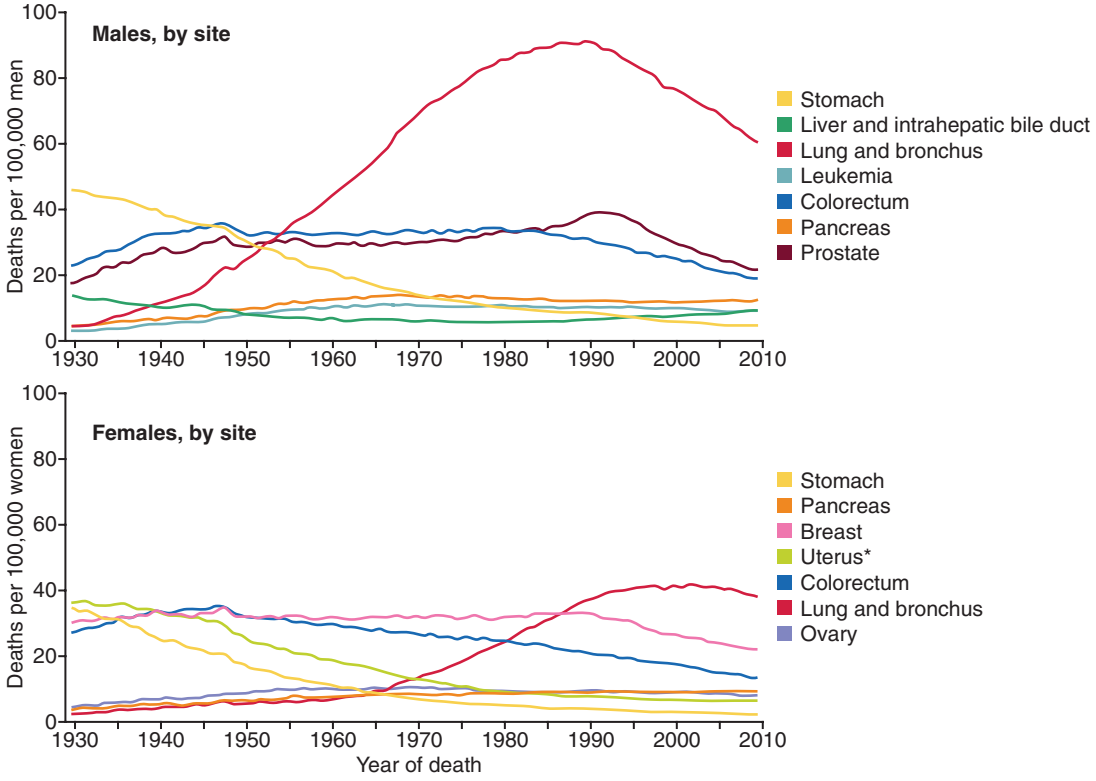

FIGURE 31-1 Death rate from lung cancer by gender from 1930 to 2010. (Modified from Siegel R, Ma J, Zou Z, et al: Cancer statistics, 2014. *CA Cancer J Clin* 64:9–29, 2014.)

smoker, the tobacco industry has focused on young people and developing countries as the primary sources of new customers.[6,7]

Other forms of exposure to tobacco-related products also pose risk for promoting lung cancer. Cigar smoking, which has increased considerably over the past several years, is known to be an independent risk factor for developing lung cancer.[8]

Exposure to *sidestream smoke,* or *passive smoking,* also may lead to an increased risk for lung cancer. The risk is generally much lower than active smoking but varies with the intensity of exposure.[7] It has been estimated that 3000 to 5000 deaths in the United States and 21,400 deaths worldwide from lung cancer occur each year because of second-hand smoke exposure.[9]

Occupational Agents and Other Risks

Many other risk factors have been identified (Box 31-1). Occupational agents are known to act as lung cancer carcinogens. Arsenic, asbestos, and chromium confer the highest risk. This risk is increased when there is concomitant exposure to tobacco products. Indoor radon exposure is also a risk factor for developing lung cancer. Radon is a naturally occurring gas produced by the breakdown of uranium ore or other rocks such as shale and granite. Indoor radon exposure generally comes from the soil underneath homes and buildings.[10] Particulates in the atmosphere (i.e., pollution) also can increase the risk for lung diseases including lung cancer.

Family members of people who develop lung cancer have an increased risk.[11–13] Women seem to have a higher baseline risk for developing lung cancer and a greater susceptibility to the effects of smoking. Differences in the metabolism of tobacco-related carcinogens and their metabolites, an effect of hormone differences, or both are thought to account for the increased susceptibility.[14] Dietary factors also can modify risks. Higher consumption of fruits and vegetables is associated with a reduced lung cancer risk, and increased dietary fat intake may lead to a higher risk.[15,16] Supplementation with vitamin A, vitamin E, or beta-carotene has not positively influenced risk.[15] The presence of chronic obstructive pulmonary disease (COPD) is an independent risk factor.[17,18]

CLASSIFICATION

Lung cancers are divided into two major groups—**small cell carcinoma** and **non–small cell carcinoma**—based on pathologic features that are visible under light microscopy. The evaluation and management of a patient are guided by the type and stage (see later) of lung cancer. The non–small cell cancer category consists of **adenocarcinoma**, **squamous cell carcinoma**, **large cell carcinoma**, and variants (Figure 31-2). Table 31-1 presents the pathologic and epidemiologic features of the four most common types of lung cancer.

PATHOPHYSIOLOGY

The pathophysiology of lung cancer development is complex and incompletely understood. Damage to genetic material in lung cells is the result of exposure to chemical carcinogens such as the carcinogens contained in tobacco smoke.[18] People who develop lung cancer may have a genetic predisposition to the effects of these carcinogens. The genes influenced in the pathogenesis of lung cancer produce proteins involved in cell growth and differentiation, cell cycle processes, *apoptosis* (programmed cell death), *angiogenesis* (production of new blood vessels), tumor progression, and immune regulation. If enough of these pathways have been affected, the uncontrolled growth of cells that defines cancer occurs. By understanding the mechanisms that lead to genetic damage and the impact of that damage, novel means of risk stratification, prevention, early detection, and therapy should be able to be developed.

CLINICAL FEATURES

The clinical features of lung cancer result from the effects of local growth of the tumor, regional spread through the lymphatic system, hematogenous (blood-borne) distant metastatic spread, and remote effects from tumor products or immune cross reaction with tumor antigens (Box 31-2). Some manifestations occur more commonly with a particular cell type. Only 15% of patients with a diagnosis of lung cancer do *not* have symptoms at the time of presentation.

Local growth in a central location (e.g., in a main stem bronchus) can cause cough, hemoptysis, or features of large airway obstruction. Squamous cell carcinoma and small cell carcinoma are more likely to grow in a central location than other cell types. Adenocarcinoma and large cell carcinoma occur more commonly in the periphery of the lung. Peripheral growths also may cause cough and dyspnea; smaller tumors may not cause any symptoms. If the pleura or chest wall is involved, pain may occur.

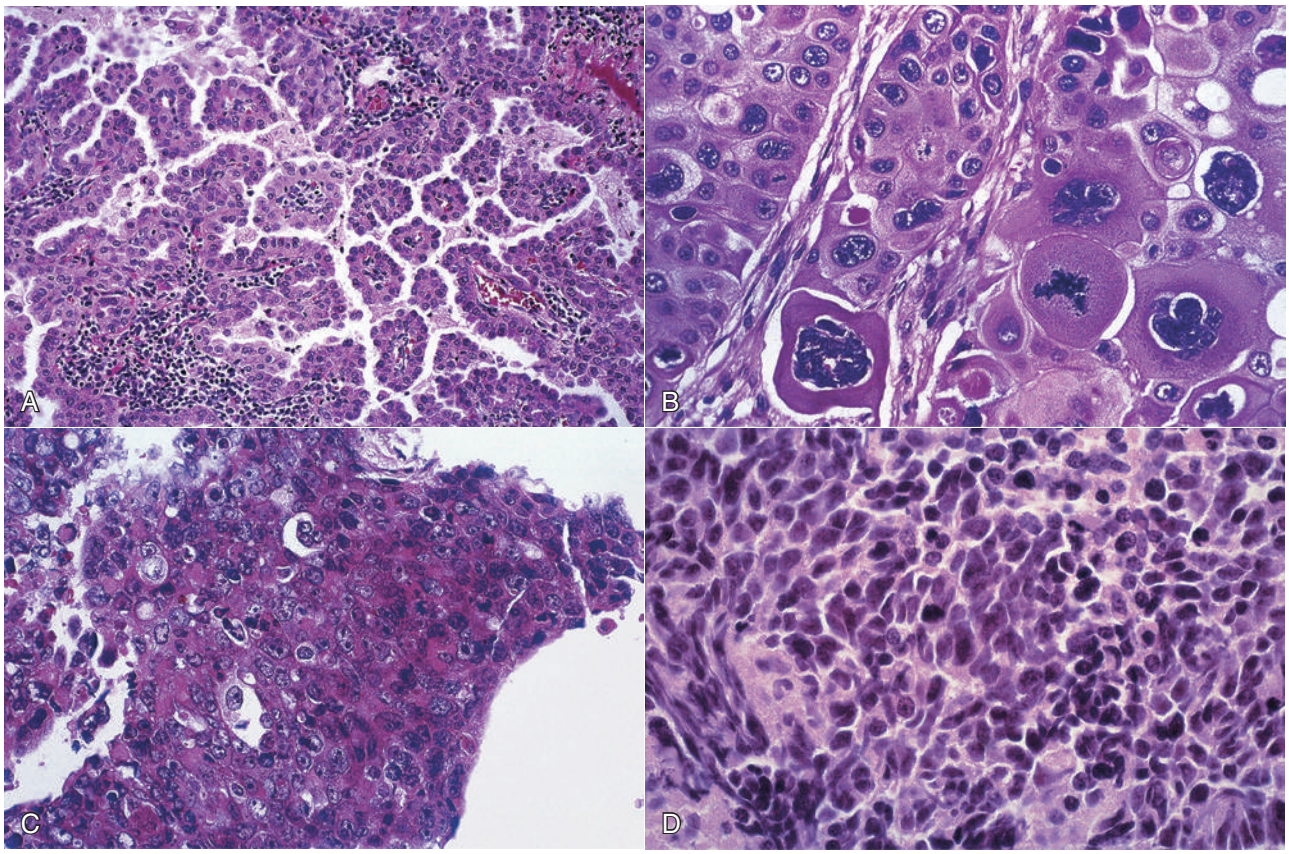

FIGURE 31-2 Lung cancer histology. **A,** Adenocarcinoma, characterized by heterogeneous differentiation in the same tumor. **B,** Squamous cell carcinoma, characterized by the presence of cytokeratin differentiation with keratinization and intercellular bridges. **C,** Large cell carcinoma, characterized by sheets and nest with extensive necrosis, large nuclei with prominent nucleoli, and lack of definitive evidence of squamous or glandular differentiation. **D,** Small cell carcinoma, characterized by round to fusiform nuclei, nuclear molding, faint or absent nucleoli, and scant cytoplasm. (Courtesy The Cleveland Clinic, Cleveland, Ohio.)

TABLE 31-1

Classification of Most Common Types of Lung Cancer

Category	Cell Type	Pathologic Features (Light Microscopy)	Epidemiology
Non–small cell carcinoma	Adenocarcinoma	Formation of glandular structures; heterogeneous differentiation	Accounts for >40% of lung cancers in North America; increasing frequency in women
	Squamous cell carcinoma	Cytokeratin and intercellular bridges	Second most frequent type of lung cancer in United States
	Large cell carcinoma	Sheets and nests of cells, necrosis, lack of squamous cell or glandular features	Less common than adenocarcinoma or squamous cell carcinoma
Small cell carcinoma	Small cell carcinoma	Round to fusiform nuclei; faint to absent nucleoli; scant cytoplasm	Accounts for 13% of lung cancers

Regional spread may lead to esophageal compression *(dysphagia)*, recurrent laryngeal nerve paralysis (hoarseness), phrenic nerve paralysis with an elevated hemidiaphragm (dyspnea), and sympathetic nerve paralysis leading to Horner syndrome (ptosis [droopy eyelid], miosis [small pupils], anhidrosis [lack of facial sweating], and enophthalmos [sunken eye]). Growth at the very top of the lung may lead to a **Pancoast syndrome**, with shoulder pain radiating in an ulnar distribution as a result of involvement of the brachial plexus. The superior vena cava can become obstructed, resulting in swelling of the face, neck, and upper chest, plethora (swollen facial veins causing a ruddy complexion), and dilation of superficial veins over these areas. This is called the *superior vena cava syndrome*. Lung cancer can grow to involve the heart and pericardium. Lymphatic obstruction and spread can lead to dyspnea, hypoxemia, and pleural effusions.

Box 31-2 Lung Cancer Manifestations

Local growth
- Cough
- Dyspnea
- Hemoptysis
- Pain

Regional growth
- Dysphagia
- Dyspnea
- Hoarseness
- Horner syndrome
- Hypoxia
- Pancoast syndrome

Pericardial and pleural effusions
- Superior vena cava syndrome

Metastatic disease
- Headache
- Hepatomegaly
- Mental status change
- Pain
- Papilledema
- Seizures
- Skin or soft tissue mass
- Syncope
- Weakness

Paraneoplastic
- Cutaneous or skeletal
  - Acanthosis nigricans
  - Clubbing
  - Dermatomyositis
  - Hypertrophic osteoarthropathy
- Endocrine
  - Cushing syndrome
  - Humoral hypercalcemia
  - Syndrome of inappropriate antidiuretic hormone
  - Tumor necrosis factor (cachexia)
- Hematologic
  - Anemia or polycythemia
  - Disseminated intravascular coagulation
  - Eosinophilia
  - Granulocytosis
  - Thrombophlebitis
- Neurologic
  - Cancer-associated retinopathy
  - Encephalomyelitis
  - Lambert-Eaton syndrome
  - Neuropathies
  - Cerebellar degeneration
- Renal
  - Glomerulonephritis
  - Nephrotic syndrome

Distant metastatic disease can affect most organs; the brain, bones, liver, and adrenal glands are most commonly involved. Neurologic symptoms such as headaches, vision changes, and seizures may suggest brain metastases. Back pain and changes in strength or sensation in an extremity may indicate spinal cord compression. Bone pain could indicate bone metastases. Laboratory abnormalities may point to bone marrow or liver involvement. Imaging may detect adrenal involvement.

MINI CLINI

Pancoast Tumor

PROBLEM: A 65-year-old man who has smoked two packs of cigarettes per day for the past 40 years has had drooping of the left eyelid for the past 3 weeks. A chest radiograph reveals a mass in the apex of the left lung. Is there a link between the drooping of the eyelid and the lung mass?

DISCUSSION: Lung tumors involving the apex of the lung (superior sulcus tumors) are also known as *Pancoast tumors*. If they involve the cervical sympathetic nerves in the neck, these tumors result in Horner syndrome. This syndrome is characterized by ptosis (drooping of the eyelid), anhidrosis (absence of sweating), and miosis (constricted pupil) on the same side as the tumor. Other manifestations of Pancoast tumor include pain and weakness in the upper extremity (owing to involvement of the brachial plexus), rib destruction, and destruction of vertebral bodies. Treatment depends on local and distant spread of the tumor.

MINI CLINI

Mediastinal Adenopathy

PROBLEM: A 60-year-old man has been found to have small cell lung cancer on the basis of results of bronchoscopic biopsy findings. Computed tomography (CT) scan of the chest shows extensive mediastinal adenopathy. The patient has been admitted to the oncology floor for chemotherapy. You are called to assess him because he cannot lie down owing to shortness of breath (orthopnea). When you arrive, the patient is sitting on the edge of the bed. You notice that his face and neck are swollen. He also has dilated veins over the face, neck, chest, and arms. How do you explain these findings?

DISCUSSION: This patient has superior vena cava obstruction caused by compression by the mediastinal tumor. The swelling of the face, neck, and arms is caused by impairment of the venous drainage from the upper body (the superior vena cava distribution). The dilated chest and arm veins are collateral vessels (or alternative pathway vessels) that compensate for the superior vena cava obstruction. Superior vena cava obstruction can be caused by various benign or malignant conditions that involve the mediastinum or the right upper lung. Treatment usually is therapy for the underlying problem.

When symptoms develop that are the result of the presence of cancer but are not related to the growth or spread of the cancer, these symptoms constitute a **paraneoplastic syndrome.** Paraneoplastic syndromes can result from the effects of proteins produced by the tumor that circulate through the body to have their effects on distant organs or result from the immune response of the body to a tumor antigen that is similar to antigens in other parts of the body, causing immune injury to the distant organ. Paraneoplastic syndromes may occur before the primary tumor appears and be the first sign of disease or an

indication of tumor recurrence. Examples of tumor secretion include the production of excess glucocorticoids (ectopic Cushing syndrome), parathyroid hormone (hypercalcemia of malignancy), and antidiuretic hormone (syndrome of inappropriate antidiuretic hormone [SIADH]). Immune cross-reactivity leads to paraneoplastic neurologic syndromes that can affect all parts of the neurologic system, resulting in emotional lability (limbic encephalitis), loss of balance (cerebellar degeneration), or proximal muscle weakness of the arms and legs with autonomic dysfunction (Lambert-Eaton myasthenic syndrome). Other paraneoplastic syndromes include skeletal and connective tissue syndromes (digital clubbing, hypertrophic pulmonary osteoarthropathy), coagulation and hematologic disorders, cutaneous and renal manifestations, and systemic symptoms (anorexia, cachexia, and weight loss).[19]

MINI CLINI

Paraneoplastic Syndrome

PROBLEM: A 55-year-old man is brought to the emergency department by family members because of confusion and progressive generalized weakness. Examination in the emergency department shows the patient is dehydrated, lethargic, and confused. Chest radiograph reveals a cavitary lesion in the right upper lobe. Results of arterial blood gas analysis are normal. Results of chemical analysis urgently performed with the blood gas analysis reveal a sodium level of 150 mEq/L (normal 135 to 145 mEq/L) and a calcium level of 17 mg/dL (normal 9 to 10.5 mg/dL). How is the lung mass related to this patient's presentation and biochemical abnormalities?

DISCUSSION: This patient's confusion and weakness are due to hypercalcemia, which is a paraneoplastic presentation of lung cancer, especially squamous cell carcinoma (the cavitating mass on the chest radiograph). Paraneoplastic syndromes are systemic manifestations of lung cancer that are not caused by metastasis. Most paraneoplastic syndromes are associated with small cell lung cancer. However, hypercalcemia is more common with squamous cell carcinoma and is caused by secretion by the tumor of parathyroid hormone–related peptide. Treatment consists of hydration, diuresis, and use of medications that can reduce the levels of calcium.

DIAGNOSIS

Approximately 85% of patients with lung cancer present with one or more of the previously described symptoms. In the remainder, lung cancer is detected by radiographic evaluation performed for an unrelated problem. This proportion may change in the future as **computed tomography** (CT) screening programs become widespread. Most patients have a chest radiograph and CT scan of the chest performed in their initial evaluation. These studies show a small spot (<3 cm in diameter) termed a **nodule** in the lungs or a larger spot (>3 cm in diameter) termed a **mass.** Other findings on imaging include enlarged lymph nodes in the hila (where the bronchi and central blood vessels emerge from the mediastinum into the lung) or mediastinum or a pleural effusion. An individual patient's clinical and radiographic presentation dictates further evaluation.

The symptoms of lung cancer are nonspecific. There are many reasons that someone could have a cough or be short of breath. Similarly, an abnormality such as a lung nodule can be present on chest imaging for various reasons. Certain clinical and radiographic features make it more likely that the presentation represents lung cancer. The older the patient is and the more he or she has smoked over time, the more likely the chest finding is lung cancer. Also, individuals with prior cancers are more likely to have lung cancer. Hemoptysis increases concern about cancer.

Radiographic features are also used to determine the probability of cancer. The larger the lung abnormality, the more likely it is to be cancer. When the abnormality has reached the size of a mass (3 cm), it needs to be considered a cancer until proved otherwise. The rate of growth of the lesion is also helpful. If a nodule grows rapidly (doubles in size in <1 month) or grows very slowly or not at all over a couple of years, it is unlikely to be due to cancer. If the nodule appears to be heavily calcified on imaging, it has likely been present for quite some time and is unlikely to represent cancer. If the abnormality has an irregular border, is lobulated, or is spiculated, it is more likely to be a cancer than if the border is smooth and rounded. Finally, if the lesion is cavitary, the thickness of the wall of the cavity can suggest cancer. A wall thickness of 14 mm or greater is likely to represent a cancer.[20]

RULE OF THUMB

A solid solitary pulmonary nodule that has not grown in 24 months is unlikely to be malignant.

MINI CLINI

No Response to Antibiotics

PROBLEM: A 55-year-old woman who does not smoke has a 3-month history of dyspnea on exertion, weight loss, and cough productive of copious amounts of clear, frothy sputum. She has no fever or chills. She has been treated for 2 weeks for "double pneumonia" without relief of the symptoms. Examination reveals finger clubbing and decreased air entry in both lung bases with dullness to percussion. A chest radiograph shows bilateral alveolar infiltrates. What should be done next?

DISCUSSION: The patient has a variant of adenocarcinoma of the lung. Cough productive of copious amounts of clear, frothy sputum is characteristic of this type of lung cancer. The radiographic appearance may be indistinguishable from that of pneumonia, especially when there is sputum production. The absence of fever, the chronic presence of infiltrates, and the lack of response to antibiotic therapy should raise suspicion for this type of lung cancer. Bronchoscopy with transbronchial biopsy would be a reasonable next step to confirm the diagnosis.

After the clinical and standard imaging features are reviewed, a probability of malignancy can be determined. If the probability is very high, the potential cancer does not seem to have spread, and the individual is fit, proceeding directly to surgery would be reasonable. If the previously mentioned features suggest a very low probability of malignancy, the clinician and patient might choose to follow along with serial chest imaging over time to assess for further growth. When the probability falls between these extremes, adjunctive imaging and invasive procedures can be used to help alter the probability. The most commonly used additional imaging technique is **positron emission tomography** (PET) with fluorodeoxyglucose (FDG-PET). Because malignant cells are metabolically very active, they take up the glucose analogue more avidly than nonmalignant cells. The attached radioactive tracer becomes trapped in the cells, allowing it to be imaged. When this test is used to help predict the presence of lung cancer, it has a sensitivity of 97% and a specificity of 78%. PET imaging can produce false-positive results in other metabolically active conditions such as infections. It can be falsely negative if the lesion is too small (<10 mm) or if the tumor is slow growing and not very metabolically active (e.g., some adenocarcinomas, carcinoid tumor).[21]

Ultimately, tissue is obtained to confirm the diagnosis of lung cancer. **Flexible bronchoscopy** and **transthoracic needle biopsy** are invasive, nonsurgical approaches used to obtain tissue. If these procedures fail or are deemed unnecessary, a surgical approach is used.

Flexible bronchoscopy is a procedure in which a long, thin, flexible camera is passed through a patient's nostril or mouth into the lungs. The camera can be extended into the branches of the lung as far as the branches are large enough to admit it. The camera has a small channel through which very thin biopsy instruments can be passed out deeper into the lung to take samples from concerning areas. Flexible bronchoscopy has a high diagnostic yield for lesions that are endoscopically visible within the larger airways. Samples are collected by washing saline over the lesion, sending a small brush through the camera to collect cells on its bristles, and taking biopsy samples with a forceps or needle.

Addition of needle aspiration to the conventional sampling techniques (washing, brushing, and forceps biopsy) improves the yield. The diagnostic yield from lesions in the periphery of the lung, beyond where the camera is able to see, is lower. Conventional sampling techniques and peripheral **transbronchial needle aspiration** complement each other. Factors that influence the diagnostic yield of flexible bronchoscopy for peripheral lesions include the size of the lesion, its location, and the presence of a "bronchus sign" on CT (an airway leading directly into the lesion). Smaller, more peripheral lesions, without a visible bronchus within or leading directly to them, are unlikely to be diagnosed by flexible bronchoscopy.[22] More recent technologic advances, such as multiplanar imaging, electromagnetic navigation of the bronchoscopy instruments, and peripheral endobronchial ultrasound, have been able to improve the yield of flexible bronchoscopy for these small peripheral lesions.[23] Not infrequently, the hilar or mediastinal lymph nodes are enlarged as a result of spread of the tumor. Diagnosis and staging can be accomplished during bronchoscopy with endobronchial ultrasound to guide biopsies of these lymph nodes.[24,25]

Transthoracic needle biopsy, using fluoroscopic or CT guidance, also can be used to obtain tissue. With this procedure, an aspirating needle is passed through the skin into the lung lesion under the guidance of chest imaging. The positive predictive value of this procedure is high, the negative predictive value is modest, and the rate of establishing a specific benign diagnosis is low. Smaller nodules in central locations have lower diagnostic rates. A higher rate of pneumothorax occurs with transthoracic needle biopsy.[24] The choice of which procedure to use is guided by the size and location of the lesion and by the local expertise with each technique.

STAGING

A major factor that determines the prognosis of lung cancer and guides the selection of appropriate treatment is the extent to which the cancer has spread in the lungs and throughout the body. The extent of cancer spread is termed the *stage* of the cancer. Non–small cell lung cancer is staged using the **TNM staging** system (*T* for extent of primary tumor, *N* for regional lymph node involvement, and *M* for metastases).

The T component of the **staging system** is divided into T1 through T4 lesions, as follows:

- A *T1 tumor* is a small tumor confined to the lung. It must be less than 3 cm in diameter and be surrounded by lung or visceral pleura and cannot extend into a main bronchus. T1a tumors are less than 2 cm in diameter, and T1b tumors are 2 to 3 cm.
- A *T2 tumor* is between 3 cm and 7 cm in diameter or any size tumor that invades the visceral pleura, or extends into the main bronchus, but remains greater than 2 cm from the main carina. It may cause segmental or lobar atelectasis.
- A *T3 tumor* is locally advanced or invasive up to but not including the major intrathoracic structures. It can be any size, and it may involve the chest wall, diaphragm, mediastinal pleura, parietal pericardium, or main bronchus within 2 cm of the main carina (but not involving the main carina). It may cause atelectasis of an entire lung. There may be separate tumor nodules in the same lobe as the primary tumor. A tumor larger than 7 cm in diameter is considered T3 even if unaccompanied by local invasion.
- A *T4 tumor* is a tumor of any size that has invaded one of the major intrathoracic structures, such as the mediastinum, heart, great vessels, trachea, esophagus, vertebral body, or main carina. The tumor is also classified T4 if there are tumor nodules in a different ipsilateral lobe of the lung.

The N component of the staging system is determined by which lymph nodes, if any, are involved with tumor, as follows:

- *N0 spread* does not involve any lymph nodes.
- *N1 spread* indicates the presence of cancer in nodes within the ipsilateral lung (the same side as the tumor).
- *N2 spread* signifies cancer in nodes in the mediastinum ipsilateral to the primary tumor.

TABLE 31-2

TNM Staging for Lung Cancer

Stage	
IA	T1a,bN0M0
IB	T2aN0M0
IIA	T1a,bN1M0, T2aN1M0, T2bN0M0
IIB	T2bN1M0, T3N0M0
IIIA	T3N1M0, T(1-3)N2M0, T4N0-1
IIIB	T4N2M0, T(1-4)N3M0
IV	T(any)N(any)M1a,b

- *N3 spread* signifies cancer in *contralateral* ("opposite side") mediastinal or hilar nodes, *ipsilateral* or contralateral scalene, or supraclavicular nodes.[25–27]

The M part of the staging system represents the absence *(M0)* or presence *(M1)* of metastases outside of the chest. *M1a* refers to metastasis of separate tumor nodules in the contralateral lung or the presence of a malignant pleural or pericardial effusion. *M1b* refers to distant metastatic spread, such as liver, bone, or brain lesions.

The most recent revision[26] to this staging system occurred in 2009 (Table 31-2 and Figure 31-3). The stages are labeled from stage IA to stage IV based on the combination of T, N, and M features.

For patients with small cell lung cancer, the TNM staging system was previously thought to be less useful. Instead, small cell lung cancer has been staged as limited or extensive disease. *Limited stage* disease is present when the tumor is confined to a hemithorax (including ipsilateral mediastinal and supraclavicular lymph nodes) and can be contained within a radiotherapy port. *Extensive stage* disease is present when the tumor extends beyond these boundaries. The recent lung cancer staging revision recognized a benefit to applying the TNM staging system used for non–small cell cancer to small cell cancer as well.[26-29]

The proper use of testing to stage a patient with lung cancer is addressed in a more recent set of guidelines.[27] The history and physical examination are important in guiding testing. The extent of spread is best evaluated using CT of the chest extending to the upper abdomen to include the liver and adrenal glands; this should be ordered in all patients. **Magnetic resonance imaging** (MRI) has not proved to be more accurate except in the setting of a Pancoast tumor. Evidence shows that integrated PET/CT scanning has better test characteristics for staging lymph node and distant disease involvement than other types of imaging (Figure 31-4).[30-32]

Because noninvasive tests can have false-positive results, tissue confirmation is necessary. Bronchoscopy with transbronchial needle aspiration is useful to stage the mediastinum. The addition of endobronchial and endoscopic ultrasound has increased the yield of nonsurgical mediastinal staging.[26,33] If such staging is negative, mediastinoscopy, mediastinotomy, or thoracoscopy can confirm the nodal status. Despite the advances in imaging technology and sampling techniques, definitive staging with **surgical resection** and mediastinal dissection remains the gold standard in a patient with resectable disease. The assigned clinical stage (determined by the previously listed testing, including mediastinoscopy) can be lower than the pathologic staging (assigned after surgery).

The evaluation of metastatic disease also takes into consideration the history, physical examination, laboratory results (electrolytes, calcium, alkaline phosphatase, liver profile, and creatinine), and pathologic examination results.

Per guidelines, a head CT or MRI scan should be performed if symptoms or signs of metastatic disease are present or when evaluating what appears to be stage IIIA through IV disease. Although there is no proved survival benefit from CT versus MRI, many clinicians prefer to use MRI of the brain because it has greater sensitivity to detect metastatic disease.[30,34] The rest of the body is assessed by PET imaging, as was the mediastinum. PET imaging is recommended for all patients.

Along with evaluating the anatomic extent of disease, a patient's performance status is important in determining his or her prognosis and ability to tolerate any proposed treatment. The two most commonly used scales of performance status are the *Zubrod scale* and the *Karnofsky scale*. Although their definitions differ, the general principles of the two scales are the same, with ratings based on activity level, independence in daily activities, and severity of symptoms.

RULE OF THUMB

Staging for lung cancer is complex and should involve a multidisciplinary team. Stage I cancers are small tumors. Stage II cancers involve hilar nearby lymph nodes or larger tumors. When mediastinal nodes are positive, the patient is at least stage III. When a malignant pleural effusion or distant sites such as the brain or bones are involved, the patient is stage IV.

PREOPERATIVE EVALUATION FOR LUNG RESECTION SURGERY

To determine if a patient would tolerate lung resection surgery, patients go through testing of their pulmonary, cardiovascular, and overall health. Reports of activity tolerance, pulmonary function testing, and exercise testing are used to assess the risk. The amount of risk is weighed against the benefit of having a traditional lung resection surgery (a lobectomy—one lobe removed, or pneumonectomy—a lung removed) versus a sublobar resection or nonsurgical treatment. Traditional resection is the best chance for cure and reduces local recurrence. As would be expected, a pneumonectomy requires better preoperative lung function than a lobectomy. When a lobe is removed, patients generally have a 10% to 15% drop in lung function. With a pneumonectomy, 30% to 35% is lost.

Cardiac conditions requiring medications, or an inability to climb two flights of stairs, should prompt a cardiac evaluation. The **thoracic revised cardiac risk index** can be used to identify

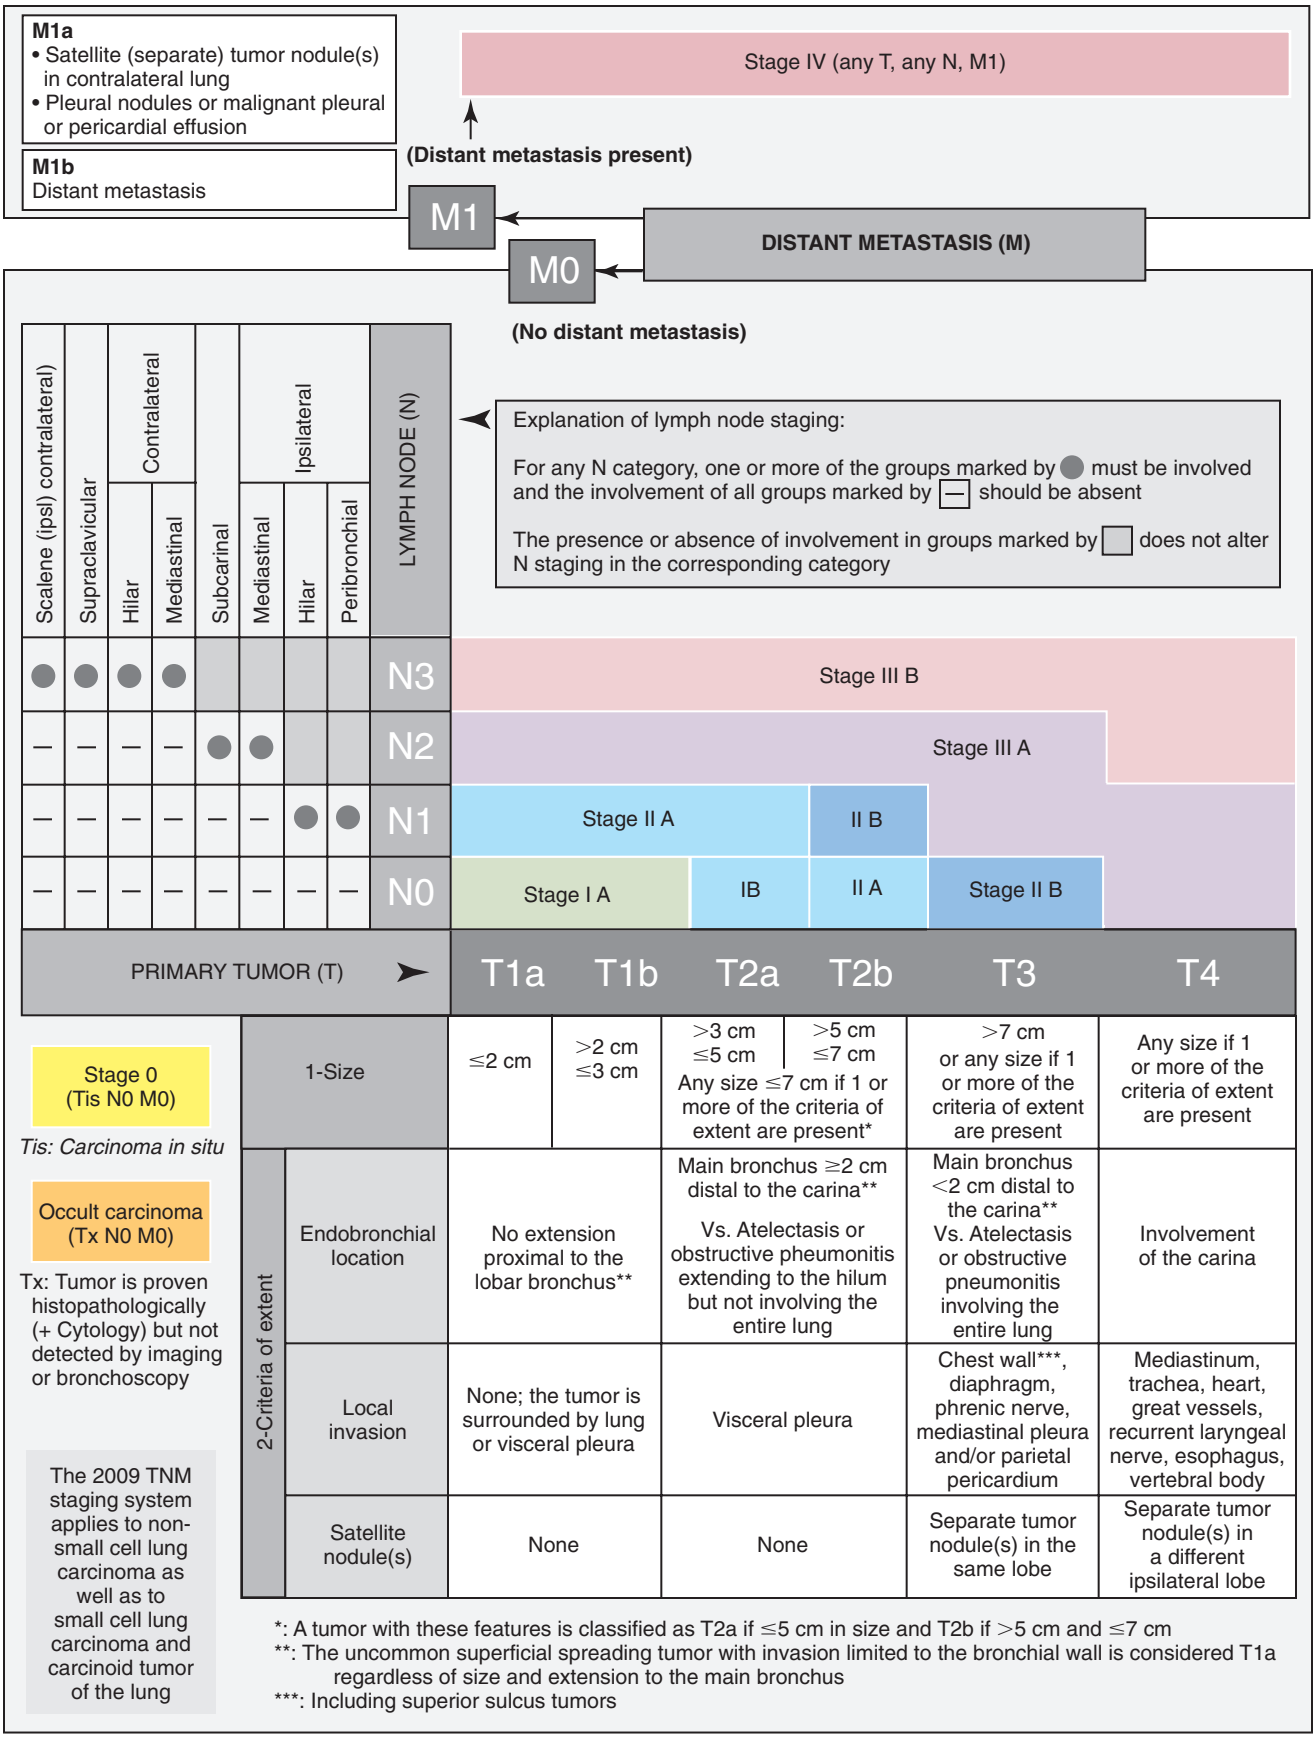

FIGURE 31-3 Reference chart for TNM staging of lung cancer. (Modified from Lababede O, Meziane P, Rice T: Seventh edition of the cancer staging manual and stage grouping of lung cancer: quick reference chart and diagrams. *Chest* 139:183–189, 2011.)

Box 31-3 To Calculate Percent Predicted Postoperative Values

The segment method

PPO FEV1 = preoperative FEV1 × (1 − number of resected segments/19)

19 representing the total number of segments in both lungs:
- Right upper lung: 3
- Right middle lung: 2
- Right lower lung: 5
- Left upper lung: 5
- Left lower lung: 4

patients at risk for cardiac complications. Those with any combination of the following conditions (i.e., score ≥ 2) should have noninvasive cardiac stress testing or a cardiology consultation: previous ischemic heart disease, stroke or transient ischemic attack, creatinine > 2 mg/dL or planned pneumonectomy. Similarly, those with a cardiac condition requiring medication, or with a newly suspected cardiac condition, and those unable to climb two flights of stairs should be considered for noninvasive cardiac stress testing or a cardiology consultation.

The evidence shows that the volume exhaled during the first second of a forced expiratory maneuver (FEV_1) (see Chapter 20) and diffusing capacity for carbon monoxide (DLCO) are the most frequently used pulmonary function tests and the best predictors for postoperative complications, including death. Traditional preoperative cutoff values have been replaced by percent predicted postoperative (PPO) values as starting points. PPO values of FEV_1 and DLCO can be calculated by multiplying the percent predicted *pre*operative value by the fraction of the total number of lung segments that will remain postoperatively. This is the segment method (Box 31-3). Alternatively, quantitative perfusion imaging can be used to guide the calculation. If the PPO FEV_1 and DLCO are greater than 60%, the patient is considered at low risk for lung resection. If PPO values fall between 30% to 60%, an exercise test should be performed. The stair climb test, shuttle walk, and 6 minute walk tests can be used. For patients with PPO values below 30%, inadequate low technology exercise testing results, or when measured values and predictions seem discordant with an individual's reported activity tolerance, a formal cardiopulmonary exercise test should be performed (Figure 31-5). If the peak oxygen uptake is greater than 20 mL/kg/min (or 75% predicted), the patient is considered at low risk for any resection. If the peak O_2 uptake is less than 10 mL/kg/min (35% predicted), the patient is considered at high risk and conventional surgery should not be performed. Patients with a maximum O_2 consumption value between these two limits are at moderate risk and should be considered on a case-by-case basis.[33]

RULE OF THUMB

Patients with an FEV_1 greater than 80% predicted value or 2 L can safely undergo surgical resection for lung cancer, even if pneumonectomy is needed.

SCREENING

Given the poor prognosis for advanced-stage lung cancer and the high proportion of patients who present in an advanced stage, there has been great interest in **screening** for lung cancer. The earliest efforts at radiographic screening involved the analysis of mass chest radiograph screenings from the population of an individual city. Subsequently in the 1970s, there were large efforts to use chest radiograph, sputum, or a combination of the two as screening tools. Finally, a large randomized trial of chest radiography as a screening did not show any benefit. Thus screening with chest radiography is not recommended.[36-38]

Given the disappointing overall results from studies of chest radiograph as a screening technique, efforts have centered on the use of low-dose CT imaging as a screening tool.[37,38]

One trial, the National Lung Screening Trial, reported a 20% reduction in lung cancer–specific mortality in patients with very high risk for developing lung cancer. This finding has changed the clinical discussion regarding lung cancer screening. The U.S. Preventive Services Task Force gave low-dose CT chest screening a grade B recommendation for high-risk individuals (age 55 to 80 and at least 30 pack-years of current smoking [pack years = the number of packs per day × years smoked], or at least 30 pack-years of former smoking and quit within 15 years). The evidence shows that CT lung screening is most effective when patient selection adheres closely to the

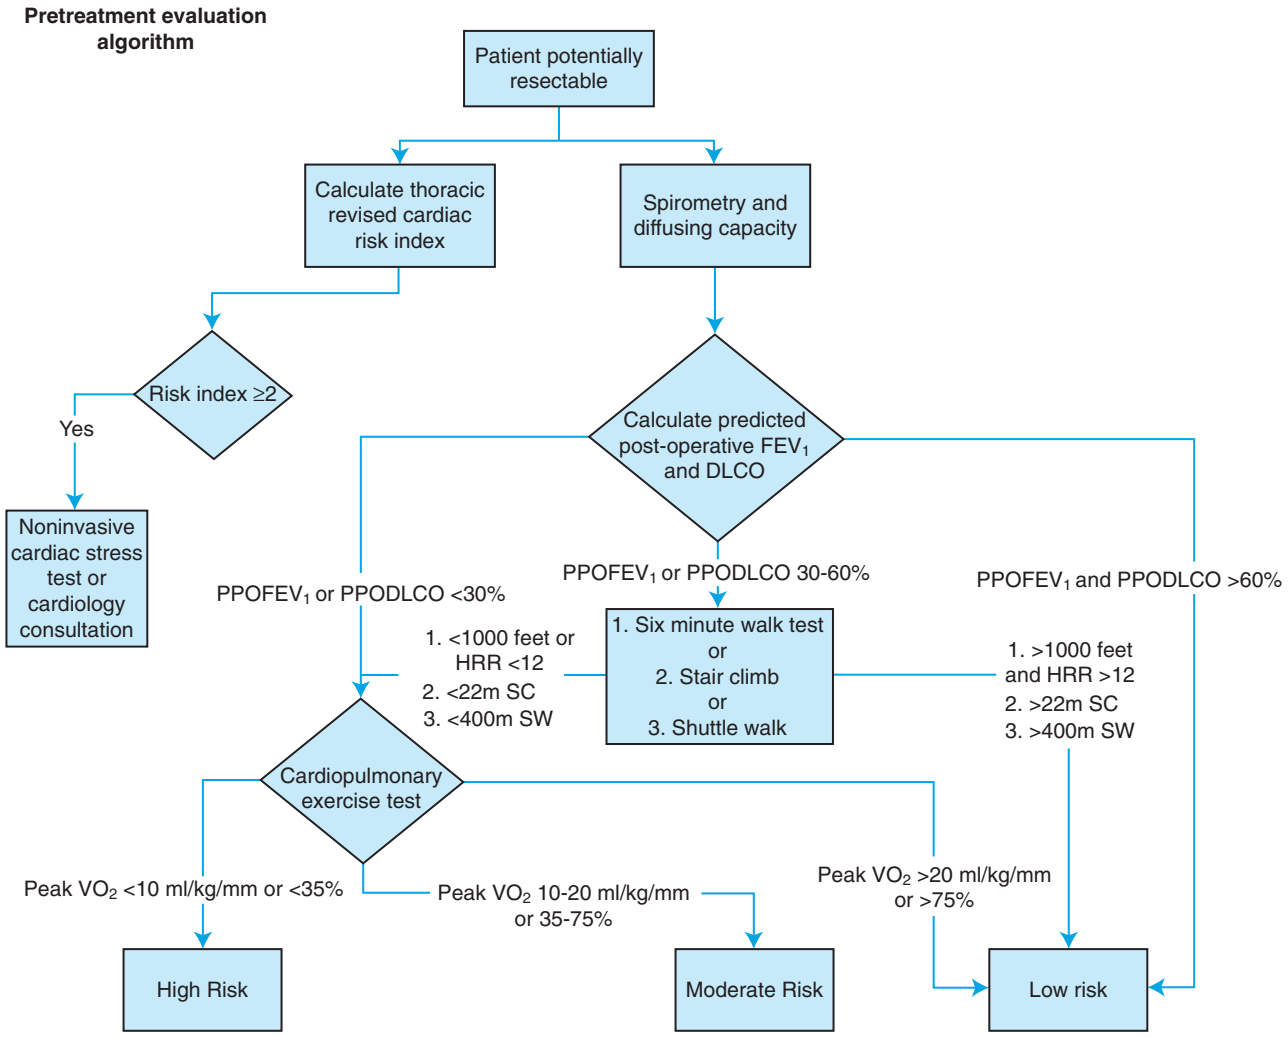

FIGURE 31-5 Algorithm for patients considered for lung resection surgery. **Note 1:** The algorithm represents an assessment of risk for traditional resection (lobectomy, pneumonectomy). One must consider the benefits of traditional resection over alternative therapies (sublobar resection, ablative therapies), the relative risks of the therapeutic choices and the patient's values when selecting treatment. **Note 2:** The 6-minute walk is included in this algorithm but is not part of other guidelines due to relatively small literature support. It is a more practical and available low-technology exercise study than the recommended tests and we have substantial experience with this test, leading us to include it in our algorithm. **Note 3:** Potential modifiers of risk include smoking cessation, adequate treatment of comorbid pulmonary conditions, preresection or postresection pulmonary rehabilitation, and the surgical approach (VATS versus thoracotomy). Each of these should be considered when assessing risk. **Note 4:** For lobectomy, the segment method or quantitative perfusion scan can be used to calculate predicted postoperative values. For pneumonectomy, the quantitative perfusion scan should be used. **Note 5:** Management of cardiac disease per American College of Cardiology/American Heart Association guidelines. *PPO,* Predicted postoperative values; *FEV_1,* forced expiratory volume in 1 second; *DLCO,* diffusion capacity for carbon monoxide; *PPO,* predicted post-operative; *HRR,* heart rate recovery; *SC,* stair climb; *SW,* shuttle walk; *VO_2,* oxygen consumption; ml/kg/min, milliliters per kilogram per minute.

criteria described earlier and when the CT is performed in a setting where expertise in lung cancer and lung nodules is available.[39–41]

TREATMENT AND OUTCOMES

Although the RT would not be administering the treatments for lung cancer, and the therapies change with advances over time, a brief discussion to familiarize the RT with the approach to treatment and the types of available therapy is important.

Non–Small Cell Lung Cancer

Three types of treatment are used to treat non–small cell lung cancer: surgical resection, **radiotherapy,** and **chemotherapy** (Box 31-4). The first two treatments provide local control of the cancer, and the last is used to treat systemic disease. Which therapy or combination of therapies is recommended depends on the stage of the cancer, the patient's ability to tolerate treatment, and the type of cancer (or its histology). Molecular changes within the tumor are beginning to influence treatment choices as well.

MINI CLINI

Lung Cancer Screening

PROBLEM: A 68-year-old man presents to the clinic with the concern of developing lung cancer in the future. He currently smokes one pack of cigarettes per day and has smoked for 45 years. He does not cough or feel shortness of breath. He has a history of high blood pressure and high cholesterol. He is otherwise in his regular state of health. Should this man have lung cancer screening?

DISCUSSION: Based on the evidence, he meets criteria to have a low-dose CT chest to screen for lung cancer. He does not have any symptoms that also make screening appropriate. A vitally important part of the conversation with this patient should be tobacco cessation. Quitting smoking at any age reduces the risk for lung cancer and other health problems.

TABLE 31-3

Non–Small Cell Lung Cancer: 5-Year Survival by Stage

Stage	Clinical Stage (%)	Pathologic Stage (%)
IA	50	73
IB	43	58
IIA	36	46
IIB	25	36
IIIA	19	24
IIIB	7	9
IV	2	13

Modified from Goldstraw P, Crowley J, Chansky K, et al; International Association for the Study of Lung Cancer International Staging Committee; IASLC Lung Cancer Staging Project: Proposals for the revision of the TNM stage groupings in the forthcoming (seventh) edition of the TNM classification of malignant tumors. *J Thorac Oncol* 2:706–714, 2007.

Early Stage Non–Small Cell Carcinoma

Surgical resection offers the best chance of cure for early stage non–small cell lung cancer (stages I and II) (Table 31-3). Survival after resection in pathologic stage IA approaches 70% at 5 years; in pathologic stage IB, 5-year survival is closer to 55%. The surgery of choice is a *lobectomy,* in which the entire lobe of the lung containing the cancer is removed. If the tumor is very central, a pneumonectomy may be required. Sublobar resections, such as *segmentectomy,* or *wedge resection,* can be performed in patients with modest lung function to spare as much lung tissue as possible. In most patients, sublobar resection leads to a slightly lower survival rate and a higher rate of local recurrence of cancer.[42,43] In the smallest cancers and in patients who are older than 70 years, a sublobar resection may be as effective as a lobectomy.[44] Recurrence usually involves distant metastases.

Survival after resection in pathologic stage IIA is 50% to 55% at 5 years and in pathologic stage IIB is approximately 40% (see Table 31-3). Sublobar resections are not typically an option in stage II cancers. Most recurrences involve distant metastases.

Box 31-4 Options for Treatment of Lung Cancer

NON–SMALL CELL

Stages IA, IB, IIA, IIB

- Surgical resection standard of care if patient deemed able to tolerate resection
- Sublobar resection if patient is unable to tolerate larger resection
- Radiotherapy, particularly stereotactic body radiotherapy in NO disease, if patient is unable to tolerate or chooses not to undergo resection
- Adjuvant radiotherapy possibly of use if incomplete resection has occurred
- Adjuvant chemotherapy in patient with stage II disease who can tolerate it; consider in stage IB

Stage IIIA

- Concurrent chemoradiotherapy using platinum-based regimen if performance status is reasonable
- Induction chemoradiotherapy followed by resection and adjuvant chemotherapy in selected patients, ideally as part of a study protocol

Stage IIIB

- Concurrent chemoradiotherapy using platinum-based regimen if performance status is reasonable
- Induction chemoradiotherapy followed by resection in highly selected patients, only as part of a study protocol

Stage IV

- Platinum-based chemotherapy regimen in patients with adequate performance status
- Targeted therapies (EGFR, VEGF, and ALK inhibitors) in appropriate subgroups

SMALL CELL

Limited Stage

- Combination chemotherapy with concurrent hyperfractionated radiotherapy if performance status is adequate
- Prophylactic cranial radiation for patients with complete response to chemoradiotherapy

Extensive Stage

- Combination chemotherapy if performance status is adequate

Courtesy The Cleveland Clinic, Cleveland, OH.
ALK, Anaplastic lymphoma kinase; *EGFR,* epithelial growth factor receptor; *VEGF,* vascular endothelial growth factor.

Radiotherapy has been used with curative intent in early-stage non–small cell lung cancer in patients who cannot tolerate surgery or in patients who elect not to undergo surgery. The 5-year survival rate in stage I and II disease approaches 15% with standard radiotherapy alone. There is a high rate of local recurrence, and most deaths are due to lung cancer. Stereotactic body radiotherapy is a novel radiation therapy technique in which multiple convergent beams of radiation are precisely targeted on the tumor. This targeting allows very high doses of radiation to be delivered to the tumor while sparing the normal lung tissue. Rates of local control and survival are impressive in selected groups reported in many case series, approaching the rates of lung resection.[45] Lung resection and stereotactic body radiotherapy have not been compared head to head. Lung

resection remains the standard of care in patients able to tolerate it. *Adjuvant* ("applied after initial treatment") radiotherapy in patients who have undergone surgical resection may improve local control but does not improve survival (with the possible exception of patients who have undergone incomplete resection).

Adjuvant platinum-based chemotherapy leads to a significant survival benefit in selected patients with completely resected stage II lung cancers.[46] The potential benefit of adjuvant chemotherapy in patients with stage IB disease is debated.

Locally and Regionally Advanced Non–Small Cell Carcinoma

Locally advanced tumors (T3) frequently can be completely resected, although central T3 tumors are less resectable than tumors involving the chest wall. The survival in patients with T3 tumors and chest wall involvement without lymph node involvement approximates the survival of other patients with stage IIB disease. The best results occur when complete resection is possible. With nodal involvement at any level, survival decreases dramatically and the tumor is classified in a higher stage. T3 involvement of the mediastinum or main stem bronchus portends a poorer prognosis, with 5-year survival rates less than 30%.

When a Pancoast tumor is present, chemoradiotherapy followed by surgical resection (lobectomy ± chest wall resection) is performed if possible. The invasion of local structures (rib, vertebral body, subclavian artery, or sympathetic chain) is a poor prognostic sign. Two-thirds of patients have a recurrence, and two-thirds of these recurrences are local.

The approach to N2 (stage IIIA, mediastinal lymph node involvement) disease varies among institutions. Patients without radiographic evidence of N2 disease but who are found at surgery to have N2 disease do better than patients with preoperative evidence of N2 disease. Adjuvant chemotherapy should be offered to this group. Generally, the more advanced the node involvement (number, extension, or location), the poorer the prognosis. Induction with chemotherapy with or without radiotherapy leads to objective responses in most patients. Patients who have bulky nodes or who require a pneumonectomy are less likely to benefit from resection after induction therapy. At the present time, concurrent chemoradiotherapy should be considered the standard of care, with resection included in specialized centers, often in the setting of a study. Survival rates are 5% to 13% at 5 years. With advances in each of the modes of therapy, treatment will evolve over time.[47–49]

T4 disease without advanced nodal status (stage IIIB) may be considered for surgical treatment in only a few settings. T4 disease involving the main carina may be considered for resection at centers with expertise. The role of induction therapy in this setting has not yet been defined. Disease at the N3 level (stage IIIB) is generally considered nonsurgical.[50,51]

Metastatic Non–Small Cell Carcinoma

In stage IV lung cancer, platinum-based chemotherapy regimens have been shown to improve survival and enhance quality of life. They are also cost-effective. This treatment is most appropriate for individuals with a good performance status. Resection of an isolated brain metastasis in patients with a good performance status can improve survival. Standard chemotherapy typically involves two agents administered in cycles, each approximately 3 weeks apart, for a total of four to six cycles. The addition of a third agent or additional cycles has traditionally added risk without benefit. More recently, agents with improved tolerance have been shown to benefit patients who have shown a good response to treatment when administered as maintenance treatment, until progression is noted.[52]

Standard chemotherapy targets all growing cells, not just cancer cells (hence the common side effects seen). Targeted therapies have been developed where the mechanism of action is more specific to the cancer cell. In lung cancer, inhibitors of epidermal growth factor receptors (EGFRs), vascular endothelial growth factor (VEGF), and anaplastic lymphoma kinase (ALK) translocations have been studied. EGFR and ALK inhibitors have been most successful in patients with EGFR-activating mutations and ALK translocations in their cancer tissue. The patients most likely to have EGFR mutations include female never-smokers with adenocarcinoma, in particular, patients of Asian origin. This subgroup has been found to have an improved survival overall, which is improved further by the use of an EGFR inhibitor. The VEGF receptor inhibitor has been shown to improve survival when added to standard chemotherapy in patients with nonsquamous cell histology. These treatments can be continued until progression is noted. Other promising agents in late-phase development include immune system stimulators.[53,54]

Small Cell Lung Cancer

Treatment of small cell lung cancer is based on its staging (see Box 31-4). In limited-stage disease, combination chemotherapy with concurrent hyperfractionated radiotherapy is recommended. The drug etoposide and a platinum agent are standard. Prophylactic brain radiation is generally recommended for patients who have a complete response to chemoradiotherapy. Surgery is limited to cases in which the diagnosis is in doubt or in rare cases that manifest as a single lung nodule. In patients with extensive-stage disease, combination chemotherapy improves the quality of life and median survival. A poor performance status and an elevated lactate dehydrogenase level portend a poor prognosis.[55]

RULE OF THUMB

Surgery is the treatment of choice for early-stage non–small cell lung cancer. Chemotherapy is the modality of choice for advanced non–small cell lung cancer. Chemotherapy with or without radiation therapy is used to treat small cell lung cancer.

Palliation of symptoms related to lung cancer is an important aspect of overall management. The judicious use of analgesic agents for pain, antiemetics for nausea, and antidepressants can improve quality of life. Radiotherapy can be used to palliate

bone pain related to metastatic disease, hemoptysis, or symptoms of airway obstruction. Invasive bronchoscopic procedures (e.g., laser ablation, electrocautery, stent placement) may be palliative in patients with airway obstruction. Evidence shows that in patients with end-stage non–small cell lung cancer early integration of palliative care has an increased median survival when compared to standard aggressive treatment.[56]

FUTURE SCENARIO

The prospect of major advances in the prevention, detection, and treatment of lung cancer is strong. An attainable vision for 2034 could be as follows: Primary prevention campaigns have successfully minimized the number of individuals who are smoking, legislation has passed broadly to prevent exposure to tobacco smoke in public places, progress has been made in occupational exposure avoidance, and successful measures have been enacted to clean the air. Individuals are now identified who have changes in lung cells that suggest lung cancer could develop and are being treated with medication to prevent it from developing. Individuals at risk for developing lung cancer are part of a screening program that detects early-stage lung cancer with a test that is inexpensive and acceptable to all. Technology has improved diagnostic abilities by making imaging more specific and biopsies more accurate. Noninvasive diagnostics have expanded with advances in blood and breath testing. In addition to tumor appearance, researchers are identifying characteristics of tumor biology that allow more selection in choosing treatments. The best form of local control for a given tumor (resection, radiation) is known, and means have been developed to minimize the effect of these interventions on the quality of life. Novel agents have been developed that can reach and kill tumor cells while avoiding injury to healthy tissue. As evidence of successes, lung cancer is no longer the leading cause of cancer-related mortality in the United States.

ROLE OF THE RESPIRATORY THERAPIST IN MANAGING PATIENTS WITH LUNG CANCER

RTs perform many important roles in the evaluation and management of patients with lung cancer. Many patients in the care of the RT are smokers, and the RT has the opportunity to educate these individuals on the dangers of smoking and on the means available to help them quit. Because many of these patients also have smoking-related lung disorders (e.g., COPD), RTs can offer guidance on the proper use of inhaled medications, the use of supplemental O_2, and the role of pulmonary rehabilitation before and after treatment. Also, many RTs assist with diagnostic tests such as bronchoscopy and the measurement of pulmonary function. Finally, in the context that the RT may spend substantial time with the patient with lung cancer, the RT may be an important source of psychologic support and help. Taken together, these various diagnostic and treatment roles establish that the RT plays a crucial role in helping to manage patients with lung cancer.

MINI CLINI

Evaluating Surgical Risk

PROBLEM: A 62-year-old man with a long history of smoking has a chronic, productive cough. A chest CT obtained because of a recent episode of hemoptysis reveals a lung mass in the right upper lobe. Results of transbronchial biopsy suggest the presence of large cell carcinoma. There is no evidence of metastasis. As part of the patient's evaluation for surgery, he has the following spirometry and diffusing capacity results:
Forced vital capacity (FVC) 4.2 L (80% of predicted value)
FEV_1 1.6 L (60% of predicted value)
FEV_1/FVC 0.4
DLCO 15.5 (60% of predicted)
Can he undergo surgery?

DISCUSSION: Assessment of lung reserve is an important step in the preoperative evaluation of patients with lung cancer being considered for surgical resection. After calculating his PPO values with the segment method ($60 \times [1 - 3/19]$), he is found to have a PPO FEV_1 and PPO DLCO of 50%. This patient, similar to most patients with lung cancer, has PPO values between 30% and 60% because of underlying COPD. He needs further evaluation with exercise testing such as a stair climb or shuttle walk test to better assess his risk. Furthermore, he needs treatment optimization for his COPD. If the patient's lung function remains at moderate risk after these steps, a cardiopulmonary exercise test may help to clarify his risk.

SUMMARY CHECKLIST

- Approximately 224,210 cases of bronchogenic carcinoma were newly diagnosed in the United States in 2014, making bronchogenic carcinoma a major health hazard. It is the leading cause of cancer-related mortality in the United States.
- Approximately 85% of all cases of bronchogenic carcinoma are linked to smoking.
- The major histopathologic types of bronchogenic carcinoma include adenocarcinoma, squamous cell carcinoma, small cell carcinoma, and large cell carcinoma. Adenocarcinoma is the most common type, representing more than 40% of all cases.
- The clinical manifestations of bronchogenic carcinoma result from local growth of the tumor, regional spread, metastases to extrathoracic and intrathoracic organs, and paraneoplastic syndromes.
- The staging system most commonly used for non–small cell bronchogenic carcinoma is based on status of the primary tumor (T), local and regional lymph node involvement (N), and the presence of metastasis (M). The TNM classification groups patients in stages or categories that correlate with survival. Small cell lung cancer is classified in two stages, limited and extensive, although the TNM system can be used as well.
- The most commonly used treatments for patients with non–small cell lung cancer are surgical resection, radiation therapy, and chemotherapy. Treatment of most patients

with small cell carcinoma includes chemotherapy, with radiation therapy added if a limited stage disease.

- The most effective way to prevent lung cancer is to prevent smoking.

CHAPTER 32

Neuromuscular and Other Diseases of the Chest Wall

RENDELL W. ASHTON

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Identify pulmonary function test results typically seen in patients with neuromuscular disease.
- List the potential respiratory complications associated with neuromuscular disease.
- Identify the clinical signs and symptoms associated with respiratory muscle weakness.
- Describe techniques for monitoring patients with respiratory muscle weakness.
- Describe general respiratory care management of patients with respiratory muscle weakness.
- Describe the clinical findings and treatment for each of the following neuromuscular disorders: Duchenne muscular dystrophy, myotonic dystrophy, polymyositis, myasthenia gravis, Lambert-Eaton syndrome, Guillain-Barré syndrome, unilateral diaphragmatic paralysis, amyotrophic lateral sclerosis, critical illness myopathy and polyneuropathy, spinal cord injury, stroke, traumatic brain injury, kyphoscoliosis, and flail chest.
- Understand the role of the RT in caring for patients with neuromuscular and chest wall diseases.

CHAPTER OUTLINE

KEY TERMS

amyotrophic lateral sclerosis
ankylosing spondylitis
apneustic breathing
ataxic breathing
Becker muscular dystrophy
central neurogenic hyperventilation
Cheyne-Stokes respirations
critical illness myopathy
critical illness polyneuropathy
dermatomyositis
Duchenne muscular dystrophy
flail chest
gasping
Guillain-Barré syndrome
inclusion body myositis
kyphoscoliosis
Lambert-Eaton syndrome
Lou Gehrig disease
myasthenia gravis
myopathy
myositis
myotonic dystrophy
neuropathy
Ondine curse
paradoxical motion
periodic breathing
polymyositis
stroke
traumatic brain injury

Neuromuscular diseases are the group of conditions that affect the strength and ability of muscles to function. In addition to the lungs, which provide an interface between inhaled air and circulating blood, the respiratory system includes the *thoracic cage,* which forms the structure of the ventilatory pump, and the *muscles of respiration,* whose action on the thoracic cage produces movement of air into and out of the lungs. Diseases that affect the brain, nerves, muscles, or thoracic cage can lead to respiratory failure or hypoxemia even if the lungs are normal.

Understanding the interactions between these components is essential to understanding how their dysfunction leads to disease. The neuromuscular components of the respiratory system are shown in Figure 32-1. Maintenance of normal ventilation depends on intact, functional components of the neuromuscular system, which contribute to breathing in three main ways: (1) regulation of respiratory drive and rate, (2) control of the mechanics of ventilation, and (3) cough and other airway protection. The pulmonary consequences of neuromuscular disease include the following:

1. Dysregulation of respiratory drive or rate
   - Hyperventilation
   - Hypoventilation
   - Central apnea
   - Other pathologic breathing patterns (listed in Table 32-4)
2. Loss of strength or control of the mechanics of breathing
   - Respiratory failure as a result of excessive work of breathing
   - Atelectasis leading to hypoxemia
   - Secondary effects of chronic hypoxemia (e.g., pulmonary hypertension, cor pulmonale)
3. Loss of strength or control of the muscles responsible for airway protection and cough
   - Aspiration
   - Obstructive apnea
   - Mucous plugging
   - Pneumonia

Some systemic diseases that affect the neuromuscular system also cause interstitial lung disease, which can lead to considerable respiratory dysfunction (see Chapter 26). Respiratory failure, often associated with pulmonary infection, is a frequent cause of death in patients with neuromuscular disorders.

A thorough understanding of the physiology of ventilation and chest wall mechanics (see Chapters 11 and 19) is needed to understand how abnormalities of the upper airway, chest wall, diaphragm, and abdominal muscles cause disease. This chapter reviews major disorders of the neuromuscular and skeletal systems that affect breathing. Disorders are grouped according to which functional unit of the neuromuscular system is affected, focusing on pulmonary manifestations of these disease processes (Table 32-1).

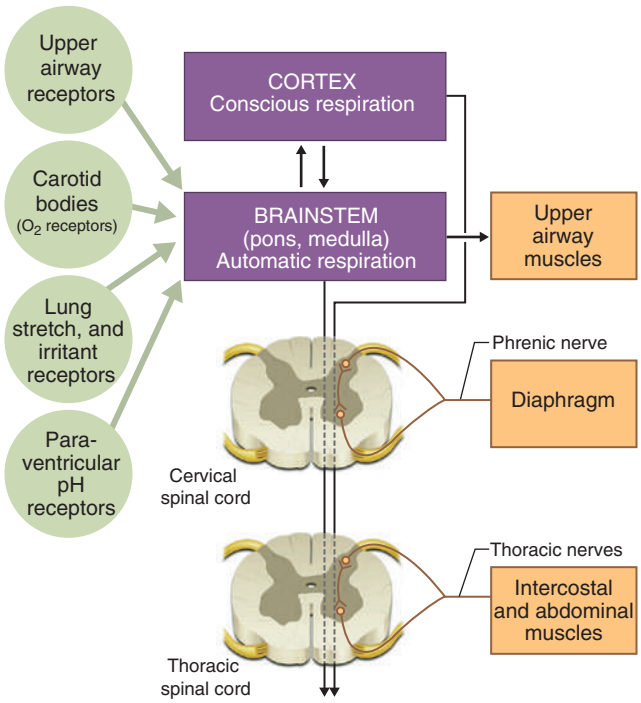

FIGURE 32-1 The neuromuscular components of the respiratory system include elements of the cortex (which allow conscious alteration of breathing) and motor centers (which maintain upper airway tone). Brainstem structures receive input from peripheral oxygen, pH, and stretch receptors and generate automatic respiration. Efferent nerves carry central nervous impulses to the muscles of respiration through the phrenic and spinal nerves, which drive the muscles of respiration.

GENERAL PRINCIPLES RELATED TO NEUROMUSCULAR WEAKNESS OF THE VENTILATORY MUSCLES

This section describes the evaluation and testing of patients with suspected neuromuscular weakness of the respiratory muscles, regardless of the disease causing the weakness.

TABLE 32-1

Locations at Which Several Neuromuscular Diseases Affect the Respiratory System

Location	Disease
Cerebral cortex, brainstem (including the respiratory center) and upper motor neurons	Stroke, traumatic brain injury
Spinal cord	Trauma, transverse myelitis, multiple sclerosis
Anterior horn cells (lower motor neurons)	ALS, spinal muscular atrophy, poliomyelitis, and postpoliomyelitis
Peripheral nerves	Guillain-Barré syndrome, critical illness polyneuropathy, Lyme disease
Neuromuscular junction	Myasthenia gravis, Lambert-Eaton syndrome, botulism
Muscle	Duchenne muscular dystrophy, polymyositis, acid maltase deficiency
Interstitial lung disease*	Polymyositis, dermatomyositis, tuberous sclerosis, neurofibromatosis

*A category of systemic diseases that can affect neuromuscular function as well as lung function.

Pathophysiology and Pulmonary Function Testing

Weakness of the respiratory muscles leads to the inability to generate or maintain normal respiratory pressures. Pulmonary function testing in patients with neuromuscular weakness typically reveals a restrictive ventilatory defect even if the lungs are normal. Vital capacity (VC), forced expiratory volume in 1 second (FEV_1), and total lung capacity (TLC) are decreased. Functional residual capacity is normal or decreased. Residual volume (RV) may be increased, especially as weakness becomes more severe. Diffusing capacity corrected for alveolar volume is usually normal or near-normal but can be decreased.[1] Comparison of spirometric results obtained with the patient in seated and supine positions can be useful in showing that orthopnea is caused by neuromuscular weakness. A decrease in VC or FEV_1 of 20% or more when a patient moves from the seated to the supine position suggests diaphragmatic weakness (Table 32-2 and Figure 32-2). The inability to generate normal respiratory pressures is reflected in a decreased maximal inspiratory pressure (PImax), which is generally specific for diaphragm weakness. Expiratory muscle weakness is characterized by a decreased maximal expiratory pressure (PEmax) and is not specific to any single muscle group.[2]

Arterial blood gases (Pmax) in the setting of a rapid, shallow breathing pattern may show a decreased $PaCO_2$, although progressive inspiratory muscle weakness leads to hypoventilation and hypercapnia. Hypoxemia can occur in patients unable to take deep breaths and may be caused by microatelectasis, which leads to ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatching within the lung and a resulting decrease in PaO_2 (Figure 32-3). Chronic hypoxemia in this situation may be protective against acute respiratory muscle failure. Some studies suggest that when hypoxemia is chronic, it may increase diaphragm muscle endurance.[3] Hypoventilation that occurs with progressive neuromuscular disease may be a protective mechanism that avoids acute respiratory muscle fatigue. However, when hypoxemia is acute, it potentiates respiratory muscle fatigue, hastening respiratory failure.[4]

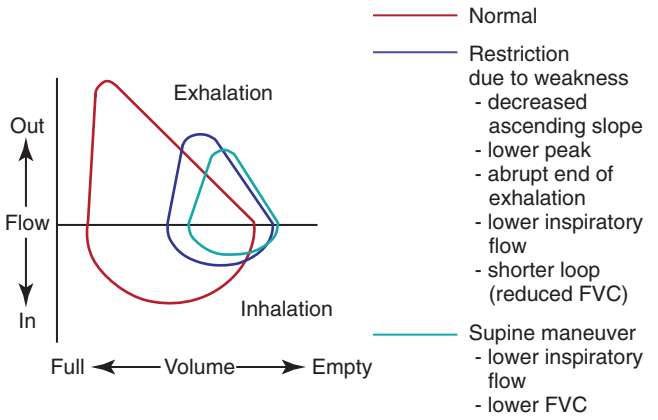

FIGURE 32-2 Normal flow-volume loop compared with loops from a patient with neuromuscular weakness, showing characteristic ventilatory restriction, which worsens when the patient is placed in the supine position. *FVC,* Forced vital capacity.

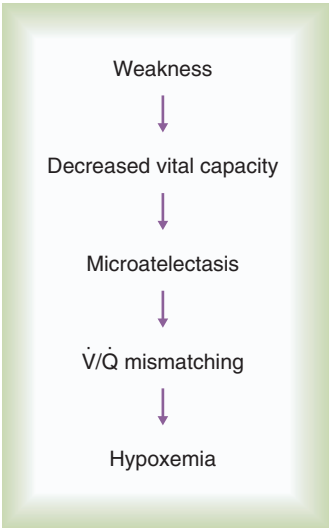

FIGURE 32-3 Atelectasis as a mechanism of hypoxemia in patients with respiratory muscle weakness. $\dot{V}/\dot{Q}$, Ventilation/perfusion.

TABLE 32-2

Pulmonary Function Testing Results from a Patient With Profound Diaphragm Weakness

	Predicted Value	Lower Limit of Normal	Sitting Position	% of Predicted	Supine Position	% Change from Sitting
FVC	4.42	3.55	1.85	42	0.89	–52
FEV_1	3.36	2.62	1.51	45	0.68	–55
FEV_1/FVC	75.88	66.20	81.75	108	75.76	–7
TLC	6.53	4.92	4.21	64		
RV	2.10	1.34	2.39	114		
DLCO	24.93	16.67	17.16	69		
DLCO/VA	3.88	2.38	5.57	144		
PImax	110.58	75.02	18.46	17		
PEmax	207.29	140.04	26.52	13		

DLCO, Diffusing capacity for carbon dioxide; *DLCO/VA, DLCO* divided by alveolar volume; *FEV_1,* forced expiratory volume in 1 second; *FVC,* forced vital capacity; *PEmax,* decreased maximum expiratory pressure; *PImax,* decreased maximal inspiratory pressure; *RV,* residual volume; *TLC,* total lung capacity.

RULE OF THUMB

Neuromuscular weakness of the respiratory muscles may be present before any substantial decrease in VC or FEV_1 is noticed. Values of PEmax may be decreased by 50% or more before any decrease in VC or FEV_1 is noticed.

Clinical Signs and Symptoms

In the early stages of neuromuscular disease, patients with respiratory muscle weakness initially report exertional dyspnea and fatigue. As the disease process progresses, patients may complain of orthopnea or symptoms of cor pulmonale (remodeling of the right ventricle, usually in response to pulmonary hypertension, which causes symptoms of dyspnea, fatigue, anorexia, chest pain, and syncope). These symptoms occur because the muscles involved with respiration can no longer generate or maintain normal ventilation. The response to hypoxemia and respiratory drive is preserved in most patients with neuromuscular weakness.[5] This drive is assessed by a measurement of the negative airway pressure generated during 100 msec of airway occlusion, the so-called *airway occlusion pressure,* abbreviated P0.1, which indicates respiratory effort and intact pathways from the respiratory center in the brainstem to the muscles of respiration. Because these patients often do not have the strength to take deep breaths, they maintain minute ventilation by increasing respiratory rate and adopting a rapid, shallow breathing pattern, which uses less respiratory muscle strength but provides less efficient ventilation. Patients with poor inspiratory muscle function (especially diaphragm weakness) may have marked orthopnea and prefer to sleep in a seated position. They also may experience a decline in voice volume, power, or quality. Muscle weakness can progress to the point at which adequate ventilation is no longer maintained and hypercapnia occurs.

RULE OF THUMB

When a patient complains of immediate shortness of breath on lying down, especially if one side is worse than the other, the problem is diaphragm weakness until proved otherwise.

Monitoring and Assessing Patients With Muscle Weakness for Respiratory Insufficiency

If respiratory muscle weakness progresses and cannot be stopped, the eventual result is respiratory failure. The onset of respiratory failure is acute or chronic depending on the time course of the disease process and the circumstances of the patient. When this progression toward respiratory failure is noted, careful follow-up and monitoring of symptoms and pulmonary function are necessary to assess the need for mechanical ventilation.

MINI CLINI

Consider Neuromuscular Weakness When a Patient Complains of Dyspnea

PROBLEM: A 27-year-old woman was referred to the pulmonary clinic for persistent shortness of breath for 2 months, along with a sore throat and a hoarse voice. The symptoms had begun with a viral syndrome including sore throat, myalgias, and fever, progressing to cough and chest discomfort. All symptoms except her shortness of breath and hoarseness had resolved. She complained of being particularly short of breath while lying down and not being able to lie down on her left side at all because she felt she could not breathe in that position. She also described running out of breath in the middle of sentences and of her voice having a hoarse, "airy" quality. She had been evaluated previously, including a normal chest radiography and spirometry, and had been told her dyspnea was due to anxiety. No other diagnosis was made. What clues in her history might suggest a pulmonary disease, and what additional testing could help identify it?

DISCUSSION: This patient had already been evaluated and had been told that her dyspnea was psychologic because her chest radiography and standard pulmonary function testing were normal. Spirometry was within the normal range of values, but when repeated in the supine position, FVC decreased by 41%. Lung volumes were normal except for a slight elevation of residual volume. Diffusing capacity also was normal. A fluoroscopic sniff test, in which her diaphragms were visualized in real time as she performed a simple sniff maneuver, showed paradoxical motion of the right hemidiaphragm. She was diagnosed with neuralgic amyotrophy, a rare neuromuscular condition affecting the phrenic nerve, which is often triggered by a viral syndrome and which usually improves gradually with time.

The important clue that led to the diagnosis of neuromuscular weakness was her complaint of orthopnea, especially the inability to breathe comfortably lying on one specific side. When one diaphragm is weak or paralyzed, a patient often cannot breathe when lying on the opposite side because this prevents the good side from compensating for the weak side. When the details of her history were recognized as classic symptoms of diaphragm weakness, testing to establish the diagnosis was straightforward.

PROBLEM: What physical findings may suggest respiratory distress in a patient with diaphragmatic weakness?

DISCUSSION: Patients whose diaphragmatic strength is inadequate to meet their ventilatory needs may use *accessory* muscles of inspiration. The sternocleidomastoid, intercostal, and scalene muscles all may be activated in the setting of respiratory distress. Use of these muscles in the setting of a weak or paralyzed diaphragm can lead to cephalad movement of the diaphragm during inspiration that is accompanied by paradoxical inward movement of the abdomen during inspiration (which is called *paradoxical breathing*). The presence of these signs in this patient should prompt evaluation of ventilatory adequacy and the need for ventilatory support.

Monitoring the ventilatory function of a patient with neuromuscular weakness can involve repeated measurement of inspiratory pressure, VC, and ABG values. Depending on the condition, the need for mechanical support can be signaled by reaching either a critical value on testing or an overall clinical condition that does not allow unassisted ventilation to continue. Additional measurements that may indicate early respiratory insufficiency, at least in amyotrophic lateral sclerosis, include maximal sniff nasal inspiratory force[2] and nocturnal oximetry.[6]

At least two caveats to this general approach should be mentioned. First, patients with myasthenia gravis having an acute myasthenic crisis may have normal test results within minutes of acute ventilatory failure because of the nature of the disorder.[7] Second, the need to protect the upper airway from secretions and aspiration may not be clearly reflected in results of pulmonary function tests, which evaluate only the mechanical function of the ventilatory pump.

Neuromuscular weakness may not manifest uniformly in all muscle groups. Ventilation may be only moderately reduced in patients with gross oropharyngeal dysfunction leading to aspiration. Patients with ventilatory weakness can have a high risk for acute respiratory failure if upper respiratory tract infection or pneumonia develops. In these patients, inability to clear secretions can increase the work of breathing; the results are muscle fatigue, hypoventilation, and acute respiratory failure.

Patients with significant weakness of the respiratory muscles can have a high risk for respiratory failure when any additional process increases the work of breathing. Pulmonary edema, pneumonia, and mucous plugging are examples of clinical conditions that can precipitate respiratory failure rapidly in patients with significant neuromuscular weakness. Although the underlying disease may not have progressed to the point that these patients need continual or routine ventilatory support at their baseline function, that support may be critical in the setting of acute, exacerbating illness.

Nocturnal oximetry or formal sleep testing with polysomnography may be suggested in some clinical settings when patients have cor pulmonale, sleep disturbance, or excessive daytime somnolence that is otherwise unexplained.

MINI CLINI

Assessment of a Patient With Neuromuscular Weakness

PROBLEM: A 50-year-old man with ALS is admitted to the hospital because of right lower lobe pneumonia. The patient is moderately hypoxemic, with PO_2 of 68 mm Hg on room air. ALS was diagnosed 3 years previously, and he has had progressive worsening of dyspnea since then. These symptoms first occurred with mild exertion and then with supine position, which the patient has noticed in the last 1 or 2 months. A recent measurement of VC at the physician's office was 35 ml/kg. The patient has recent noticed difficulty with swallowing and frequent coughing at meals. What features in the patient's history may be relevant with regard to management?

DISCUSSION: This patient has a disease that is associated with respiratory compromise, which progresses slowly in most cases, in contrast to the acute case described here. All patients with ALS ultimately have respiratory insufficiency. The earliest symptom of neuromuscular weakness in the respiratory muscles is exertional dyspnea, which this patient has had for some time. A more significant finding is orthopnea, which is highly suggestive of diaphragmatic weakness. Patients with significant diaphragmatic weakness prefer an upright position, which allows the abdominal contents to shift toward the feet and allows unimpeded diaphragmatic descent. Although the patient may not have had a critically low VC recently, this value is low. Additional loading of already compromised ventilatory machinery can lead to fatigue and frank respiratory failure. It is important to recognize that the underlying neuromuscular weakness coupled with pneumonia may predispose this patient to respiratory fatigue and subsequent respiratory failure. The history of feeding difficulty may suggest that the pneumonia is related to aspiration. The location of pneumonia in the lower lobe also favors the diagnosis if the aspiration occurred when the patient was seated upright.

MANAGEMENT OF RESPIRATORY MUSCLE WEAKNESS

Respiratory insufficiency and failure to clear secretions are the major consequences of inspiratory and expiratory muscle weakness. Treatment of these patients involves consideration of mechanical ventilation via face mask or other noninvasive interfaces or via tracheostomy. Although often overlooked, therapies to augment secretion clearance and assist with cough are important in these patients (see Chapters 42 and 43). Used together, these interventions can decrease hospitalizations for respiratory complications in patients with neuromuscular disease.[8] These measures also may be useful in delaying or preventing the need for intubation or tracheostomy, although severe bulbar muscle weakness may limit a patient's ability to avoid invasive ventilatory support.[9] In addition to these interventions, general rehabilitation focusing on aerobic conditioning, muscle strengthening, and respiratory muscle training often can delay the need for ventilatory support and improve the overall quality of life for patients with muscle weakness.[10]

Noninvasive ventilation is being used increasingly for short-term and intermittent ventilatory support of patients with neuromuscular disease.[11] Acute deterioration, such as during pneumonia, and surgical procedures such as gastrostomy tube insertion are situations in which noninvasive ventilation is safe and effective if used carefully.[9,12] If a patient needs long-term ventilatory support on an intermittent basis, such as at night only, noninvasive ventilation may be appropriate.[13] Decisions to begin mechanical ventilation in some patients with neuromuscular weakness have varied greatly among physicians[14] and may be motivated by many different patient factors.[15] No uniform guidelines exist for the use of long-term mechanical ventilation for patients with neuromuscular weakness. However, it is considered a standard option for patients who have reached the

point of respiratory failure. Starting a patient on long-term mechanical ventilation requires careful planning and consideration of various issues related to respiratory care in alternative settings. These issues have been addressed in consensus statements[16,17] and are discussed in Chapter 56.

Diaphragm pacing in patients with spinal cord injury has been described using direct stimulation of an intact phrenic nerve to contract the diaphragm and produce negative intrathoracic pressure and inspiration.[18] This technique usually requires a thoracotomy, with its associated risks and high cost, and carries some risk for phrenic nerve injury. These objections have led to the development of an alternative system for diaphragm pacing using direct pacing of the diaphragm muscle by laparoscopically implanted electrodes.[19] When the electrodes can be placed in the diaphragm muscle at an electrophysiologically mapped *motor point,* the result is often elimination of the need for mechanical ventilation in patients with spinal cord injury and delay in the need to start mechanical ventilation in patients with ALS and other progressive neuromuscular diseases.[20]

MINI CLINI

Care of a Patient With Neuromuscular Weakness

PROBLEM: A 45-year-old man has myotonic dystrophy. He has progressive dyspnea that has increased, particularly in the last year. PCO_2 determined from ABG analysis is 55 mm Hg. VC is 45% of the predicted value. The patient has no underlying lung disease. Cough is decreased, but the patient maintains adequate control of secretions. The patient sleeps in a seated to semirecumbent position. What interventions are indicated for this patient?

DISCUSSION: The patient has a disease that can result in respiratory insufficiency. VC is decreased, and arterial carbon dioxide levels are increased. These factors are consistent with hypoventilation secondary to neuromuscular weakness. The patient has dyspnea on exertion and orthopnea. All these factors suggest that mechanical ventilation should be considered.

Noninvasive positive pressure ventilation (NIPPV) may be a reasonable first choice in the care of this patient. The patient's mental status and bulbar function are intact. He has no significant problems with secretions. (Important factors for successful application of NIPPV are discussed in Chapter 49.) Use of a nasal mask with a biphasic positive airway pressure unit may be instituted and titrated to patient tolerance. (Most pressure or volume-cycled ventilators can be used to deliver NIPPV and invasive ventilation.) A time-cycled backup rate can be set on some ventilators to facilitate ventilation of patients who may inadequately trigger the ventilator. If the ability to clear secretions becomes compromised, cough augmentation strategies should be implemented. As long as bulbar function—swallowing and secretion management—are maintained, noninvasive ventilation is a reasonable choice for ventilatory support.

RULE OF THUMB

Patients with neuromuscular weakness who require noninvasive ventilation generally prefer a low expiratory pressure (2 to 3 cm H_2O) with a significantly higher inspiratory pressure (7 to 15 cm H_2O).

SPECIFIC NEUROMUSCULAR DISEASES

Disorders of the Muscle (Myopathic Disease)

Primary muscle disease can decrease the ability of a normal neural impulse to generate effective muscle contraction. Some commonly recognized myopathies include Duchenne muscular dystrophy, myotonic dystrophy, and polymyositis. Box 32-1 presents a more complete list of myopathic diseases associated with ventilatory dysfunction.

Duchenne Muscular Dystrophy and Becker Muscular Dystrophy

Duchenne muscular dystrophy (DMD) is a genetic muscle-wasting disorder caused by mutations in the dystrophin gene.[21] Because it is an X-linked recessive disorder, it affects mostly males. The diagnosis is made when a dystrophin mutation is

Box 32-1 Myopathic Diseases With Associated Respiratory Dysfunction

MUSCULAR DYSTROPHIES
- Duchenne muscular dystrophy
- Becker muscular dystrophy
- Myotonic dystrophy
- Facioscapulohumeral muscular dystrophy
- Limb-girdle dystrophy
- Oculopharyngeal dystrophy

MYOPATHIES
- Congenital myopathies
- Nemaline rod myopathy
- Centronuclear myopathy
- Metabolic myopathies
- Acid maltase deficiency
- Mitochondrial myopathies (Kearns-Sayre syndrome)
- Inflammatory myopathies
- Polymyositis
- Dermatomyositis
- Hypothyroid-related and hyperthyroid-related myopathies
- Endocrine myopathies
- Steroid-induced myopathies (including critical illness myopathy)
- Miscellaneous myopathies
- Electrolyte disorders (e.g., hypophosphatemia, hypokalemia)
- Rhabdomyolysis
- Periodic paralysis
- Postneuromuscular blockade myopathy

found in DNA from circulating white blood cells or when dystrophin is found to be absent or abnormal in biopsied muscle tissue.

DMD manifests early in life with proximal muscle weakness that leads to a waddling gait, exaggerated lumbar curvature (lordosis), and frequent falls. Most affected children need a wheelchair by 12 years of age. Death generally occurs by 20 years of age, usually as a result of declining respiratory muscle strength and subsequent infection. **Becker muscular dystrophy**, a milder form of DMD, also is associated with the dystrophin gene and manifests later in life.

Other systemic effects of DMD include scarring of the left ventricle and decreased bowel motility (intestinal pseudoobstruction). The progressive decline in respiratory function in patients with DMD parallels limb weakness and typically manifests at the time of wheelchair dependence. Respiratory failure is primarily due to loss of muscle strength and features a lower PImax at all lung volumes than is present in healthy persons.

Progressive scoliosis is associated with DMD and can contribute further to respiratory insufficiency. Many patients undergo spine fusion surgery, and often the procedure allows greater comfort and ease in maintaining an upright posture. Although no randomized trials have proved any benefit of surgery on pulmonary function,[22] it appears that the rate of respiratory decline is slower after fusion surgery.[23]

Obstructive sleep apnea is present in a significant proportion of patients with DMD, prompting some experts to recommend formal polysomnography in patients with symptoms of obstructive sleep apnea or at the time of becoming wheelchair-bound.[24] Instituting positive pressure ventilation (PPV) is a decision most patients face at some point in the disease. The point at which to begin different methods of ventilatory support depends on both test results and clinical condition. Nocturnal PPV is usually indicated when FVC reaches 30% of predicted with signs of hypoventilation.[25,26] It can be started in response to oxygen (O_2) desaturation during sleep, which is common in patients with increased disability and scoliosis.

Nocturnal ventilation usually improves daytime ventilatory function in patients with DMD,[27] presumably through prevention of respiratory muscle fatigue. Despite this improvement, studies of early "prophylactic" PPV for patients with DMD have shown that early PPV failed to delay the need for invasive ventilatory support.[28] Long-term inspiratory muscle training using resistive loading has been shown to improve PImax in patients with DMD and VC of at least 27%,[29] theoretically delaying the need for ventilatory support. Although there are concerns that pulmonary rehabilitation might produce deleterious effects through overloading weak respiratory muscles, such concerns have not been confirmed in studies in Becker muscular dystrophy.[30]

Myotonic Dystrophy

Myotonic dystrophy is the most common form of muscular dystrophy in adults, with an estimated frequency of 1 in 8000 persons.[31] *Myotonia,* or delayed muscle relaxation, is the hallmark of this neuromuscular disorder but does not clearly target respiratory muscles or directly cause respiratory insufficiency.[32] This autosomal dominant disorder causes progressive muscle weakness, abnormalities of the cardiac conduction system, endocrine dysfunction, and cataracts. There are two main types of myotonic dystrophy, both caused by an expansion of a repeated DNA sequence on chromosome 19.[33]

Respiratory dysfunction in myotonic dystrophy is common, usually occurring late in the course of disease, and can include respiratory muscle weakness, obstructive sleep apnea, central sleep apnea, and bulbar muscle dysfunction leading to aspiration. Sleep-related disorders are particularly common, even at an early age.[34]

Patients with myotonic dystrophy can be very sensitive to anesthesia and respiratory depressants. Both respiratory failure and prolonged neuromuscular blockade have been reported in patients with myotonic dystrophy given usual doses of these agents. For this reason, prolonged perioperative monitoring after surgery is important.[35,36]

Nocturnal ventilation by nasal mask often is effective for these patients and should be considered if the patient has declining SaO_2 or hypercapnia. If patients develop central hypoventilation, they may require tracheostomy and mechanical ventilation. Because cough is often weak, cough assistive devices and techniques may play an important role to clear secretions.

Polymyositis

Polymyositis, **dermatomyositis**, and **inclusion body myositis** are inflammatory myopathies of unknown cause. Respiratory compromise is rare in inclusion body myositis but can be seen in both polymyositis and dermatomyositis. Clinical respiratory muscle weakness is uncommon but can lead to respiratory weakness or failure within weeks to months in the setting of rapidly progressing disease. Diagnosis of these diseases is based on clinical findings of myalgia, elevated muscle enzyme levels (creatine phosphokinase or aldolase), and compatible electromyographic or muscle biopsy results. Diagnostic criteria may apply to any inflammatory **myopathy**, and specific findings or antibody identification may be needed to differentiate the various diseases (Table 32-3).[37,38]

Ventilatory insufficiency and failure caused by these inflammatory myopathies are unusual but tend to parallel the development of limb muscle weakness when they occur. In rare instances, diaphragmatic function is decreased disproportionately to the degree of limb weakness.[39]

Corticosteroids are important in the initial management of polymyositis and dermatomyositis, although other immunosuppressive and cytotoxic regimens are used to limit long-term steroid exposure; 35% to 40% of patients with inflammatory myopathy have interstitial lung disease associated with their myopathy. This lung disease appears as diffuse interstitial infiltrates that may be caused by various lung processes, but the most common (56%) is nonspecific interstitial pneumonia.[40] Various antisynthetase antibodies (e.g., the Jo-1 antibody) have been identified that are associated with polymyositis and dermatomyositis,[41-43] although the role of these antibodies in these

TABLE 32-3

Diagnostic Criteria for Inflammatory Myopathies

Criterion	Polymyositis	Dermatomyositis	Inclusion Body Myositis
Symmetric proximal muscle weakness on physical examination	Yes	Yes	May be asymmetric and more distal weakness
Elevation of serum muscle enzymes (creatine kinase, aldolase, glutamate oxaloacetate, pyruvate transaminases, and lactate dehydrogenase)	Yes	Yes	Yes, lower levels than in polymyositis or dermatomyositis
Electromyographic triad of (1) short, small polyphasic potentials, (2) fibrillations, (3) high-frequency repetitive discharges	Yes	Yes	Yes
Muscle biopsy showing mononuclear inflammation, phagocytosis, necrosis, degeneration, and regeneration	Yes	Yes	Yes, may have fatty infiltration
Skin findings: Gottron sign and papules; heliotrope rash	No	Common	No
Anti–Jo-1 antibody (or other antisynthetase antibodies)	30%-50%, may indicate antisynthetase syndrome		No
Interstitial lung disease	86% in patients with antisynthetase syndrome		No

MINI CLINI

Care of an Intensive Care Unit Patient to Minimize the Risk for Critical Care Myopathy

PROBLEM: A 60-year-old man is in the ICU with respiratory failure secondary to severe influenza pneumonia. He has developed acute respiratory distress syndrome (ARDS), and gas exchange is severely impaired, with a PaO_2/FiO_2 ratio of 90. He is requiring relatively high positive end expiratory pressure (PEEP) and FiO_2 to maintain adequate SaO_2. He has been hypotensive because of septic shock from his influenza and required pressors via a central line immediately after admission to the unit and intubation for the initiation of mechanical ventilation. He also has diabetes. Along with the immediate needs for stabilization, resuscitation, and supportive care, the ICU team needs to consider what impact their therapeutic choices now will have on his risk for developing critical illness myopathy.

DISCUSSION: Patients like this are commonly seen in high-acuity ICUs, in which patients with severe ARDS and sepsis are frequently found. He has a number of risk factors for critical care myopathy, some of which may be avoidable and others may not. As the critical care team provides supportive care for him, they need to consider how each risk factor could be avoided or minimized, as followed:

- *Corticosteroids:* So far he has not required corticosteroids, but they are sometimes used for refractory hypotension in septic shock. The sepsis guidelines are somewhat ambiguous about the use of corticosteroids in this setting, because the evidence for their usefulness is mixed. In this case, if the blood pressure can be maintained without them, it would eliminate one risk factor for critical care myopathy.
- *Paralytic agents:* In severe ARDS, patients are sometimes paralyzed to improve oxygenation and ventilator synchrony. There is evidence that paralysis for the first 48 hours may improve survival in such patients. If paralytics are used, they should be discontinued as soon as they are no longer needed, certainly by the 48-hour mark, thus minimizing another risk factor.
- *Hyperglycemia:* As a diabetic who is critically ill, this patient may experience wide fluctuations in his blood glucose level. ICU protocols usually aim to maintain the glucose level at about 150 mg/dl, and if this can be done, it will minimize an additional risk factor. Because corticosteroids would likely raise the blood glucose level, this is another reason to avoid them in this patient.
- *Systemic inflammatory response syndrome (SIRS):* Because this patient has septic shock, by definition he has SIRS. Once a patient has SIRS, the only option for the ICU team is to treat the underlying infection if possible and support the patient through the septic period. This risk factor is not modifiable directly, but treating the influenza appropriately should minimize the duration and severity of SIRS.

diseases is unclear. Pulmonary vasculitis can occur with polymyositis and dermatomyositis and can lead to O_2 exchange abnormalities and pulmonary hypertension.

Critical Illness Myopathy

Critical illness myopathy is a heterogeneous entity that occurs commonly in intensive care units (ICUs) in which patients develop flaccid weakness of proximal muscles. Although this condition does not specifically target the diaphragm muscle, these patients are often very difficult to wean from mechanical ventilation. Risk factors for developing this myopathy include use of corticosteroids (likely dose-dependent); use of paralytic agents; hyperglycemia; hyperthyroidism; and possibly systemic inflammatory response syndrome, with or without sepsis.[44] Weakness improves on its own in most cases but may take weeks or months to resolve, often incompletely. There is no specific therapy, and prevention by avoiding the risk factors as much as possible is the best approach.[45]

Disorders of the Neuromuscular Junction

Disorders of the neuromuscular junction decrease conduction of nervous system impulses to the peripheral muscles, resulting in muscle weakness. Different clinical syndromes are caused by defects in different molecules or components of the neuromuscular junction, which is represented schematically in Figure 32-4, which compares a normal neuromuscular junction with an abnormal junction in myasthenia gravis. Disorders of the neuromuscular junction include the following:

1. Myasthenia gravis
2. Lambert-Eaton syndrome
3. Poisoning (organophosphate, tetanus, botulism)

Myasthenia Gravis

Myasthenia gravis (MG) is characterized by intermittent muscular weakness, which worsens on repetitive stimulation and improves with administration of anticholinesterase medications, such as edrophonium (Tensilon) or neostigmine. Most cases of MG arise from production of antibodies directed against the acetylcholine receptor (ACh-R). The antibodies inactivate the ACh-R and block transmission of electrical impulses from the nerve to the muscle.[46]

Approximately 20% of patients with MG do not exhibit such antibodies but may have antibodies to alternative targets, such as muscle-specific kinase.[47] Abnormalities of the thymus gland are common in MG. Approximately 10% of patients with MG have a neoplastic growth within the thymus called *thymoma,* which can be malignant but usually is not. Patients without thymoma typically have some degree of thymic hyperplasia. Congenital or fetal myasthenic syndromes are caused by either autoantibodies or inherited defects in the ACh-R.

MG typically occurs earlier in life in women and later in men. As the population has aged, more patients are diagnosed with MG later in life, and now there are more men affected than women.[48] This disorder may be associated with other autoimmune diseases, such as thyroid disease, diabetes, rheumatoid arthritis, ulcerative colitis, sarcoidosis, and pernicious anemia.

MG is characterized by progressive loss of muscular function, which may affect only the eye muscles (ocular myasthenia) or may be more widespread. The initial symptom is diplopia (double vision) or ptosis (a drooping eyelid) in more than 65% of patients (Figure 32-5).[49] The patient typically reports weakness of the affected muscles that may vary through the day or progress, especially with repetitive use. The diagnosis of MG is supported by the detection of anti–ACh-R antibodies in the blood, a characteristic fading of nerve impulses with repeated nerve stimulation testing during electromyography, and improvement of strength or symptoms in response to an anticholinesterase inhibitor drug (edrophonium) (Figure 32-6).

The pulmonary complications of MG depend on the magnitude and location of the affected muscle groups and tend to occur in patients most severely disabled with the disease. Upper airway obstruction, exertional dyspnea, and overt ventilatory failure all are reported in MG. Pulmonary function testing of MG patients who have respiratory muscle weakness shows decreased TLC, VC, PImax, and PEmax, similar to other

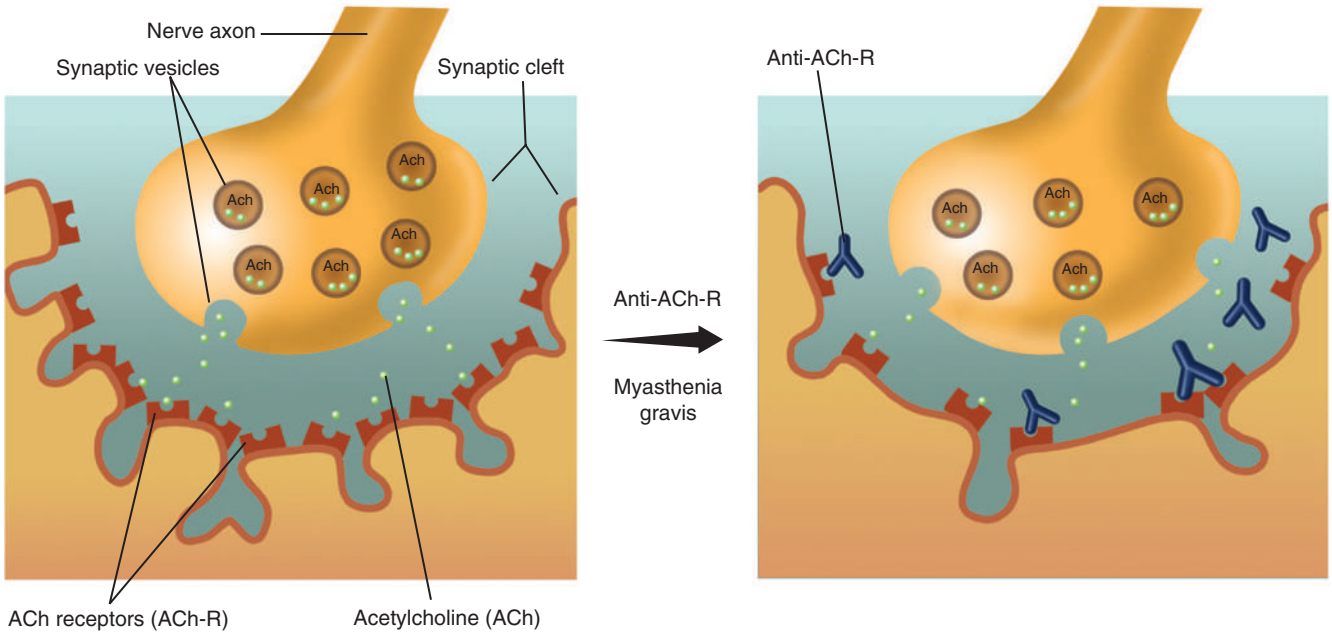

FIGURE 32-4 The neuromuscular junction with acetylcholine *(ACh)* stored in presynaptic vesicles. ACh is released by exocytosis into the synaptic cleft in response to a presynaptic nerve impulse. ACh binds to its cognate *ACh-R* on the postsynaptic membrane. This process depolarizes the nerve, propagates the impulse, and causes muscle contraction. Binding of anti–ACh-R antibodies to ACh-R mediates autoimmune destruction of the receptors. This process leads to abnormal muscle activation and the weakness that occurs in patients with myasthenia gravis.

FIGURE 32-5 Features of ocular and facial weakness in a patient with myasthenia gravis. At rest *(left),* there is slight bilateral lid ptosis, which is partially compensated by asymmetric contraction of the frontalis muscle, raising the right eyebrow. During attempted smile *(right),* there is contraction of the medial portion of the upper lip and horizontal contraction of the corners of the mouth without the natural upward curling, producing a "sneer." (From Sanders DB, Howard JF: Disorders of neuromuscular transmission. In: Bradley, editor: Neurology in clinical practice, ed 5, Philadelphia, 2008, Butterworth Heinemann.)

FIGURE 32-6 Clinical effect of edrophonium on a patient with myasthenia gravis. Before testing *(left),* the patient has ptosis of the left eyelid and lateral deviation of the left eye, and she must support her jaw. At 5 seconds after injection of 0.1 mg of edrophonium *(right)*, ptosis and lateral deviation are resolved, and her jaw no longer requires support. (From Sanders DB, Massey JM: Clinical features of myasthenia gravis. In: Engel AG, editor: Neuromuscular junction disorders, New York, 2008, Elsevier.)

neuromuscular disorders, with PImax and PEmax being more sensitive markers of early respiratory muscle weakness.[50]

Myasthenic crisis is an acute event in MG and is characterized either by respiratory failure or inability to maintain a patent airway. Myasthenic crisis can occur acutely in response to worsening of disease, intercurrent infection, or surgery or when excess anticholinesterase inhibitors have been given. Endotracheal intubation and mechanical ventilation are required immediately and may be prolonged.[51]

Treatment of MG is generally effective, although it is largely empiric because clinical trials are rare. Long-term management includes thymectomy[52] and administration of anticholinesterase medications (edrophonium, neostigmine, pyridostigmine) with or without corticosteroids or other immunosuppressants such as azathioprine or cyclosporine.[49] For patients in acute myasthenic crisis, who often have respiratory failure requiring mechanical ventilation, circulating antibodies can be removed by plasmapheresis, which results in clinical improvement[53,54] usually after five or six treatments and has been used to facilitate weaning from mechanical ventilation in the care of these patients.[55] Intravenous immunoglobulin G (IgG) has been used and can improve muscle strength and hasten recovery from respiratory failure. Neither plasmapheresis nor intravenous IgG is generally used for long-term management of MG. The effect of both treatments is temporary but may last several months.[49] Clinical trials comparing these treatments have shown a slight advantage with plasmapheresis but also a higher complication rate.[56,57]

Lambert-Eaton Syndrome

Another syndrome of neuromuscular weakness arising from a disorder at the neuromuscular junction is **Lambert-Eaton syndrome** (LES). More than 50% of cases of LES are associated with cancer. Of these cancer-related cases, greater than 80% are associated with small cell carcinoma of the lung.[58] The mean age at presentation is approximately 60 years, although LES can occur in all age groups. Autoantibodies against voltage-gated calcium channels at the nerve terminals impair the release of acetylcholine and can lead to both muscular weakness and autonomic insufficiency.[59] These autoantibodies can be detected in a patient's serum, which confirms the diagnosis.[58,60] The clinical diagnosis of LES is supported by results of nerve conduction studies. Increasing muscle strength with repetitive stimuli is a characteristic feature of LES, which differentiates it from MG, which is characterized by progressive fatigue of muscular contraction with repetitive stimulation.

Patients with LES usually present with tiredness or weakness of proximal muscle groups out of proportion to findings on clinical examination. Although patients are subject to respiratory complications because of their increased sensitivity to the effects of anesthesia, respiratory failure is rare. The clinical course of LES tends to be one of relative stability with less fluctuation than MG. Management of LES includes treatment of the underlying malignancy when present. If no malignancy is found, surveillance for lung cancer is recommended every 6 months, and LES is managed symptomatically with immunosuppressive medication or acetylcholinesterase inhibitors.[58,60]

Disorders of the Nerves

The peripheral nerves may be affected by toxic agents, inflammatory processes, vascular disorders, malignant diseases, and metabolic or nutritional imbalances. Hundreds of conditions have been associated with neuropathies leading to respiratory muscle dysfunction. Representative conditions are listed in Box 32-2.

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is acute inflammatory demyelinating polyneuropathy and is the most common peripheral **neuropathy** causing respiratory insufficiency. GBS is characterized by paralysis and hyporeflexia with or without sensory symptoms. GBS is typically a self-limited disease, but overall mortality ranges from 3% to 10%.[61] Before modern mechanical ventilation techniques, mortality in this condition was greater than 33%.[62] Most patients recover their respiratory muscle strength completely, but the proportion of patients with significant disability 1 year after onset of the disease can be 20%.[63] Autonomic nervous system problems, such as hypotension, flushing, bronchorrhea, dermatographia, and bradycardia, are common. Two-thirds of patients with GBS report a triggering event, such as respiratory or gastrointestinal infection, immunization, or surgery, 1 to 4 weeks before the onset of symptoms. Other reported triggers include pregnancy and malignancy.[62]

GBS is a demyelinating process widely believed to be caused by autoantibodies directed against the myelin constituting the nerve sheath. The diagnosis of GBS is based on a combination of clinical, laboratory, and electrophysiologic data (Box 32-3).[64] Cerebrospinal fluid protein levels are elevated, with minimal cellularity after approximately 1 week of illness. Nerve conduction studies show slowing of conduction with preserved amplitude, which is typical of demyelination. Approximately one-third of all patients with GBS have respiratory muscle compromise. Although the diaphragm is typically affected later in the course of GBS, cases of respiratory failure in the absence of substantial peripheral weakness have been reported. The need for mechanical ventilatory support for patients with GBS increases with age.[62]

Treatment strategies that have improved outcome in GBS include intravenous IV infusions and plasmapheresis. These treatments are equally effective in hastening recovery of muscle strength. The benefit is greatest when treatment is started within 2 weeks of symptom onset. There is no additional benefit of combining the two therapies. Corticosteroids have no beneficial role in GBS.[65]

Patients with dyspnea, orthopnea, or impaired ability to maintain a patent airway should receive spirometry every 4 to 6 hours for documentation of function and assessment of the need for endotracheal intubation. Patients with poor upper airway control, weak cough, or large amounts of secretions should be considered for endotracheal intubation even though their VC is greater than 20 ml/kg. The increased work of breathing imposed by mucous plugging or atelectasis can hasten

Box 32-2 Causes of Phrenic Nerve Dysfunction Leading to Respiratory Dysfunction

- Cardiac surgery (cold cardioplegia to arrest the heart can cause "frostbitten" phrenic nerves; ischemic injury to nerves also can complicate cardiac surgery)
- Diabetes
- Trauma
- Thoracic aneurysm

Box 32-3 Diagnostic Criteria for Guillain-Barré Syndrome

REQUIRED FOR DIAGNOSIS
- Progressive weakness of both legs and arms
- Areflexia

SUPPORTIVE OF DIAGNOSIS
- Symptoms progress over days to weeks
- Symmetry of weakness
- Cranial nerve involvement (facial palsies)
- Improvement begins 2 to 4 weeks after progression stops
- Absence of fever at onset of symptoms
- Pain
- Laboratory features not suggestive of alternative diagnosis
- Cerebrospinal fluid with high protein, low cell count
- Nerve conduction slowing or block with normal amplitude

decompensation. A small subgroup may need mechanical ventilation for 1 year or more. Weaning of patients with GBS from mechanical ventilation is predicted by VC greater than 18 ml/kg,[66] transdiaphragmatic pressure greater than 31 cm H_2O, or a PImax stronger than −30 cm H_2O.[67]

RULE OF THUMB

Patients with GBS whose VC becomes less than 20 ml/kg or declines more than 30% from baseline or whose PImax is less negative than −30 cm H_2O and PEmax is less than 40 cm H_2O are at risk for respiratory failure and may need ventilatory support. Patients who meet the criteria of this "20-30-40 rule" should be observed in an ICU.[66,67]

RULE OF THUMB

Patients with GBS should be intubated for mechanical ventilatory support when VC decreases to 12 to 15 ml/kg or sooner if they have bulbar dysfunction with difficulty managing oral secretions or when PaO_2 values are less than 70 mm Hg while breathing room air.[62] As with all patients requiring intubation, as soon as it is clear that intubation will exceed 2 weeks' duration, a tracheostomy should be considered.[68]

Phrenic Nerve Damage and Diaphragmatic Paralysis

Each hemidiaphragm is supplied by its own phrenic nerve. The phrenic nerves emerge from the spinal cord at level C3-5 and descend through the mediastinum along the great vessels of the chest and pericardium. Damage to or interruption of either phrenic nerve leads to paralysis of the ipsilateral hemidiaphragm. Bilateral interruption is seen in high spinal cord injury and causes complete diaphragmatic paralysis. Unilateral diaphragmatic paralysis can be seen in various disease processes. Reversible unilateral diaphragmatic paralysis is a rare complication of acute pneumonia, but it can occur in 10% of patients who undergo cardiac surgery with cardiopulmonary bypass, usually secondary to cold cardioplegia or traction on the nerve during surgery or ischemic nerve injury.[69]

Patients with unilateral diaphragmatic paralysis may have a 15% to 20% reduction in VC and TLC in the upright position and a further reduction while supine. If they have no other diseases, patients with unilateral diaphragmatic paralysis may have no symptoms. Athletes, musicians, and others who use their lungs more fully are more likely to notice the decreased ventilatory capacity caused by unilateral diaphragm weakness. Diaphragmatic paralysis is diagnosed most often with chest radiography. The paralyzed side retains its contour but is displaced upward (Figure 32-7, *A*). At fluoroscopy, the paralyzed hemidiaphragm paradoxically rises into the thorax during a sudden forceful inspiration (sniff test). This paradoxical motion damps the effect of the normal diaphragm on the opposite side.

For patients with unilateral diaphragm paralysis, surgical plication of the weak side can move the diaphragm downward to a more normal position (see Figure 32-7, *B*), minimize paradoxical motion, and improve overall lung function.[70,71] Historically, results of diaphragm plication procedures have been disappointing, but newer laparoscopic techniques are more promising.[72,73] Appropriate patient selection is crucial to avoid operating on patients whose diaphragms would recover their strength in time and patients whose weakness is due to primary neuromuscular disorders, which would not be improved by plication.

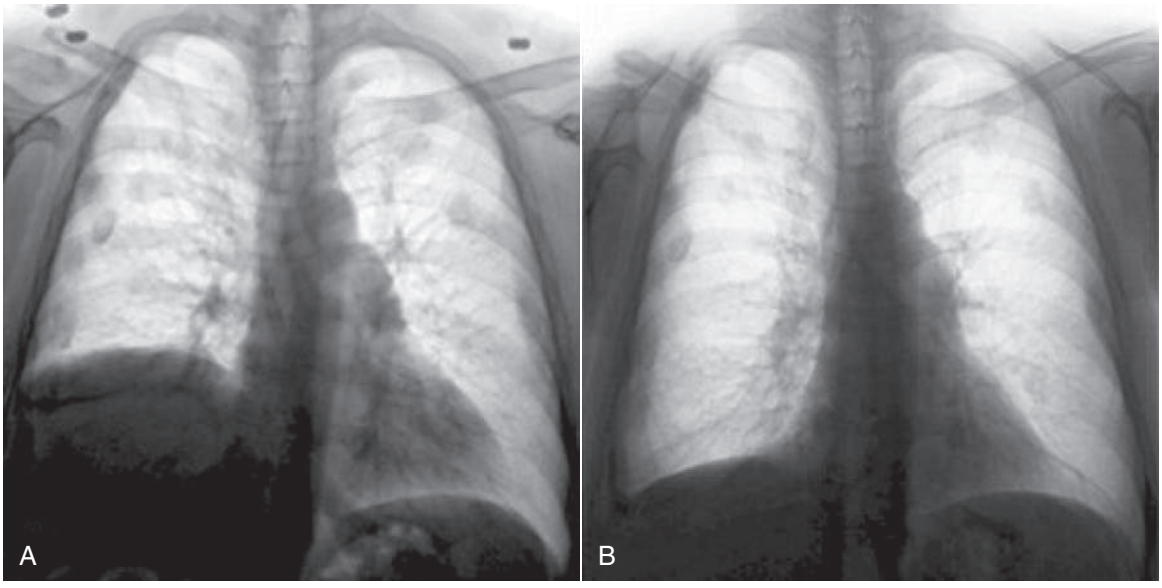

FIGURE 32-7 **A,** Chest radiograph showing elevation of a right hemidiaphragm. **B,** Chest radiograph in the same patient 1 year after laparoscopic diaphragm plication. (From Groth SS, Andrade RS: Diaphragm plication for eventration or paralysis: a review of the literature. Ann Thorac Surg 89:S2146–S2150, 2010.)

RULE OF THUMB

Diaphragm weakness resulting from phrenic nerve injury (not transection) often improves very slowly, sometimes over years, so plication should be delayed until serial testing shows that no further improvement is occurring, usually at least 1 to 2 years from the onset of weakness.

Critical Illness Polyneuropathy

In contrast to critical illness myopathy, discussed previously, **critical illness polyneuropathy** is associated almost entirely with severe sepsis in the ICU. Patients develop muscle weakness and atrophy, loss of deep tendon reflexes, and loss of peripheral sensation to pinprick and touch. Cranial nerve function is usually spared. The mechanism of nerve damage is unknown but, similar to other complications of sepsis, may be related to ischemia caused by thrombosis or underperfusion of the microcirculation, or both, in this case of the affected nerves.[45]

Effects of critical illness polyneuropathy may persist for years, or permanently, but often improve with time and rehabilitation. As in critical illness myopathy, there is no specific treatment; optimal management of the patient's severe sepsis following protocols to restore adequate circulation and limit the length of organ system failure is probably beneficial.

Disorders of the Spinal Cord

Upper motor neurons arise from cell bodies in the motor areas of the brain and terminate at the anterior horn cells in the spinal cord, which constitute the lower motor neurons because it is axons from these cells that extend out of the central nervous system to the skeletal muscles. Disorders in this group (e.g., ALS) can affect specific parts of this chain or nonspecifically disrupt these tracts (e.g., spinal cord injury). Other examples of lesions in this anatomic location include transverse myelitis, syringomyelia, poliomyelitis, and spinal cord tumors.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis, or **Lou Gehrig disease**, is a neuromuscular disease characterized by progressive degeneration of both upper and lower motor neurons; early in the disease, degeneration of either upper or lower motor neurons may predominate. Approximately 5% to 10% of cases are familial; others are sporadic. The male-to-female ratio for ALS is approximately 1.2 : 1, and the peak incidence is between 65 and 75 years old, although cases have been reported in patients younger than 30 years old. The prognosis of ALS is poor, with a mean survival from diagnosis of 3 years. By 5 years, 80% of patients have died and 90% have died by 10 years.[74] Medical treatment of ALS is disappointing. There is no cure, and therapies to halt or slow progression of the disease are few and ineffective. One approved therapy for ALS is riluzole, an antiglutamate agent. Randomized trials have shown modest improvements in median survival of 4.2 months.[75] The high cost of the medication makes it hard to get for many patients, especially in light of the modest benefits that are usually seen.

Muscle weakness from ALS usually begins in a localized muscle group and spreads out geographically from there. It most often begins in the arms but may originate in the bulbar muscles (i.e., muscles supplied by nerves in the upper spinal cord, such as the nerves controlling swallowing and speaking) 25% of the time. In 1% to 2% of cases, ALS manifests initially as isolated respiratory muscle dysfunction in an otherwise relatively intact patient. Respiratory involvement eventually occurs in all patients with ALS, and pulmonary complications are the most frequent cause of death. Muscle weakness is associated with fasciculations, or involuntary quivering of the affected muscles. If muscle fasciculation does not develop in a patient with presumed ALS soon after weakness, another diagnosis should be considered.[76]

Inspiratory muscle decline, measured by FVC, tends to be linear with time in any one patient, although the rate of decline may be different between patients. As respiratory muscle strength gradually declines, acute respiratory decompensation may occur in the setting of respiratory infection or aspiration. ALS patients may have respiratory difficulty for various disease-related reasons, not all of which are direct results of respiratory muscle weakness. Nocturnal hypoxemia and hypoventilation can lead to disrupted sleep, frequent arousal, daytime headaches, and somnolence.

Monitoring FVC, PImax, and PEmax or maximal sniff nasal inspiratory force is helpful in these patients and can provide important information regarding the ability to clear secretions and maintain gas exchange. Ineffective cough can lead to atelectasis, pneumonia, worsening gas exchange, and hypoxemia.

RULE OF THUMB

Effective cough typically requires a PEmax greater than 40 cm H_2O to compress airways and generate sufficient flow velocities within the tracheobronchial tree to clear obstructing secretions or aspirated material.

Preventing respiratory complications and assessing the need for ventilatory assistance are central in caring for patients with advancing ALS. Helpful treatments include (1) modification of food consistency or placement of feeding tubes in patients with marked bulbar dysfunction, (2) clearing of secretions with assisted cough techniques or postural drainage, and (3) ventilatory assistance with positive or negative pressure devices. Noninvasive techniques are a reasonable option for many patients and have been shown to slow the rate of pulmonary decline, improve symptoms, and prolong survival.[77] When these techniques no longer suffice, many patients with ALS choose not to receive invasive mechanical ventilation and opt for palliative management at that point. However, many patients do desire invasive ventilatory support, and up to 90% of such patients report satisfaction with their decision and would choose tracheostomy and ventilation again in the same situation.[78] Although overall survival with ALS is poor, prolonged survival of ventilated patients has been reported.

RULE OF THUMB

The timing and type of ventilatory intervention (noninvasive or invasive) in the care of patients with ALS are the subject of much discussion. General guidelines for considering ventilatory assistance[79] include VC less than 50% predicted, orthopnea, maximal sniff nasal inspiratory force more negative than –40 cm H_2O, and abnormal nocturnal oximetry.

MINI CLINI

Respiratory Care of a Patient With Amyotrophic Lateral Sclerosis

PROBLEM: A 57-year-old practicing attorney with a diagnosis of ALS for 2 years has a tracheostomy for nocturnal mechanical ventilation. He is still able to function and practice law in a specialized wheelchair and wants to maintain his independence and professional practice as long as possible. What measures can be offered to help him maintain his respiratory function, avoid exacerbations that could lead to acute respiratory failure, and preserve his quality of life?

DISCUSSION: Respiratory muscle failure can be influenced by many factors in addition to the primary neuromuscular disease. These additional factors can be significant contributors to a patient's quality of life or progressive decline in function, and they provide additional therapeutic targets for care providers trying to maintain a patient's function and comfort.

Reduced lung compliance secondary to atelectasis or retained secretions can greatly increase the work of breathing for weakened muscles and worsen gas exchange. Maneuvers to recruit collapsed alveoli and augment his cough to clear secretions can counteract these factors. These maneuvers include chest physiotherapy and mechanical insufflation and exsufflation devices. Increased secretion production is another factor in many patients' illness, which can be managed with medications such as atropine or amitriptyline. In some cases, salivary glands are treated with low-dose radiation. Patients with bulbar dysfunction may lose additional respiratory muscle strength as a result of poor nutrition; placement of a percutaneous endoscopic gastrostomy tube for nutrition may avoid this as eating becomes more difficult. Keeping these additional aspects in mind allows a care provider to address them along with the primary weakness, and it is this care in many cases that prolongs a patient's ability to breathe independently and function as he or she would like.[80]

RULE OF THUMB

ALS is a complex and devastating disease and often requires a multidisciplinary approach, with input and active participation from numerous clinical specialties, including pulmonary, neurology, critical care, gastroenterology, palliative medicine, physical therapy, occupational therapy, social work, home nursing, psychiatry, and spiritual care.

RULE OF THUMB

Patients with ALS typically need psychologic support because of the progressive, incurable nature of their disease. Care providers must address issues such as depression, social and family support and education, and end-of-life planning. Because end-of-life discussions with patients can be uncomfortable for care providers, many avoid them and assume someone else will address this difficult topic, but that is a disservice to patients who need to understand and confront issues of eventual respiratory failure and death from their disease.

Spinal Cord Trauma

Approximately 12,000 new spinal cord injuries occur in the United States each year, and 55% involve the cervical spine. The causes are varied, but the most common causes are motor vehicle accidents, falls, violence, and sports. Many patients with a spine injury have other injuries associated with their trauma, including 25% to 50% with traumatic head injury.[81] Of spinal cord injuries, 5% to 10% cause quadriplegia. Complete cord injury is associated with absent motor and sensory function below the level of injury, and the patient's condition rarely improves. Patients with incomplete injury have residual function and tend to improve to varying degrees.

The respiratory manifestations of spinal cord injury depend on the level of injury and extent of damage. Cervical cord injuries can be functionally divided into two classes: high cervical cord lesions (C1-2) and middle to low cervical cord lesions (C3-8). The diaphragm receives innervation from nerve roots exiting the spinal cord at levels C3-5. Complete injury above this level results in total respiratory muscle paralysis and death, unless urgent intubation and ventilation are performed. Injury to the cord at C3-5 can severely reduce respiratory strength, as manifested by reductions in PEmax, PImax, FVC, and FEV_1, consistent with a restrictive ventilatory defect. Patients adopt a rapid, shallow breathing pattern and use accessory inspiratory muscles (scalene and sternocleidomastoid muscles) unless these muscles are also affected. *Abdominal paradox* (inward movement of the abdomen while the thorax expands) is the hallmark of significant bilateral diaphragmatic weakness. Despite the serious nature of injury between C3 and C5, 80% of intubated patients with this lesion can ultimately be liberated from mechanical ventilation. The muscles of expiration receive neural input from spinal levels T1-L1 and are predominantly affected by middle to low cervical cord lesions. This condition manifests as a marked reduction in PEmax compared with PImax and a diminished or absent effective cough.

The differential weakness of respective muscle groups in patients with neuromuscular weakness affects ventilatory capacity in the supine and seated positions. Patients with predominantly diaphragmatic weakness have orthopnea and are most comfortable in the upright seated position. The upright seated position favors gravity-assisted descent of the diaphragm, which is less affected by the abdominal contents that shift

caudally (toward the bottom of the patient's spine) in the seated patient.

Recumbent patients with bilateral diaphragmatic weakness accompanying spinal cord injury may display paradoxical breathing, or abdominal paradox. Observation of the chest and abdomen of patients reveals paradoxic inward movement of the abdomen during inspiration. Conversely, patients with expiratory muscle weakness similar to that produced by low cervical cord injury prefer the supine position, in which the tendency of the abdominal contents to move toward the head assists expiration in the absence of marked expiratory muscle tone. These physiologic principles form the basis for the use of "rocking beds" and pneumatic belt devices as ventilatory adjuncts in the care of patients with significant respiratory muscle weakness.

MINI CLINI

Respiratory Dysfunction in Spinal Cord Injury

PROBLEM: A young man who is otherwise healthy falls from a ladder and transects the spinal cord at the level of C6. Which muscles of the respiratory system will be affected, and what will be the effect?

DISCUSSION: Transection of the spinal cord at the level of the sixth cervical vertebra paralyzes any muscle group that receives its innervation from nerve roots that exit the spinal vertebral canal below C6. A review of the innervation of the major muscles of inspiration and expiration is important:
Upper airway, tongue, palate: Cranial nerves IX, X, XI, and XII
C3-5: Diaphragm
C4-8: Shoulder girdle muscle (scalenes)
T1-12: Intercostal muscles
T7-L1: Abdominal muscles

The upper airway, tongue, shoulder girdle muscles, and diaphragm should be intact in this patient's injury. Maintenance of intrathoracic volume depends partly on continuous activation of intercostal muscles, which stabilize and expand the thoracic cage. With these muscles paralyzed, expiratory reserve volume decreases and normal activation of the diaphragm results in a tendency toward inward excursion of the chest wall and loss of effective volume. Forceful exhalation and the development of cough depend on activation of abdominal and intercostal muscle groups, both of which are paralyzed in this injury. Although he has an intact diaphragm, this patient has a poor cough, which is a predisposing factor for atelectasis, pooling of secretions, and pneumonia. Successful management of spinal cord injury at this level includes aggressive postural drainage and percussion (when the injury has been stabilized) and possibly assisted cough in the respiratory care regimen.

Disorders of the Brain

Traumatic brain injury (TBI), stroke, hemorrhage, and infection can lead to abnormality of respiration through various mechanisms. The motor cortex contains voluntary centers for control of the upper airway and pharynx (see Chapter 15). The pons and medulla, located in the brainstem, contain (1) chemoreceptors for automatic control of ventilation in response to increasing pH and hypercapnia and (2) centers that generate and modify patterns of automatic ventilation in response to visceral and chemical afferent information (see Figure 32-1). Both stroke and TBI can lead to disordered patterns of breathing, which are listed in Table 32-4,[82-84] and abnormalities in the lungs themselves, such as neurogenic pulmonary edema. This section describes the clinical entities of stroke and TBI and their effects on the respiratory system.

Stroke

Stroke is a clinical syndrome produced by acute interruption of the normal blood flow to an area of the brain. The result is persistent dysfunction related to the affected structures. Stroke can be thrombotic (related to local formation of a clot), embolic (related to a clot traveling from a remote place in the body), or hemorrhagic. The effect of a stroke on respiration depends on which of the control elements of ventilation are damaged.

Strokes in the cerebral cortex can produce decreased chest wall and diaphragmatic movement. Infarction in this area usually does not lead to significant alteration of ventilation. However, the patient may have significant impairment of speech and movement, including impairment of muscles that affect upper airway tone and control secretions. Swallowing is frequently a problem, leading to aspiration or poor nutrition. Chronic changes in pharyngeal muscle tone can lead to obstructive sleep apnea. Rarely, localized strokes lead to profound alterations of the respiratory system. These alterations often result from strokes in the midbrain and brainstem or from subarachnoid hemorrhage. They often resolve or improve after the acute timeframe of the stroke (Table 32-4).

Therapy for stroke has evolved considerably. Previous therapy for thrombotic stroke was largely supportive. At the present time, early use of thrombolytic therapy to dissolve the clot and restore circulation and function has been shown to improve function and survival, particularly if the thrombolytic agent is given less than 3 hours after the onset of symptoms.[85,86] More recent trials also have shown benefit in a more restricted patient population when thrombolytic therapy was given in the 3- to 4.5-hour time frame.[87,88] Physical therapy and occupational therapy continue to be important components for optimizing function in the setting of residual deficit after stroke. Patients with substantial impairment of speech and swallowing may be at risk for aspiration pneumonia. As in many catastrophic illnesses, stroke presents a complex set of problems, and patients do best when managed using a multidisciplinary approach in a center with high volumes of similar patients and well-developed expertise.[85,86]

Traumatic Brain Injury

Traumatic brain injury (TBI) is a general term referring to numerous focal or diffuse lesions of the brain resulting from blunt or penetrating force. In some patients, direct trauma to the respiratory centers in the brain may cause the same

TABLE 32-4

Abnormal Respiratory Patterns Associated With Stroke

Pattern	Definition
Cheyne-Stokes respiration	Common abnormal pattern characterized by crescendo-decrescendo breathing force and tidal volume; it is not specific for stroke and is more commonly the result of cardiopulmonary disease
Periodic breathing	Similar to Cheyne-Stokes but with complete central apneas in between periods of crescendo-decrescendo breathing; it is seen in 25% of acute strokes, especially in patients with subarachnoid hemorrhage
Gasping	Very short inspiration, often involving contraction of accessory muscles, with long expiratory phase; it often heralds impending respiratory failure
Ataxic breathing	Irregularly irregular respiratory rate and tidal volumes; it nearly always means a medullary stroke or lesion; it is not the sign of a poor prognosis
Apneustic breathing	Very long inspiratory phase (several seconds), then brief, rapid exhalation followed by a respiratory pause; it is usually associated with bulbar dysfunction with difficulty protecting airway from secretions, so usually requires intubation, and may be difficult to wean from ventilator
Central neurogenic hyperventilation	Rapid deep breaths resulting in hypocapnia; other causes of hyperventilation must be ruled out, but if so, this pattern signifies a poor prognosis
Apnea	Unusual in strokes except in brain death; prognosis is generally poor
Ondine curse	Apnea during sleep with normal respiration while awake; it is treated with mechanical ventilation during sleep only; some patients improve and no longer need ventilatory support

Data from North JB, Jennett S: Abnormal breathing patterns associated with acute brain damage. Arch Neurol 31:338-344, 1974; Lee MC, Klassen AC, Resch JA: Respiratory pattern disturbances in ischemic cerebral vascular disease. Stroke 5:612-616, 1974; Frank JI: Abnormal breathing patterns. FIGURE 32-8 Frontal and lateral chest radiograph views of the same patient, showing severe scoliosis and kyphosis.

abnormalities of ventilation as strokes (mentioned previously); TBI also can lead to secondary effects on the respiratory system, such as neurogenic pulmonary edema and hypersecretion of mucus, leading to hypoxemia and respiratory insufficiency through mechanisms other than muscular weakness. There may be other injuries in patients with TBI that affect the respiratory system, such as spinal cord injury or rib fractures, or there may be factors that helped lead to the injury, which may independently affect breathing, such as intoxication or underlying illness.

DISORDERS OF THE THORACIC CAGE

The thoracic cage contains the lungs and supports the muscles of respiration. Normal ventilatory mechanics depend on a compliant thoracic cage with free excursion throughout the respiratory cycle.

Kyphoscoliosis

Kyphosis is posterior angulation of the thoracic cage. *Scoliosis* is lateral curvature of the spine (Figure 32-8). These two deformities often occur together (called **kyphoscoliosis**) as a result of the compensatory effects of the spine in response to the primary lateral curve in scoliosis.

Scoliosis is typically noticed during childhood and progresses during adolescence, although idiopathic adult kyphoscoliosis has been reported. The degree of scoliosis is measured by the *Cobb angle,* which is determined by the intersection of lines drawn between the upper and lower limbs of the primary curve in scoliosis (Figure 32-9). Severe kyphoscoliosis (Cobb

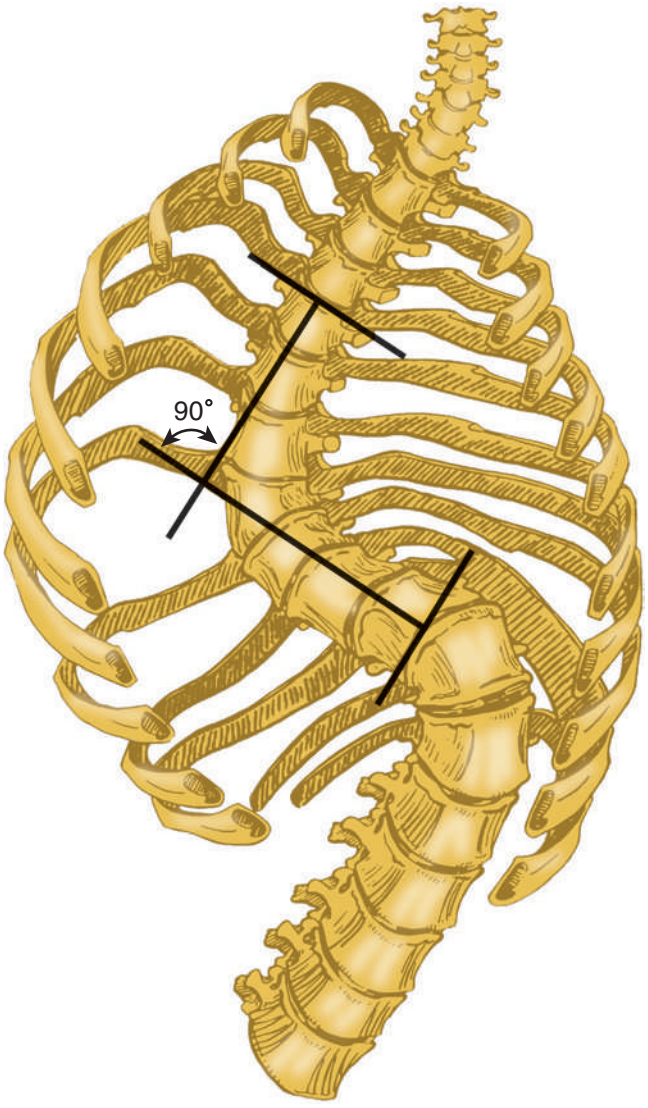

FIGURE 32-9 Scoliosis is lateral curvature of the spine. The degree of scoliosis is measured by the Cobb angle, which is determined by the intersection of lines drawn between the upper and lower limbs of the primary curve in scoliosis. Respiratory insufficiency rarely occurs until the Cobb angle exceeds 90 to 100 degrees. (Modified from Fishman AP: Acute respiratory failure. In Fishman AP, editor: Pulmonary disease, New York, 1992, McGraw-Hill, p 2300.)

angle > 90 to 100 degrees) can lead to hypoventilation, hypercapnia, and, if untreated, complications of pulmonary hypertension. However, the degree of pulmonary dysfunction cannot be predicted from the Cobb angle alone.[89,90] Respiratory dysfunction is probably multifactorial in most patients. Compliance of the chest wall and lung is decreased in patients with significant kyphoscoliosis. The result is a restrictive ventilatory defect with decreased TLC and VC in pulmonary function testing. Maximal transdiaphragmatic pressure also is decreased, a sign of impaired diaphragmatic function in the pathogenesis of respiratory dysfunction in severe kyphoscoliosis.

Anterior or posterior spinal fixation can stabilize kyphoscoliosis and restore the thoracic curvature to a condition close to normal. Fixation prevents complications resulting from progressive curvature, loss of compliance, and subsequent ventilatory dysfunction. Few options are available to restore pulmonary function to older patients with established kyphoscoliosis. Surgery to correct the deformity can be undertaken, but this treatment generally does not improve pulmonary function.[91] Better long-term results are seen when surgery or brace therapy to correct the angulation is undertaken in adolescence.[92]

Both noninvasive and invasive ventilation are used in some patients with severe kyphoscoliosis, with improvement in blood gas values, respiratory muscle strength, symptoms of dyspnea,[93] and exercise capacity.[94] Both negative pressure[95] and positive pressure[96] ventilation have been used to stabilize respiratory function in patients with severe kyphoscoliosis.

Flail Chest

Flail chest is defined in different ways but occurs as a result of multiple rib fractures that cause a portion of the chest wall to become free-floating. The destabilized segment of the thoracic cage exhibits **paradoxical motion** during the respiratory cycle, bowing out with expiration and collapsing inward during a spontaneous breath. The movement is associated with a decreased pressure gradient to drive inspiration and expiration and can result in respiratory failure. Flail chest frequently is accompanied by other pulmonary injuries as a result of the mechanism of injury and the force required to fracture multiple ribs. Pulmonary contusion, hemothorax, and pneumothorax are frequently associated with flail chest and often necessitate urgent or emergency treatment in the trauma patient.[97] Flail chest is managed by controlling pain and by PPV until the fractured ribs heal.

Ankylosing Spondylitis

Ankylosing spondylitis is a rheumatologic disease that affects the spine and thoracic cage. Chronic joint inflammation ultimately leads to fusion of the vertebral bodies and the costovertebral joints (sometimes called a "bamboo spine"), typically leading to severe kyphosis and a dramatic decrease in thoracic cage compliance. Because diaphragmatic movement is retained, TLC and VC are only slightly reduced. The most severe respiratory consequence is parenchymal lung disease, which occurs in approximately 10% of patients with ankylosing spondylitis in the form of apical fibrocystic changes that can decrease gas exchange and often provide a location for infection, especially fungal infection.[98]

THE ROLE OF RESPIRATORY THERAPISTS IN CARING FOR PATIENTS WITH NEUROMUSCULAR WEAKNESS AND OTHER DISEASES OF THE CHEST WALL

Many of the diseases discussed in this chapter are chronic, progressive conditions that evolve into respiratory failure over time. Optimal management depends on the degree, rate, and specific manifestations of the disease process, and there is

considerable variability. Physicians, nurses, and respiratory therapists (RTs) caring for these patients must be familiar with the course and symptoms of this progression, so they can provide appropriate diagnostic testing and therapy at the right time.

RTs with expertise in caring for these patients can be essential to their care. Many patients require close monitoring of their respiratory symptoms and function, and these results must be reliable and consistent, because decisions such as when to begin a new supportive therapy may rely heavily on them. Maneuvers such as spirometry and maximal respiratory pressures, as well as the use of respiratory devices such as noninvasive ventilation and cough assist technology require explanation, education, reinforcement, and troubleshooting. Without this kind of supervision and support, many patients will use their devices improperly or not at all, which will be of no benefit to them and may lead to the inaccurate conclusion that the therapies have failed.

Neuromuscular diseases also carry with them the burdens common to many chronic and progressive diseases, including depression and other psychological burdens. Respiratory therapists involved in the care of these patients can provide longitudinal support, including encouragement to not give up on therapies that may be effective and perspective when there are still additional measures that can be added to improve the patient's quality of life. The more familiar an RT is with specific disease entities as well as the diagnostic and therapeutic options, the better they can help patients understand and cope with their chronic diseases.

SUMMARY CHECKLIST

- The components of the neuromuscular system that affect respiration include the brain (especially respiratory centers in the brainstem), the nerves (the phrenic nerve supplying the diaphragm, the intercostal nerves supplying many of the other respiratory muscles, and the bulbar muscles coordinating the throat), the neuromuscular junction, and the muscles of inspiration, expiration, and upper airway control.
- Respiratory muscle weakness or ventilatory failure is often the most important clinical dysfunction for many patients with neuromuscular diseases.
- Other effects of neuromuscular disease on the respiratory system include hyperventilation or hypoventilation, sleep apnea, aspiration, atelectasis, pulmonary hypertension, and cor pulmonale.
- Signs and symptoms that may indicate weakness of the respiratory muscles include exertional dyspnea, orthopnea, decreased volume of voice, weak or ineffective cough, accessory muscle use, and paradoxical breathing pattern (abdominal paradox).
- Pulmonary function abnormalities in patients with inspiratory muscle weakness typically include decreases in PImax, TLC, VC, and FEV_1. Residual volume can be increased. There often is an abnormally large decrease in FVC and FEV_1 (30% to 50%) when patients repeat testing in the supine position, compared to the seated position. Diffusing capacity corrected for alveolar volume typically is normal.
- Common neuromuscular disorders that cause respiratory compromise include ALS, myotonic dystrophy, spinal cord injury, GBS, Duchenne muscular dystrophy, and MG.
- Cervical spine injury above the C3 level results in complete paralysis of the respiratory muscles and necessitates emergency mechanical ventilation. Cervical spine injury below C5 leads to weakness of the expiratory muscles with decreased ability to cough and clear secretions.
- Unilateral diaphragmatic paralysis resulting from phrenic nerve damage usually is asymptomatic and is associated with minor reductions in respiratory function in an otherwise healthy patient.
- Scoliosis is abnormal lateral curvature of the spine. Respiratory insufficiency can occur if the curve is severe.
- Flail chest typically results from trauma to the chest. Multiple fractures of adjacent ribs produce a free-floating segment of the thoracic cage, which displays paradoxical excursion during the respiratory cycle. Flail chest often is associated with serious damage to the lungs, heart, or great vessels. Respiratory insufficiency in patients with flail chest can occur through numerous mechanisms.

CHAPTER 33

Disorders of Sleep

EUHAN JOHN LEE AND PATRICK J. STROLLO, JR.

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Define obstructive sleep apnea (OSA).
- Identify why airway closure occurs only during sleep.
- State the long-term consequences of uncontrolled OSA.
- State how a diagnosis of OSA is made.
- Identify what groups of patients are at particular risk for OSA.
- State the treatments available for patients with OSA.
- Describe how continuous positive airway pressure (CPAP) works.
- Identify problems associated with CPAP.
- Determine when bilevel pressure is useful in the treatment of OSA.
- Define "auto-titrating" CPAP.
- Identify the surgical alternatives for patients with severe OSA.

CHAPTER OUTLINE

KEY TERMS

bilevel positive airway pressure
central sleep apnea
continuous positive airway pressure
excessive daytime sleepiness
obesity hypoventilation
obstructive sleep apnea
sleep-disordered breathing
uvulopalatopharyngoplasty
upper airway stimulation

Obstructive sleep apnea (OSA) syndrome is a common clinical problem that is underdiagnosed.[1] It is estimated that approximately 2% to 4% of adults have OSA.[2] This prevalence is equivalent to those of asthma and diabetes in the general population. The spectrum of disease ranges from sleep disruption related to increased airway resistance to profound daytime sleepiness in conjunction with severe oxyhemoglobin desaturation, pulmonary hypertension, and right heart failure. The common feature in all variants of OSA syndrome is sleep disruption secondary to increased ventilatory effort that results in increased daytime sleepiness (or hypersomnolence) (Figure 33-1).[3] Treatment decreases morbidity and mortality.

Sleep apnea is defined as repeated episodes of complete cessation of airflow for 10 seconds or longer. The events can be obstructive (caused by upper airway closure) or central (caused by lack of ventilatory effort). Primary central nervous system lesions, stroke, congestive heart failure, and high-altitude

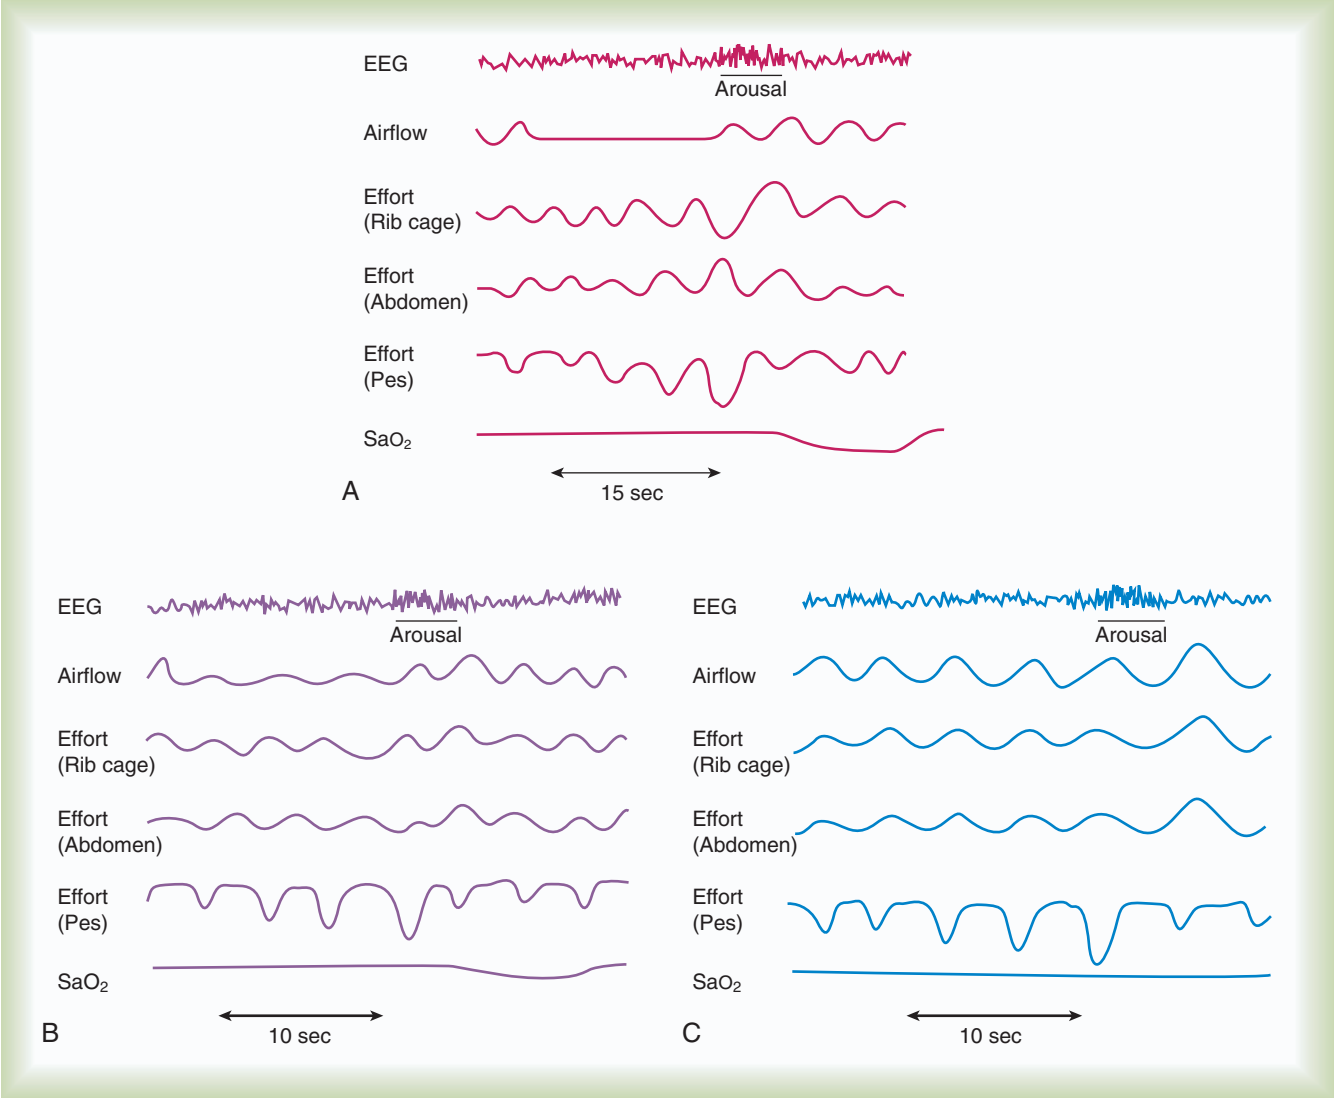

FIGURE 33-1 Spectrum of sleep-related upper airway obstruction. **A,** Obstructive sleep apnea. These events are defined as cessation of airflow for 10 seconds or longer. Paradoxical movement of the rib cage and abdomen in response to the closed airway occurs. Ventilatory effort, measured with an esophageal pressure balloon, usually increases until a threshold is reached that triggers a brief arousal seen on the electroencephalogram *(EEG),* and airway opening occurs. Oxyhemoglobin desaturation usually accompanies the event. **B,** Obstructive hypopnea. These events have been defined as a reduction of airflow by 30% to 50% for 10 seconds or longer. Paradoxical movement of the rib cage and abdomen in response to the narrowed airway occurs. Ventilatory effort, measured with an esophageal pressure balloon, usually increases until a threshold is reached that triggers a brief arousal seen on the EEG, and complete airway opening occurs. Oxyhemoglobin desaturation usually accompanies the event and usually is of a lesser degree than occurs with apnea. **C,** Respiratory effort–related arousals. These events are characterized by no discernible reduction in airflow. Subtle paradoxical movement of the rib cage and abdomen in response to narrowing of the airway may occur. As in apnea and hypopnea, ventilatory effort, measured with an esophageal pressure balloon, usually increases until a threshold is reached that triggers a brief arousal seen on the EEG, and complete airway opening occurs. By definition, no oxyhemoglobin desaturation is associated with the event.

hypoxemia can diminish respiratory control and cause central apnea events.[3] **Central sleep apnea** (CSA) is not as common as OSA. Only 10% to 15% of patients with sleep-disordered breathing are classified as having CSA.[4] Mixed sleep apnea has an initial central component followed by an obstructive component (Figure 33-2).

Hypopnea is a significant decrease in breathing without complete cessation of airflow.[5] Hypopnea is defined as a 30% decrease in airflow in conjunction with 4% oxygen (O_2) desaturation.[6] Most investigators agree that physiologically significant hypopnea is associated with a decrease in O_2 saturation (SaO_2) and/or arousal from sleep.[7]

Respiratory therapists (RTs) are likely to encounter both OSA and CSA when treating patients. OSA is the most commonly encountered type of sleep apnea and is underdiagnosed by health professionals; therefore the focus of this chapter is on the pathophysiology and management of the variants of OSA.

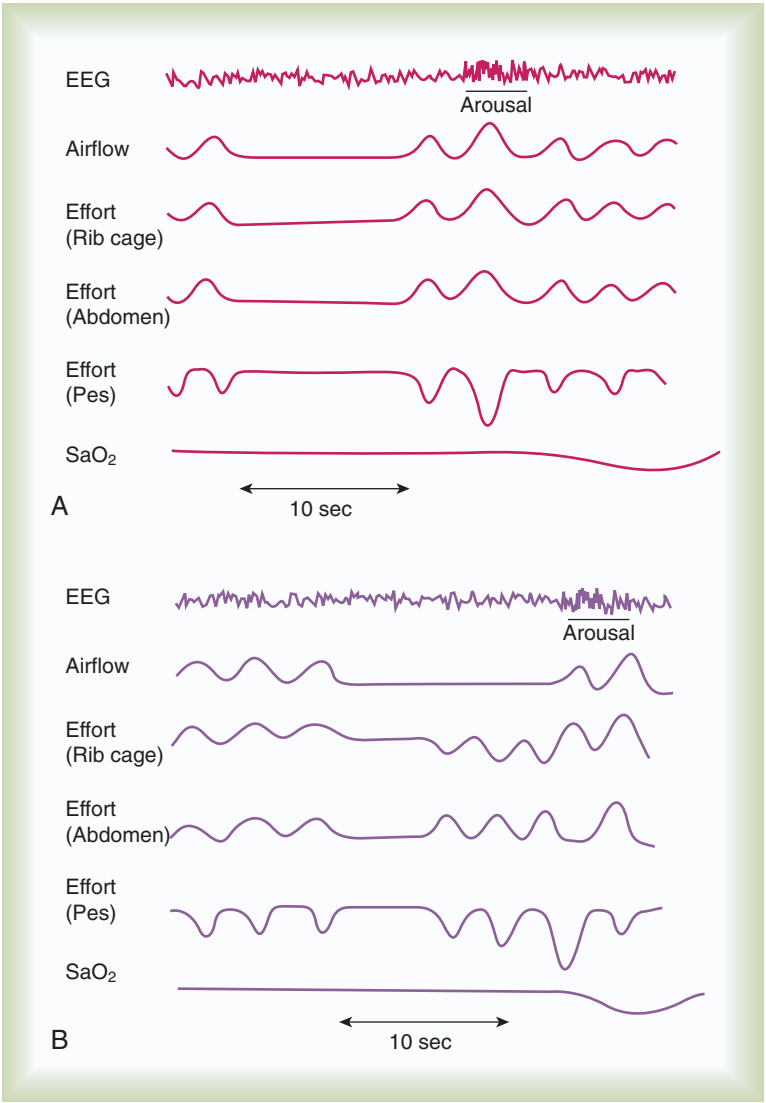

FIGURE 33-2 Central sleep apnea (CSA) and mixed sleep apnea. **A,** CSA. These events are defined as cessation of airflow for 10 seconds or longer. Compared with the events of obstructive sleep apnea (OSA), no movement of the rib cage or abdomen is present and the airway remains open. During an apneic event, there is a lack of ventilatory effort, measured with an esophageal pressure balloon. A brief arousal on the electroencephalogram *(EEG)* is associated with a maximal ventilatory effort that usually follows the episode of apnea. Oxyhemoglobin desaturation may be associated with the event. **B,** Mixed sleep apnea. These events have characteristics of both CSA and OSA. They are 10 seconds or longer in duration, and the central portion precedes the obstructive component. As with other sleep-related upper airway obstructive events, termination of the event is characterized by a maximal ventilatory effort and is associated with brief arousal on the EEG. Mixed sleep apnea usually is associated with oxyhemoglobin desaturation.

PATHOPHYSIOLOGY

Obstructive Sleep Apnea

The primary cause of OSA is a small or unstable pharyngeal airway. This condition can be caused by soft tissue factors, such as upper body obesity or tonsillar hypertrophy (rare in adults), and skeletal factors, such as a small or recessed chin.[8] During the waking state, pharyngeal patency is maintained by increased activity of the upper airway dilator muscles. Sleep onset is associated with a decrease in the activity of these muscles. The result is airway narrowing or closure of airways that are at risk.[9] In an unstable upper airway, narrowing and closure during sleep frequently involves multiple sites.[10]

Partial or complete closure of the upper airway during sleep is associated with a number of serious neurobehavioral, metabolic, and cardiopulmonary consequences (Box 33-1). Compared with the general population, patients with untreated OSA have an increased risk for systemic and pulmonary hypertension, stroke, nocturnal arrhythmia, heart failure, and myocardial infarction.[11,12] The repetitive cycle of upper airway closure and opening during sleep is believed to have effects on the autonomic nervous system—specifically, an increase in sympathetic tone.[13] These effects are caused in part by recurrent

Box 33-1 Adverse Consequences of Obstructive Sleep Apnea

CARDIOPULMONARY
- Nocturnal arrhythmia
- Diurnal hypertension
- Pulmonary hypertension
- Right or left ventricular failure
- Myocardial infarction
- Stroke

NEUROBEHAVIORAL
- Excessive daytime sleepiness
- Diminished quality of life
- Adverse personality change
- Motor vehicle accidents

METABOLIC
- Insulin resistance
- Altered lipid metabolism

episodes of hypoxemia and hypercapnia that are due to airway closure and hypoventilation that can occur throughout the night in patients with OSA. The arousals and microarousals during sleep also play an important role in the increase in sympathetic tone.[13] Over time, increased sympathetic tone may result in systemic hypertension and modest pulmonary hypertension.[14] Patients with OSA may develop right ventricular hypertrophy and right heart failure if they are not treated.[15,16]

Obesity, especially of the upper body, has been found to correlate positively with the presence of OSA. In most instances, patients with OSA are obese with a large amount of pharyngeal adipose tissue along with adipose tissue in the neck.[17] A body mass index greater than 28 (>120% of ideal body weight normalized for height) should alert the practitioner to the possibility of OSA, particularly if the patient has excessive daytime sleepiness.[2]

Patients who are of normal body weight can be predisposed to OSA if they have an abnormal craniofacial configuration. Men may grow a beard to disguise such a craniofacial abnormality. If the chin is recessed (retrognathic) or small (micrognathic), the upper airway space may be narrow, and the risk for airway closure during sleep increases.[2, 8, 14] Patients with a deviated nasal septum or trauma to the nasal passages may be predisposed to upper airway closure during sleep as a result of the increased resistive load to the upper airway. An isolated nasal abnormality is an unusual cause of OSA.

OSA also can have a genetic predisposition.[18] There have been reports of families in which obesity alone does not explain the increased prevalence of OSA.[19] It has been postulated that craniofacial abnormalities and defects in ventilatory control explain the increased frequency of OSA in these families.

Central Sleep Apnea

Although a detailed discussion of the pathophysiology of CSA is beyond the scope of this chapter, several concepts are important to RTs. In contrast to OSA, which represents a spectrum of the same disease, CSA is a heterogeneous group of disorders. Patients have a ventilatory pattern known as *periodic breathing,* in which there is a waxing and waning of respiratory drive, which is reflected clinically as an increase and then a decrease in respiratory rate and tidal volume (V_T). Cheyne-Stokes respiration, which often occurs in patients with congestive heart failure or stroke, is a severe type of periodic breathing characterized by a crescendo-decrescendo pattern of hyperpnea alternating with apnea. After apnea occurs, there may be an increase in central ventilatory drive and an increase in V_T.[3]

Overlap Syndrome

Some patients with chronic obstructive pulmonary disease (COPD) have coexisting OSA. This combination is referred to as *overlap syndrome*.[20] Patients are usually obese and have a history of smoking. They have moderate to severe nocturnal oxyhemoglobin desaturation secondary to both OSA and COPD. The worst desaturation values occur during rapid eye movement (REM) sleep and are related to the loss of accessory muscle use encountered in this physiologic state. Patients with overlap syndrome tend to have a worse prognosis and more severe blood gas abnormalities than patients with the same degree of OSA but without COPD.[20] they may arrive in the intensive care unit with a "COPD exacerbation" and decompensated right heart failure. Undiagnosed OSA complicates the course at night with arousals, increased dyspnea, and O_2 desaturation values resistant to supplemental O_2.[20]

Hypoventilation Syndromes

In addition to OSA and CSA, chronic hypoventilation syndromes are increasingly being recognized.[21, 22] Patients with neuromuscular disorders such as amyotrophic lateral sclerosis (ALS) or muscular dystrophy, obesity hypoventilation syndrome, and spinal cord injury with diaphragm dysfunction may have underlying restrictive lung physiology. These patients may benefit from early detection of sleep-related hypoventilation. Treatment with nocturnal noninvasive ventilation may result in improved breathing during sleep, as well as better daytime energy and quality of life.[21, 22] Alternative therapies such as placement of a diaphragm pacer also may benefit a select subset of these patients.[23]

CLINICAL FEATURES

Patients with sleep apnea are more commonly men (three times greater frequency than among women), are older than 40 years, and have hypertension (Box 33-2). Most patients with sleep apnea report habitual snoring that has become progressively worse.[2, 24] Sensations of nocturnal choking, gasping, or resuscitative snorting are frequently reported. If a bed partner observes periods of apnea, the diagnosis of OSA is highly likely.

The presence of **excessive daytime sleepiness** (EDS) may be underestimated because OSA manifests in a subacute manner. As a result, patients with OSA may report symptoms of fatigue alone. These patients also frequently report nocturnal reflux, nocturia, chronic nasal congestion, morning headaches, and symptoms of depression.

Box 33-2 Common Clinical Features of Obstructive Sleep Apnea

- Male
- Age greater than 40 years
- Upper body obesity (neck >16.5 inches)
- Habitual snoring
- Fatigue or daytime sleepiness
- Diurnal hypertension

Patients with OSA have arousals from sleep and sleep fragmentation, which can lead to fatigue, EDS, and irritability.[25] Patients who have an increased frequency of awakenings and microarousal have more daytime sleepiness and greater difficulty with daytime functioning than the general population.[26] Patients with OSA may have neuropsychologic deficits and impaired vigilance.[27] Compared with the general population, untreated OSA patients are at increased risk for motor vehicle accidents because of EDS.[28-30]

The physical examination of most patients reveals evidence of obesity, particularly in the upper body. Upper body obesity can be quantitated with neck size. A neck circumference of 42 cm (16.5 inches) in men increases the likelihood of the diagnosis of sleep apnea.[14] Examination of the oropharynx frequently reveals a long soft palate. Although tonsillar hypertrophy is common in children with sleep apnea, it is seldom found in adults. Large palatine tonsils may increase the risk for airway closure during sleep. A retrognathic or micrognathic mandible can narrow the pharyngeal airway, placing a patient of normal weight at risk for airway closure during sleep.[8]

The cardiovascular examination may reveal evidence of pulmonary hypertension or right heart failure (lower extremity edema).[31,32] These findings are determined primarily by the hypoxic burden experienced by the patient. Pulmonary hypertension or right heart failure is more commonly encountered in patients with concomitant daytime hypoxemia. Patients with OSA and COPD or severe obesity (body mass index > 40) appear to be at particular risk for this complication.[33] Recurrent moderate to severe oxyhemoglobin desaturation secondary to OSA can be associated with an increased incidence of cardiac arrhythmias.[34,35] Repeated nocturnal desaturation also can cause secondary polycythemia.[14,36]

OSA and poor sleep quality are also associated with the metabolic syndrome independent of obesity.[37,38] The metabolic syndrome includes three of the following: waist circumference 102 cm or greater in men or 88 cm or greater in women, hypertension, impaired glucose tolerance, insulin resistance, and elevated triglycerides.[39,40] These interactions also can increase a patient's cardiac risks and are associated with increased morbidity and mortality from cardiovascular disease.[12,41]

In the acute care setting, patients who present with previously undiagnosed OSA can pose a particular challenge for diagnosis and management.[42-44] A high clinical suspicion for OSA in hospitalized patients is necessary because untreated or unrecognized OSA can complicate recovery from acute illness, trauma, heart failure, and recent surgery.[45-52] Patients with known OSA are frequently not placed on continuous positive airway pressure (CPAP) while in the hospital or may require a temporary adjustment in pressure settings.[53] Patients who are unstable for testing in a sleep laboratory can undergo portable bedside testing or empiric treatment with positive pressure if the diagnosis cannot be confirmed.[54] Outpatient follow-up with confirmatory sleep evaluation is important for long-term treatment and compliance.

RULE OF THUMB

Untreated OSA can cause daytime hypoxemia. The diagnosis of OSA should be considered when the degree of hypoxemia is out of proportion to the defect on pulmonary spirometry. When the arterial partial pressure of O_2 is less than 60 mm Hg but the FEV_1 is greater than 30% of predicted, COPD alone is inadequate to explain the hypoxemia and coexisting OSA should be considered. OSA in this setting is frequently associated with pulmonary hypertension and evidence of right heart failure on physical examination. Hypoxemia, pulmonary hypertension, and right heart failure can be substantially improved with management of OSA. If the patient adheres to therapy, the need for supplemental O_2 may be reduced or eliminated.

SCREENING QUESTIONNAIRES

An initial history and physical examination may be inadequate for identifying OSA. Several screening questionnaires have been developed to aid in rapidly identifying individuals with OSA. In general, screening questionnaires have good sensitivity but limited specificity for diagnosis of OSA. The Berlin Questionnaire, the American Society for Anesthesiology (ASA) screening questionnaire, and the Sleep Apnea Clinical Score (SACS) have been validated for use as screening for OSA.[48-50] The STOP-BANG has been used commonly because of simplicity and ease of use, particularly in patients undergoing elective surgery[50] (Box 33-3). However useful and suggestive these questionnaires may be, a diagnostic sleep study remains the gold standard for diagnosing OSA.

LABORATORY TESTING

When sleep apnea is suspected, an overnight polysomnogram (PSG) should be obtained to confirm the clinical diagnosis. A full-night PSG in the sleep laboratory monitored by a sleep technologist is considered the standard method for diagnosing OSA.

In a laboratory sleep study, several physiologic signals are recorded to determine whether airway closure occurs during sleep and to what extent the events disturb sleep continuity and cardiopulmonary function. An electroencephalogram (EEG), electrooculogram (EOG), and chin electromyogram (EMG) are obtained for assessment of sleep stage and documentation of sleep disruption secondary to sleep-related breathing disturbance. Airflow (measured at the nose and mouth), ventilatory

Box 33-3 STOP-BANG Questionnaire to Screen for Obstructive Sleep Apnea

***S**nore:*	Do you snore loudly (louder than talking or loud enough to be heard through closed doors)?
***T**ired:*	Do you often feel tired, fatigued, or sleepy during the daytime?
***O**bserved:*	Has anyone observed you stop breathing during sleep?
***P**ressure:*	Do you have or are you being treated for high blood pressure?
***B**MI:*	Greater than 35 kg/m^2?
***A**ge:*	Age older 50 years?
***N**eck:*	Neck circumference greater than 40 cm?
***G**ender:*	Gender male?

One point assigned for each positive question.
Total score less than three = low probability for OSA.
Total score three or greater = high probability for OSA.
Total score five or greater = high probability of moderate to severe OSA.

Box 33-4 Key Features of Sleep Studies to Be Analyzed and Reported for Obstructive Sleep Apnea

- Apnea-hypopnea index
- Arousal index
- Sleep stage distribution
- Frequency of oxyhemoglobin desaturations
- Mean oxyhemoglobin saturation
- Nadir of oxyhemoglobin saturation

effort (using inductive plethysmography or piezoelectric belts), cardiac rhythm (with a modified lead II electrocardiogram [ECG]), and SaO_2 (measured with pulse oximetry) are included in the standard testing montage.

In obstructive apnea or hypopnea, airflow is absent or decreased in the presence of continued ventilatory effort. Asynchronous (paradoxical) movement of the abdomen and rib cage can be observed. O_2 desaturation may or may not occur. The degree of the O_2 desaturation depends on the length of the apneic event or the patient's baseline saturation (see Figure 33-1). Respiratory effort–related arousals are characterized by increased respiratory effort, leading to arousal from sleep that does not meet the criterion of an apneic or a hypopneic event (see Figure 33-1).[55,56]

Measuring devices that are adequate for assessing hypopnea also are adequate for assessing apnea; however, devices used for measuring apnea cannot always detect hypopnea. The diagnosis of hypopnea may be affected by the measurement technique used. In 1999, an American Academy of Sleep Medicine (AASM) task force conducted an evidence-based review of measurement techniques for detection of hypopnea.[57] The scoring system was as follows: *A,* good to excellent agreement with a reference standard (face mask pneumotachygraph); *B,* limited data, but good theoretical framework and clinical experience suggest the method is valid; *C,* no data, weak theoretical framework or clinical experience; and *D,* research or clinical experience suggests the method is invalid.

The measuring techniques were scored as follows: nasal pressure, B; respiratory inductance plethysmography (RIP) with sum of chest and abdominal signals, B; dual-channel RIP, C; single-channel RIP, C; piezoelectricity sensors, strain gauges, and thoracic impedance, D; breathing measurement signal with a desaturation or arousal, B; expired carbon dioxide (CO_2), D; and thermal sensors, D. A face mask pneumotachygraph allows the greatest precision in measuring airflow, but it is poorly tolerated. Nasal pressure is a reliable way to detect hypopnea and is well tolerated by patients undergoing a diagnostic PSG.[5,57]

After the sleep study is completed, the sleep technologist scores it. The number of apneas and hypopneas per hour of sleep are reported as an apnea-hypopnea index (AHI) or respiratory disturbance index (RDI). The AASM has operationally defined the severity of OSA as follows: mild, AHI 5 to 15; moderate, AHI 15 to 30; and severe, AHI greater than 30. AHI less than 5 is considered within the normal range for adults. The number of arousals per hour (arousal index), percentage of each sleep stage, frequency of SaO_2, mean SaO_2, and nadir of SaO_2 also are reported (Box 33-4).

RULE OF THUMB

Intermittent checks of SaO_2 cannot reliably exclude sleep-related desaturation secondary to OSA. Placing the oximetry probe on the patient frequently awakens the patient. In addition, isolated readings may not allow sampling of all sleep stages, especially rapid eye movement (REM) sleep, during which sleep-disordered breathing and nocturnal desaturation tend to be prominent. Continuous overnight oximetry is a better assessment of the degree of oxyhemoglobin desaturation with sleep.

Abbreviated (portable) cardiopulmonary testing has been used to confirm a diagnosis of OSA. These studies do not record the electrophysiologic signals (EEG, EOG, and EMG) required to stage and score sleep. The portable studies vary in the type and number of cardiopulmonary values recorded. Controversy exists whether portable systems are sufficient to diagnose OSA. Many variables, such as airflow, ventilatory effort, sleep stage, and SaO_2 values, may be less precise or may not be measured at all with these devices. Currently, portable monitoring for the diagnosis of OSA is acceptable in patients with high pretest probability but without significant comorbidities that may affect the accuracy of testing.[58] A growing body of evidence supports the use of portable testing for additional patient populations, including patients undergoing elective surgery and patients admitted to the hospital with acute heart failure or stroke.[59]

Excerpts of American Association for Respiratory Care (AARC) Clinical Practice Guidelines for a PSG are provided in Clinical Practice Guideline 33-1.

TREATMENT

Management of OSA should be individualized but generally can be classified into three options: behavioral, medical, and surgical interventions.[60] Behavioral therapy should be pursued in the care of all patients. Medical and surgical therapy must be tailored to the individual patient. The likelihood of acceptance and adherence to the prescribed therapeutic intervention must be considered. The goals of treatment are to normalize SaO_2 and ventilation; eliminate apnea, hypopnea, and snoring; and improve sleep architecture and continuity (Box 33-5).

Behavioral Interventions and Risk Counseling

Patients must be informed of the risks of uncontrolled sleep apnea. Several behavioral interventions can be beneficial,

33-1 Polysomnography

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

Polysomnography may be indicated in patients with:

- COPD whose awake PaO_2 is greater than 55 mm Hg but whose illness is complicated by pulmonary hypertension, right heart failure, polycythemia, or excessive daytime sleepiness
- Restrictive ventilatory impairment secondary to chest wall and neuromuscular disturbances whose illness is complicated by chronic hypoventilation, polycythemia, pulmonary hypertension, disturbed sleep, morning headaches, or daytime somnolence or fatigue
- Disturbances in respiratory control whose awake $PaCO_2$ is greater than 45 mm Hg or whose illness is complicated by pulmonary hypertension, polycythemia, disturbed sleep, morning headaches, or daytime somnolence or fatigue
- Nocturnal cyclic bradyarrhythmia or tachyarrhythmia, nocturnal abnormalities of atrioventricular conduction, or ventricular ectopy that seems to increase in frequency during sleep
- Excessive daytime sleepiness or insomnia
- Snoring associated with observed apneas or excessive daytime sleepiness or both
- Other symptoms of sleep-disordered breathing as described in *The International Classification of Sleep Disorders, Diagnostic and Coding Manual*

CONTRAINDICATIONS

There are no absolute contraindications to polysomnography when indications are clearly established. However, risk-to-benefit ratios should be assessed if transferring medically unstable inpatients.

PRECAUTIONS AND COMPLICATIONS

- Skin irritation may occur as a result of the adhesive used to attach electrodes to the patient.
- At the conclusion of the study, adhesive remover is used to dissolve adhesive on the patient's skin. Adhesive removers (e.g., acetone) should be used only in well-ventilated areas.
- The integrity of the electrical isolation of polysomnographic equipment must be certified by engineering or biomedical personnel qualified to make such assessment.
- The adhesive used to attach EEG electrodes should not be used to attach electrodes near the patient's eyes and should always be used in well-ventilated areas.
- Because of the high flammability of adhesives and acetone, these substances should be used with caution, especially in patients who require supplemental O_2.
- Adhesives should be used with caution in patients with reactive airways disease and in small infants.
- Patients with parasomnias or seizures may be at risk for injury related to movements during sleep.
- Institution-specific policies and guidelines describing personnel responsibilities and appropriate responses should be developed.

ASSESSMENT OF NEED

Polysomnography is indicated for patients suspected to have sleep-related respiratory disturbances described in *The International Classification of Sleep Disorders, Diagnostic and Coding Manual*.

ASSESSMENT OF TEST QUALITY

- Polysomnography should either confirm or eliminate a sleep-related diagnosis.
- Documentation of findings, suggested therapeutic intervention, and other clinical decisions resulting from polysomnography should be noted in the patient's chart.
- Each laboratory should implement a quality assurance program that addresses equipment calibration and maintenance, patient preparation and monitoring, scoring methodology, and intertechnician scoring variances.

MONITORING

- Patient variables to be monitored include EEG, EOG, EMG, ECG, respiratory effort, nasal or oral airflow, SpO_2, body position, and limb movement; intervention should occur if the physiologic signals are lost.
- Infrared or low-light video cameras and recording equipment should permit visualization of the patient by the technician throughout the procedure.
- The technician should intervene if an acute change in physiologic status occurs and communicate that change to appropriate medical personnel.

Box 33-5 Goals of Treating Obstructive Sleep Apnea

- Eliminate apnea, hypopnea, and snoring
- Normalize SaO_2 and ventilation
- Improve sleep architecture and continuity

including weight loss in obese patients; avoiding alcohol, sedatives, and hypnotics; and avoiding sleep deprivation. Although weight loss clearly influences the severity of sleep apnea, it is frequently difficult to accomplish. Involving the patient with a dietitian or nutritionist can be helpful. Alcohol decreases the arousal threshold and so can increase the duration of apnea. Alcohol also reduces upper airway muscle tone, causing the airway to be more compliant and more prone to complete or partial closure.[61] For these reasons, alcohol should be avoided by patients believed to have sleep apnea. Sedatives and hypnotics can decrease the stability of the upper airway and suppress certain stages of sleep.[62]

Positional Therapy

When a sleep study indicates that apnea and snoring occur only in the supine position, instruction on sleeping in the lateral position or head of bed elevation can be beneficial.[63,64] Use of the "tennis ball" technique, in which a ball is sewn onto the back of the patient's sleeping garment, or other positional devices that discourage the patient from rolling into the supine position can be effective in treating positional OSA.[65] However, the long-term effects of positional therapy are unknown. Positional therapy is generally recommended for milder cases of positional OSA.

Medical Interventions

Positive Pressure Therapy

Continuous Positive Airway Pressure Therapy. **Continuous positive airway pressure** (CPAP) therapy was introduced for management of OSA in 1981.[66] CPAP has become the first-line medical therapy for OSA. Many studies have documented the effectiveness of CPAP in decreasing the morbidity and mortality associated with OSA.[9,11,67,68] For most patients, obstruction of the upper airway is abolished by CPAP pressures between 7.5 cm H_2O and 12.5 cm H_2O.[69] The level of CPAP required for optimal management of OSA is best determined with a titration performed in the sleep laboratory.[68] Attempts to use an algorithm or a prediction equation as a replacement for in-laboratory titration have not been uniformly successful.[70]

CPAP therapy has been shown to decrease daytime sleepiness and improve neurocognitive testing, vigilance scores, insulin sensitivity, and lipid profiles. CPAP decreases the incidence of pulmonary hypertension and right heart failure and decreases the number of ventilation-related arousals and nocturnal cardiac events. Reductions in daytime hypoxemia and hypercapnia also have been attributed to CPAP therapy.[69,71-75]

CPAP therapy primarily works by splinting the upper airway open, increasing the intraluminal pressure of the upper airway

MINI CLINI

Nocturnal Angina in an Obese Middle-Aged Man

HISTORY: A 45-year-old, morbidly obese nonsmoker is admitted to the coronary care unit after awakening at 4 AM with chest pain typical of angina pectoris. The pain has resolved by the time he reaches the emergency department. The patient is unsure of the duration of the pain before he called for his wife, who sleeps in a separate bedroom because of his very loud habitual snoring. The patient reports exertional shortness of breath but no chest pain before this event. He states that he frequently gets "indigestion" that sometimes is worse at night, but that this pain was different.

MEDICATIONS:

- Captopril, 25 mg by mouth twice per day
- Furosemide (Lasix), 20 mg by mouth every day
- Cimetidine (Tagamet), 300 mg by mouth at bedtime

MEDICAL HISTORY:

- Hypertension and gastroesophageal reflux
- No significant cardiac disease
- Cardiac catheterization 1 year ago showed normal left ventricular function and minimal coronary artery occlusion

PHYSICAL EXAMINATION:

- *Vital signs:* Blood pressure 160/98 mm Hg, heart rate 100 beats/min, temperature 98.6° F (37° C), respiration 18 breaths/min
- *General:* Mildly diaphoretic obese white man
- *Neck:* 52 cm (20.5 inches) in circumference
- *Lungs:* Clear breath sounds bilaterally
- *Heart:* Regular rate and rhythm
- *Abdomen:* Obese; soft, normal bowel sounds
- *Extremities:* 4-mm pretibial pitting edema

LABORATORY DATA:

- *Room air arterial blood gases (ABGs):* pH 7.36, PCO_2 37 mm Hg, PO_2 62 mm Hg, SaO_2 92%
- *Chest radiograph:* Pulmonary congestion, otherwise normal
- *ECG:* Sinus tachycardia without acute changes

PROBLEM: Why did this patient experience angina during sleep?

DISCUSSION: Serial cardiac enzyme values show no myocardial infarction. A stress test result is negative, but a submaximal effort is obtained. The patient's weight precludes an adenosine thallium stress test. A repeat cardiac catheterization shows no change in the minimal coronary artery occlusion reported previously. The pulmonary consultant called to evaluate the patient's shortness of breath recommends a nocturnal PSG to rule out sleep apnea. The sleep study result is positive for severe sleep apnea (AHI 110; lowest SaO_2 70% on the oximeter during REM sleep). A CPAP titration test is performed. The patient is discharged home on CPAP 17.5 cm H_2O via a nasal mask. He returns to the pulmonary clinic 1 month after discharge. He reported no further episodes of nocturnal angina. Reflux and shortness of breath have been relieved. The patient has lost 10 lb (4.5 kg) without dieting. Lower extremity edema is markedly relieved. A download of data from his CPAP machine shows excellent compliance with usage on 85% of nights, as well as good response to therapy with an average estimated AHI 3.5.

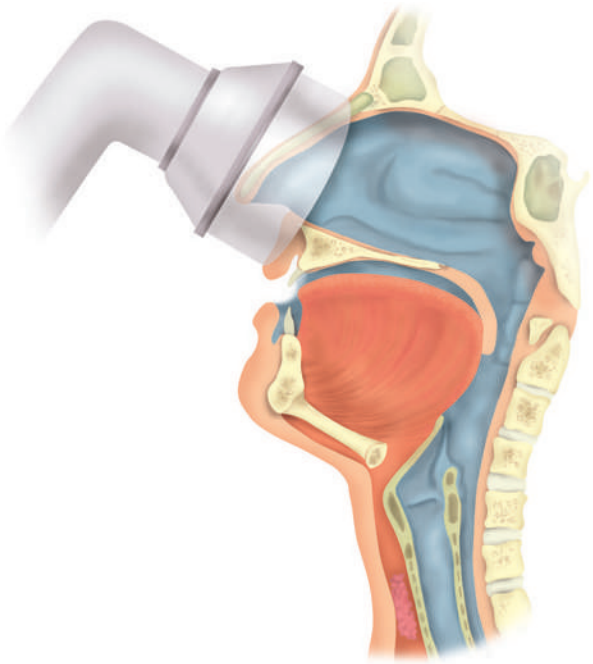

FIGURE 33-3 Nasal continuous positive airway pressure (CPAP). Positive airway pressure is applied with a nasal mask. The soft palate falls against the base of the tongue so that the upper airway is pneumatically splinted open.

above a critical transmural pressure of the pharynx and hypopharynx that is associated with airway closure. The soft palate is effectively moved anteriorly up against the tongue, "pressurizing" the upper airway (Figure 33-3).[76] CPAP allows the upper airway to be splinted open whether there is a single site (uncommon) or multiple sites (more common) of airway narrowing or closure. Investigators have found that when nasal CPAP is applied, EMG activity of the upper airway dilator muscles is decreased.[77]

To be successful, CPAP titration should eliminate all apneic episodes and reduce the number of hypopneic episodes for preventing arterial O_2 desaturation. Paradoxical thoracoabdominal movement and snoring should be eliminated.[78] For improvement of sleep continuity, respiration-related EEG arousals and microarousals must be abolished. There is no evidence to support the misconception that a higher level of CPAP always is necessary in patients with severe sleep apnea. There is variability in the CPAP requirement to treat OSA effectively. Some patients with relatively mild elevation of the AHI need higher levels of CPAP than patients with a substantially higher AHI.[79]

Patients who report EDS without an increase in AHI may have repetitive 2- to 3-second transient EEG arousals during episodes of snoring. These short arousals occur during episodes of increased upper airway resistance, and although not associated with any significant arterial O_2 desaturation, they may cause EDS and fatigue.[80,81] This pattern is known as *upper airway resistance syndrome,* generally occurs in younger patients, and is characterized by respiratory effort–related arousals (see Figure 33-1). With the emergence of upper airway resistance syndrome as a clinical entity, some researchers have suggested that CPAP titrations may be suboptimal without measurement of esophageal pressure.[79,82,83] Many sleep laboratories do not measure esophageal pressure. In addition, many patients refuse this type of monitoring because of perceived or real discomfort.

The contour of the inspiratory flow signal, when measured by a pressure transducer, correlates with ventilatory effort as reflected by esophageal pressure.[55] When esophageal pressure is not used, nasal pressure can be useful to facilitate CPAP titrations.[83] It has been hypothesized that during CPAP titration, there is a period during the transition to deeper stages of sleep when there is flow limitation and increased intrathoracic pressure without EEG arousals.[63] It has been suggested that if this condition is not corrected, patients may have incomplete and suboptimal titrations. The clinical significance of flow limitation without EEG arousals is currently uncertain.

Despite numerous studies documenting the efficacy of CPAP in treating patients in the sleep laboratory, many patients have difficulty adhering to CPAP therapy. Approximately 80% of patients accept CPAP initially, although long-term objective compliance is frequently lower. *Objective compliance*—defined as use of the machine for more than 4 hours per night for more than 70% of observed nights—has been measured to be 46%.[84,85] Data can be downloaded from CPAP machines that reveal patient compliance, average usage per night, average estimated AHI, presence of air leak, and other parameters.

The severity of AHI does not always correlate with compliance, and the benefit perceived by the patient is a better predictor. Research indicates that patients who are subjectively sleepy and have an AHI of 30 or greater are likely to accept and comply with CPAP therapy.[94] Clinic follow-up with objective compliance monitoring is essential. Compliance 1 month after the initiation of therapy is reported to be a good predictor of CPAP use at 3 months.

It is unclear whether higher levels of CPAP cause a decrease in compliance. Some patients report that breathing against a continuous pressure is uncomfortable. Discomfort with the interface and the device also may reduce acceptance and compliance.[87-89] Since introducing CPAP, various interfaces have been designed to improve comfort and have a favorable impact on compliance. Nasal pillows or prongs, nasal masks with comfort flaps or bubbles, oronasal masks, and full-face masks are available.[90-94] No studies have been conducted to directly compare efficacy, subjective patient comfort, or objective patient compliance with these interfaces.[90] In clinical practice, some patients tolerate one interface better than another. Technician bias may affect the choice of an interface, and this may have a positive or negative impact.

Bilevel Pressure Therapy. Another form of positive pressure therapy is **bilevel positive airway pressure (bilevel PAP).** Bilevel PAP therapy was developed to take advantage of the fact that some patients may have different pressure requirements between inspiration and expiration.[89] It was hypothesized that because a patient may have a lower expiratory pressure

MINI CLINI

Young Man Hospitalized for Observation After a Single-Vehicle Accident in the Midafternoon

HISTORY: A 27-year-old nonsmoker is admitted to the coronary care unit for monitoring so that the diagnosis of cardiac contusion can be ruled out. The patient has been involved in a single-vehicle automobile accident. The accident occurred at 3:30 PM on a clear day. The patient felt drowsy immediately before the event. He became conscious after hitting the guardrail. The patient's chest hit the steering wheel. The patient reports anterior chest wall pain and denies having angina or feeling faint.

MEDICATIONS:

- None

MEDICAL HISTORY:

- Negative

PHYSICAL EXAMINATION:

- *Vital signs:* Blood pressure 140/88 mm Hg, heart rate 100 beats/min, temperature 98.6° F (37° C), respirations 16 breaths/min
- *General:* Well-developed, well-nourished white man
- *Head, eyes, ears, nose throat:* Elongated soft palate, mild crowding of tonsillar pillars, retrognathic chin
- *Neck:* 40 cm (16 inches) in circumference
- *Chest:* Contusion on anterior portion of the chest
- *Lungs:* Clear breath sounds bilaterally
- *Heart:* Regular rate and rhythm
- *Abdomen:* Soft with normal bowel sounds
- *Extremities:* No clubbing, cyanosis, or edema
- *Skin:* Multiple small lacerations

LABORATORY DATA:

- *Chest radiograph:* No cardiomegaly, mass, infiltrate, or effusion
- *ECG:* Sinus tachycardia
- *Creatine kinase:* 350 international/L (no myocardial bond fraction)

PROBLEM: What caused the patient to fall asleep at the wheel?

DISCUSSION: The patient is found to have bradycardia during sleep on the night of admission. These episodes appear to be associated with snoring and oxyhemoglobin desaturation on O_2 at 2 L/min through a nasal cannula. The cardiology consultant recommends a diagnostic nocturnal PSG to rule out sleep apnea. The study shows severe sleep apnea (AHI 85 with a low SaO_2 of 60%). A CPAP titration study reveals that the patient requires 10 cm H_2O of CPAP via nasal pillows. At follow-up 1 month later, the patient states he no longer experiences the fatigue he had previously. In retrospect, the patient believes that before treatment with CPAP, he was quite sleepy during the day. Despite this improvement, he wants to explore other treatment options. A surgical consultation is obtained.

RULE OF THUMB

Retrognathia can be the cause of OSA in young patients who are at or close to ideal body weight. CPAP therapy is highly effective for these patients, but upper airway reconstruction (phases I and II surgery) can be curative.

requirement to splint the airway open, patient acceptance and compliance would be favorably affected. Bilevel units operate on household electricity and are similar in size and appearance to conventional CPAP units. There is a difference in cost, however, with bilevel devices generally more expensive than CPAP devices.

Although patient acceptance may be slightly better with bilevel PAP, published data have shown no difference in compliance between conventional CPAP and bilevel PAP in patients who have not previously received CPAP therapy.[95] However, bilevel PAP may be better tolerated by the subgroup of patients who need higher CPAP settings or who are uncomfortable exhaling against a continuous pressure.

In contrast to conventional CPAP, bilevel PAP is titrated by increasing inspiratory positive airway pressure and expiratory positive airway pressure separately in response to apnea, hypopnea, and desaturation. The specific titration algorithm may vary from laboratory to laboratory. Generally, inspiratory positive airway pressure and expiratory positive airway pressure are titrated upward together (as CPAP) until apnea is eliminated. Inspiratory positive airway pressure is then increased independently to eliminate hypopnea, snoring, and arousals.

Autotitrating Devices. A new generation of self-titrating CPAP devices has been developed to address issues of patient compliance, patient comfort, and variability of the CPAP requirement throughout the night.[96-99] These devices are referred to as *auto-CPAP, intelligent CPAP,* or *smart CPAP*. These devices use a computer algorithm for adjusting the level of CPAP in response to dynamic changes in airflow or vibration caused by snoring or both. Abnormal function manifests as snoring, hypopnea, and apnea. The average overnight pressure required to treat OSA effectively may be decreased, which may have a favorable impact on interface-related leaks. It is unknown whether these devices are capable of eliminating the need for standard CPAP titration in a sleep laboratory. Self-titrating devices may help facilitate therapeutic CPAP titrations by technologists in the sleep laboratory but cannot replace proper diagnostic testing.[54] Further studies are needed to determine whether self-titrating CPAP devices provide any improvement over conventional CPAP units in the areas of compliance and EDS, particularly in patients who have not previously received CPAP therapy. More advanced auto-titrating devices can be used for CSA and hypoventilation syndromes.

Side Effects and Troubleshooting Strategies. Side effects of positive pressure therapy are related to the interface and to the pressure prescribed. These effects include feelings of claustrophobia, nasal congestion, rhinorrhea, skin irritation, and

MINI CLINI

Middle-Aged Woman With Pulmonary Hypertension

HISTORY: A 59-year-old former smoker is admitted to the hospital for right and left heart catheterization. A previous ECG showed pulmonary hypertension. The patient denies having angina or exertional chest discomfort. She admits to dyspnea on exertion that has been increasing over the past few months and to a chronic nonproductive cough. She denies taking "diet pills."

MEDICATIONS:
- Nifedipine, 10 mg by mouth three times per day
- Furosemide (Lasix), 20 mg by mouth daily
- Potassium chloride, 20 mEq by mouth twice per day

MEDICAL HISTORY:
- Hypertension and allergic rhinitis
- No cardiac disease

PHYSICAL EXAMINATION:
- *Vital signs:* Blood pressure 140/88 mm Hg, heart rate 90 beats/min, temperature 98.6° F (37° C), respirations 12 breaths/min
- *General:* Obese white woman in no acute distress
- Neck: 40 cm (16 inches) in circumference
- Lungs: Clear breath sounds bilaterally
- *Heart:* Regular rate and rhythm, increased second heart sound (P_2)
- *Abdomen:* Obese; soft, normal bowel sounds
- *Extremities:* 2-mm pretibial pitting edema

LABORATORY DATA:
- *Chest radiograph:* Mildly enlarged heart, no mass, infiltrate, or effusion
- *ECG:* Normal sinus rhythm with P pulmonale
- *Left heart catheterization:* No significant coronary artery disease, normal left ventricular function
- *Right heart catheterization:* Pulmonary hypertension (75/25 mm Hg), pulmonary artery wedge pressure 23 mm Hg
- *Room air ABGs:* pH 7.45, PCO_2 41 mm Hg, PO_2 54 mm Hg, SaO_2 84%
- *Spirometry:* Forced vital capacity (FVC) 1.69 L (55% of predicted value), FEV_1 1.27 L (55% of predicted value), FEV_1/FVC 75, forced expiratory flow midexpiratory phase ($FEF_{25\%–75\%}$) 0.96 L/sec (37% of predicted value); no significant improvement with single-dose bronchodilator

PROBLEM: What is the cause of the pulmonary hypertension?

DISCUSSION: The pulmonary service is consulted for evaluation for pulmonary hypertension in association with abnormal spirometric results. Results of bilateral lower extremity Doppler examinations and a ventilation/perfusion scan are normal. Because of a history of snoring, an overnight portable cardiopulmonary sleep study is performed. The study reveals evidence of snoring, nonpositional apnea and hypopnea, and desaturation to less than 60% on the oximeter for most of the monitoring period. Results of a PSG performed in the sleep laboratory verify the presence of moderate to severe OSA with AHI 28, which responds well to the application of CPAP titrated to 12 cm H_2O. Follow-up examinations show the dyspnea is relieved and that ABG values have improved. The patient no longer needs portable liquid O_2 to maintain SaO_2 greater than 90% at rest or with exercise.

It is likely this patient has pulmonary hypertension that is due to OSA, as opposed to idiopathic pulmonary artery hypertension, which generally affects younger women. Chronic thromboembolic disease should be excluded, as it was in this case. Chronic right heart failure secondary to sleep apnea can be improved with proper treatment.

nasal dryness (Figure 33-4). Claustrophobia and skin irritation can be managed by changing the interface to one that is more easily tolerated by the patient. Nasal congestion, rhinorrhea, skin irritation, and nasal dryness can be managed by using combinations of topical nasal steroids, antihistamines, nasal saline sprays, and lotions. A humidifier can be used in-line with the machine. Heated humidification has been shown to improve compliance.[100] If the patient has a sensation of too much pressure in the nose, adding a system equipped with a ramp may be beneficial.[62] The ramp allows a gradual increase in pressure over 5 to 45 minutes. The ramp time is empirically determined by the prescribing physician. There is no objective evidence that a ramp feature improves patient acceptance or compliance.[84]

Pressure leaks are another problem that RTs may encounter. Most interfaces use the nose. Some patients tend to breathe partially or mainly through the mouth. The addition of a chin strap may not resolve the problem. Changing the interface to an oronasal mask may be required for effective "pressurization" of the upper airway in these patients.[90] Mask and equipment availability varies depending on the home care company or medical facility, which can affect patient accommodation and long-term adherence to therapy

Oral Appliances

Oral appliances are devices that enlarge the airway by moving the mandible forward or by keeping the tongue in an anterior position (Figure 33-5). Patients who have mild sleep apnea and are unwilling to use CPAP may benefit from these devices. Oral appliances are worn only during sleep and come in various forms. The appliances are custom-fitted by dentists and are generally well tolerated by patients. They are overall less effective than CPAP therapy and are regarded as a second-line intervention, particularly for severe OSA.[101,102] The role of oral appliance therapy in the acute care setting, such as patients hospitalized for acute heart failure or after elective surgery, is unclear.

Medications

Medications have proved ineffective for most patients with sleep apnea. Benzodiazepines and other sedative-hypnotics

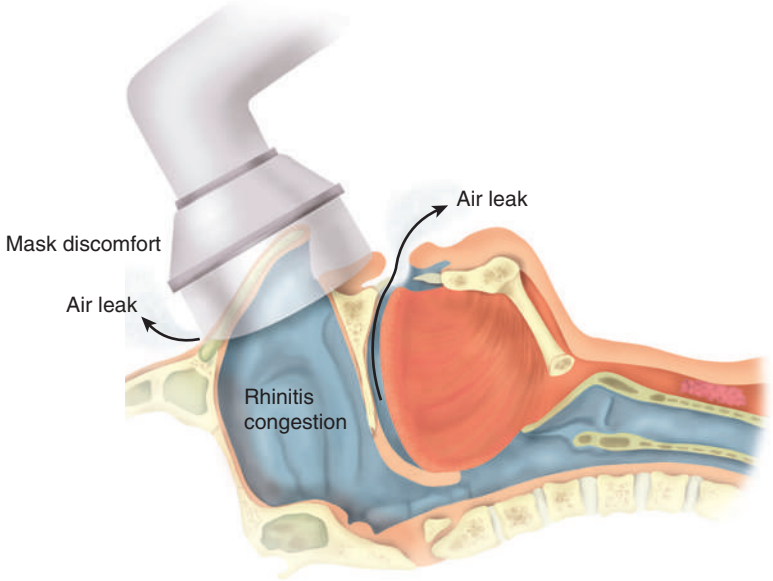

FIGURE 33-4 Positive airway pressure problems. Various problems can be encountered with continuous positive airway pressure.

MINI CLINI

Worsening Right-Sided Heart Failure in a Patient With Chronic Obstructive Pulmonary Disease Who Is Using Oxygen

HISTORY: A 50-year-old former smoker previously found to have severe COPD, with FEV_1 of 0.9 L (30% of predicted value), is admitted to the hospital for evaluation and management of worsening shortness of breath and persistent bilateral leg swelling. He has been using O_2 at 2 L/min 24 hours per day for the last 3 months. A chronic productive cough of clear sputum has been unchanged. He denies having chest pain.

MEDICATIONS:

- Ipratropium bromide by metered dose inhaler, 2 puffs four times per day
- O_2, 2 L/min 24 hours per day
- Hydrochlorothiazide, 50 mg by mouth daily
- Theophylline, 300 mg by mouth twice per day

MEDICAL HISTORY:

- Hypertension and chronic bronchitis
- No cardiac disease

PHYSICAL EXAMINATION:

- *Vital signs:* Blood pressure 150/90 mm Hg, heart rate 100 beats/min, temperature 98.6° F (37° C), respirations 18 breaths/min
- *General:* Obese white man who appears short of breath
- *Neck:* 46 cm (18 in) in circumference
- *Lungs:* Decreased breath sounds bilaterally
- *Heart:* Faint sounds but regular rate and rhythm
- *Abdomen:* Obese; soft, normal bowel sounds
- *Extremities:* "Dusky" lower extremities with 4 mm pitting edema to the knees

LABORATORY DATA:

- *Theophylline level:* 12 mcg/ml
- *ABGs:* pH 7.36, PCO_2 44 mm Hg, PO_2 56 mm Hg, SaO_2 89% (on 2 L/min O_2)
- *Chest radiograph:* "Pulmonary congestion"; otherwise normal
- *ECG:* Sinus tachycardia without acute changes
- *Echocardiogram:* "Technically limited" but reported to be without segmental wall abnormalities or to show normal left ventricular function
- *Bilateral lower extremity Doppler examination:* Negative for deep venous thrombosis

PROBLEM: What could be the cause of this patient's continued signs of right heart failure?

DISCUSSION: The patient has overlap syndrome (COPD and OSA). He has been appropriately treated for COPD (bronchodilators and O_2) but has not been treated for OSA. His physician never asked and the patient never volunteered a history of nightly loud snoring with observed apnea and daytime fatigue. Subsequent evaluation with a nocturnal PSG reveals severe nocturnal desaturation to 40% on the oximeter despite treatment with O_2 at 2 L/min. A CPAP titration study is performed. The patient is discharged with CPAP set at 15 cm H_2O via a nasal mask. He returns to the outpatient clinic 3 months later and reports "feeling great." He reports that the shortness of breath has decreased and that he has much more energy during the day. Physical examination shows trace pedal edema. ABG studies on 2 L/min of O_2 reveal pH 7.40, PCO_2 40 mm Hg, PO_2 75 mm Hg, and SaO_2 93%.

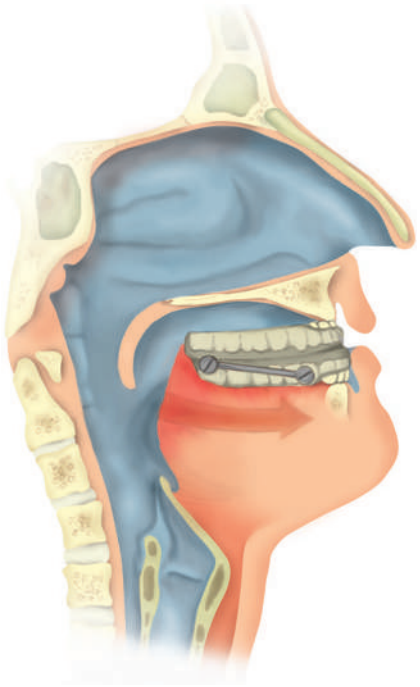

FIGURE 33-5 Oral appliance. The oral appliance covers the teeth of the upper and lower jaws and is adjusted to move the mandible (lower jaw) forward mechanically to open the airway.

Box 33-6 Surgical Alternatives for Obstructive Sleep Apnea

- Bypass of the upper airway
- Tracheostomy
- Reconstruction of the upper airway
- Nasal surgery
- Palatal surgery
- Maxillofacial surgery

should be avoided because they can potentiate upper airway collapse. The antidepressants protriptyline and fluoxetine have been used to manage mild sleep apnea but are ineffective in most patients.[14] O_2 therapy is useful for patients with oxyhemoglobin desaturation who refuse positive pressure therapy. O_2 therapy can improve nocturnal desaturation but has no significant effect on ventilatory arousals and daytime sleepiness.[103] O_2 therapy should be used with caution by patients with concomitant severe COPD, who may retain CO_2.

Surgical Interventions

Surgical alternatives can be divided into two broad categories: procedures that bypass the upper airway and procedures that reconstruct the upper airway (Box 33-6). Before the advent of CPAP therapy, tracheostomy was the primary therapy for severe OSA. Because of the psychosocial and medical morbidity associated with the procedure, use of tracheostomy today is limited to managing severe OSA when all other therapies have been exhausted.[104,105]

Palatal Surgery

Uvulopalatopharyngoplasty (UPPP) is palatal surgery performed with a standard "cold knife" technique or a laser. Portions of the soft palate, the uvula, and additional redundant tissue are removed in these procedures. The success rate of UPPP is reported to be less than 50% overall.[106] The site of the physiologic obstruction cannot be predicted correctly with preoperative imaging. Laser-assisted UPPP has been marketed as an outpatient procedure; however, substantial efficacy in managing OSA has not been documented. UPPP cannot be recommended for the management of OSA at the present time.[107,108]

Maxillofacial Surgery

Maxillofacial surgery shows more promise for patients with OSA (Figure 33-6). Phase I surgical procedures combine UPPP with genioglossal advancement. Patients are identified preoperatively with a combination of radiologic imaging and direct visualization of the upper airway. It is beneficial to have these patients use CPAP therapy perioperatively to reduce the chronic upper airway swelling and edema present before surgery and to reduce postoperative airway edema.[109] When phase I surgery is unsuccessful, phase II surgery involves advancement of the maxilla and the mandible.[110] These surgical procedures are performed at only a few specialized centers. A coordinated effort by a dedicated team of otolaryngologists, oral surgeons, and sleep specialists is essential. Regardless of the surgical option chosen, a postoperative PSG should be obtained to document improvement objectively.[111]

Additional Therapies

Newer treatment options for OSA are being developed and tested, including nasal resistance devices, negative pressure appliances, and implantable **upper airway stimulators**.[112,113] Long-term benefits have yet to be established, but initial results have been promising.

RULE OF THUMB

Sleep symptoms may present early in patients with neuromuscular disease. Treatment with noninvasive ventilation during sleep may improve daytime symptoms.

ROLE OF THE RESPIRATORY THERAPIST IN DISORDERS OF SLEEP

RTs play a vital role in diagnosing and treating OSA. As part of the multidisciplinary team, RTs prepare patients for the overnight PSG and obtain key information relating to their sleep history. During the study, RTs assess for **sleep-disordered breathing** and apply and titrate positive pressure. They are also involved with education, which is important in assisting with the patient's understanding and compliance with positive

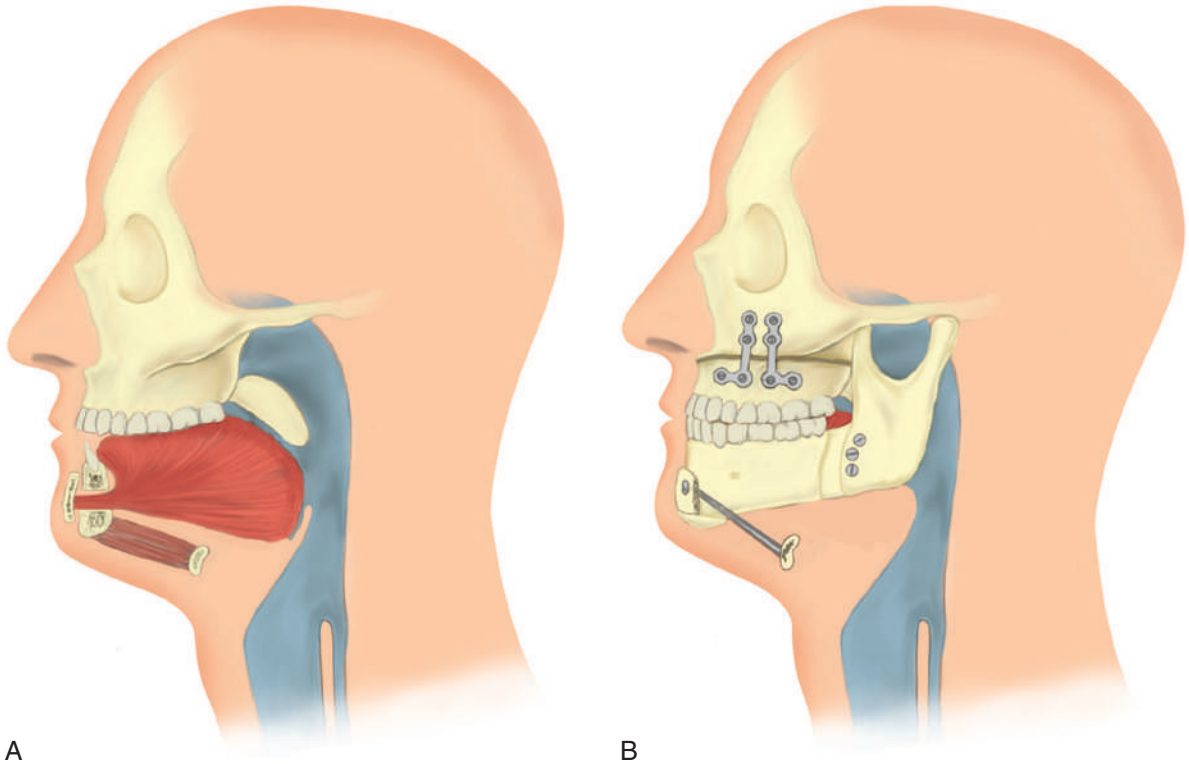

FIGURE 33-6 Phase I and phase II upper airway reconstruction. **A,** Phase I surgery. Lateral cutaway view of the skull shows tongue (genioglossal) and hyoid bone advancement in conjunction with uvulopalatopharyngoplasty. **B,** Phase II surgery. Lateral cutaway view of the skull shows advancement of the maxilla (upper jaw) and mandible (lower jaw) in a patient who has undergone a phase I procedure.

MINI CLINI

Young Woman With Mental Status Changes After Orthopedic Surgery

HISTORY: A 37-year-old obese smoker is admitted to the hospital after elective surgical repair of a biceps tendon and ulnar collateral ligament. She initially sustained the injury after a fall when riding a bicycle. After outpatient orthopedic evaluation and preoperative cardiac clearance, an elective repair of the tendon and ligament was scheduled. She was intubated electively for the procedure, and her operative course was unremarkable. Postoperatively, she was extubated and noted to be slightly lethargic but easily arousable and in pain while in postoperative recovery. On transfer to the floor, she became increasingly lethargic and hypoxemic despite the addition of up to 6 L/min of supplemental O_2 via nasal cannula. An emergency code is called. She is transferred to a step-down bed and further testing is performed.

MEDICATIONS AT HOME:
- None

MEDICAL HISTORY:
- Hypertension, not on medications

PHYSICAL EXAMINATION:
- *Vital signs:* Blood pressure 158/74 mm Hg, heart rate 68 beats/min, temperature 98.6° F (38.6° C), respirations 12 breaths/min
- *General:* Obese woman, lethargic and arousable
- *Neck:* 46 cm (18 in) in circumference
- *Lungs:* Diminished breath sounds bilaterally
- *Heart:* Faint sounds but regular rate and rhythm
- *Abdomen:* Obese; soft, normal bowel sounds
- *Extremities:* Right arm wound intact with bandages in place, pulses equal

LABORATORY DATA:
- *ABGs on 6 L/min O_2 via nasal cannula:* pH 7.11, PCO_2 109 mm Hg, PO_2 110 mm Hg, SaO_2 87%
- *Chest x-ray:* No mass, infiltrate, or effusion
- *ECG:* Normal sinus rhythm
- *CT scan of the head without contrast agent:* No mass, hemorrhage, or midline shift
- *CT scan of the chest with contrast agent:* No evidence of pulmonary embolism or parenchymal abnormality
- *EEG:* No seizure activity

PROBLEM: How should this patient be managed?

DISCUSSION: The patient requires bilevel noninvasive ventilator support intermittently for the next several days. After her workup reveals nothing remarkable, a pulmonary and sleep consultation is obtained. Review of the medical records reveals the patient has been receiving hydromorphone (Dilaudid) frequently for pain control. After stopping opioid medication, the patient's mental status gradually returns to baseline. Repeat ABGs on room air show pH 7.39, PCO_2 62 mm Hg, PO_2 110 mm Hg, and SaO_2 93%. A diagnostic nocturnal PSG is performed, which reveals severe OSA with AHI of 55 and low SaO_2 of 72% and evidence of chronic **obesity hypoventilation.** Positive pressure titration is performed successfully with average volume assisted pressure support with goal V_T of 8 ml/kg. The patient is discharged home with a follow-up appointment in the sleep clinic.

MINI CLINI

Fatigue in a Patient With Neuromuscular Disease

HISTORY: A 54-year-old man with recent diagnosis of ALS presents to the outpatient clinic with fatigue. He states he has been more tired and sleepy for the last few months. He had been diagnosed with ALS approximately 6 months ago, but has been doing fairly well at home. He does notice he has some difficulty sleeping at night, sometimes sleeping in a reclining chair. He denies snoring or weight gain, and in fact has lost 15 lb in the last few months. On further questioning, he reports feeling short of breath with exertion or when lying flat.

MEDICATIONS:
- None

MEDICAL HISTORY:
- Hypertension and gastroesophageal reflux
- No significant cardiac disease

PHYSICAL EXAMINATION:
- *Vital signs:* Blood pressure 135/70 mm Hg, heart rate 80 beats/min, temperature 98.6° F (37° C), respiration 16 breaths/min
- *General:* Thin, no distress, pleasant man
- *Neck:* 52 cm (20.5 in) in circumference
- *Lungs:* Clear breath sounds bilaterally
- *Heart:* Regular rate and rhythm
- *Abdomen:* Thin; soft, normal bowel sounds
- *Extremities:* no edema

LABORATORY DATA:
- *Room air ABGs:* pH 7.38, PCO_2 52 mm Hg, PO_2 88 mm Hg, SaO_2 94%
- *Chest radiograph:* Normal
- *Pulmonary function tests:* FVC 1.52 L (42% predicted), FEV_1 1.41 L (53% predicted), FEV_1/FVC ratio 0.73

PROBLEM: Why does this patient have fatigue?

DISCUSSION: The patient's symptoms are concerning for respiratory compromise because of his neuromuscular disease. His pulmonary function tests reveal restrictive lung physiology, with decreased FVC and FEV_1 on spirometry. He also has evidence for chronic hypoventilation with elevated PCO_2 on ABG analysis. He may benefit from starting noninvasive ventilation. The patient was started on positive pressure therapy with average volume assist pressure support and his sleep quality and daytime energy improved.

pressure therapy. Some RTs pursue special certification in Sleep Technology.

RTs may see patients with sleep disorder–related symptoms in the course of their clinical practice and can encourage diagnostic testing by discussion with the patient or the managing physician or both. In the acute care setting, RTs and nursing staff are in a unique position to observe directly evidence of abnormal breathing during sleep or other clinical clues that may prompt further clinical action.

Therapeutically, RTs may see patients in their home and help manage the CPAP or bilevel PAP machines, interfaces, and supplemental O_2. In the context of rehabilitation or bariatric surgery, RTs may help care for patients recovering from surgery or participating in rehabilitation programs for weight loss or improvement in cardiopulmonary function. The role of the RT may be key in serving as the bridge between physician and patient to enable education, identify obstacles to therapy, and improve overall compliance. In all these ways, RTs play an invaluable role as members of the sleep medicine team.

SUMMARY CHECKLIST

- There are three types of sleep apnea: OSA, CSA, and mixed sleep apnea; OSA is the most common.
- OSA is common, underdiagnosed, and controllable.
- The major risk factor for airway narrowing or closure during sleep is a small or unstable upper airway.
- The shift in the physiologic state from wakefulness to sleep and the consequent decrease in muscle tone result in partial or complete airway closure of the upper airway in patients with OSA.
- The long-term harmful effects of OSA include poor daytime functioning, impaired metabolic function, and increased risk for cardiovascular morbidity and mortality.
- Risk factors for OSA include male sex, age greater than 40 years, upper body obesity (neck size >16.5 in), habitual snoring, and diurnal hypertension.
- PSG is the most accurate way to make the diagnosis of OSA. The PSG measures several physiologic variables and allows for the staging of sleep and measurement of airflow, ventilatory effort, ECG, and SaO_2.
- First-line medical therapy for OSA is CPAP. This modality is almost always effective in the laboratory, although long-term adherence with CPAP therapy may be suboptimal.
- Bilevel PAP therapy may be useful in salvaging selected patients who have difficulty accepting or complying with CPAP.
- The role of auto-titrating positive airway pressure devices (auto-CPAP or auto–bilevel PAP) in managing OSA remains to be defined.
- Oral appliances can be effective, in particular, in patients with mild to moderate OSA.
- Surgical therapy may be an option for a select group of patients who have undergone an extensive preoperative analysis of the upper airway and do not accept or comply poorly with medical therapy. Optimal management of OSA, regardless of the modality, requires patient education, continued monitoring, and reassessment.

CHAPTER 34

Neonatal and Pediatric Respiratory Disorders

DOUGLAS D. DEMING AND KIMBERLY N. OTSUKA

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the clinical findings, radiographic abnormalities, and treatment of patients with respiratory distress syndrome.
- Describe the clinical manifestations and treatment of patients with transient tachypnea of the newborn.
- Describe the pathophysiology, presentation, and treatment of meconium aspiration syndrome.
- Identify the clinical signs and symptoms associated with bronchopulmonary dysplasia and the approaches used to manage these infants.
- State the cause and treatment of apnea of prematurity.
- Describe the pathophysiology, diagnosis, and treatment of persistent pulmonary hypertension of the newborn.
- Discuss the pathophysiology, diagnosis, and treatment of congenital diaphragmatic hernia.
- Identify the anatomic defects associated with tetralogy of Fallot.
- Describe the clinical presentation of a ventricular septal defect.
- Describe types and associated conditions for abdominal wall defects.
- Define the epidemiologic factors associated with increased risk for sudden infant death syndrome.
- Identify the respiratory problems associated with gastroesophageal reflux disease.
- State the clinical findings commonly observed in patients with bronchiolitis.
- Describe the clinical features and treatment of children with epiglottitis.
- Describe the clinical manifestations and treatment of cystic fibrosis.

CHAPTER OUTLINE

KEY TERMS

apnea of prematurity
bronchiolitis
bronchopulmonary dysplasia
croup
cystic fibrosis
ductus arteriosus
epiglottitis
gastroesophageal reflux disease
meconium aspiration syndrome
nasal flaring
persistent pulmonary hypertension of the newborn
respiratory distress syndrome
sudden infant death syndrome
tetralogy of Fallot
transient tachypnea of the newborn
transposition of the great arteries

Many perinatal disorders affect the respiratory system. Some disorders are developmental abnormalities of the heart, lungs, or airways; some are caused by prematurity; some are caused by problems during labor and delivery; and some are caused by treatments. Common disorders in the neonatal period with which respiratory therapists (RTs) should be familiar are respiratory distress syndrome, transient tachypnea of the newborn, meconium aspiration syndrome, apnea of prematurity, bronchopulmonary dysplasia, persistent pulmonary hypertension of the newborn, and congenital cardiopulmonary abnormalities.

NEONATAL RESPIRATORY DISORDERS

Lung Parenchymal Disease

Respiratory Distress Syndrome

Background. Neonatal **respiratory distress syndrome** (RDS) affects approximately 40,000 infants each year in the United States.[1] Although the death rate has decreased dramatically over the past 4 decades, many infants still die or have chronic effects of the syndrome. RDS, also known as *hyaline membrane disease,* is a disease of prematurity. The incidence increases with decreasing gestational age. The major factors in the pathophysiology of RDS are qualitative surfactant deficiency, decreased alveolar surface area, increased small airways compliance, and presence of a **ductus arteriosus**.

RULE OF THUMB

The incidence of RDS increases with decreasing gestational age.

Surfactant production depends on both the relative maturity of the lung and the adequacy of fetal perfusion. Maternal factors that impair fetal blood flow, such as abruptio placentae and maternal diabetes, also may lead to RDS.

Pathophysiology. In preterm infants, adequate amounts of surfactant are present in the lung; however, the surfactant is trapped inside type II cells. In infants with RDS, type II cells do not release adequate amounts of surfactant. The surfactant that is released is incompletely formed, so it does not make tubular myelin and does not decrease alveolar surface tension. Because the surfactant molecule in the alveolus is structurally abnormal, the type II cells and alveolar macrophages have more rapid uptake for recycling. Thus, there is a qualitative deficiency of alveolar surfactant.

Figure 34-1 outlines the pathophysiologic events associated with RDS. A qualitative decrease in surfactant increases alveolar surface tension forces, which causes alveoli to become unstable and collapse and leads to atelectasis and increased work of breathing. At the same time, the increased surface tension draws fluid from the pulmonary capillaries into the alveoli. In combination, these factors impair oxygen (O_2) exchange and cause severe hypoxemia. The severe hypoxemia and acidosis increase

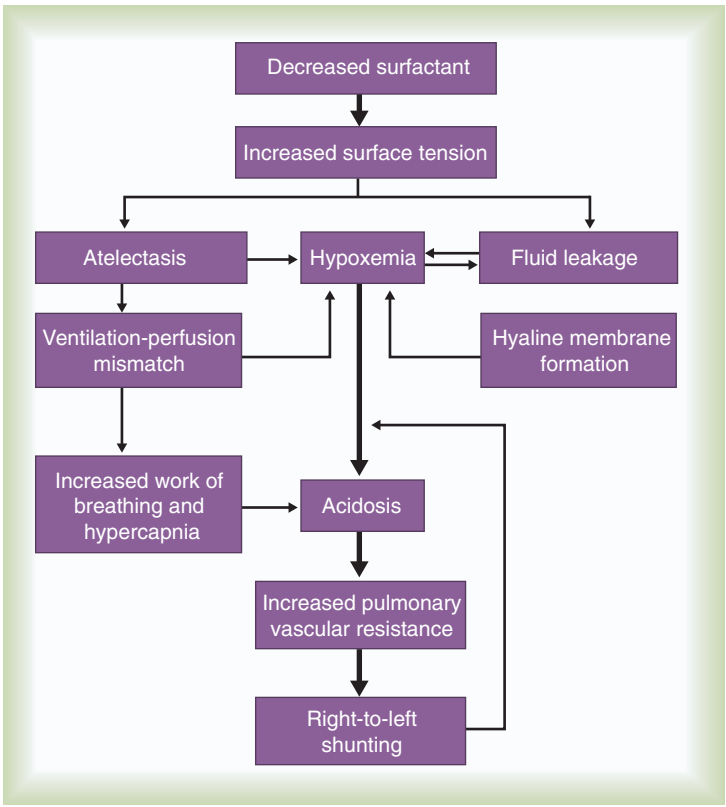

FIGURE 34-1 Pathophysiology of respiratory distress syndrome.

pulmonary vascular resistance (PVR). As pulmonary arterial pressure increases, extrapulmonary right-to-left shunting increases, and hypoxemia worsens. Hypoxemia and acidosis also impair further surfactant production. Steroids given before birth (antenatally) have been shown to mature surfactant function in the fetus, decrease the severity of RDS, and improve outcomes.[2,3]

Clinical Manifestations. The first signs of respiratory distress in infants with RDS normally appear soon after birth. Tachypnea usually occurs first. After tachypnea, worsening retractions, paradoxical breathing, and audible grunting are observed. **Nasal flaring** also may be seen. Chest auscultation often reveals fine inspiratory crackles. Cyanosis may or may not be present. If central cyanosis is observed, it is likely that the infant has severe hypoxemia. Certain other conditions, such as systemic hypotension, hypothermia, and poor perfusion, can mimic this aspect of RDS.

A definitive diagnosis of RDS usually is made with chest radiography (Figure 34-2). Diffuse, hazy, reticulogranular densities with the presence of air bronchograms with low lung volumes are typical of RDS. The reticulogranular pattern is caused by aeration of respiratory bronchioles and collapse of the alveoli. Air bronchograms appear as aerated, dark, major bronchi surrounded by the collapsed or consolidated lung tissue.

Treatment. *Continuous positive airway pressure (CPAP)* and *positive end expiratory pressure (PEEP)* are the traditional support modes used to manage RDS. Surfactant replacement therapy and *high-frequency ventilation (HFV)* have been added to these traditional approaches.[1-8] Unless the infant's condition is severe, a trial of nasal CPAP is indicated (4 to 6 cm H_2O).[4-6,8-13] Because of the hazards of endotracheal tubes (ETTs), nasal prongs are preferred. If the infant's clinical condition deteriorates rapidly, a more aggressive approach is required. Endotracheal intubation should be performed under controlled conditions as an elective procedure. Mechanical ventilation with PEEP should be initiated if oxygenation does not improve with CPAP or if the patient is apneic or acidotic. There is significant interest in an approach comprising intubation, delivery of surfactant, extubation, and then nasal CPAP.[14,15] However, more research is needed to understand the risks and benefits of this approach.

The aim of mechanical ventilation for RDS is to prevent lung collapse and maintain alveolar inflation. In severe RDS, collapse of alveoli with every breath necessitates very high reinflation pressure. To prevent the need for this high reinflation pressure, use of end-tidal pressure is necessary.

Because of the relationship between arterial partial pressure of carbon dioxide ($PaCO_2$) and functional residual capacity (FRC), $PaCO_2$ is lowest when PEEP is used to optimize FRC.

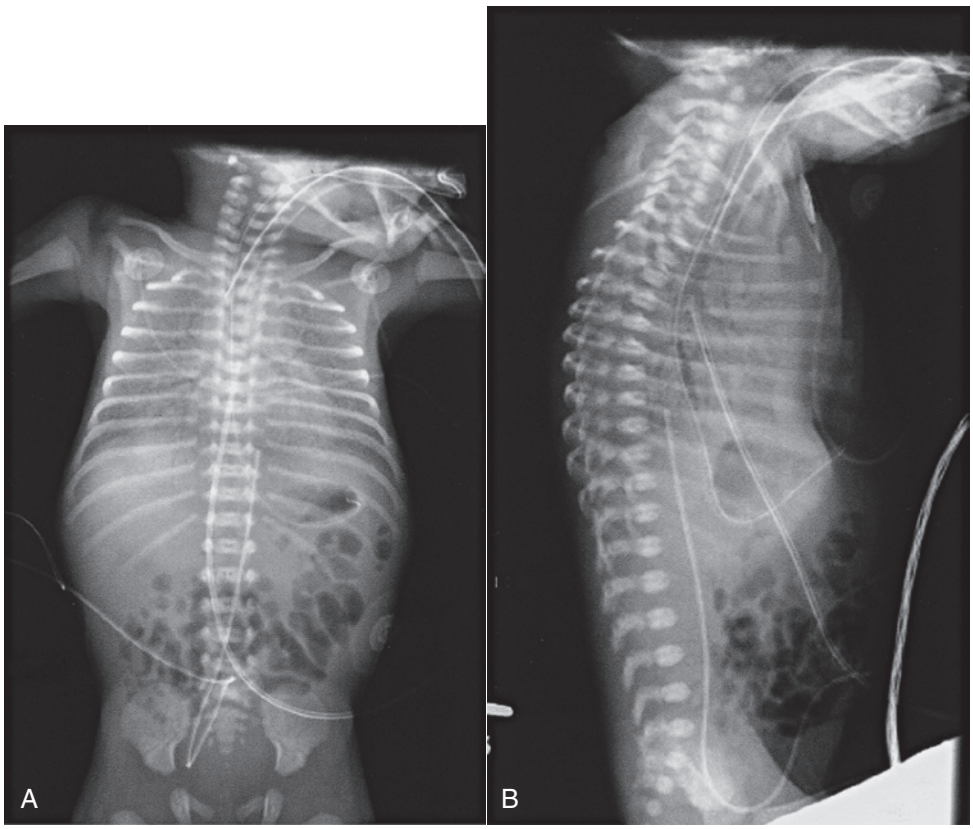

FIGURE 34-2 Radiopaque appearance of severe respiratory distress syndrome. Anteroposterior **(A)** and lateral **(B)** radiographs show diffuse hazy appearance with low lung volumes and air bronchograms that extend into the periphery.

TABLE 34-1

Surfactant Dosing

Dosing Information	Beractant (Survanta)	Calfactant (Infasurf)	Poractant Alfa (Curosurf)	Lucinactant (Surfaxin)
Dose mg/kg of birth weight	100	100	100-200	20
Dose: mL/kg birth weight	4	3	1.25-2.5	5.8
Administration	¼ dose quickly in each of four positions	½ dose slowly supine then rotated	Whole or ½ dose supine	Dose in each of four positions
Dosing interval	Every 6 hr or more often	Every 12 hr or more often	Every 12 hr or more often	Up to 4 doses in 48 hr, minimum of 6-hr interval

The time constant of the lungs in RDS is short, so the lung empties very quickly with each ventilator cycle. If alveolar ventilation is inadequate, either peak inspiratory pressure or rate should be increased. For minimizing the possibility of volutrauma, the peak inspiratory pressure should be kept less than 30 cm H_2O for larger premature infants, and even lower peak inspiratory pressure is indicated for more immature infants.

Four surfactant preparations are currently available in the United States for managing neonatal RDS: beractant (Survanta; Abbott Laboratories, North Chicago, IL), calfactant (Infasurf; ONY, Amherst, NY), poractant alfa (Curosurf; Chiesi, Cheadle, United Kingdom), and lucinactant (Surfaxin, Discovery Labs, Warrington, PA).[4,5,7,8,16-26]

Beractant and calfactant are natural bovine surfactant extracts. Poractant alfa is a natural porcine surfactant extract. Lucinactant is a completely synthetic surfactant. Each of three natural surfactants has surfactant proteins B and C as part of the formulation. The synthetic surfactant uses an amino acid sequence that acts like surfactant protein. Surfactant proteins are important for decreasing alveolar surface tension. All of these preparations are liquid suspensions that are instilled directly into the trachea. The current standard of care is to deliver replacement surfactant to all infants with RDS. There are investigations of an aerosol delivery system that would not require intubation for the synthetic surfactant. Currently, there is no evidence to support the use of a particular brand of surfactant over another.

Surfactant replacement therapy also is used as both a rescue treatment (in infants who already have RDS) and a prophylactic therapy (in the care of infants delivered prematurely).[4,7-9,27] Some centers use prophylactic surfactant replacement therapy in the care of all very small infants (<1500 g). Therapies aimed at decreasing pulmonary edema, improving cardiac output, and weaning from O_2 and high ventilator pressures are essential in the successful treatment of infants receiving surfactant. Recent evidence supports the use of noninvasive ventilatory support (e.g., bubble CPAP) to support even the smallest of infants.[13,28-30]

RULE OF THUMB

FRC is best supported by positive end-expiratory pressure (CPAP or PEEP).

All surfactants are delivered by ETT. Animal studies suggest that surfactant is rapidly distributed throughout the lung.[6] Each specific surfactant has different dosing volumes and intervals (Table 34-1). The surfactant product insert describes the positioning of the infant for surfactant delivery. Basically, the infant is positioned with different sections of the lung dependent so that the surfactant enters that section of the lung with gravity flow. If the infant is very sick and cannot be repositioned, surfactant can be administered with the infant in the supine position.

MINI CLINI

Respiratory Distress Syndrome

PROBLEM: A woman is about to deliver at 26 weeks of gestational age. What should the RT have available for resuscitation of the infant?

DISCUSSION: An infant at 26 weeks of gestational age is most likely going to have RDS—ranging from mild to severe disease. The RT should have equipment, supplies, and drugs necessary to support the infant. Many infants require mask-bag ventilation. It is crucial that the RT be acutely attuned to using the lowest pressures necessary to move the chest. It is very easy to injure the lung with high V_T. Most authorities recommend the use of a T-piece resuscitator that delivers manual breaths at fixed pressures, decreasing the risk for traumatic injury from high V_T.[31]

Some infants have severe disease that requires intubation and immediate administration of surfactant. Some infants have only mild disease. These less sick infants may require only nasal CPAP. For infants who have intermediate disease, at some centers clinicians intubate the infant, administer surfactant, and then extubate the infant back to nasal CPAP.[14,15,28,32]

Transient Tachypnea of the Newborn

Background. **Transient tachypnea of the newborn** (TTN), often called *type II RDS,* is probably the most common respiratory disorder of newborns.[33-36] The cause of TTN is unclear, but it is most likely related to delayed clearance of fetal lung liquid.[36-42] During most births, approximately two-thirds of this

fluid is expelled by thoracic squeeze in the birth canal; the rest is reabsorbed through the lymphatic vessels during initial breathing. These mechanisms are impaired in infants born by cesarean section or infants with incomplete development of the lymphatic vessels (preterm or small-for-gestational-age infants). The residual lung fluid causes an increase in airway resistance and an overall decrease in lung compliance. Because compliance is low, the infant must generate more negative pleural pressure to breathe. This process can result in hyperinflation of some areas and air trapping in others. Most infants with TTN are born at term without any specific predisposing factors in common. Mothers of neonates who have TTN tend to have longer labor intervals and a higher incidence of failure to progress in labor, which leads to cesarean delivery. In many cases, however, maternal history and labor and delivery are normal.

Clinical Manifestations. During the first few hours of life, infants with TTN breathe rapidly. Alveolar ventilation, as measured by arterial pH and $PaCO_2$, usually is normal. The chest radiographic findings, which may initially be indistinguishable from pneumonia, are hyperinflation, which is secondary to air trapping, and perihilar streaking. The perihilar streaking probably represents lymphatic engorgement. Pleural effusions may be evident in the costophrenic angles and interlobar fissures.

Treatment. Infants with TTN usually respond readily to a low FiO_2 by infant O_2 hood or nasal cannula. Infants requiring a higher FiO_2 may benefit from CPAP. Because the retention of lung fluid may be gravity-dependent, frequent changes in the infant's position may help speed lung fluid clearance. Because TTN and neonatal pneumonia have similar clinical signs, intravenous administration of antibiotics should be considered for at least 3 days after appropriate culture samples are obtained. Mechanical ventilation is rarely needed, and, when it is, this probably indicates a complication. Clearing of the lungs evident on a chest radiograph and with clinical improvement usually occurs within 24 to 48 hours. A few infants with TTN eventually have persistent pulmonary hypertension.

Meconium Aspiration Syndrome

Background. **Meconium aspiration syndrome** is a disease of term and near-term infants. It involves aspiration of meconium into the central airways of the lung. It usually is associated with perinatal depression and asphyxia.

Pathophysiology. Amniotic fluid consists mainly of fetal lung fluid, fetal urine, and transudate from the uterine wall. *Meconium,* the contents of the fetal intestine, occasionally is expelled from the fetus into the surrounding amniotic fluid. Meconium consists of mucopolysaccharides, cholesterol, bile acids and salts, intestinal enzymes, and other substances. Meconium normally is not passed until after delivery.[43] Infants who have marked perinatal depression or perinatal asphyxia may pass meconium in utero. The pathophysiologic control mechanisms for the passage of meconium in utero are not completely understood. It is widely accepted that infants can have meconium aspiration in utero. Amniotic fluid stained with meconium is found in approximately 12% of all births.[43] Meconium-stained amniotic fluid is rare among infants younger than 37 weeks of gestational age. The clinical syndrome develops in 2 of every 1000 infants. Of infants with inhaled meconium, 95% clear their lungs spontaneously.[30] Amniotic fluid infusion into the uterus before the delivery of infants with meconium-stained fluid has been shown to improve neonatal outcomes.[44,45]

For many years, the aspirated meconium itself was considered the primary cause of MAS. More recent evidence suggests that the real causative agent is fetal asphyxia that precedes aspiration. Fetal asphyxia causes pulmonary vasospasm and hyperreactivity of the vasculature, which lead to persistent pulmonary hypertension.[46-48]

MAS involves three primary problems: pulmonary obstruction, lung tissue damage, and pulmonary hypertension.[46] Obstruction occurs because of plugging of the airways with particulate meconium. This obstruction often is of the ball-valve type, which allows gas entry but prevents gas exit. Ball-valve obstruction causes air trapping and can lead to volutrauma (Figure 34-3). The lung tissue injury caused by MAS is chemical pneumonitis. Additionally, there are various chemical effects, inflammatory responses, cytokine and chemokine activations, complement activation, and phospholipase A_2 activation.[45,46,49-54] Persistent pulmonary hypertension with intracardiac and extracardiac right-to-left shunting frequently complicates MAS.[46]

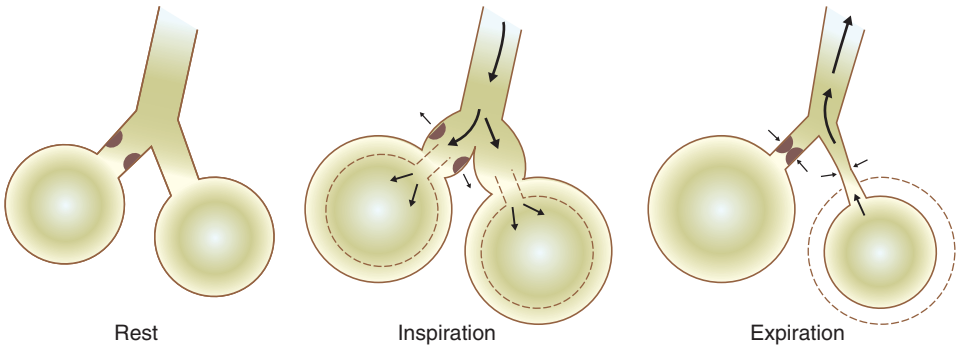

FIGURE 34-3 Ball-valve effect. At rest, the airway lumen is partially obstructed. With inspiration, negative intrathoracic pressure opens the airway and relieves obstruction. Gas enters and expands the alveoli. With expiration, intrathoracic pressure changes to positive force, which narrows the airway and causes total occlusion. Gas cannot be expelled and is trapped within the alveoli. (Modified from Koff PB, Eitzman DV, Neu J: Neonatal and pediatric care, ed 2, St Louis, 1993, Mosby.)

Clinical Manifestations. Before birth, thick meconium, fetal tachycardia, and absent fetal cardiac accelerations during labor are evidence that the fetus is at high risk for MAS.[55] After delivery, if the infant has a low umbilical artery pH, an Apgar score less than 5, and meconium aspirated from the trachea, intensive care and close observation for MAS are warranted. Infants with MAS typically have gasping respirations, tachypnea, grunting, and retractions. The chest radiograph usually shows irregular pulmonary densities, which represent areas of atelectasis, and hyperlucent areas, which represent hyperinflation secondary to air trapping (Figure 34-4). Arterial blood gases (ABGs) typically show hypoxemia with mixed respiratory and metabolic acidosis. In the most severe cases, there is right-to-left shunting and persistent pulmonary hypertension.[43]

Treatment. It is no longer recommended that vigorous infants with meconium-stained fluid be intubated and suctioned.[44,50,56-60] However, it is important that an ETT be inserted immediately in severely depressed infants with thick meconium, and suction should be applied directly to the ETT.[58] The ETT is removed and inspected for meconium. If meconium is present, the procedure is repeated with a new ETT until no further meconium is aspirated or until two to four aspirations have been performed. The ETT should be left in place, and mechanical ventilation should be started. For prevention of hypoxemia, a flow of warmed 100% O_2 should be blown across the infant's face during the aspiration efforts. No evidence suggests an improved outcome because of endotracheal suctioning in the care of infants who have meconium and are vigorous and would not otherwise require intubation.[56,60] There is evidence that tracheal lavage with dilute surfactant improves the clinical course and outcome of infants with MAS.[51,61,62]

If the infant's condition worsens, CPAP or mechanical ventilation may be indicated. CPAP is indicated if the primary problem is hypoxemia. By distending the small airways, CPAP can sometimes overcome the ball-valve obstruction and improve both oxygenation and ventilation. If respiratory acidosis is severe or clinical assessment indicates excessive work in breathing, mechanical ventilation should be started. Figure 34-3 shows the ball-valve effect. At rest, the airway lumen is partially obstructed. With inspiration, negative intrathoracic pressure opens the airway and relieves the obstruction. Gas enters and expands the alveoli. With expiration, intrathoracic pressure changes to a positive force, which narrows the airway and causes total occlusion. Gas cannot be expelled and is trapped within the alveoli. It is difficult to provide ventilation to infants with severe MAS. These infants often retain CO_2 and need increased ventilator support. Because of high airway resistance, the lungs have a long time constant. High ventilator rates and pressures increase the risk for air trapping and volutrauma.

Evidence suggests that both HFV and synchronous intermittent mechanical ventilation decrease the risk for air leak.[63,64] Various studies have shown improvement in MAS with the use of HFV and surfactant.[51,54,61,65-67] Nitric oxide (NO) has become a major adjunct in the management of persistent pulmonary hypertension.[47-49,68] Corticosteroids have not yet been shown to improve outcomes for infants with MAS.[69] High mean airway pressures may worsen pulmonary hypertension and aggravate right-to-left cardiac shunting.[55]

MINI CLINI

Meconium Aspiration Syndrome

PROBLEM: The RT is called to the delivery room to attend the delivery of a term infant with meconium-stained amniotic fluid. What should the RT have available for the resuscitation of this infant?

DISCUSSION: The RT should have the standard resuscitation equipment available. Current recommendations for resuscitating a newborn with meconium staining do not include immediate intubation and tracheal suctioning for a vigorous infant. If the infant is depressed and not breathing, the infant should be resuscitated similar to any other depressed and apneic infant, which includes intubation. However, there is no evidence for whether the depressed infant would benefit from intubation and tracheal suctioning.[57,58,70]

Bronchopulmonary Dysplasia

Background. Infants, especially preterm infants, with severe respiratory failure in the first few weeks of life may develop a chronic pulmonary condition called **bronchopulmonary dysplasia** (BPD). BPD is a complex disease that is poorly defined.[71-75] Historical definitions have included radiographic patterns and the requirement for supplemental O_2 at fixed time points in the infant's life. Immaturity, genetics, malnutrition, O_2 toxicity, and mechanical ventilation all have been suspected to cause BPD.[56,73,76-79]

Pathophysiology. The development of BPD is complex and involves many pathways. The initiating factors are related to *atelectrauma* (lung collapse) and *volutrauma* (large tidal volume [V_T]). Factors such as hyperoxia and hypoxia, mechanical forces, vascular maldevelopment, inflammation, nutrition, and genetics contribute to the abnormal development of the lung and lead to BPD.[77,78,80-86] *Atelectrauma* is a term coined to describe loss of alveolar volume that is both a result and a cause of lung injury. *Volutrauma* is the term used to describe local overinflation (and stretch) of airways and alveoli. Atelectrauma leads to derecuitment (e.g., areas of alveolar collapse) of the lung. Volutrauma leads to damage to airways, pulmonary capillary endothelium, alveolar and airway epithelium, and basement membranes. The combination of atelectrauma and volutrauma synergistically increases lung injury.[87]

Both atelectrauma and volutrauma cause a need for increased supplemental O_2 concentrations. This use of supplemental O_2 leads to overproduction of superoxide, hydrogen peroxide, and perhydroxyl radicals. Preterm infants are particularly susceptible to O_2 radicals because the antioxidant systems develop in the last trimester of pregnancy. Prolonged hyperoxia begins a sequence of lung injury that leads to inflammation, diffuse alveolar damage, pulmonary dysfunction, and death.

The response of the lungs to the combination of trauma and O_2 toxicity is the production and release of soluble mediators. These mediators probably are released from granulocytes residing in the lung. The release of these mediators can injure the alveolar-capillary barrier and cause an inflammatory response.[71,79] A "new" BPD is being described that shows decreased alveolarization rather than the prominent airway damage of the "old" BPD.[77-88] This change in the pathologic characteristics of BPD is thought to be related to improvements in ventilator management, the use of surfactant, and processes that interrupt alveolar development (e.g., postnatal steroid therapy).[74,89,90]

Clinical Manifestations. BPD has various clinical manifestations. Some very immature infants may start with little or no O_2 requirement and little or no mechanical ventilation requirement. Progressive respiratory distress develops at approximately 2 to 3 weeks of life, and then the infant needs O_2 and mechanical ventilation. Other immature infants may begin with pneumonia or sepsis and need very high levels of O_2 and mechanical ventilation. In either of these scenarios, progressive vascular leakage and areas of atelectasis and emphysema develop in the lungs, and progressive pulmonary damage occurs. The chest radiograph in severe disease shows areas of atelectasis, emphysema, and fibrosis diffusely intermixed throughout the lung (Figure 34-5).[77,78] ABG measurements reveal varying degrees of hypoxemia and hypercapnia secondary to airway obstruction, air trapping, pulmonary fibrosis, and atelectasis. There is a marked increase in airway resistance with an overall decrease in lung compliance.

Treatment. The best management of BPD is prevention. Prevention of atelectrauma and volutrauma begins in the delivery room. Establishment of an optimal FRC without overstretching the lung requires careful attention to detail in providing end-tidal pressure and avoiding large V_T. Surfactant should be delivered early in the course of treatment.

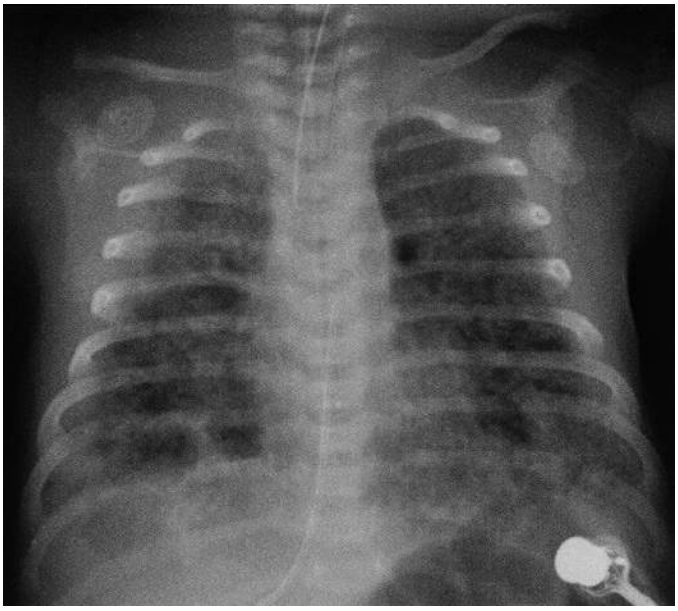

FIGURE 34-5 Radiograph of a patient with bronchopulmonary disease (BPD). Anteroposterior radiograph shows areas of scarring, atelectasis, emphysema, and cysts. This film is consistent with severe BPD.

Treatment of infants with BPD involves steps to minimize additional lung damage and prevent pulmonary hypertension and cor pulmonale. Infants with severe disease may be dependent on supplemental O_2 or mechanical ventilation for months and have symptoms of airway obstruction for years. Therapy usually is supportive throughout the course of the disease. An infant with BPD is given respiratory support as needed. Supplemental O_2 can help decrease the pulmonary hypertension that is common with BPD.[80]

Multiple treatments have been suggested for infants with BPD.[73,76,84,90-92] Diuretics are given as needed to decrease pulmonary edema; antibiotics are given to manage existing pulmonary infection.[93-95] Chest physical therapy may help mobilize secretions and prevent further atelectasis. Bronchodilator therapy may help decrease airway resistance.[93] Steroid therapy with dexamethasone can produce substantial short-term improvement in lung function, often allowing rapid weaning from ventilatory support. However, steroid therapy has little effect on long-term outcome such as mortality and duration of O_2 therapy.[96] Steroid therapy also has been implicated in decreased alveolarization and increased developmental delay.[92] Although steroids are still given in clinical practice, they should be used cautiously and only after the risks have been thoroughly explained to the parents. The use of NO to prevent or improve BPD is controversial.[97,98]

Control of Breathing

Apnea of Prematurity

Background. **Apnea of prematurity** is a common, controllable disorder among premature infants. It usually resolves over

time.[99-103] Premature infants frequently have periodic respiration, which comprises sequential short apneic episodes of 5 to 10 seconds followed by 10 to 15 seconds of rapid respiration. Apneic spells are abnormal if (1) they last longer than 15 seconds or (2) they are associated with cyanosis, pallor, hypotonia, or bradycardia.

If no effort to breathe occurs during a spell, the apnea is called *central* apnea. If breathing efforts occur, but obstruction prevents airflow, the apnea is termed *obstructive*. Mixed apnea is a combination of the central and obstructive types that starts as obstructive apnea and then develops into central apnea.[99,100,104,105]

Cause. Premature infants have immature control of respiratory drive in response to O_2 and carbon dioxide (CO_2). In mature animals, an increase in alveolar $PaCO_2$ elicits an increase in V_T and respiratory rate. A decrease in FiO_2 below room air also triggers an increase in V_T. Conversely, in premature animals, an increase in $PaCO_2$ temporarily increases V_T but does not increase respiratory rate. A decrease in FiO_2 below room air decreases V_T and respiratory rate. This effect can lead to apnea in a premature infant. Several factors in addition to prematurity can cause apnea in infants. Table 34-2 summarizes the potential causes, associated signs, and diagnostic indicators.[99,105-107]

Treatment. Infants with apnea need continuous monitoring of heart and respiratory rates. Continuous noninvasive monitoring of oxygenation by transcutaneous electrode or pulse oximetry is recommended. Most apneic incidents can be quickly ended with gentle mechanical stimulation, such as picking the infant up, flicking the sole of the foot, or rubbing the skin.[106,108] If the cause of apnea is not prematurity, treatment must be directed at resolving the underlying condition. Table 34-3 outlines current treatment strategies for infants with apnea.[86,109] Apnea secondary to prematurity responds well to methylxanthines, especially theophylline and caffeine.[110-112] These agents stimulate the central nervous system and increase the infant's responsiveness to CO_2. For infants with apnea that does not respond to treatment with theophylline, doxapram can be used.[113-115] However, doxapram is delivered by continuous infusion and has multiple toxicities.

The "Back to Sleep" program initiated by the American Academy of Pediatrics has significantly decreased the incidence of SIDS.[116] It is thought that when a newborn, which has a relatively heavy head and weak neck muscles, manages to position its face into a soft surface (e.g., mattress, pillow, bunting, etc.) it will develop increased CO_2 retention and become apneic. Unlike older infants, newborns will not have a response to awaken and move, they become apneic, then become bradycardic, then have cardiopulmonary arrest.[100-116]

CPAP also can be used to manage infant apnea.[117] Although the mechanism of action is not established, CPAP probably increases FRC and improves arterial partial pressure of oxygen (PaO_2) and $PaCO_2$. CPAP may stimulate vagal receptors in the lung, increasing the output of the brainstem respiratory centers. Severe or recurrent apnea that is unresponsive to these interventions may necessitate mechanical ventilatory support.

As the respiratory control mechanisms mature, apnea of prematurity normally resolves without intervention. Apneic spells begin to disappear by weeks 37 to 44 of postmenstrual age with no apparent long-term effects. Infants who have apnea of prematurity are not at higher risk for **sudden infant death syndrome** (SIDS) than other infants.

Apnea monitoring can allow infants who are otherwise ready for discharge but still having occasional episodes of apnea to go home.[103,109,118] However, the presence of a home apnea monitor

TABLE 34-2

Evaluation of an Infant With Apnea

Possible Cause	Associated Signs	Investigation
Infection	Lethargy, respiratory distress, temperature instability	Complete blood count, sepsis evaluation
Metabolic disorder	Poor feeding, lethargy, jitteriness	Glucose, calcium, electrolyte levels
Impaired oxygenation	Respiratory distress, tachypnea, cyanosis	O_2 monitoring, arterial blood gases, chest radiograph
Maternal drugs	Maternal history, hypotonia, central nervous system depression	Magnesium level, urine drug screen
Intracranial lesion	Abnormal neurologic findings, seizures	Cranial ultrasonography
Environmental	Lethargy	Monitor temperature (infant and environment)
Gastroesophageal reflux	Feeding difficulty	Specific observation, radiographic barium swallow examination

From Stark AR: Disorders of respiratory control in infants. Respir Care 36:673, 1991.

TABLE 34-3

Treatment Strategies for Infants With Apnea

Treatment	Rationale
Manage underlying cause if identified	Removes precipitating factor
Tactile stimulation	Increases respiratory drive by sensory stimulation
CPAP	Reduces mixed and obstructive apnea by splinting the upper airway
Theophylline or caffeine	Increases respiratory center output and CO_2 response, enhances diaphragm strength, adenosine antagonist
Doxapram	Stimulates respiratory center and peripheral chemoreceptors
Transfusion	Decreases hypoxic depression by increasing O_2-carrying capacity
Mechanical ventilation	Provides support when respiratory effort is inadequate

From Stark AR: Disorders of respiratory control in infants. Respir Care 36:673, 1991.
CPAP, Continuous positive airway pressure.

is a significant inconvenience to the family. Home monitors lack the sophisticated filtering systems of hospital monitors, and they have very frequent false alarms.[118] Also, there is no evidence that apnea monitors prevent SIDS.

Pulmonary Vascular Disease

Persistent Pulmonary Hypertension of the Newborn

Background. **Persistent pulmonary hypertension of the newborn** (PPHN) is a complex syndrome with many causes.[119-132] The common denominator in PPHN is a return to fetal circulatory pathways, usually because of elevated PVR. This condition results in further right-to-left shunting, severe hypoxemia, and metabolic and respiratory acidosis.

Pathophysiology. In the uterus, the fetus does not use the lungs as a gas-exchange organ. PVR is high, and systemic vascular resistance (SVR) is low. This condition produces a PVR/SVR ratio greater than 1. A fetus has two anatomic shunts that are not present in older infants, children, or adults: the foramen ovale and ductus arteriosus. With a PVR/SVR ratio greater than 1 and the anatomic shunts, blood flow bypasses the lung either at the atrial level (foramen ovale) or at the pulmonary artery (ductus arteriosus). Intrauterine total pulmonary blood flow and systemic arterial O_2 saturation (SaO_2) are low.

In the transition to extrauterine life, PVR decreases owing to gas filling the lungs and increasing PaO_2 in the pulmonary venous circulation. SVR increases with the removal of the placenta from the circulation, and this makes the PVR/SVR ratio less than 1. If PVR does not decrease to allow the PVR/SVR ratio to become less than 1, the infant has PPHN.

The three fundamental types of PPHN are vascular spasm, increased muscle wall thickness, and decreased cross-sectional area of pulmonary vessels.[123] Vascular spasm is an acute event that can be triggered by many different conditions, including hypoxemia, hypoglycemia, hypotension, and pain. Increased muscle wall thickness is a chronic condition that develops in utero in response to several different causative factors, including chronic fetal hypoxia, increased pulmonary blood flow (e.g., intrauterine closure of the ductus arteriosus), and pulmonary venous obstruction (e.g., total anomalous pulmonary venous return with obstructed below-diaphragm return). Decreased cross-sectional area is related to hypoplasia of the lungs and occurs with congenital diaphragmatic hernia, Potter sequence (absent kidneys), and oligohydramnios syndromes (decreased amniotic fluid).

Clinical Manifestations. PPHN should be suspected when an infant has rapidly changing O_2 saturation (SaO_2) without changes in FiO_2 or has hypoxemia out of proportion to the lung disease detected with chest radiography or $PaCO_2$ measurement. In infants with a significant shunt through the ductus arteriosus, there usually is a substantial gradient (>5%) between preductal and postductal O_2 saturation. This gradient can be found easily if two pulse oximeters are placed on the infant, one on the right arm and the other on either leg.

Treatment. Initial therapy for PPHN is removal of the underlying cause, such as administration of O_2 for hypoxemia, surfactant for RDS, glucose for hypoglycemia, and inotropic agents for low cardiac output and systemic hypotension. If correction of the underlying problem does not correct hypoxemia, the infant needs intubation and mechanical ventilation. Because pain and anxiety may contribute to PPHN, the infant may need sedation and, frequently, paralysis. If these measures do not improve oxygenation, the next step is HFV. This mode of ventilation allows a higher FRC without a large V_T. Inhaled NO is considered the next intervention.[68,133-136] If all of these modalities fail to improve oxygenation, the infant may be a candidate for extracorporeal membrane oxygenation (ECMO).[137-139] Also, types 3 and 5 phosphodiesterase inhibitors are being used in infants and children with refractory pulmonary hypertension.[140-143] Even with all of these treatments, PPHN remains a complex disease with high morbidity and mortality.

MINI CLINI

PROBLEM: The RT is called to the bedside of a term infant who has mild respiratory distress, is receiving nasal cannula O_2 of 1 L/min, has an FIO_2 of 1.0, and has a SpO_2 of 75%. Shortly after birth, the infant's chest radiograph revealed a normal size heart and clear, slightly hyperlucent lung fields with no infiltrates. The bedside nurse describes that she has just finished taking the infant's vital signs and changing its diaper. Before her touching the infant, the infant's saturation was 96%. What is this infant's problem? What should the RT do?

DISCUSSION: This infant is exhibiting signs of persistent pulmonary hypertension. The immediate interventions potentially could include increasing the O_2 flow, lowering the lights in the room, decreasing the activity and ambient noise in the room, swaddling the infant, and minimizing the physical contact with the infant. All of these interventions are aimed at getting the infant into a quiet, calm environment and allowing the infant to relax.

Additionally, the RT and nurse should contact the physician who is caring for this infant and alert him or her to the possibility of persistent pulmonary hypertension. Potential additional therapies could include sedation, intubation, mechanical ventilation, and inhaled NO.

Congenital Abnormalities Affecting Respiration

Congenital abnormalities that affect respiration can be divided into several groups: airway diseases, lung malformations, chest wall abnormalities, abdominal wall abnormalities, and diseases of neuromuscular control.

Airway Diseases

Airway abnormalities have three fundamental mechanisms: internal obstruction, external obstruction, and disruption. Internal obstruction includes common problems, such as laryngomalacia, that cause obstructive apnea. Less common

problems caused by internal obstruction are tracheomalacia, laryngeal webs, tracheal stenosis, and hemangiomas. All of these diseases usually manifest as a combination of inspiratory stridor, gas trapping, expiratory wheezing, and accessory respiratory muscle activity.

External compression can be caused by hemangiomas, neck or thoracic masses, and vascular rings. These lesions are far less common than diseases caused by internal obstruction, but they are not rare. The symptoms are similar to those of internal obstruction. Neck masses usually are obvious at visual inspection. Intrathoracic masses and vascular rings must be suspected on the basis of the clinical manifestations: noise during the respiratory cycle that worsens with exertion. The infant may have difficulty with swallowing.

Airway disruptions usually are related to tracheoesophageal fistula (TEF) in a newborn. This malformation usually is associated with esophageal atresia. There are five types of TEF: esophageal atresia with a proximal fistula, esophageal atresia with a distal fistula, esophageal atresia with both a proximal and a distal fistula, esophageal atresia without either fistula, and an intact esophagus with a so-called *H fistula*.[144] The most common of these malformations is esophageal atresia with a distal fistula, which accounts for 85% to 90% of all TEFs. The least common is the H fistula. All of these malformations manifest as difficulty swallowing, bubbling and frothing at the mouth, and choking, particularly during attempts at feeding. These anomalies can occur in isolation or as part of an association of defects. The most common is the VATER or VACTERL association of vertebral anomalies, imperforate anus, TEF, and renal or radial anomalies. In VACTERL, cardiac anomalies are added, and renal and limb anomalies replace renal or radial anomalies in the acronym. These associated anomalies must be sought in any infant with TEF. TEF is managed with surgical ligation of the fistula (tying it closed) and reconnection of the interrupted esophagus.[145] Most infants with TEF have a good outcome; however, some infants have severe malformations that can cause chronic problems. Infants with TEF usually need only supportive respiratory care. They usually do not have lung disease. However, some infants need HFV because the air leak through the fistula can become larger than the airflow to the alveoli.

Lung Malformations

There is a broad spectrum of rare lung malformations that occur in the newborn period.[106-108] These lesions are thought to be part of a continual spectrum of diseases that originate as defects in lung segmentation. The most common is congenital pulmonary adenomatoid malformation (CPAM); this was previously known as *cystic adenomatoid malformation of the lung*. CPAM is classified into five types on the basis of the type and size of the cyst.[146,147] The disease may affect entire lobes of the lung. The affected parts of the lung do not exchange gas and can become infected. The usual treatment is surgical removal of the affected lobe. There is also the potential for malignant transformation.

Some affected fetuses can develop hydrops in utero. Most infants with CPAM have symptoms of lung volume loss. As the mass expands, the normal surrounding lung is compressed. Some CPAMs resolve spontaneously. A few infants have severe cardiorespiratory compromise and need respiratory support and emergency surgery. However, better results are seen when surgery can be performed electively.

Other, less common lung malformations include pulmonary sequestration and lobar emphysema. Both of these diseases involve maldevelopment of lobes of the lung. Sequestration is a primitive, frequently cystic, lung lobe that is not in communication with the tracheobronchial tree and frequently receives no pulmonary vascular blood flow.

Lobar emphysema is an airway malformation that causes gas trapping in a lobe of the lung. These malformations manifest as space-occupying masses within the thorax. They usually are treated by surgical removal.

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia is a severe disease that usually manifests in newborns as severe respiratory distress.[148-150] The pathophysiologic mechanism is a complex combination of lung hypoplasia, including decreased alveolar count and decreased pulmonary vasculature, pulmonary hypertension, and unusual anatomy of the inferior vena cava.[148-150] This disorder varies between asymptomatic (rare) and severe life-threatening disease (frequent). There are two types of hernia: Bochdalek hernia (lateral and posterior defect, usually on the left) and Morgagni hernia (medial and anterior, may be on either side). Hernias that occur in the right hemidiaphragm may be less severe because the liver can block the defect and decrease the volume of abdominal contents that can enter the thorax.[150]

Some authors speculate that the diaphragmatic hernia complex is a developmental field defect and not just a simple cascade of events related to a hole in the diaphragm. This theory is partly based on long-term outcomes of survivors with diaphragmatic hernias. These survivors frequently have severe scoliosis in the direction of the diaphragm defect. They also frequently have severe esophageal reflux disease.

Most cases of congenital diaphragmatic hernia can be diagnosed in utero with ultrasonography. Physical examination may yield the following findings: scaphoid abdomen (because the abdominal contents are in the thorax), decreased breath sounds, displaced heart sounds (because the heart is pushed away from the hernia), and severe cyanosis (from lung hypoplasia and pulmonary hypertension). The diagnosis is established with chest radiography.

The general treatment of infants with congenital diaphragmatic hernia involves neonatologists and pediatric surgeons. Initial treatment is insertion of an ETT, paralysis, and mechanical ventilation. A large sump tube is placed in the stomach and connected to continuous suction. These therapies allow adequate ventilation and oxygenation and prevent gas insufflation of the intestine. Most centers delay surgical repair for several days to allow the natural decrease in PVR. On day 7 to 10 of life, a surgeon closes the defect. This scenario occurs only for infants with easily correctable pulmonary hypertension. Infants with severe pulmonary hypertension may need HFV

and ECMO. At some centers, the diaphragm is repaired during ECMO. Most centers try to wean the infant from ECMO and then perform the repair. Despite all these advanced therapies, the mortality for this disease is high.[151] Survival depends on many complex variables (e.g., liver herniation into the thorax, fetal head-to-lung ratio, initial PaO_2, and $PaCO_2$).[149,151]

Abdominal Wall Abnormalities

Because all newborns are primarily abdominal breathers, the abdominal wall is an intrinsic part of the respiratory system. Large defects in the abdominal wall can cause severe respiratory compromise.[152-154] One of the most common of these defects is omphalocele. An omphalocele is an abdominal wall defect that involves the insertion of the umbilical cord. The umbilical cord goes into the omphalocele. The bowel of an infant with an omphalocele is usually covered by a membrane that looks like the surface of the umbilical cord. Occasionally, the omphalocele membrane ruptures and exposes the bowel of the infant. Omphaloceles must be distinguished from gastroschisis. Gastroschisis is an abdominal wall defect that is completely separate from the insertion of the umbilical cord. The bowel of an infant with a gastroschisis is not covered by a membrane and is outside of the abdomen. Because the bowel has been out of the abdomen, the abdominal cavity is small. There are two methods of repairing gastroschisis. If the abdominal cavity is of sufficient size and the amount of bowel outside is small, a primary closure is done in which all of the bowel is returned to the abdominal cavity and the small defect is closed. However, if the abdominal cavity is too small or the amount of bowel is too large, the surgeons will place the bowel into a Silastic chimney (or silo). The open end is inserted into the defect and the closed end is suspended from the bed. Over the next several days, gravity and the gradual stretching of the abdominal wall will allow the bowel to come back into the abdomen.

Usually only large omphaloceles cause respiratory distress. When they are greater than 10 cm in diameter, these defects can cause severe respiratory distress and frequently require prolonged mechanical ventilation. Infants with gastroschisis usually have normal lungs. However, if they need to be have a silo placed, this is like a water column (the height of bowel in the silo) applying pressure against the diaphragm. These infants will need an end-tidal pressure to support FRC.

Neuromuscular Control

Many diseases of poor neuromuscular control affect newborns,[155-159] including spinal muscular atrophy, congenital myasthenia gravis, and myotonic dystrophy. These diseases frequently require respiratory support in the newborn and pediatric periods. The morbidity and mortality of these diseases are extremely variable. New technologies may allow noninvasive respiratory support of some patients.[158,160,161] Some diseases can be quite severe in the newborn period and be relieved with age. It is important to make an accurate diagnosis to be able to estimate prognosis and provide genetic counseling. Many of these diseases are inherited with known inheritance patterns.

MINI CLINI

Delivery of an Infant With an Abdominal Wall Defect

PROBLEM: The RT is called to the delivery room to assist in the delivery of a term infant with an abdominal wall defect. What should the RT consider for assisting this infant?

DISCUSSION: There are many types of abdominal wall defects. The two most common are gastroschisis and omphalocele. These anomalies can be differentiated by whether the insertion of the umbilical cord into the abdomen is involved in the defect. In a gastroschisis, the umbilical cord inserts directly into the abdomen and is separate from the defect. In an omphalocele, the umbilical cord inserts directly into the defect. Although there is usually a membrane covering the bowel in an omphalocele, if the membrane has ruptured, the only means of distinguishing an omphalocele is by the umbilical cord insertion.

Most infants with these abdominal wall defects are term. Most do not have significant lung disease. An abdominal wall defect increases the intraabdominal pressure. It pushes the diaphragm up into the thorax, decreasing FRC. The RT should be aware that these patients will need support of their FRC. Typically, if the FRC can be supported with CPAP or PEEP, the infant will not need high rates or a high V_T to achieve adequate gas exchange.

Congenital Heart Disease

A full discussion of congenital heart disease is beyond the scope of this chapter. However, basic knowledge of the common defects is essential to good practice in pediatric and neonatal respiratory care. Congenital heart diseases usually are divided into two large categories: cyanotic and acyanotic heart disease.[162,163] Cyanotic heart diseases are diseases in which blood shunts from right to left, bypassing the lungs, and is deoxygenated. Acyanotic heart diseases are diseases in which blood shunts from left to right, causing congestive heart failure. Figure 34-6 compares normal cardiac anatomy with the features of the five most common congenital defects.

Cyanotic Heart Diseases

The two most common cyanotic heart diseases are tetralogy of Fallot and transposition of the great arteries.

Tetralogy of Fallot. **Tetralogy of Fallot** is a defect that includes (1) obstruction of right ventricular outflow (pulmonary stenosis), (2) ventricular septal defect (a hole between the right and left ventricles), (3) dextroposition of the aorta, and (4) right ventricular hypertrophy. Tetralogy of Fallot varies between mild disease, which is initially diagnosed in early childhood, and severe disease, which is diagnosed in the newborn period.[163-165] The mild form of the disease manifests as a heart murmur, intermittent severe cyanotic spells, a history of the infant squatting or entering a knee-chest position, or a combination of these features. The severe form of the disease manifests as a heart murmur and severe continuous cyanosis. Most

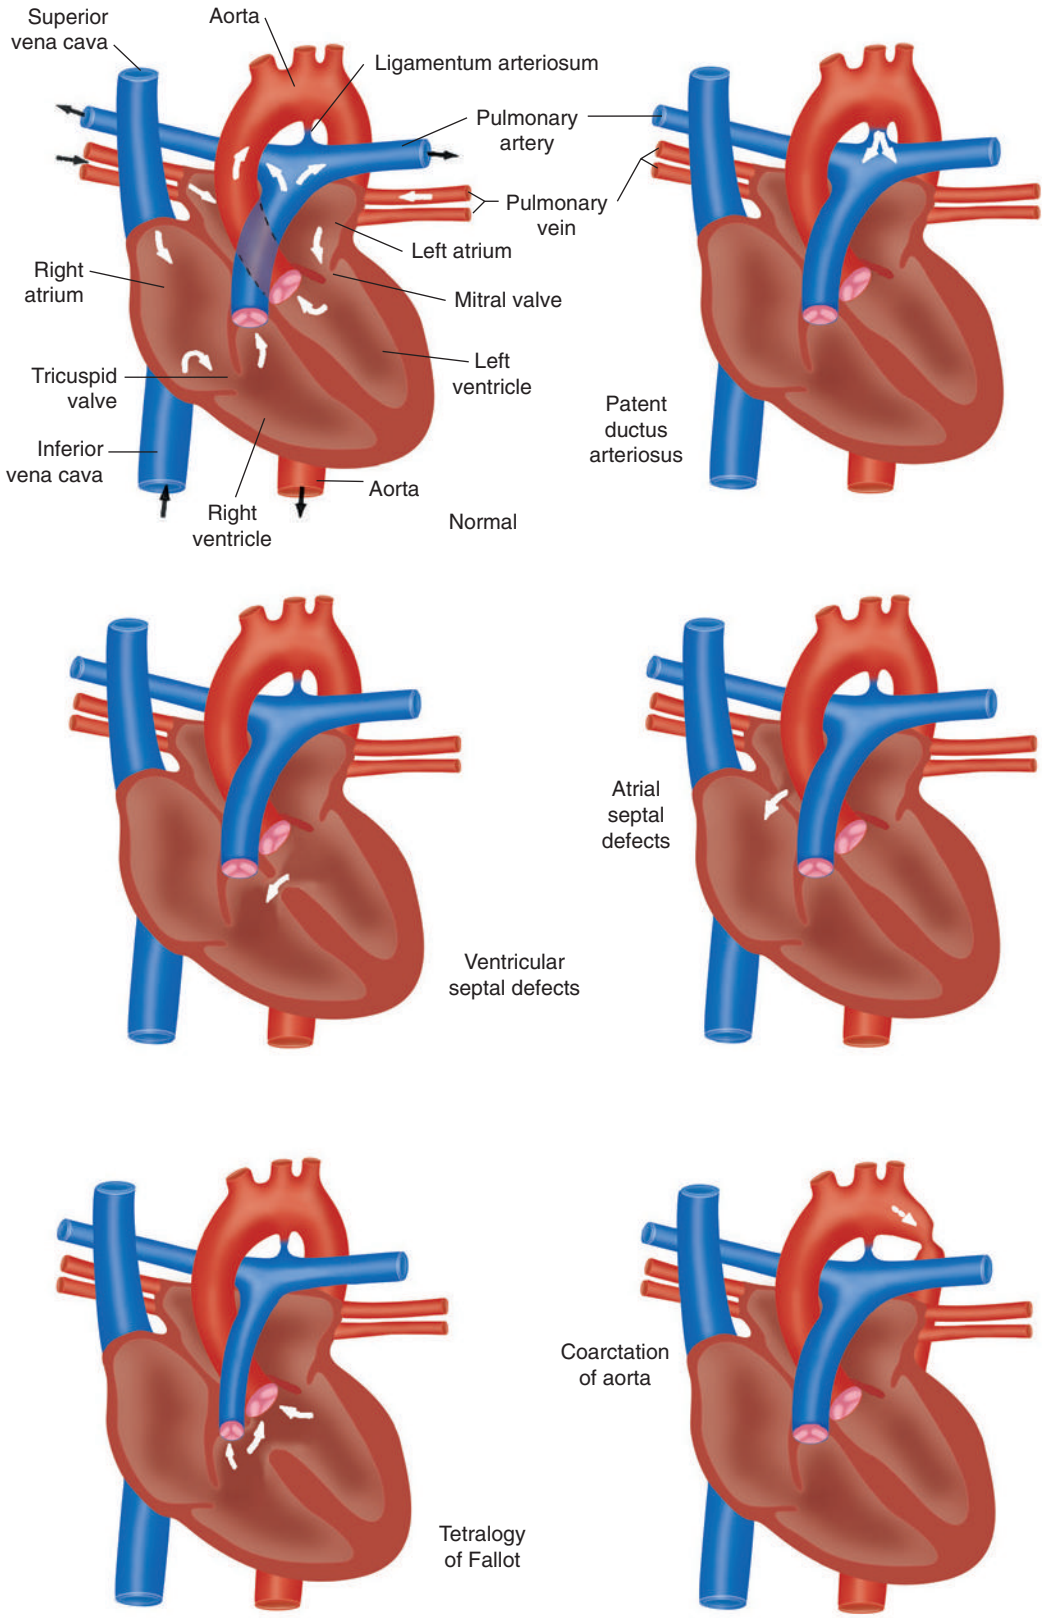

FIGURE 34-6 Normal flow of blood through the heart and some congenital defects that cause abnormal flow. (Modified from Jacob S, Francone C, Lossow WJ: Structure and function in man, ed 5, Philadelphia, 1982, Saunders.)

types of tetralogy of Fallot can be managed surgically. All infants with tetralogy of Fallot should be evaluated for deletions on chromosome 22 (22q11).[166] The type and timing of the surgery depend on the anatomy of the defects. Children with this defect are at increased risk for sudden death from arrhythmia later in life.

Transposition of the Great Arteries. **Transposition of the great arteries** is the heart disease that most frequently causes severe cyanosis.[162,163,167,168] It usually manifests as moderate to severe cyanosis immediately after birth. A murmur may be present. Infants with this abnormality frequently need emergency atrial septostomy (cutting a hole in the wall between the two atria). This procedure historically has been performed in heart catheterization laboratories. Many pediatric cardiologists who perform invasive procedures have begun performing this procedure with ultrasound guidance in the neonatal intensive care unit. The condition of infants who need atrial septostomy usually stabilizes. The goal is to allow PVR to decrease and then to perform the arterial switch operation in week 2 or 3 of life.

RULE OF THUMB

An infant with profound cyanosis at birth most likely has cyanotic heart disease or PPHN.

Hypertension of the Newborn

Acyanotic Heart Diseases

Some of the most common and most severe congenital heart diseases are acyanotic. Ventricular septal defect is probably the most common congenital heart disease. Hypoplastic left heart syndrome is one of the most severe congenital heart diseases.

Ventricular Septal Defect. Defects along the septum separating the right and left ventricles are quite common. Ventricular septal defect (VSD) can occur alone or in combination with other anomalies. A simple VSD usually causes left-to-right shunting and congestive heart failure. This defect usually does not appear immediately after birth. It appears at 6 to 8 weeks of age, when the PVR has decreased enough that the shunt becomes large.

Historically, closure of VSDs has required surgery. In the last few years many VSDs have been able to be closed during heart catheterization.[169-173]

Atrial Septal Defect. The most common type of atrial septal defect is a small, slitlike opening that persists after closure of the foramen ovale.[174] An isolated atrial septal defect is of little clinical importance. As with VSDs, some ASDs can be closed during heart catheterization.[171,175-178]

Patent Ductus Arteriosus. In a fetus, most of the pulmonary blood flow is shunted through the ductus arteriosus to the aorta. Closure of the ductus normally occurs 5 to 7 days after birth of a term infant. Patent ductus arteriosus usually is a disease of immature, preterm infants. Factors altering pressure gradients or affecting smooth muscle contraction can cause the ductus not to close or to reopen after it has closed. Depending on the pressure gradients established, shunting through an open ductus may be either right to left (pulmonary pressure greater than aortic) or left to right (aortic pressure greater than pulmonary). Treatment is either pharmacologic (indomethacin) or surgical (ligation). In recent years, the best timing of treatment and the treatment mechanism have become quite controversial.[179,180]

Left Ventricular Outflow Obstructions. Hypoplastic left heart syndrome (Figure 34-7), interrupted aortic arch, and coarctation of the aorta have in common obstruction of left ventricular outflow.[181] They all manifest in the newborn period with symptoms of acute heart failure. Systemic blood flow depends on patency of the ductus arteriosus. When the ductus spontaneously closes (usually at 5 to 7 days of age), severe congestive heart failure develops. The symptoms range from moderate respiratory distress to complete cardiovascular collapse.

MINI CLINI

Newborn With Transposition of the Great Arteries

PROBLEM: The RT is called to the delivery room to assist in the delivery of an infant to be born by repeat cesarean section without rupture of membranes. The fetus has had reassuring heart rate patterns in utero. There is no evidence of meconium. After delivery, the infant is breathing comfortably but fails to "pink up" (i.e., the infant is cyanotic). The transcutaneous O_2 saturation stabilizes in the low 70s despite mask-bag ventilation with an FiO_2 of 1. What should the RT consider as the source of this problem?

DISCUSSION: The most common reasons for a significantly cyanotic term infant immediately after delivery include pneumothorax, persistent pulmonary hypertension, and cyanotic heart disease. Spontaneous pneumothorax occasionally can occur. The infant should have decreased breath sounds in the affected hemithorax. These infants usually have a significant increase in work of breathing; excluding pneumothorax leaves persistent pulmonary hypertension and cyanotic congenital heart disease as the main differential diagnoses. The two most likely cyanotic congenital heart diseases to manifest with significant cyanosis immediately after birth are transposition of the great arteries (particularly with an intact ventricular septum) and tetralogy of Fallot (particularly with pulmonary atresia instead of pulmonary stenosis). An echocardiogram must be done as soon as possible to distinguish between these three possibilities.

Infants with cyanotic heart diseases are cyanotic. Some of these infants have saturations in the low 80s. Some of them have saturations in the 40s to 50s. Attempts to improve oxygenation with increased delivery of O_2 would be unsuccessful. Increased O_2 delivery would lead to problems with O_2 toxicity. Improvement in systemic oxygenation occurs only by developing a left-to-right shunt in the central circulation. Acutely, this shunt can be managed with administration of prostaglandin to reopen the ductus arteriosus. Long-term management requires intervention by cardiac catheterization or surgery.

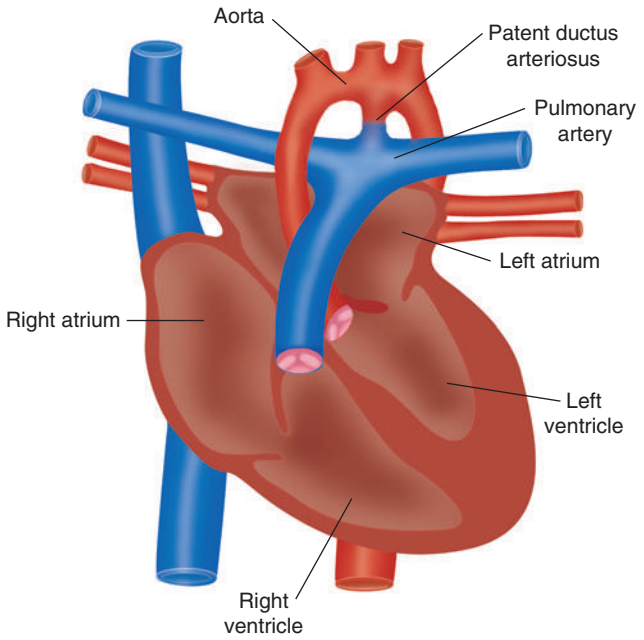

FIGURE 34-7 Hypoplastic left heart syndrome.

Box 34-1 Factors Associated With Increased Frequency of Sudden Infant Death Syndrome

MATERNAL CHARACTERISTICS
- Younger than 20 years
- Poor
- African American, Native American, or Alaskan Native
- Previous fetal loss
- Cigarette smoking
- Narcotic abuse
- Illness during pregnancy
- Inadequate prenatal care

INFANT CHARACTERISTICS AT BIRTH
- Male gender
- Premature birth
- Small for gestational age
- Low Apgar score
- Resuscitation with O_2 and ventilation at birth
- Second or third in birth order or of a multiple birth
- Sibling death from SIDS

From Koff PB, Eitzman DV, Neu J: Neonatal and pediatric respiratory care, ed 2, St Louis, 1993, Mosby.

Initial treatment is intravenous administration of prostaglandin E_1. Most infants with these defects need support with mechanical ventilation. These infants do not have lung disease. The pressures and rates used should be set appropriately.

There are standard surgical repairs for both interrupted aortic arch and coarctation of the aorta. Hypoplastic left heart syndrome has several accepted treatments, including a palliative surgical procedure (Norwood) and transplantation.[181-184] Neither the Norwood procedure nor transplantation is ideal, and each option has significant associated problems. The decision must be made in consultation with the family.

NEONATAL RESUSCITATION

Resuscitation of the newborn is a subset of resuscitation techniques. Most infant resuscitations occur in the delivery room. Although these resuscitations can range from minimal intervention to full resuscitation, more than 90% of them can be successfully dealt with by stimulation, ensuring the presence of an airway, and providing breathing support.[185-188] RTs are very important members of any resuscitation team. Their expertise in establishing and supporting an airway and initiating respiratory support is essential. It is beyond the scope of this chapter to delineate the guidelines of neonatal resuscitation. The reader should refer to the neonatal resuscitation guidelines published by the American Academy of Pediatrics (AAP).[185-188]

PEDIATRIC RESPIRATORY DISORDERS

Compared with the common cardiopulmonary diseases in the neonatal period, the pulmonary conditions that occur among older infants and children commonly result from airway obstruction caused by bacterial or viral infections. Other entities discussed in this section include asthma, SIDS, gastroesophageal reflux disease, and cystic fibrosis.

Sudden Infant Death Syndrome

SIDS is the leading cause of death (40%) among infants younger than 1 year in the United States. Approximately 7000 infants die of SIDS each year in the United States.[99,102,189,190] A presumptive diagnosis is based on the conditions of death in which a previously healthy infant dies unexpectedly, usually during sleep. Autopsy shows that many infants who die of SIDS have evidence of repeated episodes of hypoxemia or ischemia. Factors associated with increased frequency of SIDS are presented in Box 34-1. If the infant is found and resuscitation is successful, the diagnosis would be apparent.

Cause

The cause of SIDS is unknown. Apnea of prematurity is not a predisposing factor, and there is no evidence that immaturity of the respiratory centers is a cause. Although infants in families in which two or more SIDS deaths have occurred are at slightly higher risk, there is no evidence of a genetic link. The best knowledge of SIDS comes from population or epidemiologic studies and is summarized in Box 34-2. An infant who dies of SIDS typically is a preterm African-American boy born to a poor mother younger than 20 years of age who received inadequate prenatal care. Infants 1 to 3 months old are most susceptible, and death is most likely to occur at night during the winter. The risk for SIDS also is high among infants who previously experienced an apparent life-threatening event. Such an event occurs when an infant becomes apneic, cyanotic, or limp enough to frighten the parent or caregiver. The prone sleeping position has been strongly associated with increased risk for SIDS. It is difficult to differentiate death from SIDS and death

Box 34-2 Infant Characteristics Near the Time of Death From Sudden Infant Death Syndrome

- Age younger than 6 months (peak between 1 month and 3 months)
- Winter season
- Asleep at night
- Mild illness in week before death
- History of apparent life-threatening event
- Prone sleep position
- Mother smokes cigarettes

from intentional suffocation. The possibility of intentional suffocation must be investigated but with great sensitivity.[109,191,192]

Prevention

Because of the unknown causation and unexpected occurrence, there is no therapy for SIDS. Prevention is the goal. Successful prevention requires that infants at high risk be identified through a history of risk factors and documented monitoring or event recording. After identification that an infant is at risk, the family is trained in apnea monitoring and cardiopulmonary resuscitation. The AAP recommends placing infants in either the supine or the side-lying position for the first 6 months of life and reducing soft objects in the infant's sleeping environment.[109,191-193] To define the need and appropriate approach for home monitoring of infants, the AAP has developed a policy statement on infantile apnea and home monitoring.[109,191] The AAP recommendations for the need for and use of home monitoring are summarized in Box 34-3.

Box 34-3 American Academy of Pediatrics Recommendations on Home Apnea Monitoring

1. Home cardiorespiratory monitoring should not be prescribed to prevent SIDS.
2. Home cardiorespiratory monitoring may be warranted for premature infants who are at high risk for recurrent episodes of apnea, bradycardia, and hypoxemia after hospital discharge. The use of home cardiorespiratory monitoring in these infants should be limited to approximately 43 weeks postmenstrual age or after the cessation of extreme episodes, whichever comes last.
3. Home cardiorespiratory monitoring may be warranted for infants who are technology-dependent (tracheostomy, CPAP), have unstable airways, have rare medical conditions affecting regulation of breathing, or have symptomatic chronic lung disease.
4. If home cardiorespiratory monitoring is prescribed, the monitor should be equipped with an event recorder.
5. Parents should be advised that home cardiorespiratory monitoring has not been proved to prevent sudden unexpected deaths in infants.
6. Pediatricians should continue to promote proved practices that decrease the risk for SIDS, including supine sleep position, safe sleeping environments, and elimination of prenatal and postnatal exposure to tobacco smoke.

From Committee on Fetus and Newborn: American Academy of Pediatrics: Apnea, sudden infant death syndrome, and home monitoring. Pediatrics 111(4 Pt 1):914–917, 2003.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is the regurgitation of stomach contents into the esophagus and is common in childhood. Some causes of GERD are not pathologic. There is general agreement that there are important interactions between GERD and various disorders of the respiratory system.[194] Respiratory problems caused by gastroesophageal reflux include reactive airways disease, wheezing, aspiration pneumonia, laryngospasm, stridor, chronic cough, choking spells, and apnea.[194-198] GERD should be considered when an infant has faced a sudden life-threatening event and when an older child has unexplained chronic head and neck problems. GERD can be diagnosed with esophageal pH testing, upper gastrointestinal contrast studies, and gastric scintiscan. When GERD has been diagnosed, medical therapy can begin.[199-205] Occasional cases that do not respond to medical management may require surgical intervention.

Bronchiolitis

Bronchiolitis is an acute infection of the lower respiratory tract, usually caused by respiratory syncytial virus (RSV). Nearly 1 in 10 infants younger than 2 years of age acquires a bronchiolitis infection. The outcome is generally good, although approximately 1% of infants hospitalized for bronchiolitis die of respiratory failure. Infants most prone to respiratory failure as a consequence of bronchiolitis are very young and immunodeficient and have a comorbidity, such as congenital heart disease, BPD, CF, or childhood asthma.[206-210]

Clinical Manifestations

The clinical manifestations of bronchiolitis are inflammation and obstruction of the small bronchi and bronchioles. Bronchiolitis commonly occurs soon after a viral upper respiratory tract infection. The infant may have a slight fever with an intermittent cough. After a few days, signs of respiratory distress develop, particularly dyspnea and tachypnea. Progressive inflammation and narrowing of the airways cause inspiratory and expiratory wheezing and increase airway resistance. A chest radiograph shows signs of hyperinflation with areas of consolidation. The diagnosis of RSV infection can be established by immunofluorescent assay the same day and assists in the implementation of a treatment plan.

Prophylaxis. In recent years, passive immunization for RSV has become available.[208,210-216] Initially, passive immunization was recommended only for preterm infants with BPD. However, passive immunization is now recommended for high-risk infants younger than 2 years of age who require medical therapy for chronic lung disease, infants born at less than 32 weeks of gestational age, and infants with congenital heart disease who have cardiovascular compromise (Box 34-4).[216]

Box 34-4 American Academy of Pediatrics Recommendations for Respiratory Syncytial Virus Prophylaxis

INDICATIONS FOR RSV PROPHYLAXIS

- Preterm infants without CLD or congenital heart disease
  - Preterm infants born before 29 weeks, 0 days gestation who are younger than 12 months at the start of the RSV season
  - Not recommended for the 2 year of life
- Preterm infants with CLD
  - Infants with CLD of prematurity defined as gestational age <32 weeks, 0 days and requiring FiO_2 >21% oxygen for at least the first 28 days after birth
  - Second year of life recommendation only for those infants who continue requiring medical support during the 6-month period before the start of the second RSV season
- Infants with hemodynamically significant CHD
  - Acyanotic heart disease requiring medications to control congestive heart failure and will require cardiac surgical procedures in infants with moderate to severe pulmonary hypertension
  - Cyanotic heart defects in the first year of life
  - Infants after surgical procedures that involve cardiopulmonary bypass
    - These infants may need a postoperative dose.
  - Infants younger 2 years of age undergoing cardiac transplantation
- Children with anatomic pulmonary abnormalities or neuromuscular disorder
- Immunocompromised children
  - Children younger than 24 months of age with severe immunocompromise
- Children with Down syndrome
  - Routine us is not recommended unless they have qualifying heart disease, CLD, airway clearance issues, or prematurity
- Children with cystic fibrosis
  - Routine use not recommended unless other indications are present
  - Infants with CF and CLD or nutritional compromise in the first year of life
  - Infants with CF and severe lung disease requiring hospitalization, or abnormalities on chest radiograph/computed tomography, or weight for length less than 10%
- Alaska Native and American Indian Infants

CF, Cystic fibrosis; *CLD,* chronic lung disease; *RSV,* respiratory syncytial virus.

Treatment. Treatment of a patient with bronchiolitis varies with the severity of the infection and the clinical signs and symptoms. Many patients can be treated at home with humidification and oral decongestants. Patients with more severe symptoms (apnea) and comorbidity usually are hospitalized, and treatment is directed at relieving the airway obstruction and associated hypoxemia. Hospitalized children frequently are treated with systemic hydration and O_2 via nasal cannula, high-flow nasal cannula, hood, croup tent, or nasal cannula and assisted with airway clearance.[208,212,215,217-220] Antibiotics may be administered to control secondary bacterial infections. If bronchiolitis progresses to acute respiratory failure, mechanical ventilation is required. Because of the obstructive nature of this disorder, low respiratory rates and long expiratory times may be needed to prevent air trapping. Heliox has been used for severe airways disease requiring mechanical ventilation.[219] Vigorous bronchial hygiene, occasionally including tracheobronchial aspiration, usually is needed to maintain a patent airway (Box 34-5).

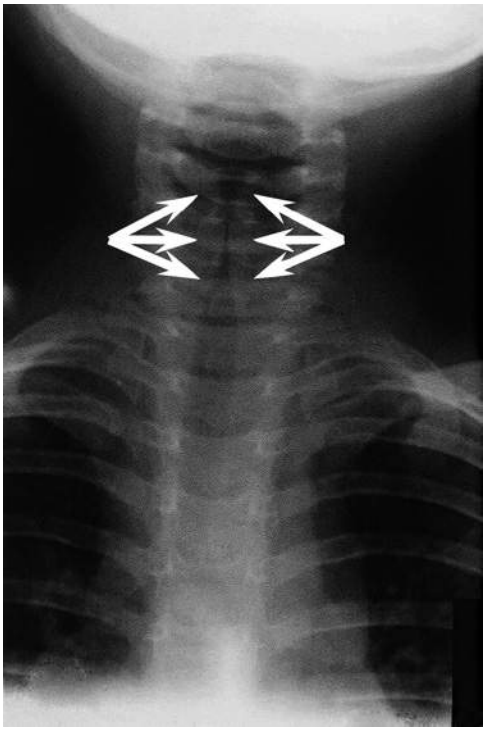

FIGURE 34-8 Anteroposterior chest radiograph of a patient with croup. Subglottic narrowing typical of croup is evident *(arrows).*

Croup

Croup is a viral disorder of the upper airway that normally results in subglottic swelling and obstruction. Termed *laryngotracheobronchitis,* viral croup is usually caused by the parainfluenza virus and is the most common form of airway obstruction in children 6 months to 6 years old. RSV and influenza virus are less common as causative agents. Bacterial superinfection with *Staphylococcus aureus,* group A *Streptococcus pyogenes,* or *Haemophilus influenzae* may worsen croup.

Clinical Manifestations

Symptoms become evident after 2 or 3 days of nasal congestion, fever, and coughing. A child typically has slow, progressive inspiratory and expiratory stridor and a barking cough. As the disease progresses, dyspnea, cyanosis, exhaustion, and agitation occur. A radiograph of the upper airway is helpful in confirming the diagnosis and ruling out epiglottitis but is usually not needed in most cases of croup. Classic croup is seen on an anteroposterior radiograph as characteristic subglottic narrowing of the trachea, called the *steeple sign* (Figure 34-8).

Box 34-5 American Academy of Pediatrics Recommendations for Diagnosis and Management of Bronchiolitis

DIAGNOSIS

1a Diagnosis and severity should be made on the basis of history and physical examination. Routine laboratory and radiologic studies are not needed.
1b Assess for history of risk factors in patients younger than 12 weeks of age.
Prematurity
Underlying cardiopulmonary disease
Immunodeficiency

TREATMENT

2a Bronchodilators should not be routinely used.
2b A carefully monitored trial of α-adrenergic or β-adrenergic is an option. Inhaled bronchodilators should be continued only if there is a documented positive clinical response.
3 Corticosteroids should not be used routinely.
4 Ribavirin should not be used routinely.
5 Antibacterial medications should be used only with specific indications of the coexistence of a bacterial infection.
6a Assess hydration and the ability to take oral fluids.
6b Chest physiotherapy should not be used routinely.
Supplemental oxygen is indicated if oxyhemoglobin saturation (SpO_2) falls persistently below 90%.
7a Supplemental O_2 should be discontinued if SpO_2 is ≥90% and the infant is feeding well and has minimal respiratory distress.
7b As the child's clinical course improves, continuous measurement of SpO_2 is not routinely needed.
7c Infants with a known history of hemodynamically significant heart or lung disease and premature infants require close O_2 monitoring as the O_2 is being weaned.

PROPHYLAXIS

8a Palivizumab prophylaxis should be done according to the new AAP Guidelines (Box 34-4).
9a Hand decontamination is the most important step in preventing nosocomial spread of RSV.
Hands should be decontaminated before and after direct contact with the patient and after contact with inanimate objects in the direct vicinity of the patient.
9b Alcohol-based rubs are preferred for hand decontamination.
9c Educate personnel and family members on hand sanitation.
10a Infants should not be exposed to passive smoking.
10b Breastfeeding is recommended to decrease a child's risk for developing a lower respiratory tract disease.
11 Inquire about the use of complementary and alternative medicines.

- Infants with chronic lung disease
  - Infants born at younger than 32 weeks of gestational age
  - Infants born at 32 to 35 weeks to gestational age who are at high risk for severe infection and younger than 90 days of age
- If two or more of following risks are present
  - Child care attendance
  - School-age siblings
  - Exposure to environmental air pollutants
  - Congenital abnormalities of the airways
  - Severe neuromuscular disease
- Infants with hemodynamically significant congenital heart disease (cyanotic and acyanotic)
- Following cardiopulmonary bypass

American Academy of Pediatrics Subcommittee on Diagnosis and Management of Bronchiolitis: Diagnosis and management of bronchiolitis. Pediatrics 118:1774–1193, 2006.

Treatment

The evaluation and treatment of a child with croup must focus on the degree of respiratory distress and associated clinical findings. If stridor is mild or occurs only on exertion and cyanosis is not present, hospitalization is generally not required and the child is treated at home. If there is stridor at rest (accompanied by harsh breath sounds, suprasternal retractions, and cyanosis with breathing of room air), hospitalization is indicated. The traditional treatment of a child with mild to moderate croup has involved cool mist therapy with or without supplemental O_2. However, there is no evidence that this practice is beneficial.[221] Corticosteroids and epinephrine have been shown to have the greatest benefit for decreasing the length and severity of respiratory symptoms associated with viral croup.[222-225] The addition of budesonide has been shown to reduce the severity of symptoms in mild to moderate cases of croup.[222-225] Progressive worsening of the clinical signs despite treatment indicates the need for intubation and mechanical ventilation. Heliox has been used for infants and children with severe disease. There is some evidence to show short-term benefit; however, long-term benefit has not yet been shown.[226]

Epiglottitis

Epiglottitis is an acute and often life-threatening infection of the upper airway that causes severe obstruction secondary to supraglottic swelling. Evidence suggests that the incidence of epiglottitis is decreasing among children and increasing in adults,[227] probably because of the use of vaccines. The most common cause is *H. influenzae* type B infection. Other organisms that are increasingly found to be causes of acute epiglottitis include group A *S. pneumoniae, S. aureus, Klebsiella pneumoniae, Haemophilus parainfluenzae,* and beta-hemolytic streptococci (groups A, B, C, and F).[228]

Clinical Manifestations

A child with epiglottitis usually has a high fever, sore throat, stridor, and labored breathing.[228-233] The patient does not have a croupy bark but instead has a muffled voice. Older children may report a sore throat and difficulty swallowing. Difficulty swallowing may cause drooling. Lateral radiographs of the neck (Figure 34-9) show the epiglottis is markedly thickened and flattened (thumb sign) and the aryepiglottic folds are swollen; the vallecula may not be visualized. Visual examination of the

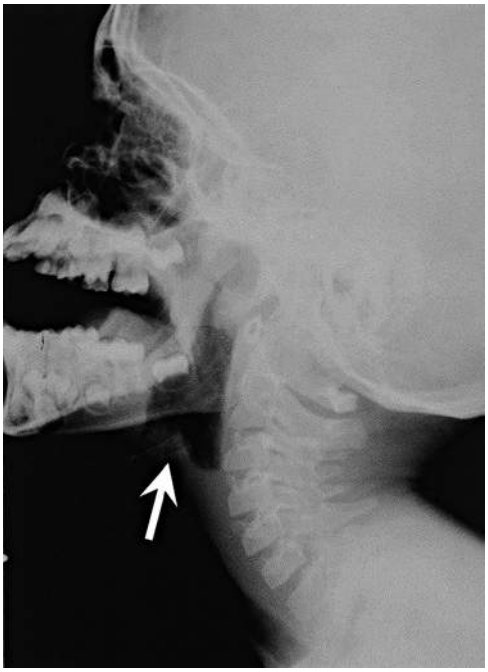

FIGURE 34-9 Lateral radiograph of the neck of a patient with epiglottitis. The thumb sign is prominent *(arrow)*.

upper airway is dangerous in these children and always should be performed in a controlled setting by personnel expert in emergency intubation. Inadvertent traction of the tongue can cause further and immediate swelling of the epiglottis and abrupt and total upper airway obstruction. Children with suspected epiglottitis should be accompanied by personnel expert in emergency intubation during any transport for diagnostic procedures.

MINI CLINI

Extubation

PROBLEM: A 3-year-old child underwent emergency intubation 5 days earlier for epiglottitis. The physician asks the RT to evaluate the patient for extubation. What would the RT evaluate before making the decision to extubate? What equipment would the RT want to have at the bedside during extubation?

DISCUSSION: Clinical examination of vital signs (e.g., body temperature), breath sounds, sensorium, and degree of airway leak should be considered. Equipment for rapid reintubation must be at the bedside, including racemic epinephrine for aerosolization.

Extubation of any patient should take into consideration the pathophysiologic condition that led to intubation. In this case, the RT should look for evidence that the infection is resolving and that the upper airway is no longer inflamed. A lack of fever for at least 12 hours and visual inspection of the throat that reveals minimal inflammation would be most helpful. After extubation, close monitoring must be performed for evidence of airway compromise. Cool mist may be helpful to minimize inflammation after extubation.

Treatment

Children with epiglottitis need elective intubation under general anesthesia in the operating room. Tracheostomy may be needed if the patient's condition warrants it; however, this procedure is rarely used. There should be no attempt to lie the child down or attempts to intubate until the child is sedated. Premature attempts at intubation can precipitate acute airway obstruction and respiratory arrest. After an airway is secured, a sample for bacterial culture should be obtained and antibiotic therapy should be started. Corticosteroids may decrease the swelling.[228,229,231,233] Children with an ETT should be sedated and restrained to prevent inadvertent extubation. Extubation should not be attempted until an upper airway leak is readily detected.

Cystic Fibrosis

Cystic fibrosis (CF) is one of the most common life-limiting autosomal recessive diseases, occurring in approximately 1 in every 3500 newborns in the United States.[234] It affects approximately 30,000 persons in the United States and 70,000 persons worldwide.[234] The incidence varies by race and ethnicity affecting approximately 1:3200 whites, 1:9500 Hispanics, 1:15,000 African Americans, and 1:31,000 in Asian Americans.[235] CF is caused by mutations in the gene that encodes a multifunctional protein called the *CF transmembrane conductance regulator (CFTR)*.[236] One of the main functions of this protein is to serve as an apical chloride channel in airway, intestinal, and exocrine cells.[237] The movement of chloride ions and regulation of sodium ions is important to the proper regulation of the water content of secretions.[238] The dehydrated viscous secretions that result from the *CFTR* abnormality lead to organ dysfunction resulting in the clinical manifestations of the disease.[238] There are over 1900 known *CFTR* mutations,[239] which are grouped into six classes that result in varying levels of *CFTR* production and dysfunction.[237] The variety of *CFTR* mutations explains some of the variability in the severity of the clinical manifestations of the disease.

RULE OF THUMB

Both parents must be carriers of the mutated CF gene *(CFTR)* for a child to be born with CF. If both parents have a deleterious *CFTR* mutation, the chance that CF will develop in their offspring is 1 in 4.

Clinical Manifestations

Patients with CF primarily experience abnormalities in the respiratory, digestive, and reproductive tracts.[240] Complications of lung disease are the leading cause of death in patients with CF.[241] The decreased airway surface liquid secondary to *CFTR*

dysfunction leads to impaired mucus clearance, resulting in inflammation and infection of the airways[238] that causes a patient to have a chronic productive cough. Chronic airway infections can occur early in life, most frequently with *S. aureus, H. influenzae,* or *Pseudomonas aeruginosa*.[234] Certain organisms, including *P. aeruginosa,* methicillin resistant *S. aureus,* and *Burkholderia cepacia,* have been associated with greater declines in lung function.[242-244] There are infection control guidelines to reduce the risk for acquiring pathogens that can be detrimental to the health of patients with CF.[245] As the disease progresses, the cycle of inflammation, infection, and lung damage results in lung hyperinflation and bronchiectasis.[237] Patients with end-stage CF lung disease have severe debility from respiratory failure and may develop pulmonary hypertension and cor pulmonale.[241]

Approximately 85% of patients with CF have exocrine pancreatic insufficiency.[234] *CFTR* dysfunction in the pancreas dramatically reduces the amount of digestive enzymes, leading to malabsorption of fats and proteins and less so for carbohydrates.[246] Malabsorption results in bulky, greasy, foul-smelling stools, fat-soluble vitamin deficiencies, and poor weight gain with failure to thrive. Some newborns present with a condition called *meconium ileus* secondary to bowel obstruction of thick and hardened meconium that sometimes results in intestinal perforation.[247] Rectal prolapse also can occur as a result of malabsorption and elimination of bulky stools.[248] Patients with pancreatic sufficiency can have recurrent bouts of pancreatitis.[249] Liver disease can result in prolonged obstructive jaundice in the newborn period.[250] Some children and adults have progressive liver disease leading to cirrhosis and portal hypertension.[251]

Males with CF have obstructive azospermia as a result of congenital absence of the vas deferens.[252] Males and females with CF often have pubertal delays.[253] Females also have reduced fertility.[254]

As children with CF age, the risk for diabetes increases, and by adulthood the majority of patients have abnormal glucose tolerance testing.[234]

The electrolyte composition of sweat in CF patients is abnormal because of the higher content of salt.[255] Increased salt losses in the sweat may lead to the initial presentation of some CF patients with hyponatremic hypochloremic metabolic alkalosis.[256] The sweat chloride test used for the diagnosis of CF is based on the abnormal concentration of chloride in the sweat of patients with the disease.[257]

Diagnosis

Since 2010, screening for CF in newborns indicating persistent hypertrypsinogenemia is performed in all 50 states and the District of Columbia.[234] The diagnosis is confirmed by a sweat chloride test performed at an accredited CF center. The skin is stimulated to produce sweat (pilocarpine iontophoresis), and a sweat chloride level greater than 60 mEq/L confirms the diagnosis of CF.[258] The diagnosis in some infants is challenging because they have two *CFTR* mutations, but a normal sweat chloride (<30 mEq/L in infants younger than 6 months).[258]

The diagnosis of CF in patients not identified by newborn screening can be made by performing a sweat test in children or adults with signs or symptoms suggestive of CF, including recurrent sinus or lung infections, bronchiectasis, nasal polyps, digital clubbing, malabsorption, failure to gain weight as expected, recurrent pancreatitis, salt-losing syndromes, and male infertility resulting from obstructive azoospermia, or if they have a sibling with CF.[258] Having two sweat chloride test results greater than 60 mEq/L confirms the diagnosis.[258]

Pancreatic insufficiency is most often diagnosed with a stool fecal elastase testing.[259]

Monitoring

CF patients should be managed at an accredited CF center.[234] The CF Foundation recommends that newborns with CF are seen soon after a positive newborn screen result and then at least on a monthly basis until 6 months of age, then every 2 months until age 1 year, and every 2 to 3 months thereafter.[259] It is recommended that older children and adults are seen quarterly at a minimum. Because CF lung disease is progressive, patients are closely monitored by symptom assessment, physical examinations, sputum cultures to monitor airway flora, and objective measurements with spirometry and chest radiography.[234] The nutritional status of each patient is also monitored very closely, including their growth, body mass index, protein stores, and fat-soluble vitamin levels.

Treatment

Multiple therapies are used to maintain a patient's lung health. Airway clearance has been a mainstay of therapy in CF.[260] There are many options for airway clearance, including percussion and postural drainage, positive expiratory pressure, autogenic drainage, autocycle of breathing technique, oscillatory positive expiratory pressure, and high-frequency chest compression.[260] Airway clearance therapies have been shown to increase sputum production, improve exercise tolerance, and decrease the rate of lung function decline.[260] In general, no specific airway clearance technique is superior to another; therefore airway clearance must be tailored to the individual patient.[260]

As a result of the cellular debris from chronic infection and inflammation, there is free DNA in the airways that contributes to the viscosity of secretions. To treat this, inhaled recombinant deoxyribonuclease (DNase) is used to degrade the viscous DNA.[261] The routine daily use of inhaled DNase has been shown to improve pulmonary function and reduce exacerbations in patients with CF.[261,262] Inhaled DNase is recommended for daily use in patients 6 years of age and older.[263] Nebulized 7% hypertonic saline is thought to improve mucociliary clearance and has been shown to improve lung function and reduce exacerbations.[264] Nebulized 7% hypertonic saline is currently recommended for twice-daily use in patients 6 years and older.[263] High doses of the antiinflammatory drug ibuprofen, when used at doses resulting in appropriate levels, reduce the progression of CF lung disease and is recommended for use in children 6 to 17 years of age with a forced expiratory volume in 1 second greater than 60% predicted.[263] The regular use of azithromycin,

possibly through its antiinflammatory and antimicrobial properties, helps preserve lung function and decreases the frequency of pulmonary exacerbations. Azithromycin is recommended in patients 6 years and older.[263] Patients taking azithromycin should be monitored for the acquisition of nontuberculous mycobacteria, at which time their azithromycin monotherapy should be discontinued.[263]

The lungs of CF patients are chronically colonized with bacteria. One of the most common organism is *P. aeruginosa,*[234] which has been associated with more rapid decline in lung function and decreased survival.[242] Inhaled antibiotics directed against this organism are recommended for eradiation and chronic suppression. Currently two inhaled antibiotics—inhaled tobramycin and inhaled aztreonam—are available for use.[263,265,266]

More recently developed therapies are aimed at correcting the underlying *CFTR* defect or potentiating its function.[237] In 2012, ivacaftor, a potentiator that activates defective *CFTR,* was approved for use in the United States in patients with a specific variant of CF—the G551D *CFTR* mutation. In 2014 the approval for use of ivacaftor was expanded to some other gating *CFTR* mutations. Ivacaftor has been shown to improve lung function and significantly reduce pulmonary exacerbations.[267] Ivacaftor also was observed to significantly decrease the sweat chloride concentration.

Lung transplantation is an option for patients with advanced severe CF lung disease.

The malabsorption secondary to deficiency of pancreatic enzymes is managed with pancreatic enzyme supplementation and vitamin supplementation.[240] Some patients also require oral calorie supplements to assist with their nutritional needs.

Prognosis

When CF was first described in 1938, children lived approximately 6 months.[268] As a result of improvements in CF care and advances in therapies, survival has significantly improved.[234] In 2002 the median age of survival was 31.3 years, and 10 years later in 2012, the median survival of patients with CF rose to 41.1 years.[234] In the near future, the number of adults will outnumber the children with CF.[234]

ROLE OF THE RESPIRATORY THERAPIST IN NEONATAL AND PEDIATRIC RESPIRATORY DISORDERS

As with any clinical situation, the role of the RT in the special environment of neonatal and pediatric care is to use his or her expertise and knowledge to improve patient outcome. Because there are significant differences in the diseases, pathophysiologies, and function of respiratory support equipment between adult and pediatric patients, the RT must be thoroughly familiar with all aspects of pediatric care. The old adage "children are not little adults" is true. Equally, newborns are not little children. Each of these age groups has unique characteristics that require specialized knowledge and experience. The RT is an important part of a team that is dedicated to the health and well-being of these fragile patients.

Also, the RT has an important role in providing education and emotional support, not only of the pediatric patient but also of the families and caregivers. Frequently, the RT is at the bedside of patients when the parents or caregivers are present. The RT is invaluable in helping patients and parents understand the respiratory goals of each individual patient.

SUMMARY CHECKLIST

- The incidence of RDS increases with decreasing gestational age.
- A qualitative decrease in surfactant increases alveolar surface tension forces in RDS patients. This process causes alveoli to become unstable and collapse and leads to atelectasis and increased work of breathing.
- The definitive diagnosis of RDS usually is made with chest radiography. Diffuse, hazy, reticulogranular densities with the presence of air bronchograms and low lung volumes are typical of RDS.
- TTN, often referred to as type II RDS, is probably the most common respiratory disorder of the newborn. The cause of TTN is unclear but is most likely related to delayed clearance of fetal lung liquid. Infants with TTN usually respond readily to low FiO_2 by O_2 hood or nasal cannula. Infants who need higher FiO_2 levels may benefit from CPAP.
- MAS is a disease of term and near-term infants. It involves aspiration of meconium into the central airways of the lung. This disorder usually is associated with perinatal depression and asphyxia.
- The best management of BPD is prevention. Prevention of atelectrauma and volutrauma begins in the delivery room.
- PPHN should be suspected when an infant has rapidly changing SaO_2 without changes in FiO_2 or has hypoxemia out of proportion to the lung disease detected on the chest radiograph or on the basis of $PaCO_2$.
- Congenital diaphragmatic hernia is a severe disease that usually manifests as severe respiratory distress in the newborn period. The pathophysiologic mechanism is a complex combination of lung hypoplasia, including decreased alveolar count and decreased pulmonary vasculature; pulmonary hypertension; and unusual anatomy of the inferior vena cava.
- The cause of SIDS is unknown. Apnea of prematurity is not a predisposing factor, and there is no evidence that immaturity of the respiratory centers is a cause.
- Bronchiolitis is an acute infection of the lower respiratory tract usually caused by RSV.
- Croup is a viral disorder of the upper airway that normally results in subglottic swelling and obstruction. Termed *laryngotracheobronchitis,* viral croup is caused by the parainfluenza virus and is the most common form of airway obstruction in children 6 months to 6 years old.
- Epiglottitis is an acute, often life-threatening infection of the upper airway that causes severe obstruction secondary to supraglottic swelling. Evidence suggests that the incidence of epiglottitis is decreasing among children,

probably because of the use of vaccines. A child with epiglottitis usually has a high fever, sore throat, stridor, and labored breathing.

- CF is the most common lethal genetic disorder among whites. It is inherited as an autosomal recessive trait that affects approximately 30,000 people in the United States. Treatment of CF lung disease requires aggressive efforts to control pulmonary infections and clear pulmonary secretions. RTs often play a key role in treating patients with CF.

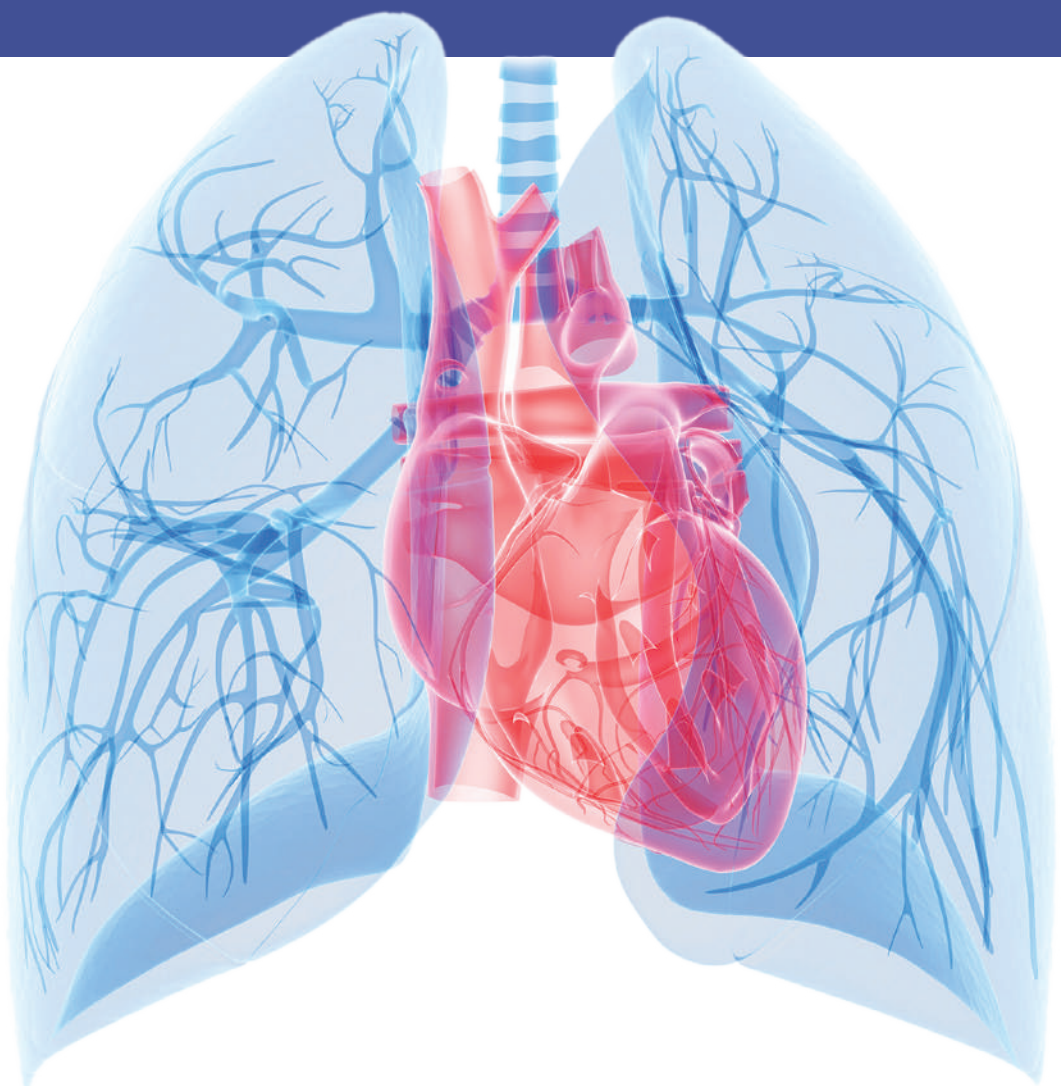
BASIC THERAPEUTICS



CHAPTER 35

Airway Pharmacology

DOUGLAS S. GARDENHIRE

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Analyze three phases that constitute the course of drug action from dose to effect.
- Describe classes of drugs that are delivered via the aerosol route.
- Compare mode of action, indications, and adverse effects that characterize each major class of aerosolized drug.
- Compare available aerosol formulations, brand names, and dosages for each specific drug class.
- Select the appropriate drug class for a specific patient or clinical situation.
- Assess the outcomes for each class of aerosol drug therapy.

CHAPTER OUTLINE

KEY TERMS

adrenergic
agonists
antagonists
antiadrenergic
anticholinergic
catecholamine
cholinergic
drug signaling
L/T ratio
leukotriene
muscarinic
neutropenia
pharmacodynamic phase
pharmacokinetic phase
prodrug
tachyphylaxis
vasopressor

The primary focus of respiratory care pharmacology is the delivery of inhaled aerosols to the respiratory tract for the diagnosis and treatment of pulmonary diseases. Although other drug classes are used in respiratory care, discussion in this chapter is limited to bronchoactive inhaled aerosols. Other drug classes are discussed in pharmacology texts.[1,2]

PRINCIPLES OF PHARMACOLOGY

The course of drug action from dose to effect comprises three phases: *drug administration, pharmacokinetic,* and *pharmacodynamic phases*. These three phases of drug action can be applied to drug treatment of the respiratory tract with inhaled agents.

Drug Administration Phase

The drug administration phase describes the method by which a drug dose is made available to the body. Administering drugs directly to the respiratory tract uses the inhalation route, and the dose form is an aerosol of liquid solutions, suspensions, or dry powders. The most commonly used devices to administer orally or nasally inhaled aerosols are the metered dose inhaler (MDI), the soft-mist inhaler Respimat, the small volume nebulizer (SVN), and the dry powder inhaler (DPI). Reservoir devices, including holding chambers with one-way inspiratory valves and simple, nonvalved spacer devices, are often added to MDIs to reduce the need for complex hand-breathing coordination and to reduce oropharyngeal impaction of the aerosol drug (see Chapter 39).

The advantages of treatment of the respiratory tract with inhaled aerosols are as follows:

- Aerosol doses are usually smaller than doses for systemic administration.
- Onset of drug action is rapid.
- Delivery is targeted to the organ requiring treatment.
- Systemic side effects are often fewer and less severe.

Disadvantages of the delivery of inhaled aerosols in treating respiratory disease include the number of variables affecting the delivered dose and lack of adequate knowledge of device performance and use among patients and caregivers.[3]

Pharmacokinetic Phase

The **pharmacokinetic phase** of drug action describes the time course and disposition of a drug in the body based on its absorption, distribution, metabolism, and elimination. Inhaled aerosols are intended for local effects in the airway. Undesired systemic effects result from absorption and distribution throughout the body.

An inhaled aerosol distributes to the lung by inhalation and the stomach through swallowing of drug that deposits in the oropharynx. The therapeutic effect of the aerosol drug is caused by the portion in the airway, whereas systemic effects are due to absorption of the drug from the airway and gastrointestinal (GI) tract. The ideal aerosol would distribute only to the airway, with none reaching the stomach. The ratio of lung availability to total systemic availability (**L/T ratio**) quantifies the efficiency of aerosol delivery to the lung:

$$\text{L/T ratio} = \text{Lung availability}/(\text{Lung} + \text{GI availability})$$

This concept, proposed by Borgström[4] and elaborated by Thorsson,[5] is illustrated in Figure 35-1, showing delivery of albuterol by inhalation using an MDI and a DPI.

Pharmacodynamic Phase

The **pharmacodynamic phase** describes the mechanisms of drug action by which a drug molecule causes its effects in the body. Drug effects are caused by the combination of a drug with a matching receptor. **Drug signaling** mechanisms include the following:

Signaling Mechanism	Example
Mediation by G protein (guanine nucleotide)–linked receptors	Beta-adrenergic agonists, antimuscarinic agents
Attachment to intracellular receptors by lipid-soluble drugs	Corticosteroids

The mechanisms of drug action are briefly described for each class of bronchoactive drug.

Airway Receptors and Neural Control of the Lung

Pharmacologic control of the airway is mediated by receptors found on airway smooth muscle, secretory cells, bronchial epithelium, and pulmonary and bronchial blood vessels. There are *sympathetic (adrenergic)* and *parasympathetic (cholinergic)* receptors in the lung. The terminology for drugs acting on these receptors is based on the usual neurotransmitter that acts on the receptor. The usual neurotransmitter in the sympathetic system is norepinephrine, which is similar to epinephrine. The usual neurotransmitter in the parasympathetic system is acetylcholine. The receptors responding to these neurotransmitters are termed *adrenergic* and *cholinergic*. **Agonists** (stimulating agents) and **antagonists** (blocking agents) that act on these receptors are given the following classifications:

- **Adrenergic** (adrenomimetic): Drug that stimulates a receptor responding to norepinephrine or epinephrine
- **Antiadrenergic:** Drug that blocks a receptor for norepinephrine or epinephrine
- **Cholinergic** (cholinomimetic): Drug that stimulates a receptor for acetylcholine
- **Anticholinergic:** Drug that blocks a receptor for acetylcholine
- **Muscarinic:** Drug that stimulates acetylcholine receptors specifically at parasympathetic nerve–ending sites

Because cholinergic receptors exist at autonomic ganglia and at the myoneural junction in skeletal muscle, the terms *muscarinic* and *antimuscarinic* distinguish cholinergic agents whose action is limited to parasympathetic sites. Neostigmine is a cholinergic (indirect-acting) drug that increases receptor stimulation at both the myoneural junction and the parasympathetic sites. By contrast, atropine is an antimuscarinic agent that blocks the action of acetylcholine only at the parasympathetic sites. Table 35-1 summarizes receptors and their effects for the cardiopulmonary system. A more detailed description of the

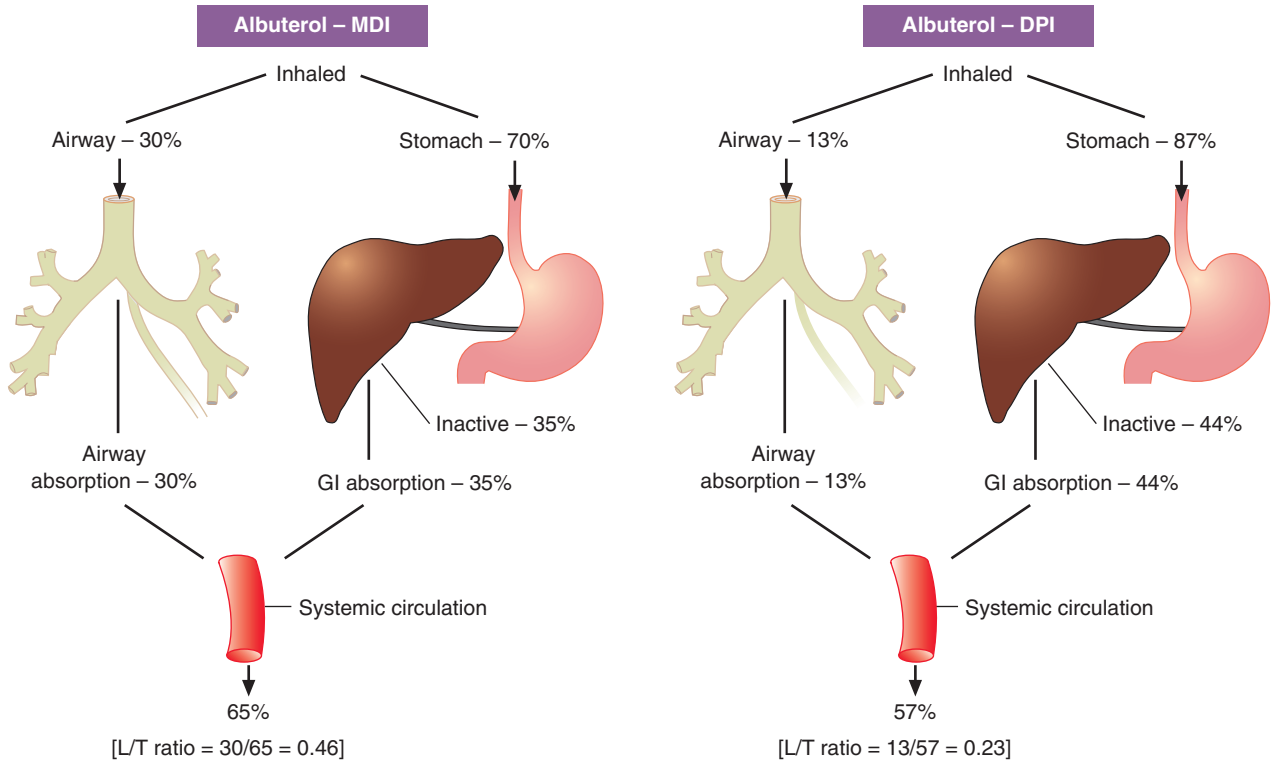


FIGURE 35-1 Comparison of efficiency of aerosol delivery with MDI and DPI using the L/T availability ratio. *L/T,* Ratio of lung availability to total systemic availability. (From Gardenhire DS: Rau's respiratory care pharmacology, ed 9, St. Louis, 2016, Elsevier.)

TABLE 35-1

Airway Receptors and Their Effects in the Cardiopulmonary System*

Location	Receptor	Effect
Heart	Beta-1-adrenergic	Increased rate, force
	M_2-cholinergic	Decreased rate
Bronchiolar smooth muscle	Beta-2-adrenergic	Bronchodilation
	M_3-cholinergic	Bronchoconstriction
Pulmonary blood vessels	Alpha-1-adrenergic	Vasoconstriction
	Beta-2-adrenergic	Vasodilation
	M_3-cholinergic	Vasodilation
Bronchial blood vessels	Alpha-1-adrenergic	Vasoconstriction
	Beta-2-adrenergic	Vasodilation
Submucosal glands	Alpha-1-adrenergic	Increased fluid, mucin
	Beta-2-adrenergic	Increased fluid, mucin
	M_3-cholinergic	Exocytosis, secretion

autonomic nervous system and receptor subtypes is provided by Katzung and colleagues.[2]

ADRENERGIC BRONCHODILATORS

Adrenergic bronchodilators represent the largest group of drugs among the aerosolized agents used for oral inhalation. Table 35-2 lists bronchodilators in this group, with their aerosol formulations, selected brand names, and dosages.

Indications for Use

The general indication for use of an adrenergic bronchodilator is the presence of reversible airflow obstruction. The most common use of these agents clinically is to improve flow rates in asthma (including exercise-induced asthma), acute and chronic bronchitis, emphysema, bronchiectasis, cystic fibrosis (CF), and other obstructive airway states.

Indication for Short-Acting Agents

Short-acting beta-2 agonists (SABAs), such as albuterol and levalbuterol, are indicated for relief of acute reversible airflow obstruction in asthma or other obstructive airway diseases. Short-acting agents are termed *rescue agents* in the 2007 National Asthma Education and Prevention Program Expert Panel III (NAEPP EPR III) guidelines.[6]

Indication for Long-Acting Agents

Long-acting beta agonists (LABAs), such as salmeterol, formoterol, arformoterol, indacaterol, and olodaterol are indicated for maintenance bronchodilation and control of bronchospasm and nocturnal symptoms in asthma or other obstructive diseases, such as chronic obstructive pulmonary disease (COPD). NAEPP EPR III guidelines consider LABAs a *controller;* its slower time to peak effect makes it a poor rescue drug. In

TABLE 35-2

Adrenergic Bronchodilator Agents Available in the United States

Drug	Brand Name	Receptor Preference	Adult Dosage	Time Course (Onset, Peak, Duration)
Ultra-Short-Acting Adrenergic Bronchodilator Agents				
Racemic epinephrine	Asthmanefrin*	Alpha, beta	SVN: 2.25% solution, 0.25-0.5 ml (5.63-11.25 mg) 4 times daily	*Onset:* 3-5 min *Peak:* 5-20 min *Duration:* 0.5-2 hr
Short-Acting Adrenergic Bronchodilator Agents				
Metaproterenol	Alupent	Beta-2	SVN: 0.4%, 0.6% solution, tid, qid Tab: 10 mg and 20 mg, tid, qid Syrup: 10 mg per 5 ml	*Onset:* 1-5 min *Peak:* 60 min *Duration:* 2-6 hr
Albuterol	Proventil HFA999, Ventolin HFA, ProAir HFA, AccuNeb, VoSpire ER	Beta-2	SVN: 0.5% solution, 0.5 ml (2.5 mg), 0.63 mg, 1.25 mg and 2.5 mg unit dose, tid, qid MDI: 90 µg/puff, 2 puffs tid, qid Tab: 2 mg, 4 mg, and 8 mg, bid, tid, qid Syrup: 2 mg/5 ml, 1-2 tsp tid, qid	*Onset:* 15 min *Peak:* 30-60 min *Duration:* 5-12 hr
Levalbuterol	Xopenex, Xopenex HFA	Beta-2	SVN: 0.31 mg/3 ml 3 times daily, 0.63 mg/3 ml 3 times daily, or 1.25 mg/3 ml 3 times daily, concentrate 1.25 mg/0.5 ml, 3 times daily MDI: 45 µg/puff, 2 puffs every 4-6 hr	*Onset:* 15 min *Peak:* 30-60 min *Duration:* 5-8 hr
Long-Acting Adrenergic Bronchodilator Agents				
Salmeterol	Serevent Diskus	Beta-2	DPI: 50 µg/blister twice daily	*Onset:* 20 min *Peak:* 3-5 hr *Duration:* 12 hr
Formoterol	Perforomist, Foradil	Beta-2	SVN: 20 µg/2 ml unit dose, bid DPI: 12 µg/inhalation, bid	*Onset:* 15 min *Peak:* 30-60 min *Duration:* 12 hr
Arformoterol	Brovana	Beta-2	SVN: 15 µg/2 ml unit dose, twice daily	*Onset:* 15 min *Peak:* 30-60 min *Duration:* 12 hr
Indacaterol	Arcapta Neohaler	Beta-2	DPI: 75 µg/inhalation, once daily	*Onset:* 5 min *Peak:* 30 min *Duration:* 24 hr
Olodaterol	Stiverdi Respimat	Beta-2	SMI: 2.5 µg/actuation, 2 actuations daily	*Onset:* 15 min *Peak:* 30-60 min *Duration:* 12 hr

DPI, Dry powder inhaler; *MDI,* metered dose inhaler; *SMI,* soft mist inhaler; *SVN,* small volume nebulizer.
*Available over-the-counter.

asthma, a long-acting bronchodilator is usually combined with antiinflammatory medication for control of airway inflammation and bronchospasm. Although some LABAs have a rapid onset and peak effect similar or better than that of albuterol, its prolonged activity makes it a better maintenance drug compared with an acute reliever or rescue agent.

Indication for Racemic Epinephrine

Racemic epinephrine is often used by inhaled aerosol or direct lung instillation for its strong vasoconstricting effect to reduce airway swelling after extubation or during epiglottitis, croup, or to control airway bleeding during endoscopy.

Mode of Action and Effects

Adrenergic bronchodilators can stimulate one or more of the following receptors, with the effects described:

- *Alpha-receptor stimulation:* Causes vasoconstriction and a **vasopressor** effect (increased blood pressure)
- *Beta-1-receptor stimulation:* Causes increased heart rate and myocardial contractility
- *Beta-2-receptor stimulation:* Relaxes bronchial smooth muscle, stimulates mucociliary activity, and has some inhibitory action on inflammatory mediator release

Bronchodilation, through stimulation of beta-2 receptors, is the desired therapeutic effect. Both alpha-adrenergic and beta-adrenergic receptors are G protein–linked receptors. Figure 35-2 illustrates the mode of action for relaxation of airway smooth muscle when a beta-2 receptor is stimulated. The nature of the beta receptor and its activity is presented in more detail by Chung and colleagues.[7]

Adrenergic Bronchodilator Agents

Adrenergic bronchodilator agents represent the evolution of a drug class. Although all of these agents are adrenergic agonists, the differences among individual agents are due to their receptor preference (alpha-adrenergic, beta-1-adrenergic,

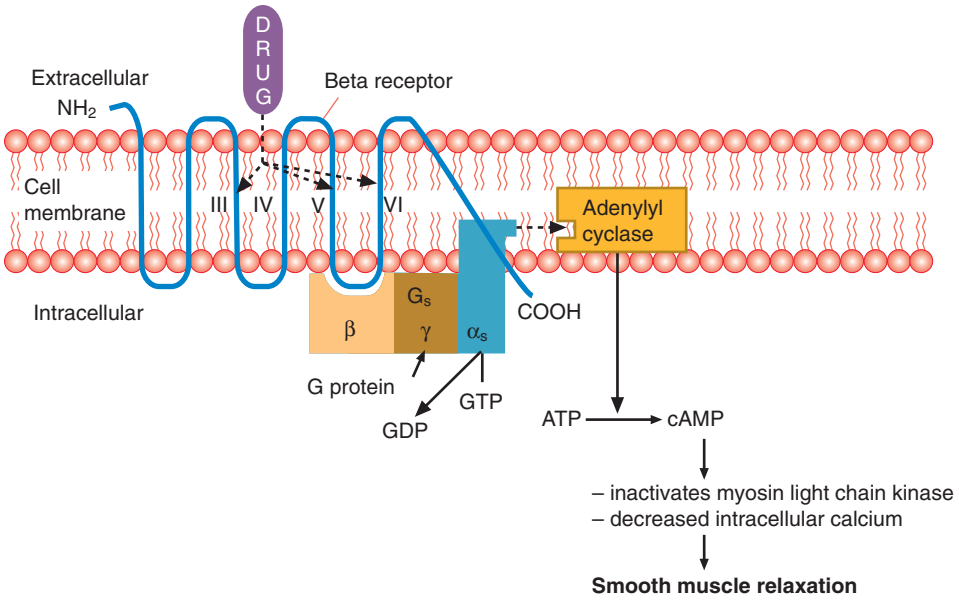

FIGURE 35-2 Mode of action by which a beta agonist stimulates the G protein–linked beta receptor to cause smooth muscle relaxation. Adrenergic agonists, such as albuterol or epinephrine, attach to beta receptors, which are polypeptide chains traversing the cell membrane seven times. This causes activation of the stimulatory G protein, designated G_S, linked to the receptor. When stimulated, the receptor undergoes a conformational change, and the alpha subunit of the G protein attaches to adenyl cyclase. Activation of adenyl cyclase by the G_S protein causes an increased synthesis of the second messenger, cyclic adenosine monophosphate (cAMP). This ultimately causes smooth muscle relaxation and bronchodilation. *ATP,* Adenosine triphosphate; *COOH,* carboxy terminus; *GDP,* guanosine diphosphate; *GTP,* guanosine triphosphate. (From Gardenhire DS: Rau's respiratory care pharmacology, ed 9, St. Louis, 2016, Elsevier.)

beta-2-adrenergic) and their different pharmacokinetics, as listed in Table 35-2. These differences determine the clinical application of individual agents. The adrenergic bronchodilators form three subgroups.

Ultra-Short-Acting Catecholamines

The older agent racemic epinephrine is a **catecholamine.** This agent lacks beta-2 specificity. As a result, cardiac effects, especially tachycardia and increased blood pressure, are common. Catecholamines are metabolized by the enzyme catechol *O*-methyltransferase, which causes a short duration of action. Because of a strong alpha-1 activity and vasoconstricting effect, racemic epinephrine is used to reduce swelling in the nose (nasal decongestant) and larynx (croup, epiglottitis) and to control bleeding during bronchoscopic biopsy.

Short-Acting Noncatecholamine Agents

Because of their short duration of action and lack of beta-2 specificity, catecholamines were replaced with longer acting, beta-2-specific agents, including metaproterenol, albuterol, and levalbuterol. Because their duration of action averages 4 to 6 hours, these drugs are better bronchodilating agents than catecholamines and can be taken on a four-times-daily schedule. However, their modest duration of action results in loss of bronchodilating effect overnight.

Single-Isomer Beta Agonists. Levalbuterol is approved as a single-isomer beta-2-selective agonist. Previous inhaled formulations of adrenergic bronchodilators all were synthetic racemic mixtures, containing both the *(R)*-isomer and the *(S)*-isomer in equal amounts. Levalbuterol is the pure *(R)*-isomer of racemic albuterol. Both stereoisomers of albuterol are shown in Figure 35-3 with the single-isomer (*R*-isomer) form of levalbuterol. Although the *(S)*-isomer is physiologically inactive on adrenergic receptors, there is evidence that the *(S)*-isomer is not completely inactive. Box 35-1 lists some of the physiologic effects of *(S)*-albuterol noted in the literature.[8-14] The effects antagonize the bronchodilating effects of the *(R)*-isomer and promote bronchoconstriction. In addition, the *(S)*-isomer is more slowly metabolized than the *(R)*-isomer.

Box 35-1 Effects and Characteristics of *(S)*-Isomer of Albuterol

- Increases intracellular calcium concentration in vitro[8]
- Activity is blocked by the anticholinergic atropine[8]
- Does not produce pulmonary or extrapulmonary beta-2–mediated effects[9]
- Enhances experimental airway responsiveness in vitro[10]
- Increases contractile response of bronchial tissue to histamine or leukotriene C_4 in vitro[11]
- Enhances eosinophil superoxide production with interleukin-5 stimulation[12]
- Slower metabolism than *(R)*-albuterol in vivo[13]
- Preferential retention in the lung when inhaled by MDI (in vivo)[14]

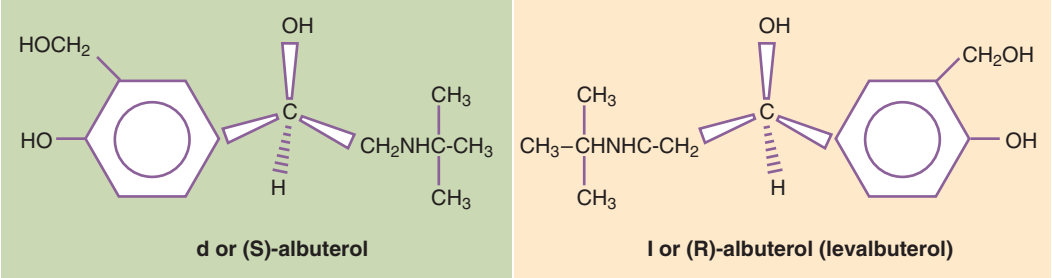

FIGURE 35-3 *(R)*- and *(S)*-isomers of racemic albuterol. Levalbuterol is the single, *(R)*-isomer form of racemic albuterol and contains no *(S)*-isomer.

Levalbuterol is available in many strengths and formulas that can be found in Table 35-2. Side effects of tremor and heart rate changes were less with the single-isomer formulation.[15] The 1.25-mg dose showed a higher peak effect on forced expiratory volume in 1 second (FEV_1) with an 8-hour duration compared with racemic albuterol. Side effects with this dose were equivalent to the side effects seen with racemic albuterol. An equivalent clinical response was seen with one-fourth of the racemic dose (0.63 mg) using the pure isomer, although the racemic mixture contains 1.25 mg of the *(R)*-isomer (half of the total 2.5-mg dose).

Long-Acting Adrenergic Bronchodilators

The release of salmeterol offered the first LABA in the United States. In contrast to previous agents, the duration of action of salmeterol is approximately 12 hours. The pharmacokinetics of salmeterol makes it suitable for maintenance therapy, in particular, with nocturnal asthma. However, it should not be used for relief of acute airflow obstruction or bronchospasm because its onset is longer than 20 minutes, with a peak effect occurring by 3 to 5 hours. Although this agent is a beta-2 agonist, its exact mode of action differs from previous beta-2 agonists, allowing persistent receptor stimulation over a prolonged period of hours.

Formoterol has a duration of effect of approximately 12 hours, but in contrast to salmeterol, the onset of action and peak effect of formoterol are rapid and similar to those of albuterol.[16] Formoterol should not be used as a rescue inhaler. As with salmeterol, the extensive side chain or tail makes formoterol more lipophilic than shorter acting bronchodilators and is the basis for its longer duration of effect.

Arformoterol, the single *(R)*-isomer of formoterol is available as a 2-ml unit dose vial inhalation solution delivering 15 mcg per dose. The recommended dosage is 1 unit dose twice daily. Arformoterol is indicated for the maintenance of bronchospasm in COPD, including chronic bronchitis and emphysema.

Indacaterol (Arcapta Neohaler) a novel once-daily therapy, LABA has been used mainly to treat asthma; however, in the United States it is indicated only in the treatment of COPD. Indacaterol is similar to formoterol, with a quick onset; however, it is even faster—with onset at approximately 5 minutes and a duration of 24 hours.[17] Indacaterol is also being studied in combination with tiotropium bromide with successful preliminary outcomes.[1]

Olodaterol is an ultra-long-acting beta agonist for once-daily treatment of COPD. Olodaterol has a quick onset similar to that of formoterol and indacaterol, with a change in FEV_1 at approximately 5 minutes.[18] Currently, olodaterol is not approved for asthma; however, it has been shown to be effective as monotherapy and in combination with tiotropium.[19]

Vilanterol is an ultra-long-acting beta agonist that is available in fixed combinations with fluticasone (Breo Ellipta) and umeclidinium (Anoro Ellipta). Vilanterol in not available as monotherapy, but has been studied with effective results in COPD.[20]

Adverse Effects

Older adrenergic agents, such as isoproterenol, commonly caused tachycardia, palpitations, and an "adrenaline effect" of shakiness and nervousness. Newer, more beta-2-selective agents are safer and typically cause tremor as the main side effect. Other common side effects with the inhaled agents include headache, insomnia, and nervousness. Patients should be reassured that some tolerance to these effects does occur. Potential adverse effects with use of adrenergic bronchodilators include the following:

- Dizziness
- Hypokalemia
- Loss of bronchoprotection
- Nausea
- Tolerance (**tachyphylaxis**)
- Worsening ventilation/perfusion ($\dot{V}/\dot{Q}$) ratio (decrease in PaO_2/SpO_2)

Inhalation results in fewer and less severe side effects than oral administration. Although tolerance develops to the bronchodilating effect, this is not a contraindication to use of the drugs, and relaxation of airway smooth muscle still occurs. Desaturation resulting from mismatching of $\dot{V}/\dot{Q}$ with inhalation of the aerosol is not clinically significant and reverses quickly. The implication of beta-2-adrenergic agonists in deaths from asthma—termed the *asthma paradox* or the *beta agonist*

controversy—remains debated.[21] There is evidence of loss of a bronchoprotective effect with use of beta agonists, and patients should be cautioned to avoid asthma triggers. The increased prevalence of asthma in general remains a troublesome and unresolved issue.

Assessment of Bronchodilator Therapy

Assessment of therapy with adrenergic bronchodilators should be based on the indication for the aerosol agent (presence of reversible airflow obstruction owing to primary bronchospasm or other obstruction secondary to an inflammatory response or secretions, either acute or chronic). Basic vital signs (respiratory rate and pattern, pulse, breath sounds) should be assessed before and after treatment, especially for initial drug use, and the patient's subjective reaction (complaints of breathing difficulty). Patients should be instructed in the correct use of the aerosol device, with verification of correct use. Finally, the patient's subjective reaction to the treatment should be monitored for any change in breathing effort. This assessment applies to all subsequent drug groups by aerosol and is not repeated for each class. The following specific actions are suggested to evaluate patient response to this class of drugs:

- Monitor flow rates using bedside peak flowmeters, portable spirometry, or laboratory reports of pulmonary function before and after bronchodilator studies to assess reversibility of airflow obstruction.
- Assess arterial blood gases (ABGs) or pulse oximetry saturation, as needed, for acute states with asthma or COPD to monitor changes in gas exchange.
- Beta agonists increase blood glucose and decrease K^+ if using high doses, such as with continuous nebulization or emergency department treatments.
- In the long term, monitor pulmonary function studies of lung volumes, capacities, and flows.
- Instruct asthmatic patients in the use and interpretation of disposable peak flowmeters to assess severity of asthmatic episodes and provide an action plan for treatment modification.
- Emphasize in patient education that beta agonists do not treat underlying inflammation and do not prevent progression of asthma and that additional antiinflammatory treatment or more aggressive medical therapy may be needed if there is a poor response to the rescue beta agonist.
- Instruct and then verify correct use of aerosol delivery device (SVN, MDI, reservoir, Respimat, DPI).
- Instruct patients in use, assembly, and cleaning of aerosol inhalation devices.

The following actions are suggested to evaluate patient response to long-acting beta agonists:

- Assess ongoing lung function, including predose FEV_1 over time and variability in peak expiratory flows.
- Assess amount of rescue beta agonist use and nocturnal symptoms.
- Assess number of exacerbations, unscheduled clinic visits, and hospitalizations.
- Assess days of absence from school or work because of symptoms.
- Assess ability to reduce the dose of concomitant inhaled corticosteroids.

Note: Death has been associated with excessive use of inhaled adrenergic agents in severe acute asthma crises. Individuals using such drugs should be instructed to contact a physician or an emergency department if there is no response to the usual dose of the inhaled agent.

Because of the ongoing safety concerns of long-acting beta-2 agonists, the U.S. Food and Drug Administration (FDA) is requiring changes on how long-acting beta-2 agonists are used in the treatment of asthma. The FDA suggests that if a LABA is used, it should be done in conjunction with a corticosteroid. Once the asthma episode has improved, the LABA should be discontinued. If a child needs a LABA it is preferred that a combination product (with a corticosteroid) be used to increase adherence.

MINI CLINI

Assessing Beta-Agonist Side Effects

PROBLEM: The respiratory therapist (RT) has administered an aerosol treatment of albuterol using an MDI with a holding chamber to a 67-year-old patient with newly diagnosed COPD who was admitted for an acute exacerbation and shortness of breath. When the RT returns for the second treatment that day, the patient informs the RT that he began to feel very shaky and nervous, beginning about 30 minutes after the previous treatment. He also noticed a tremor when he held his water cup and took a drink. His pulse during the earlier treatment was 84 beats/min. Clinical assessment shows that he is coherent, has good color, is not diaphoretic, and is in no respiratory distress. His respiratory rate is 16 breaths/min and regular, and his pulse is 82 beats/min and regular. Auscultation reveals mild wheezing and scattered rhonchi, with little change from earlier breath sounds. A mild tremor is apparent when he holds his hand out. On questioning, he states that he is now feeling better, and the "shakiness" has subsided a bit.

DISCUSSION: This patient's situation exemplifies a common reaction to inhaled adrenergic bronchodilators. Although albuterol is beta-2 preferential, it is still an epinephrine-like drug and can produce side effects secondary to sympathetic stimulation. The description of the symptoms is suggestive of common adrenergic side effects (tremor, shakiness). The timing of the symptoms coincides with the pharmacokinetics of albuterol (peak effect in 30 to 60 minutes). As presented in the case description, it is important to rule out other complications. The physical examination shows no changes from the earlier treatment in his vital signs.

It is important to caution patients about "normal" expected side effects and to reassure them that the side effects decrease with tolerance to the medication. In addition, the RT needs to be alert to the possibility that patients may have deteriorated or changed their respiratory status.

RULE OF THUMB

Choosing an Aerosol Agent

An aerosol agent to treat the respiratory tract is chosen based on the indication for the agent or class of drugs and a corresponding presence of the indication in the patient.

- *Example:* Adrenergic bronchodilator. The indication is presence of reversible airflow obstruction. The patient shows a 20% improvement in FEV_1 on spirometry with use of inhaled albuterol. Choose an adrenergic bronchodilator.
- *Example:* Inhaled corticosteroid. The indication is mild, moderate, or persistent asthma. The patient with asthma reports a need to use a beta-agonist inhaler more than a few days each week and complains of waking up at night with shortness of breath. Choose an inhaled corticosteroid.

ANTICHOLINERGIC BRONCHODILATORS

A second method of producing airway relaxation is through blockade of cholinergic-induced bronchoconstriction. An important difference between beta agonists and anticholinergic bronchodilators is the active stimulatory action of the former versus the passive blockade of the latter. A cholinergic blocking agent is effective only if bronchoconstriction exists secondary to cholinergic activity.

Indications for Use

Table 35-3 lists the dosage, forms, and pharmacokinetics of anticholinergic bronchodilators available in the United States. Generally, anticholinergic agents have been found to be as effective as beta agonists in airflow improvement in COPD but less so in asthma. A nasal formulation of ipratropium is also available for relief of allergic and nonallergic perennial rhinitis, including the common cold.

Indication for Anticholinergic Bronchodilators

Anticholinergic agents are indicated as bronchodilators for maintenance treatment in COPD, including chronic bronchitis and emphysema.

Indication for Combined Anticholinergic and Beta-Agonist Bronchodilators

A combination anticholinergic and beta agonist, such as ipratropium bromide and albuterol (Combivent Respimat; DuoNeb), is indicated for use in patients with COPD receiving regular treatment who require additional bronchodilation for relief of airflow obstruction. Ipratropium bromide is also commonly used in severe asthma in addition to beta agonists, especially in acute bronchoconstriction that does not respond well to beta agonist therapy.

Mode of Action

Anticholinergic or antimuscarinic agents act as a competitive antagonist for acetylcholine at muscarinic receptors on airway

TABLE 35-3

Inhaled Anticholinergic Bronchodilator Agents*

Drug	Brand Name	Adult Dosage	Time Course (Onset, Peak, Duration)
Ipratropium bromide	Atrovent HFA	HFA MDI: 17 µg/puff, 2 puffs 4 times daily SVN: 0.02% solution (0.2 mg/ml), 500 µg 3-4 times daily Nasal spray: 21 µg or 40 µg, 2 sprays per nostril 2-4 times daily (dosage varies)	*Onset:* 15 min *Peak:* 1-2 hr *Duration:* 6 hr
Ipratropium bromide and albuterol	Combivent Respimat	SMI: Ipratropium 20 µg/puff and albuterol 100 µg/puff, 1 inhalation qid	*Onset:* 15 min *Peak:* 1-2 hr *Duration:* 6 hr
	DuoNeb	SVN: Ipratropium 0.5 mg and albuterol 2.5 mg	
Aclidinium Bromide	Tudorza Pressair	DPI: 400 µg/inhalation, 1 inhalation bid	*Onset:* 10 min *Peak:* 2 hr *Duration:* 12 hr
Tiotropium bromide	Spiriva	DPI: 18 µg/inhalation, 1 inhalation daily (1 capsule)	*Onset:* 30 min *Peak:* 3 hr *Duration:* 24 hr
Umeclidinium bromide	Incruse Ellipta	DPI: 62.5 µg/inhalation, 1 inhalation daily	*Onset:* 5-15 min *Peak:* 1-3 hr *Duration:* 24 hr
Umeclidinium bromide and vilanterol	Anoro Ellipta	DPI: Umeclidinium 62.5 µg/inhalation and vilanterol 25 µg/inhalation, 1 inhalation daily	*Onset:* 5-15 min *Peak:* 1-3 hr *Duration:* 24 hr

DPI, Dry powder inhaler; *HFA,* hydrofluoroalkane; *MDI,* metered dose inhaler; *SMI,* soft mist inhaler; *SVN,* small volume nebulizer.
*A holding chamber is recommended with MDI administration to prevent accidental eye exposure.

smooth muscle. Part of the airflow obstruction in COPD may be due to vagally mediated, reflex cholinergic stimulation. Airway irritation and inflammation stimulate afferent sensory C-fibers in the airway, which synapse with efferent vagal (cholinergic) fibers to the airway and mucous glands. The muscarinic receptor subtype on smooth muscle and submucosal mucous glands is the M_3 receptor, which is a G protein–linked receptor. The effect of acetylcholine, the usual neurotransmitter, on the muscarinic (M_3) receptors on airway smooth muscle is bronchoconstriction. The M_1 receptor at the ganglionic junction enhances cholinergic nerve transmission. The M_2 receptor is an autoreceptor inhibiting further release of acetylcholine so that blockade can increase acetylcholine release and may offset the bronchodilating effect of antimuscarinics.[22]

All anticholinergic agents have affinity for M_1, M_2, and M_3 receptors; however, the main difference is how slowly they dissociate from the receptor. Ipratropium dissociates much faster; therefore it does not have as long duration. Aclidinium, tiotropium, and umeclidinium dissociate from the M_3 receptor much slower, allowing for a much longer duration.[1] The site of action of anticholinergic agents in reversing cholinergic-induced airflow obstruction is shown in Figure 35-4.

Adverse Effects

Side effects of inhaled anticholinergics usually include the local topical effect of dry mouth, pupillary dilation, lens paralysis, increased intraocular pressure, increased heart rate, urinary retention, and altered mental state. Box 35-2 details the side effects of anticholinergics.

The actual amount of drug delivered should be considered; for example, the nebulizer dose of ipratropium is more than 10 times greater than the MDI dose (500 mcg vs. 34 mcg). If a patient receives approximately 10% of the SVN volume in the lung, a much larger dose is given with an SVN than with an MDI. Although ipratropium is not contraindicated in patients with prostatic hypertrophy, urinary retention, or glaucoma, the drug should be used with caution and adequate evaluation for possible systemic side effects in these patients. The eyes must be protected from drug exposure with aerosol use owing to accidental spraying from an MDI or with nebulizer-mask delivery. There is less chance for eye exposure with the MDI formulation than the SVN solution; a holding chamber is recommended with MDI use.

Box 35-2 Side Effects Seen With Anticholinergic Aerosol Agents*

SVN, MDI, AND DPI (COMMON)
- Cough, dry mouth

MDI (OCCASIONAL)
- Nervousness, irritation, dizziness, headache, palpitation, rash

SVN AND DPI
- Pharyngitis, dyspnea, flulike symptoms, bronchitis, upper respiratory tract infections, nausea, occasional bronchoconstriction, eye pain, urinary retention

PRECAUTIONS: Use with caution in patients with narrow-angle glaucoma, prostatic hypertrophy, bladder neck obstruction, constipation, bowel obstruction, or tachycardia.
DPI, Dry powder inhaler; *MDI,* metered dose inhaler; *SVN,* small volume nebulizer.
*Side effects were reported in a small percentage (1% to 5%) of patients.

Mucoactive Agents Available for Aerosol Administration

Drug	Brand Name	Adult Dosage	Use
N–Acetylcysteine 10%	Mucomyst	SVN: 3-5 ml	Efficacy has not been demonstrated for any lung disease
N–Acetylcysteine 20%			
Dornase alfa	Pulmozyme	SVN: 2.5 mg/ampule, 1 ampule daily*	CF
Aqueous water, saline		SVN: 3-5 ml, as ordered	Sputum induction
Hyperosmolar 7% saline		SVN: 4 ml	Airway clearance
Hyperosmolar 3% saline		SVN: 4 ml	Infantile bronchiolitis
Mannitol	Bronchitol†	DPI: 400 mg, bid	Airway clearance in CF

CF, Cystic fibrosis; *DPI,* dry power inhaler; *SVN,* small volume nebulizer.
*Nebulizer system recommended (see package insert).
†Orphan designation only.

Assessment

The assessment of bronchodilator therapy with an anticholinergic agent is the same as assessment for adrenergic agents. In addition, preexisting conditions of narrow-angle glaucoma, prostatic hypertrophy, or urinary retention warrant caution with continued evaluation.

MUCUS-CONTROLLING AGENTS

The two agents approved in the United States for oral inhalation with an effect on mucus are *N*-acetyl cysteine (NAC) and dornase alfa. Both agents are mucolytic, although their modes of action differ. Table 35-4 lists these agents, their formulations, dosages, and bland aqueous aerosols. A review by Rubin[23] provides additional detail.

N-Acetyl Cysteine

NAC is the *N*-acetyl derivative of the amino acid L-cysteine and is given by either nebulization or direct tracheal instillation.

Indications for Use

NAC is indicated to reduce accumulation of airway secretions, with concomitant improvement in pulmonary function and gas exchange and prevention of recurrent respiratory infection and airway damage. Diseases of excessive viscous mucous secretions and poor airway clearance include COPD, acute tracheobronchitis, and bronchiectasis. NAC also is used to treat or prevent liver damage that can occur when a patient takes an overdose of acetaminophen.[24] Despite excellent in vitro mucolytic activity and a long history of use, no data clearly demonstrate that oral or aerosolized NAC is effective therapy for treating any lung disease.[25] This situation may be partially due to NAC selectively depolymerizing the essential mucin polymer structure and leaving the pathologic polymers of DNA and F-actin intact in respiratory secretions.[26]

Mode of Action

NAC acts as a classic mucolytic to reduce the viscosity of mucus by substituting its own sulfhydryl group for the disulfide group in mucus, breaking a portion of the bond forming the gel structure.[26] When NAC comes into physical contact with mucus it begins to reduce viscosity and mucolytic activity increases with a higher pH of 7.0 to 9.0.

MINI CLINI

Calculating Drug Doses

PROBLEM: The dose of ipratropium bromide (Atrovent) released from the valve of the MDI is 17 mcg. With a usual dose of two actuations, this would release 34 mcg total. The SVN solution is a vial of 2.5 ml of a 0.02% strength concentration, all of which is placed in the nebulizer. Does the nebulizer dose contain the same amount of drug as the two actuations from the MDI?

DISCUSSION: The amount of drug in milligrams or micrograms can be calculated for the nebulizer solution, using the following formula for percentage strength:

$$\%\,(\text{as decimal}) = \frac{\text{Drug solute (in g)}}{\text{Total solution (in ml)}}$$

$$0.0002 = \frac{x\ \text{g}}{2.5\ \text{ml}}$$

$$x\ \text{g} = 0.0002 \times 2.5\ \text{ml} = 0.0005\ \text{g}$$

Converting 0.0005 g to milligrams gives 0.5 mg, or 500 mcg. Two actuations of the MDI release 34 mcg, whereas the dose contained in the SVN is 500 mcg (or >10 times more). The lower dose MDI is the reason that additional actuations of four or six are needed if a patient does not obtain relief. The SVN solution also may provide relief by giving a higher dose of the drug.

Side Effects

Several side effects to NAC have led to less use in patients with hypersecretory states. The drug is irritating to the airway and can produce bronchospasm, especially in subjects with asthma and hyperreactive airways. The general effect of airway irritation is counterproductive to reduction of mucus hypersecretion. To reduce the occurrence of bronchospasm, use of the 10% solution, which is less hypertonic than the 20% solution, is recommended. Pretreatment with an adrenergic bronchodilator, allowing adequate time for production of a bronchodilatory effect, can prevent or reduce airway resistance with NAC.

Other side effects that can occur include the following:

- Airway obstruction secondary to rapid liquefaction of secretions
- Disagreeable odor secondary to hydrogen sulfide
- Incompatibility with certain antibiotics (sodium ampicillin, amphotericin B, erythromycin, tetracyclines, and aminoglycosides) if mixed in solution
- Increased concentration and toxicity of nebulizer solution toward end of treatment. It is recommended to dilute with equal volume of sterile water to reduce concentration that may lead to airway irritation
- Nausea and rhinorrhea
- Stomatitis
- Reactivity of acetylcysteine with rubber, copper, iron, and cork

Dornase Alfa

Dornase alfa (Pulmozyme) is a genetically engineered clone of the natural human pancreatic DNase enzyme, which can digest extracellular DNA material. It is a peptide mucolytic and can reduce extracellular DNA and F-actin polymers. It is occasionally referred to as *rhDNase* (recombinant human DNase). It is designated as an orphan drug. Administration and dosage are given in Table 35-4.

Indication for Use

Dornase alfa is indicated in the management of CF to reduce the frequency of respiratory infections requiring parenteral antibiotics and to improve pulmonary function of these patients.[27]

Mode of Action

Dornase alfa is a proteolytic enzyme that can break down the DNA material from neutrophils found in purulent secretions (Figure 35-5). This agent is more effective than acetylcysteine in reducing the viscosity of infected sputum in CF.[28]

Side Effects

In contrast to its predecessor, pancreatic dornase (Dornavac), a natural enzyme obtained from animal preparations, dornase alfa has not been shown to produce antibodies that might cause allergic reactions, including bronchospasm. Common side effects associated with the drug include pharyngitis and voice alteration, laryngitis, rash, chest pain, and conjunctivitis. Other effects are less common but are reported as various respiratory symptoms (cough, dyspnea, pneumothorax, hemoptysis, rhinitis, sinusitis), flu syndrome, GI obstruction, hypoxia, malaise, and weight loss. Contraindications to the drug include hypersensitivity to dornase, Chinese hamster ovary (CHO) cell products, or other components of the drug preparation.

Other Mucoactive Agents

Bland aerosols of water, including distilled water and normotonic, hypertonic, and hypotonic saline, have traditionally been nebulized to improve mobilization of secretions in respiratory disease states. The mucous gel layer is relatively resistant to the addition or removal of water after it is formed. Bland aerosols have been found to increase secretion clearance and sputum production and cause productive coughing.[29] The effect is probably a vagally mediated reflex production of cough and mucus secretion. Bland aerosols are more properly considered expectorants rather than mucolytic agents. Clinicians must be alert to the possibility of bronchospasm with nonisotonic solutions, in particular, in patients with hyperreactive airways.

Inhaled mannitol administered by DPI (Bronchitol) has been approved outside the United States. Studies have shown Bronchitol to be safe and well tolerated in treating patients with CF or bronchiectasis. However, because some children with CF experience bronchial hyperreactivity with inhaled mannitol,[30] it is important to pretreat with a short-acting bronchodilator before use.

Sodium bicarbonate has been aerosolized and directly instilled into the airway in intubated patients to reduce the

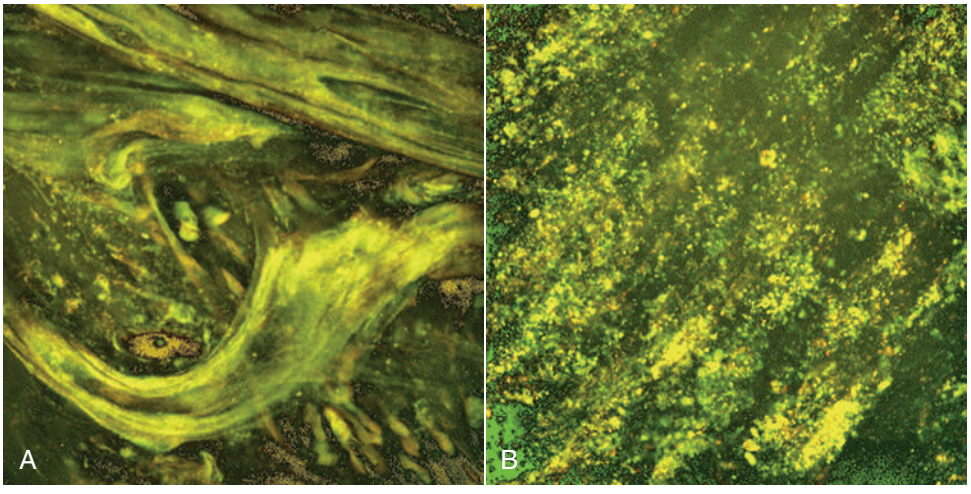

FIGURE 35-5 Illustration of the mode of action of dornase alfa in reducing DNA polymers in cystic fibrosis (CF) sputum. Confocal micrograph showing CF sputum stained (with YOYO-1) for DNA before **(A)** and after **(B)** treatment with dornase alfa in vitro. The long DNA polymers are degraded after dornase treatment. (From Gardenhire DS: Rau's respiratory care pharmacology, ed 9, St. Louis, 2016, Elsevier.)

viscosity of airway secretions. This agent is not approved for such use. The reduction in secretion viscosity is thought to be caused by the increase in topical airway pH, with degradation of bonding in the mucin polysaccharide.

Expectorants are mucoactive but stimulate the production and clearance of airway secretions rather than cause mucolysis. Examples of such agents include guaifenesin (also known as *glyceryl guaiacolate*), iodinated glycerol, and saturated solution of potassium iodide (SSKI). Guaifenesin is found in many over-the-counter cough and cold products.

Assessment of Mucoactive Drug Therapy

Assessment of drug therapy for respiratory secretions is difficult. FEV_1 is relatively insensitive to changes in mucociliary clearance. The rate of change in lung function over time is a better marker. In addition, during maintenance therapy, the volume of sputum expectorated varies from day to day and does not reflect effective therapy. The following assessments should be performed.

Before Treatment

- Assess the patient's adequacy of cough and level of consciousness to determine need for treatment with mechanical suctioning or adjunct bronchial hygiene (postural drainage or percussion, positive expiratory pressure therapy) to clear the airway or if treatment is contraindicated.

During Treatment and Short Term

- Teach and then verify correct use of aerosol nebulization system, including cleaning.
- Assess therapy based on indication for drug.
- Monitor changes in FEV_1.
- Assess the patient's breathing pattern and rate.
- Assess the patient's breathing effort or pattern.
- Discontinue therapy if the patient experiences adverse reactions.

Long Term

- Discontinue therapy if the patient experiences adverse reactions.
- Monitor number and severity of respiratory tract infections and need for antibiotic therapy, emergency visits, and hospitalizations.
- Monitor pulmonary function for improvement or slowing in the rate of deterioration.

General Contraindications

Mucoactive therapy should be used with caution in patients with severely compromised vital capacity and expiratory flow, such as in the presence of end-stage pulmonary disease or neuromuscular disorders. Generally, if FEV_1 is less than 25% of predicted, it becomes difficult to mobilize and expectorate secretions. Theoretically, with profound airflow compromise, secretion clearance could decline.

Gastroesophageal reflux and inability of the patient to protect the airway are risk factors for postural drainage that should be considered if postural drainage is necessary with mucoactive therapy. Mucoactive agents should be discontinued if there is evidence of clinical deterioration. Patients with acute bronchitis or exacerbation of chronic disease (CF, COPD) may be less responsive to mucoactive therapy, possibly secondary to infection and muscular weakness, which can reduce airflow-dependent mechanisms further.

INHALED CORTICOSTEROIDS

Corticosteroids are endogenous hormones produced in the adrenal cortex that regulate basic metabolic functions in the body and exert an antiinflammatory effect.[30] The use of aerosolized corticosteroids is reviewed in this section. All corticosteroids used to treat asthma and COPD are glucocorticoids.

Indications and Purposes

The two general formulations of aerosolized glucocorticoids are orally inhaled and intranasal aerosol preparations. Orally inhaled preparations are listed in Table 35-5. The primary use of orally inhaled corticosteroids is for antiinflammatory maintenance therapy of persistent asthma[6] and severe COPD.[31] The use of intranasal steroids is for control of seasonal allergic or nonallergic rhinitis. Most agents in Table 35-5 are available as intranasal preparations, with the exception of the combination drugs.

Mode of Action

Glucocorticoids are lipid-soluble drugs that act on intracellular receptors. The complex action of steroids is illustrated in Figure 35-6.[32-34] It is important for patients to understand that inhalation of an aerosolized steroid does not provide immediate relief as with an adrenergic bronchodilator. However, daily compliance with the inhaled medication is essential to controlling the inflammation of asthma. Oral corticosteroids may be needed initially to clear the airway or as "burst" therapy to control asthma exacerbations.

Adverse Effects

The type and severity of side effects seen with inhaled aerosolized corticosteroids are much less than with systemic use, as with other classes of aerosolized drugs. Box 35-3 lists systemic and local effects that can occur with inhaled steroids. The systemic effect of adrenal suppression is not usually seen with inhaled doses less than 800 mcg/day in adults or less than 400 mcg/day in children. Use of a reservoir device should be routine with inhaled steroids to prevent the swallowed portion adding to the systemic effect and to prevent the local effects of oral candidiasis and dysphonia. Allen and colleagues[35] published a comprehensive review of inhaled steroids.

Special Considerations

The modes of action of all inhaled glucocorticoids are the same with one exception. Ciclesonide, a **prodrug,** is given as an

TABLE 35-5

Corticosteroids and Combination Products Available by Aerosol for Oral Inhalation*

Drug	Brand Name	Formulation and Dosage
Beclomethasone dipropionate	QVAR	MDI: 40 and 80 μg/puff Adults and children ≥12 yr: 40-80 μg twice daily† or 40-160 μg twice daily‡ Children ≥5 yr: 40-80 μg twice daily

¶This dose should be used regardless of previous therapy.

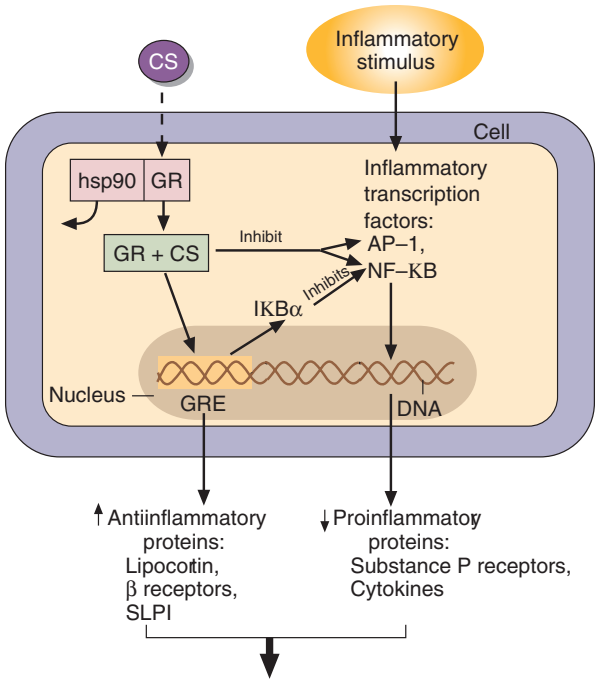

FIGURE 35-6 Mode of action by which corticosteroids modify cell response to inhibit inflammatory response in the airway. Corticosteroids *(CS)* diffuse into the cell and bind to a glucocorticoid receptor *(GR).* When the steroid binds to the GR, a protein, heatshock protein 90 (hsp 90), dissociates from the GR, and the steroid-GR complex moves into the cell nucleus. The drug-receptor complex binds to glucocorticoid response elements *(GRE)* of the nuclear DNA to upregulate transcription of antiinflammatory substances such as lipocortin, a protein that inhibits the generation of the arachidonic acid cascade by phospholipase A_2. There is evidence that steroids also upregulate inhibitors of factors in the cell, such as nuclear factor-κB (NF-κB), which can cause transcription of inflammatory substances. There may be direct inhibition of factors such as NF-κB to limit the inflammatory process further. *AP-1,* Activator protein-1; *iκBα,* inhibitor of nuclear factor-κBα; *SLPI,* secretory leukocyte protease inhibitor. (From Gardenhire DS: Rau's respiratory care pharmacology, ed 9, St. Louis, 2016, Elsevier.)

inactive compound and is converted to an active metabolite, desisobutyryl ciclesonide, by intracellular enzymes. Ciclesonide is available as an intranasal formulation (Omnaris and Zetonna) and a pressurized MDI (Alvesco).

Assessment of Drug Therapy

The basic actions to evaluate an aerosol drug treatment should be followed (see section on Assessment of Bronchodilator Therapy). As with other drug therapy, the indications for this class of drug should be present. The NAEPP and Global Initiative on Obstructive Lung Disease (GOLD) COPD guidelines are recommended for guidance.[6,31] In addition, with inhaled corticosteroids, the following actions are suggested:

- Verify that the patient understands that a corticosteroid is a controller agent and is different from a rescue bronchodilator; assess the patient's understanding of the need for consistent use of an inhaled corticosteroid (compliance).
- Instruct the patient in the use of a peak flowmeter to monitor baseline peak expiratory flow (PEF) and changes. Verify that there is a specific action plan, based on symptoms and PEF results. The patient should understand when to contact a physician with deterioration in PEF or exacerbation of symptoms.

Long Term

- Assess severity of symptoms (coughing, wheezing, nocturnal awakenings, symptoms during exertion; use of rescue bronchodilator; number of exacerbations; missed work or school days; and pulmonary function) and modify level or dosage as recommended by NAEPP and GOLD guidelines.[6,31]
- Assess for the presence of side effects with inhaled steroid therapy (oral thrush, hoarseness or voice changes, cough or wheezing with MDI use); use a reservoir (preferably a holding chamber) with MDI use, and verify correct technique.

NONSTEROIDAL ANTIASTHMA DRUGS

Nonsteroidal antiinflammatory drugs constitute a growing class of drugs in the treatment of asthma. These include mast cell stabilizers (cromolyn sodium); antileukotrienes, also termed **leukotriene** modifiers (zafirlukast, zileuton, montelukast); and monoclonal antibodies or antiimmunoglobulin E (IgE) agents (omalizumab). Antileukotrienes are administered orally, and the monoclonal antibody agent omalizumab is given parenterally, but these are included as bronchoactive drugs. Table 35-6 lists pharmaceutical details for each agent.

Indication for Use

The general indication for clinical use of nonsteroidal antiasthma agents is prophylactic management (control) of persistent asthma (Step 2 or greater asthma, using the classification in the NAEPP guidelines[6]). *Step 2 asthma* is defined as more than 2 days per week with but not daily symptoms and more than 2 nights per month with awakenings and FEV_1 of 80% or greater. *Step 3 asthma* is defined as daily symptoms and 3 to 4

MINI CLINI

Patient Education

PROBLEM: A 24-year-old patient with asthma has complained of waking up at night and being short of breath. She also reports feeling tight in her chest and needs to use her albuterol inhaler 5 to 6 days per week to get relief. She is not currently on other inhaled medications. Her allergist prescribes an inhaled MDI corticosteroid and salmeterol to be taken on a daily basis. What instructions should she be given in using these agents by inhalation?

DISCUSSION: The key points with corticosteroid inhalation should be reviewed. These are small doses and safe to take. However, it is important to take the prescribed corticosteroid dose regularly every day if the drug is to have an antiinflammatory effect in the lung. She should also use a reservoir device with the MDI. Rinsing her mouth with water after a treatment can reduce further the chance of oral candidiasis or dysphonia. With salmeterol, she should be instructed to follow her prescribed dose, which is usually two inhalations, twice daily. Because of its pharmacokinetics, salmeterol is considered a long-term controller and not a quick reliever. It is not helpful in relieving bronchospasm if she experiences acute difficulty in breathing. For acute respiratory problems, she should have a quick-acting adrenergic agent such as albuterol or levalbuterol. If she experiences wheezing or chest tightness, one or two actuations of one of these agents would help. Salmeterol should be taken at the regularly prescribed time, usually every 12 hours.

nights per month with awakening and FEV_1 greater than 60% but less than 80%. *Step 4 and above asthma* is defined as symptoms throughout the day and night awakenings more than once per week and FEV_1 less than 60%. For children older than 12 years and adults, omalizumab is available for use in asthma above Step 4.[36]

The following are qualifications to the general indications for use of these agents:

- Cromolyn sodium and antileukotrienes are typically recommended as alternatives to introducing inhaled corticosteroids in Step 2 and Step 3 asthma.
- Cromolyn sodium and montelukast in particular are often used in infants and young children as alternatives to inhaled corticosteroids in Step 2 asthma because of their safety profiles.
- Antileukotrienes can be useful in combination with inhaled steroids to reduce the dose of the steroid and are listed as alternatives in Step 2 through Step 4 asthma.
- The monoclonal antibody omalizumab is available for consideration in the appropriate population.[37]

All of the nonsteroidal antiasthma drugs described in this chapter are controllers, not relievers, and are used in asthma requiring antiinflammatory drug therapy (Box 35-4).

Mode of Action

Cromolyn sodium acts by inhibiting the degranulation of mast cells in response to allergic and nonallergic stimuli. This inhibition prevents release of histamine and other mediators of

TABLE 35-6

Nonsteroidal Antiasthma Medications*

Generic Drug	Brand Name	Formulation and Dosage
Mast Cell Stabilizer		
Cromolyn sodium		SVN: 20 mg/ampule or 20 mg/2 ml Adults and children ≥2 yr: 20 mg inhaled 4 times daily Spray†: 40 mg/ml (4%) (5.2 mg per actuation) Adults and children ≥32 yr: 1 spray each nostril, 3-6 times daily every 4-6 hr
	Gastrocrom	Oral concentrate: 100 mg/5 ml Adults and children ≥13 yr: 2 ampules 4 times daily, 30 min before meals and at bedtime Children 2-12 yr: 1 ampule 4 time daily, 30 min before meals and at bedtime
Antileukotrienes		
Zafirlukast	Accolate	Tablets: 10 and 20 mg Adults and children ≥12 yr: 20 mg twice daily, without food Children 5-11 yr: 10 mg twice daily
Montelukast	Singulair	Tablets: 10 mg and 4-mg and 5-mg cherry-flavored chewable; 4-mg packet of granules Adults and children ≥15 yr: One 10-mg tablet daily Children 6-14 yr: One 5-mg chewable tablet daily Children 2-5 yr: One 4-mg chewable tablet or one 4-mg packet of granules daily 6-23 mo: One 4-mg packet of granules daily
Zileuton	Zyflo; Zyflo CR	Tablets: 600 mg Adults and children ≥12 yr: One 600-mg tablet 4 times per day; CR, 2 tablets twice daily, within 1 hr of morning and evening meals
Monoclonal Antibody		
Omalizumab	Xolair	Adults and children ≥12 yr: subcutaneous injection every 4 wk; dose dependent on weight and serum IgE level

*Detailed prescribing information should be obtained from the manufacturer's package insert.
†Available over-the-counter.

inflammation. These mediators cause bronchospasm and trigger an increasing cascade of further mediator release and inflammatory cell activity in the airway.[38]

Zafirlukast and montelukast act as leukotriene receptor antagonists and are selective competitive antagonists of leukotriene receptors LTD_4 and LTE_4. Leukotrienes such as LTC_4, LTD_4, and LTE_4 (previously known as *SRS-A*) stimulate leukotriene receptors termed $CysLT_1$ to cause bronchoconstriction, mucus secretion, vascular permeability, and plasma exudation into the airway. The mode of action is shown in Figure 35-7. The drug inhibits asthma reactions induced by exercise, cold air, allergens, and aspirin.[39]

Zileuton inhibits the 5-lipoxygenase enzyme that catalyzes the formation of leukotrienes from arachidonic acid (see Figure 35-7).[40] Omalizumab is a recombinant DNA–derived humanized antibody that binds to IgE. The agent inhibits the attachment of IgE to mast cells and basophils, reducing the release of chemical mediators of the allergic response.[41]

Box 35-4 Bronchoactive Agents Distinguished as Controllers or Relievers in Treating Asthma

LONG-TERM CONTROL
- Inhaled corticosteroids
- Cromolyn sodium
- Long-acting beta-2 agonists
  - Inhaled: Salmeterol, formoterol
  - Oral: Sustained-release albuterol
- Leukotriene modifiers
- Systemic corticosteroids
- Methylxanthines (theophylline)

QUICK RELIEF
- Short-acting inhaled beta-2 agonists: Albuterol, levalbuterol
- Anticholinergic (antimuscarinic): Ipratropium
- Systemic corticosteroids (oral burst therapy, IV)

Adverse Effects

A potential adverse effect with any nonsteroidal antiasthma drug is inappropriate use. These agents are not bronchodilators and offer no benefit for acute airway obstruction in asthma.

Table 35-7 summarizes information and comparative features of the three antileukotriene agents, including drug interactions, common side effects, and contraindications. The most

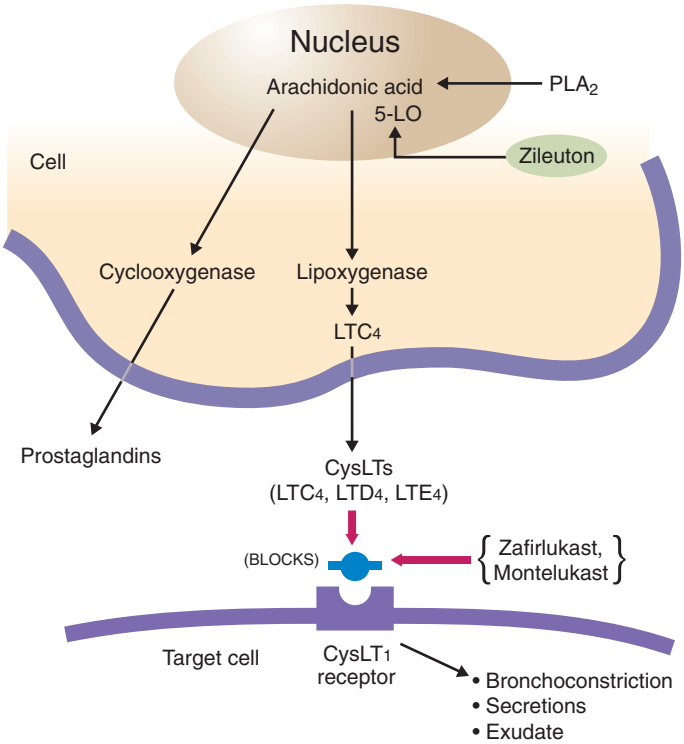

FIGURE 35-7 Modes and sites of action for leukotriene modifiers zileuton, zafirlukast, and montelukast. Zileuton inhibits the 5-LO enzyme, whereas zafirlukast and montelukast block the leukotriene receptor ($CysLT_1$). *LT,* Leukotriene; *PLA,* phospholipase A.

TABLE 35-7
Summary of Comparative Features of Three Available Antileukotriene Agents

Features	Zileuton	Zafirlukast	Montelukast
Brand name	Zyflo; Zyflo CR	Accolate	Singulair
Action	5-LO inhibitor	$CysLT_1$ receptor block	$CysLT_1$ receptor block
Age range	≥12 yr	≥5 yr	≥6 mo
Dosage	600-mg tab, qid; CR: 2 600-mg tab bid; 1 hr within morning and evening meal	Adult: 20-mg tab bid Children 5-11 yr: 10-mg tab bid	Adult: 10-mg tab q evening 6-14 yr: 5-mg tab q evening 2-5 yr: 4-mg tab q evening 6-23 mo: 4-mg oral granules q evening
Administration	Can be taken with food	1 hr before or 2 hr after meal	Taken with or without food
Drug interaction	Yes (theophylline, warfarin, propranolol)	Yes (warfarin, theophylline, aspirin)	No
Side effects (common)	Headache, dyspepsia, unspecified pain, liver enzyme elevations	Headache, infection, nausea, possible liver enzyme changes	Headache, influenza, abdominal pain
Contraindications	Active liver disease or elevated liver enzyme levels, hypersensitivity to components	Hypersensitivity to components	Hypersensitivity to components

common adverse reactions seen with omalizumab include injection site reaction, viral infections, respiratory tract infections, headache, sinusitis, and pharyngitis.

Assessment of Drug Therapy

The basic actions to evaluate an aerosol drug treatment should be followed (see section on Assessment of Bronchodilator Therapy). As with other drug therapy, the indication for this class of drug should be present.

- Verify that the patient understands that nonsteroidal antiasthma agents are controller drugs and their difference from rescue bronchodilators; assess the patient's understanding of the need for consistent use of these agents (compliance).
- Instruct the patient in use of a peak flowmeter to monitor baseline PEF and changes. Verify that there is a specific action plan, based on symptoms and PEF results. The patient should be clear on when to contact a physician with deterioration in PEF or exacerbation of symptoms.

Long Term

- Assess severity of symptoms (coughing, wheezing, nocturnal awakenings, symptoms during exertion); use of rescue medication; number of exacerbations; missed work or school days; pulmonary function), and modify level of asthma therapy (up or down, as described in the NAEPP EPR III guidelines for step therapy).
- Assess for the presence of side effects with nonsteroidal antiasthma agents; refer to the particular agent and its side effects (listed previously).

AEROSOLIZED ANTIINFECTIVE AGENTS

Multiple aerosolized antiinfective agents are available. Some agents may be used less often than others in respiratory therapy. The antiinfective agents pentamidine, ribavirin, inhaled tobramycin, inhaled aztreonam, and zanamivir are briefly outlined here. Drug formulations and dosages are given in Table 35-8.

Pentamidine Isethionate

Pentamidine isethionate (NebuPent) is an antiprotozoal agent that has been used in the treatment of opportunistic pneumonia caused by *Pneumocystis jiroveci,* which is the causative agent of *Pneumocystis* pneumonia (PCP). PCP is seen in immunocompromised patients, especially patients with AIDS.

Indication for Use

General recommendations for prophylaxis of PCP were published by the U.S. Centers for Disease Control and Prevention (CDC) for HIV-positive children[42] and adults.[43] In the 2013 CDC recommendations, oral trimethoprim-sulfamethoxazole (TMP-SMX) was preferred for prophylaxis of PCP as long as adverse side effects from TMP-SMX were absent or acceptable.[43] Aerosolized pentamidine is recommended as an alternative therapy for prophylaxis of PCP if TMP-SMX cannot be tolerated.

Adverse Effects

Possible side effects with aerosolized pentamidine include cough, bronchial irritation, bronchospasm, wheezing, shortness of breath, fatigue, bad or metallic taste, pharyngitis, conjunctivitis, rash, and chest pain. Systemic effects also have been noted with inhaled pentamidine, including decreased appetite, dizziness, rash, nausea, night sweats, chills, spontaneous pneumothoraces, **neutropenia**, pancreatitis, renal insufficiency, and hypoglycemia. Extrapulmonary infection with *P. jiroveci* can occur with prophylactic inhaled pentamidine.

Assessment

When administering aerosolized pentamidine, isolation, an environmental containment system (e.g., a booth or negative pressure room), and personnel barrier protection should be provided. Patients should be screened for tuberculosis. The drug is given using a nebulizer system with one-way valves and scavenging expiratory filters (e.g., Respirgard); this reduces environmental contamination. Nebulizer systems capable of

TABLE 35-8

Inhaled Antiinfective Agents*

Drug	Brand Name	Formulation and Dosage	Clinical Use
Pentamidine isethionate	NebuPent	300 mg powder in 6 ml sterile water; 300 mg once every 4 wk	PCP prophylaxis
Ribavirin	Virazole	6 g powder in 300 ml sterile water (20 mg/ml solution); given every 12-18 hr/day for 3-7 days by SPAG nebulizer	RSV
Tobramycin	TOBI	300-mg/5-ml ampule; adults and children ≥6 years: 300 mg bid, 28 days on/28 days off drug	*Pseudomonas aeruginosa* infection in CF
Tobramycin	Bethkis	300-mg/4-ml ampule; adults and children ≥6 years: 300 mg bid, 28 days on/28 days off drug	*P. aeruginosa* infection in CF
Aztreonam	Cayston	75 mg/1 ml; adults and children ≥7 yr: 75 mg tid, 28 days on/28 days off drug	*P. aeruginosa* infection in CF
Zanamivir	Relenza	DPI: 5 mg/inhalation; adults ≥5 years: 2 inhalations (one 5-mg blister per inhalation) bid, 12 hr apart for 5 days	Influenza

CF, Cystic fibrosis; *RSV,* respiratory syncytial virus; *PAP, Pneumocystis jiroveci* pneumonia; *SPAG,* small particle aerosol generator.
*Details on use and administration should be obtained from manufacturer's drug insert material before use.

producing a mass median diameter of 1 to 2 μm for peripheral lung deposition may reduce coughing. The patient should be monitored for onset of any of the previously described adverse reactions. In addition, the following actions are recommended:

- If coughing and bronchospasm are present, provide a short-acting beta agonist or an anticholinergic bronchodilator such as ipratropium with inhaled pentamidine.
- Monitor for occurrence rate of PCP and rate of long-term hospitalizations.
- Monitor for presence of side effects (shortness of breath, possible pneumothorax, conjunctivitis, rash, neutropenia, dysglycemia) or appearance of extrapulmonary *P. jiroveci* infection.
- Evaluate need for prior use of a bronchodilator if symptoms of bronchospasm or coughing occur after inhalation of pentamidine.

Long Term. Over the long term, monitor the efficacy of pentamidine prophylaxis in preventing episodes of PCP.

Ribavirin

Ribavirin (Virazole) is an antiviral agent used in the treatment of severe lower respiratory tract infections caused by respiratory syncytial virus (RSV). RSV is a common seasonal respiratory infection in infants and young children that is usually self-limiting. Recommendations for use of the drug were published in a statement by the American Academy of Pediatrics.[44] Generally, the drug is not recommended for routine RSV infection, but it may be considered for life-threatening infections.

Administration of the aerosol requires use of a special large-reservoir nebulizer called a *small particle aerosol generator (SPAG)*. The mode of action of ribavirin is similar to that of the drug guanosine, a natural nucleoside. Substitution of ribavirin for the natural nucleoside interrupts the viral replication process in the host cell.

Adverse Effects

Skin rash, eyelid erythema, and conjunctivitis have been noted with aerosol administration. Important equipment-related effects during mechanical ventilation include endotracheal tube occlusion and occlusion of ventilator expiratory valves or sensors. Deterioration of pulmonary function can occur. Patients or practitioners who are pregnant should not have exposure to ribavirin.

Assessment

- Monitor signs of improvement in RSV infection severity, including vital signs, respiratory pattern and work of breathing, level of FiO_2 needed, level of ventilatory support, ABGs, body temperature, and other indicators of pulmonary gas exchange.
- Monitor the patient for evidence of side effects, such as deterioration in lung function, bronchospasm, occlusion of endotracheal tube, cardiovascular instability, skin irritation from the aerosol drug, and equipment malfunction related to drug residue.

Inhaled Tobramycin

Patients with CF have chronic respiratory infection with *Pseudomonas aeruginosa* and other microorganisms. Such chronic infection causes recurrent acute respiratory infections and deterioration of lung function. With the exception of the quinoline derivatives such as ciprofloxacin, antibiotics such as the aminoglycosides (e.g., tobramycin), which are effective against *Pseudomonas* organisms, have poor lung bioavailability when taken orally. Consequently, these antibiotics must be given either intravenously or by inhalation. The aminoglycoside tobramycin has been approved for inhaled administration (TOBI) and is intended to manage chronic infection with *P. aeruginosa* in patients with CF. Goals of therapy are to treat or prevent early colonization with *P. aeruginosa* and maintain present lung function or reduce the rate of deterioration. The emergence of bacterial resistance has not been seen in clinical trials with inhaled tobramycin.[45]

Adverse Effects

Side effects with parenteral aminoglycosides include possible auditory and vestibular damage with potential for deafness and nephrotoxicity. Other possible effects are listed in Box 35-5. Risk for more serious side effects with tobramycin, whether by inhaled or parenteral routes, increases with the use of other aminoglycosides, in the presence of poor renal function and dehydration, with preexisting neuromuscular impairment, or with use of other ototoxic drugs.

The following precautions are suggested with use of inhaled tobramycin:

- Inhaled tobramycin should be used with caution in patients with preexisting renal, auditory, vestibular, or neuromuscular dysfunction.
- Tobramycin solution should not be mixed with beta-lactam antibiotics (penicillins, cephalosporins) because of admixture incompatibility, and mixing with other drugs in general is discouraged.
- Nebulization of antibiotics during hospitalization should be performed under conditions of containment, as previously described for pentamidine and ribavirin, to prevent

Box 35-5 Side Effects With Aminoglycosides and Tobramycin

PARENTERAL ADMINISTRATION

- Ototoxicity (auditory and vestibular)
- Nephrotoxicity
- Neuromuscular blockade
- Hypomagnesemia
- Cross-allergenicity
- Fetal harm (deafness)

INHALED NEBULIZED TOBRAMYCIN

- Voice alteration
- Tinnitus
- Nonsignificant increase in bacterial resistance

environmental saturation and development of resistant organisms in the hospital.
- Aminoglycosides can cause fetal harm if administered to pregnant women; exposure to ambient aerosol drug should be avoided by women who are pregnant or trying to become pregnant.
- Local airway irritation resulting in cough and bronchospasm with decreased ventilatory flow rates is possible with inhaled antibiotics and seems to be related to the osmolality of the solution.[46,47] Peak flow rates and chest auscultation should be used before and after treatments to evaluate airway changes. Pretreatment with a beta agonist may be needed.
- Allergic reactions in the patient, staff, or family should be considered if exposure to the aerosolized drug is not controlled. The use of a nebulizing system with a scavenging filter, one-way valves, and thumb control could reduce ambient contamination with the drug, as previously described.

In clinical trials, inhaled tobramycin was administered using the PARI LC Plus nebulizer with a DeVilbiss Pulmo-Aide compressor. Studies have reported that not all nebulizer-compressor systems perform adequately with antibiotic solutions, and higher flow rates of 10 to 12 L/min may be needed with nebulizers.[48,49]

Assessment

- Verify that the patient understands that nebulized tobramycin should be given after other CF therapies, including other inhaled drugs.
- Check whether the patient has renal, auditory, vestibular, or neuromuscular problems or is taking other aminoglycosides or ototoxic drugs. Consider whether tobramycin should be used for the patient based on severity of preexisting or concomitant risk factors.
- Monitor lung function to note improvement in FEV_1.
- Assess rate of hospitalization before and after institution of inhaled tobramycin.
- Assess need for intravenous antipseudomonal therapy.
- Assess improvement in weight.
- Monitor for occurrence of side effects, such as tinnitus or voice alteration; have the patient rinse and expectorate after aerosol treatments.
- Evaluate for changes in hearing or renal function during use of inhaled tobramycin.

Inhaled Aztreonam

Aztreonam was approved in December 1986 by the FDA as a monobactam, a synthetic bactericidal antibiotic; it is given as an intravenous solution. Inhaled aztreonam (Cayston) was approved in 2010 to improve pulmonary symptoms in patients with CF colonized with *P. aeruginosa*.[50] Inhaled aztreonam is not indicated for patients younger than 7 years old or patients with *Burkholderia cepacia* infection. This agent has been studied only in patients with FEV_1 greater than 25% or less than 75% of predicted. The agent is delivered by itself using the Altera Nebulizer System.

Adverse Effects

Inhaled aztreonam can cause bronchospasm and decrease FEV_1. All patients should be screened for baseline pulmonary function results and treated with a bronchodilator before administering inhaled aztreonam.

Patients have been reported to experience severe allergic reactions with injectable aztreonam. Careful observation is warranted when first using inhaled aztreonam because it could cause an allergic reaction.

The use of antibiotics in the absence of infection may lead to the development of drug-resistant bacteria. Inhaled aztreonam should not be used in patients with CF not infected with *P. aeruginosa.*

Colistimethate Sodium

Colistimethate sodium (colistin) is an antibiotic used to treat sensitive strains of gram-negative bacilli, particularly *P. aeruginosa.* Colistimethate sodium is available as an inhaled formulation in Europe as Promixin; this agent is not approved by the FDA for inhalation. However, nebulization of the parenteral formulation is commonly used in patients with CF. Falagas and colleagues[51] published a review of intravenous and aerosolized colistimethate sodium.

Adverse Effects

Side effects seen with parenteral administration include neurotoxic events and nephrotoxicity. Because colistimethate sodium is mainly eliminated by the renal system, renal insufficiency should be considered. Neurotoxic events associated with colistimethate sodium include dizziness, confusion, muscle weakness, and possible neuromuscular blockade, leading to respiratory arrest. When using aerosolized colistimethate sodium, the most common complication seen is bronchospasm. Pretreatment with a beta agonist can decrease the potential for this complication.

Inhaled Zanamivir

Zanamivir is an inhaled powder aerosol (DPI). Despite the availability of zanamivir and the oral antiinfluenza agent oseltamivir (Tamiflu), prophylactic vaccination against influenza is still recommended, especially in high-risk individuals with cardiovascular or pulmonary disease. Zanamivir and oseltamivir represent a new class of antiviral agents termed *neuraminidase inhibitors.*

Indication for Use

Inhaled zanamivir is indicated for the treatment of uncomplicated acute illness caused by influenza virus in adults and children 5 years or older who have been symptomatic for no longer than 2 days. The agents have an off-label use for treatment and prophylaxis of H1N1 influenza A.

Mode of Action

The influenza virus attaches to respiratory tract cells by binding of viral surface hemagglutinin to the cell's surface molecule of sialic acid (Figure 35-8). The viral particle also has an enzyme,

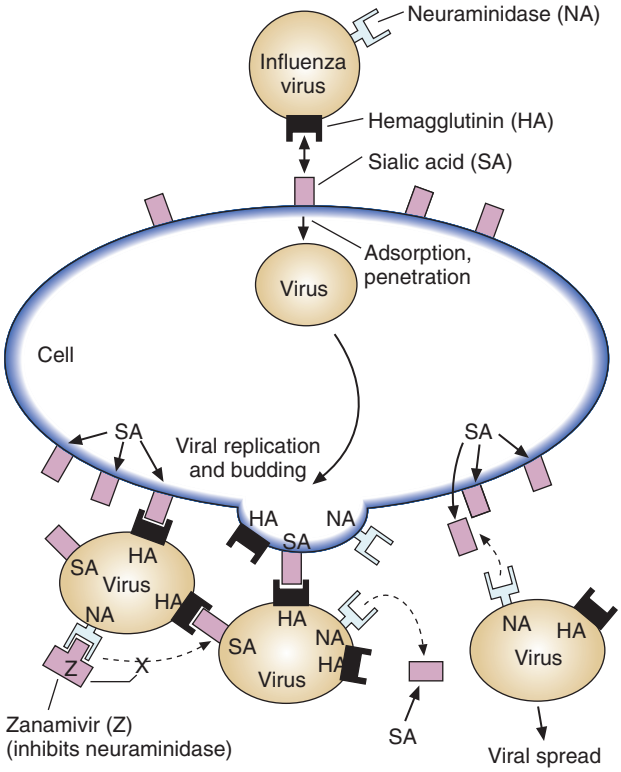

FIGURE 35-8 Mode of action by which inhaled zanamivir exerts an antiviral effect on influenza virus. Zanamivir is a sialic acid analogue and binds to neuraminidase, the enzyme responsible for cleaving sialic acid and preventing viral binding to sialic acid. This causes viral aggregation, with binding of viral particles to each other and to the host cell, preventing viral spread. *HA,* Hemagglutinin; *NA,* neuraminidase; *SA,* sialic acid. (From Gardenhire DS: Rau's respiratory care pharmacology, ed 9, St. Louis, 2016, Elsevier.)

neuraminidase, on its surface. When replicated viral particles are released from the host cell after infection, the viral neuraminidase cleaves the sialic acid on both the host cell surface and other viral particle surfaces so that mature virus can be released and spread. Without neuraminidase, influenza virus would clump together and to the host cell, preventing spread. Zanamivir and oseltamivir combine with the surface neuraminidase, preventing its action and the spread of viral particles.

Adverse Effects

Several adverse effects can occur with inhaled zanamivir:

- Bronchospasm and deterioration in lung function, especially in patients with COPD or asthma
- Possible undertreatment of bacterial infection masquerading as a viral infection or a secondary bacterial infection in the presence of influenza
- Allergic reactions, as may occur with any drug
- Adverse reactions, such as diarrhea, nausea, vomiting, bronchitis, cough, sinusitis, dizziness, and headaches

Because of the effect on lung function in patients with respiratory disease and reports of adverse reactions, revised labeling for the drug carries a warning that zanamivir is not generally recommended for patients with underlying airways disease.[52] However, other studies have determined that high-risk patients such as patients with asthma and COPD were not affected by the use of zanamivir.[53]

Clinical Efficacy

In studies of clinical efficacy, the use of zanamivir resulted in shortening of the median time to alleviation of symptoms by 1 day. In subjects who began treatment within 30 hours of illness, the median time to alleviation of symptoms was reduced by approximately 3 days.[54] Zanamivir is not approved for prophylaxis of influenza, although some data suggest a preventive effect in patients exposed to influenza virus.[53] Cost-versus-efficacy issues revolve around the modest reduction in symptoms and inability to confirm the presence of influenza quickly, easily, and inexpensively as the basis for the drug treatment.

Assessment

- Assess improvement in influenza symptoms, including fever reduction, less myalgia and headache, reduced coughing and sore throat, and less systemic fatigue.
- Monitor for airway irritation and symptoms of bronchospasm, especially during initial use of the dry powder aerosol. Provide a short-acting beta agonist if needed or if the patient is at risk for airway reactivity (COPD, asthma).

INHALED PULMONARY VASODILATORS

The use of nitric oxide gas to treat neonates with persistent pulmonary hypertension is approved by the FDA and is discussed in detail in Chapters 41 and 53. In addition to this medical gas, inhaled medications are being tested and used to treat pulmonary hypertension. Several such agents are being studied, including epoprostenol (Flolan) and alprostadil (Prostin VR Pediatric); however, only two, iloprost, and treprostinil, are approved by the FDA for widespread use. Siobal[55] published a review of aerosolized prostacyclins and nitric oxide (NO).

Nitric Oxide

Indications for Use

As described in more detail in Chapters 41 and 53, NO (INOmax) is indicated in the treatment of neonates (>34 weeks of gestational age) with hypoxic respiratory failure.[56] The patient should have evidence of pulmonary hypertension in which NO would improve oxygenation and decrease the need for extracorporeal membrane oxygenation. Off-label uses include reducing pulmonary artery pressure in the neonate, pediatric patient, and adult.[57] NO is frequently used in cardiac surgical patients who present with perioperative pulmonary hypertension although this indication is considered off label.

Mode of Action

NO is produced by cells in the body. It relaxes vascular smooth muscle by binding to the heme group of cytosolic guanylate cyclase, activating guanylate cyclase, and increasing cyclic

guanosine monophosphate. When inhaled, NO produces pulmonary vasodilation, reducing pulmonary artery pressure and improving $\dot{V}/\dot{Q}$ mismatching.

Adverse Effects

NO is contraindicated in neonates with dependent right-to-left shunts. Precautions include methemoglobinemia and NO_2 formation. The most common adverse events are hypotension and withdrawal.[58]

Iloprost

Indications for Use

Iloprost (Ventavis) inhalation is indicated for the treatment of pulmonary hypertension.[59] Iloprost inhalation is administered with the I-neb nebulizer.

Mode of Action

Iloprost is a synthetic analogue of prostacyclin (PGI_2). This agent dilates pulmonary arterial vascular beds and affects platelet aggregation. It is unknown whether platelet aggregation plays a role in the treatment of pulmonary hypertension.

Adverse Effects

Syncope and pulmonary edema may occur secondary to the vasodilatory properties of iloprost. During the 12-week clinical trial, headache and increased cough were the most noted adverse reactions.

Treprostinil

Indication for Use

Treprostinil (Tyvaso) is indicated for the treatment of pulmonary arterial hypertension to increase walking distance in patients with New York Heart Association class III symptoms.[60] It is administered using the Tyvaso Inhalation System, which is an ultrasonic, pulsed-delivery device.

Mode of Action

Treprostinil is a prostacyclin analogue that causes vasodilation of the pulmonary and systemic arterial vascular beds and inhibits platelet aggregation. Treprostinil is available in a 2.9-mL ampule, which contains 1.74 mg of treprostinil (0.6 mg/mL). It is provided as an aerosol in the Tyvaso Inhalation System.

Adverse Effects

Treprostinil has not been studied in patients with underlying lung disease (e.g., asthma, COPD). Treprostinil may cause bronchospasm. This agent should not be mixed with any other agents.

SUMMARY CHECKLIST

- Orally inhaled aerosol drug classes include beta-agonist bronchodilators, anticholinergic (antimuscarinic) bronchodilators, mucolytics, corticosteroids, nonsteroidal antiasthma drugs, antiinfective agents, and anti–pulmonary hypertensive agents.
- Beta-agonist and anticholinergic bronchodilators are used to reverse or improve airflow obstruction; mucolytics are used to reduce mucus viscosity and improve mucociliary clearance; corticosteroids and nonsteroidal antiasthma agents are used to reduce or prevent airway inflammation in asthma; the antiinfective agent pentamidine is used to treat PCP, especially in patients with acquired immunodeficiency syndrome; ribavirin is used to treat respiratory syncytial virus infection in at-risk infants and children; inhaled tobramycin and aztreonam are used in patients with CF to prevent or manage gram-negative *Pseudomonas* infections; and inhaled zanamivir is used to treat acute influenza.
- All aerosol treatments are assessed immediately by monitoring respiratory vital signs, which include respiratory rate and pattern, pulse, breath sounds on auscultation, general patient appearance (e.g., color, diaphoresis), and patient report of subjective reaction (e.g., chest tightness). Additional assessment should be related to the indication for the drug (e.g., monitoring of peak flow rates or bedside spirometry with bronchodilator use; frequency of exacerbation or beta agonist use with inhaled corticosteroids in asthma).
- Each class of aerosol drug has its own mode of action. Practitioners should be familiar with how agents they administer work. Common side effects with each class of drug include tremor and shakiness with beta agonists, dry mouth with anticholinergic agents, bronchial irritation with acetylcysteine, dysphonia and voice changes with dornase alfa, and oral fungal infections with corticosteroids.
- Agents used in asthma that provide quick relief include short-acting beta agonists (albuterol, levalbuterol, metaproterenol) and anticholinergic bronchodilators. Agents that provide long-term control include long-acting beta agonists (salmeterol, formoterol, arformoterol, indacaterol, olodaterol); inhaled corticosteroids; and nonsteroidal antiasthma drugs (cromolyn, montelukast, and other leukotriene antagonists). Systemic corticosteroids are used for both quick relief (intravenously) and long-term control (orally).
- Newer inhaled medications within a class known as *aerosolized prostacyclins* are being introduced to help treat pulmonary hypertension. Several agents are being studied, including epoprostenol (Flolan) and alprostadil (Prostin VR Pediatric); however, only treprostinil (Tyvaso) and iloprost (Ventavis) are being used on a widespread basis.

CHAPTER 36

Airway Management

NEILA ALTOBELLI

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe how to perform endotracheal and nasotracheal suctioning safely.
- Describe how to obtain sputum samples properly.
- Assess the need for and select an artificial airway.
- Identify the complications and hazards associated with insertion of artificial airways.
- Describe how to perform orotracheal and nasotracheal intubation of an adult.
- Assess and confirm proper endotracheal tube placement.
- Describe the rationale and the methods for performing a tracheotomy.
- Identify the types of damage that artificial airways can cause.
- Describe how to maintain and troubleshoot artificial airways properly.
- Describe techniques for measuring and adjusting tracheal tube cuff pressures.
- Identify when and how to extubate or decannulate a patient.
- Describe how to use alternative airway devices.
- Describe how to assist a physician in setting up and performing bronchoscopy.

CHAPTER OUTLINE

KEY TERMS

bronchoscopy
decannulation
endotracheal tubes
extubation
fenestrated
intubation
laryngectomy
obturator
pharyngeal airways
radiopaque
stenosis
suctioning
tracheoesophageal fistula
tracheoinnominate artery fistula
tracheomalacia
tracheostomy
tracheostomy tubes
tracheotomy

Respiratory therapists (RTs) are an important part of the health care team who aim to optimize patient ventilation and gas exchange. Because adequate ventilation and gas exchange are impossible without a patent airway, RTs often assume responsibility for airway management of patients in both the acute care and the post–acute care settings. RTs must develop skills in three broad areas of airway care. First, the RT must be proficient in airway clearance techniques, including methods designed to ensure the patency of the patient's natural or artificial airway. Second, the RT must be able to insert and maintain artificial airways designed to support patients whose own natural airways are inadequate. Third, the RT must be able to assist physicians in performing special procedures related to airway management. This chapter explores each of these areas.

SUCTIONING

Airway obstruction can be caused by retained secretions, foreign bodies, and structural changes such as edema, tumors, or trauma. Retained secretions increase airway resistance and the work of breathing and can cause hypoxemia, hypercapnia, atelectasis, and infection. Difficulty in clearing secretions may be due to the thickness or amount of the secretions or to the patient's inability to generate an effective cough.

RTs can remove retained secretions or other semi-liquid fluids from the airways by suctioning. **Suctioning** is the application of negative pressure (vacuum) to the airways through a collecting tube (flexible catheter or suction tip). Removal of foreign bodies, secretions, or tissue masses beyond the main stem bronchi requires bronchoscopy, which is generally performed by a physician; however, an increasing number of centers have trained RTs to perform therapeutic bronchoscopy. RTs often assist physicians in performing bronchoscopy, which is discussed at the end of the chapter.

Suctioning can be performed by way of either the upper airway (oropharynx) or the lower airway (trachea and bronchi). Secretions or fluids also can be removed from the oropharynx by using a rigid tonsillar or Yankauer suction tip (Figure 36-1). Access to the lower airway is by introduction of a flexible suction catheter (Figure 36-2) through the nose (nasotracheal suctioning) or artificial airway (endotracheal suctioning). Tracheal suctioning through the mouth should be avoided because it causes gagging.

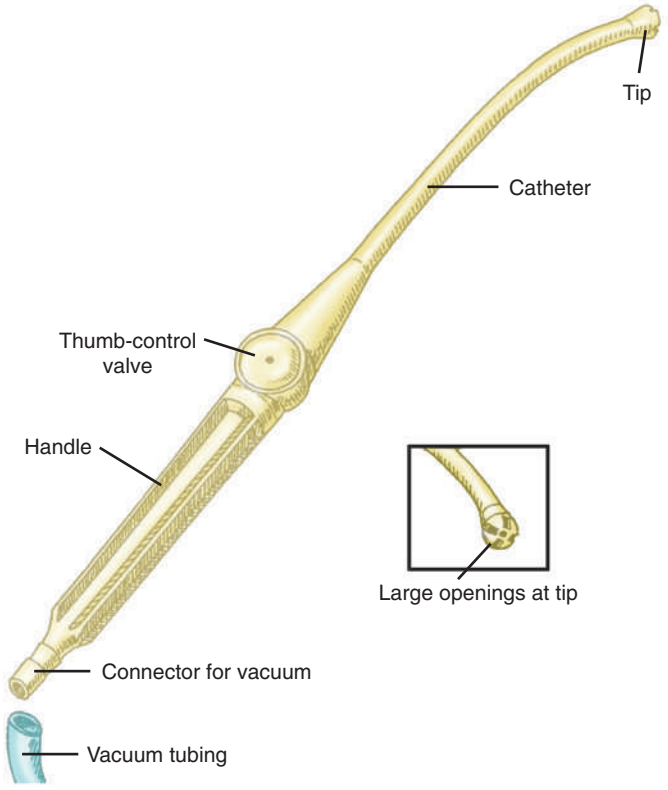

FIGURE 36-1 Rigid tonsillar, or Yankauer, suction tip. (Modified from Sills JR: The comprehensive respiratory therapist exam review, entry and advanced levels, ed 5, St. Louis, 2010, Mosby.)

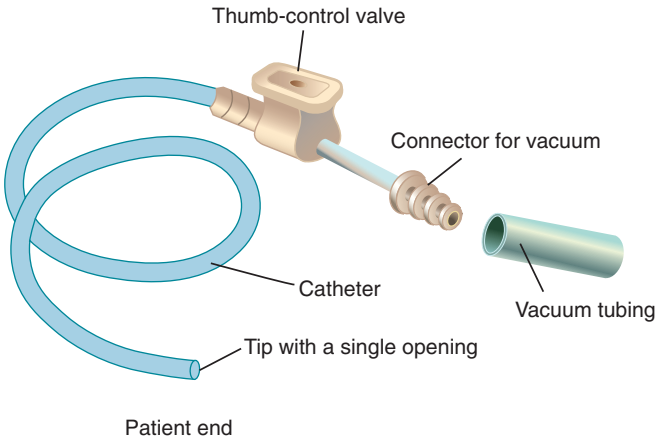

FIGURE 36-2 Flexible suction catheter for lower airway suctioning.

Endotracheal Suctioning

Clinical Practice Guideline

To guide practitioners in safe and effective application of this procedure, the American Association for Respiratory Care (AARC) has developed a clinical practice guideline on endotracheal suctioning of mechanically ventilated patients with artificial airways. Excerpts from the AARC guideline, including indications, contraindications, hazards and complications, assessment of need, assessment of outcome, and monitoring, appear in Clinical Practice Guideline 36-1.[1]

Equipment and Procedure

The procedure described here is for endotracheal suctioning of adults or children. Nasotracheal suctioning is described separately later in this chapter. There are two techniques for endotracheal suctioning: open and closed. The open, sterile technique requires disconnecting the patient from the ventilator. The closed technique uses a sterile, closed, in-line suction catheter that is attached to the ventilator circuit so that the suction

36-1 Endotracheal Suctioning of Mechanically Ventilated Patients With Artificial Airways

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

- Need to maintain patency and integrity of the artificial airway
- Need to remove accumulated pulmonary secretions as evidenced by one of the following:
  - Sawtooth pattern on the flow-volume loop on the monitor screen of the ventilator or the presence of coarse crackles over the trachea—both are strong indicators of retained pulmonary secretions
  - Increased peak inspiratory pressure on volume-control ventilation or decreased tidal volume on pressure control ventilation
  - Deterioration of O_2 saturation or blood gas values
  - Visible secretions in the airway
  - Inability of patient to generate an effective cough
  - Acute respiratory distress
    - Suspected aspiration of gastric or upper airway secretions
- Need to obtain a sputum specimen to rule out or identify pneumonia or other pulmonary infection or for sputum cytology

CONTRAINDICATIONS

Endotracheal suctioning is a necessary procedure for patients with artificial airways. Most contraindications are relative to the patient's risk for developing adverse reactions or worsening clinical condition as a result of the procedure. When indicated, there is no absolute contraindication to endotracheal suctioning because the decision to withhold suctioning to avoid possible adverse reaction may be lethal.

HAZARDS AND COMPLICATIONS

- Decrease in dynamic lung compliance and functional residual capacity
- Atelectasis
- Hypoxia or hypoxemia
- Tissue trauma to the tracheal or bronchial mucosa
- Bronchoconstriction or bronchospasm
- Increased microbial colonization of lower airway
- Changes in cerebral blood flow and increased intracranial pressure
- Hypertension
- Hypotension
- Cardiac dysrhythmias

Routine use of normal saline instillation may be associated with the following adverse events:

- Excessive coughing
- Decreased O_2 saturation
- Bronchospasm
- Dislodgment of the bacterial biofilm that colonizes the endotracheal tube into the lower airway
- Pain, anxiety, dyspnea
- Tachycardia
- Increased intracranial pressure

ASSESSMENT OF NEED

Qualified personnel should assess the need for endotracheal suctioning as a routine part of a patient and ventilator system assessment as detailed under Indications.

ASSESSMENT OF OUTCOME

- Improvement in appearance of ventilator graphics and breath sounds
- Decreased peak inspiratory pressure with narrowing of peak inspiratory pressure to plateau pressure difference; decreased airway resistance or increased dynamic compliance; increased tidal volume delivery during pressure-limited ventilation
- Improvement in arterial blood gas values or saturation as reflected by pulse oximetry (SpO_2)
- Removal of pulmonary secretions

MONITORING

The following should be monitored before, during, and after the procedure:

- Breath sounds
- O_2 saturation
- Skin color
- Pulse oximeter
- Respiratory rate and pattern
- Hemodynamic parameters
- Pulse rate
- Blood pressure, if indicated and available
- Electrocardiogram, if indicated and available
- Sputum characteristics—color, volume, consistency, odor
- Cough characteristics
- Intracranial pressure, if indicated and available
- Ventilator parameters
- Peak inspiratory pressure and plateau pressure
- Tidal volume
- Pressure, flow, and volume graphics, if available
- FiO_2

**For complete guidelines, see American Association for Respiratory Care: Clinical practice guideline: endotracheal suctioning of mechanically ventilated patients with artificial airways. Respir Care 55:758, 2010.*

catheter can be advanced into the patient's endotracheal airway without disconnecting the patient from the ventilator.

There are also two methods of suctioning based on how deep the suction catheter is inserted in the artificial airway: deep suctioning and shallow suctioning. Deep suctioning is when the catheter is inserted until resistance is met and then withdrawn approximately 1 cm before applying suction. Shallow suctioning is when the catheter is advanced to a predetermined depth, which is usually the length of the airway plus the adapter.[2] Using shallow suctioning rather than deep suctioning is recommended in infants and children.[3]

Step 1: Assess Patient for Indications.

Generally, a patient should never be suctioned according to a preset schedule. Although very thick secretions may not move with airflow and may not create any adventitious sounds, the patient should be assessed for clinical indicators, such as rhonchi heard on auscultation, which suggest the need for suctioning (see Clinical Practice Guideline 36-1).

Step 2: Assemble and Check Equipment.

The equipment needed for endotracheal suctioning is listed in Box 36-1. The suction catheter, gloves, and cup are often prepackaged together in disposable sterile kits for use during the open suctioning technique. The AARC Clinical Practice Guideline suggests the closed suctioning technique to avoid disconnecting the patient from the ventilator, which interrupts ventilation and exposes the patient to infection risk. Suction pressure should always be checked by occluding the end of the suction tubing before attaching the suction catheter. The suction pressure should be set at the lowest effective level. Negative pressures of 80 to 100 mm Hg in neonates and less than 150 mm Hg in adults are generally recommended.[4]

Suction catheters are available in various designs, most with side ports to minimize mucosal damage. Most suction catheters for adult general purposes are 22 inches long (sufficient to reach the main stem bronchi) and sized in French units (external circumference). A curved-tip catheter, or catheter coudé, is available to help direct access to the left main stem bronchus. The size of the catheter may be more important than its design. A catheter that is too large can obstruct part or all of the airway by occupying too much of its opening. Too large a suction catheter combined with negative pressure quickly evacuates lung volume and can cause atelectasis and hypoxemia. To avoid this problem, the diameter of the catheter should be less than 50% of the internal diameter of the artificial airway in adults.[5,6] In infants and small children, the diameter of the suction catheter should be less than 70% of the internal diameter of the artificial airway.[7]

Box 36-1 Equipment Needed for Suctioning

- Vacuum source
- Calibrated, adjustable regulator
- Collection bottle and connecting tubing
- Disposable gloves: sterile (open suction) or clean (closed suction)
- Sterile suction catheter
- Sterile water and cup (open suction), if needed to clear catheter
- Goggles, mask, and other appropriate equipment for standard precautions
- Oxygen (O_2) source with a calibrated flowmeter (open suction) or ventilator (closed suction)
- Pulse oximeter
- Manual resuscitation bag equipped with O_2-enrichment device for emergency backup use
- Stethoscope

OPTIONAL EQUIPMENT

- Electrocardiograph
- Sterile sputum trap for culture specimen

RULE OF THUMB

To estimate quickly the proper size of suction catheter to use with a given tracheal tube, first multiply the tube's inner diameter by 2. Then use the next smallest size catheter.

Example: 6-mm endotracheal tube: $2 \times 6 = 12$; next smallest catheter is 10F

Example: 8-mm endotracheal tube: $2 \times 8 = 16$; next smallest catheter is 14F

An in-line suction catheter can be used for patients receiving ventilatory support (Figure 36-3). These systems are incorporated directly into the ventilator circuit and used repeatedly. Because this system allows suctioning without disconnecting the patient from the ventilator, it is recommended for suctioning patients who require high fractional inspired oxygen (FiO_2) and positive end-expiratory pressure (PEEP), who are at risk for lung derecruitment, and for neonates.[8-10] In addition, cross contamination is less likely with such systems. The use of in-line suction catheters has been shown to be cost-effective because they need to be changed only if soiled or malfunctioning and not on a daily basis.[11] However, in-line suction catheters have not been shown either to increase or to decrease the risk for ventilator-associated pneumonia (VAP).[12] The extra weight an in-line catheter adds to a ventilator circuit may increase tension on the endotracheal tube (ETT), so care should be taken to support the ventilator tubing appropriately.

Basic indications for the use of closed suction catheters are listed in Box 36-2.[13] Routine instillation of sterile normal saline to aid secretion removal before suctioning is not recommended because there is insufficient evidence that this practice is beneficial, and it may increase infection risk (see Hazards and Complications in Clinical Practice Guideline 36-1). If the secretions are extremely tenacious, instillation of acetylcysteine or sodium bicarbonate (2%) may be more effective than normal saline; this generally requires a physician's order. The use of these medications is discussed in more detail in Chapter 35.

After connecting the catheter to the suction source, the level of suction pressure should be checked by closing the

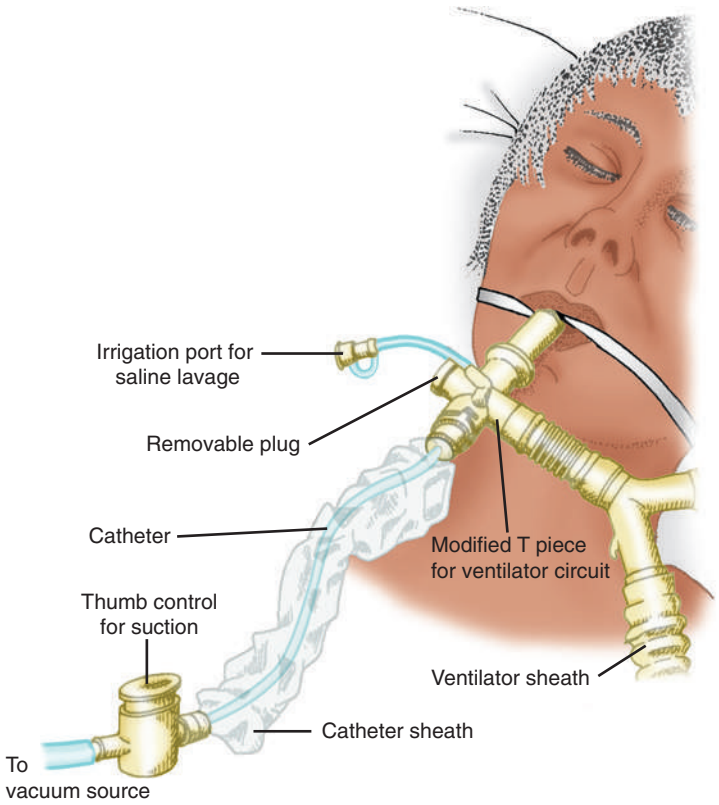

FIGURE 36-3 In-line, closed-system multiuse suction catheter. (Modified from Sills JR: The comprehensive respiratory therapist exam review, entry and advanced levels, ed 5, St. Louis, 2010, Mosby.)

Box 36-2 Indications for Use of Closed Suctioning Technique

Mechanically ventilated patients, especially neonates and patients with:

- Positive end expiratory pressure ≥10 cm H_2O
- Mean airway pressure ≥20 cm H_2O
- Inspiratory time ≥1.5 seconds
- FiO_2 ≥0.60
- Frequent suctioning (≥6 times/day)
- Hemodynamic instability associated with ventilator disconnection
- Respiratory infections requiring airborne or droplet precautions (see Chapter 4)
- Inhaled agents that cannot be interrupted by ventilator disconnection (e.g., nitric oxide, helium/oxygen mixture)

catheter thumb port and aspirating some sterile water or saline from the basin. If no vacuum is generated, it is necessary to check for leaks in the tubing, at the collection container, or at the suction regulator. In addition, if the collecting bottle is full, the float-valve closes and prevents vacuum transmission.

RULE OF THUMB

Set suction pressure 120 to150 mm Hg for adults, 100 to 120 mm Hg for children, and 80 to 100 mm Hg for infants.

Step 3: Assess Patient for Hyperoxygenation.

Before suctioning, delivery of 100% oxygen (O_2) for 30 to 60 seconds to pediatric and adult patients is suggested, especially to patients who are at risk for hypoxemia. Also, the O_2 concentration should be increased by 10% in neonates before suctioning[14]; this may be done by increasing the set FiO_2 or activating the temporary 100% setting on microprocessor ventilators. Manual ventilation is not recommended because it is sometimes difficult to deliver 100% O_2 this way and high pressure potentially causing lung injury can inadvertently be applied.[15] However, if there is no other alternative to hyperoxygenate the patient, PEEP should be maintained by adding a PEEP valve to the manual resuscitator during manual ventilation with 100% O_2.

Step 4: Insert Catheter.

To prevent tracheal mucosal trauma, especially in infants, the shallow suction method should be used, advancing the catheter just to the end of the artificial airway as recommended in the AARC guidelines.

Step 5: Apply Suction and Clear Catheter.

Suction is applied while withdrawing the catheter. Total suction time should be kept to less than 15 seconds.[16,17] After removing the catheter, it should be cleared using a sterile cup filled with sterile water or saline. The closed suction catheter has an adapter for saline vials to be placed in line with the device. The catheter is cleared by squeezing the saline vial and applying suction at the same time. Caution must be used to ensure saline is being drawn into the catheter and not

down the airway. If any untoward response occurs during suctioning, the catheter should be immediately removed, and the patient should be oxygenated.

Step 6: Reoxygenate Patient.

The patient should be hyperoxygenated by the same method used in Step 3 for at least 1 minute. Routine hyperventilation is not recommended. If there are indications of derecruitment, lung recruitment maneuvers may be used.

Step 7: Monitor Patient and Assess Outcomes.

Steps 3 through 7 are repeated as needed until improvement is seen or an adverse response is observed. Any necessary corrective steps should be taken.

Minimizing Complications and Adverse Responses

Careful adherence to procedure is the best way to avoid or minimize complications of endotracheal suctioning. Potential complications are as follows:

- Hypoxemia
  - Minimized by preoxygenating the patient, preferably without disconnecting patient from the ventilator.[18]
  - Minimized by using closed suction technique, especially in neonates and adults requiring high FiO_2 or PEEP, or both or at risk for lung derecruitment.
- Cardiac dysrhythmias
  - Bradycardia may occur secondary to vagal nerve stimulation.
  - Tachycardia may occur as a result of agitation and/or hypoxemia.
  - If either occurs, stop suctioning, administer O_2 and ventilation, and notify the nurse and physician.
- Hypotension or hypertension
  - May occur as a result of cardiac dysrhythmia, hypoxemia, anxiety, stress, pain, or coughing.
  - If either occurs, stop suctioning, administer O_2 and ventilation, and notify the nurse and physician.
- Atelectasis (collapse of alveoli)/lung derecruitment
  - Limit amount of negative suction pressure used (see Rule of Thumb).
  - Keep duration of suctioning less than 15 seconds.
  - Use appropriate-size catheter (see Rule of Thumb).
  - Avoid disconnection from ventilator by using closed suction technique, especially in neonates and adults who require high FiO_2 or PEEP.
- Mucosal trauma
  - Limit amount of negative suction pressure used (see Rule of Thumb).
  - Use shallow suctioning method.
- Increased intracranial pressure (ICP)
  - Usually transient and returns to baseline within 1 minute.
  - For patients who already have increased ICP, administer aerosolized topical anesthetic (lidocaine) 15 minutes before suction to minimize cough, discomfort, and increased ICP.[19]
- Bacterial colonization of lower airway
  - Use sterile technique during open suctioning.
  - Do not routinely instill normal saline; only instill normal saline to help mobilize very thick secretions.
  - Use closed suction technique to avoid disconnection from ventilator.

RULE OF THUMB

To minimize hypoxemia and lung derecruitment when suctioning a mechanically ventilated patient, preoxygenate and suction the artificial airway with a closed-system in-line catheter to avoid disconnecting the patient from the ventilator.

Nasotracheal Suctioning

Nasotracheal suctioning is indicated for patients who have retained secretions but do not have an artificial airway.

Clinical Practice Guideline

The AARC has published a clinical practice guideline on nasotracheal suctioning to guide practitioners in safe and effective application of this procedure. Excerpts from the AARC guideline, including indications, contraindications, hazards and complications, assessment of need, assessment of outcome, and monitoring, appear in Clinical Practice Guideline 36-2.[20]

Equipment and Procedure

The equipment and procedure for nasotracheal suctioning are similar to the equipment and procedure for endotracheal suctioning. Only the key differences are highlighted here. In addition to the equipment and supplies used for endotracheal suctioning (see Box 36-1), sterile water-soluble lubricating jelly is needed to aid catheter passage through the nose. Use of a nasopharyngeal airway should be considered to help reduce mucosal trauma in the nose of patients who require repeated, long-term nasotracheal suctioning.

The key aspect of the nasotracheal suctioning procedure is catheter insertion. After lubricating the catheter, the RT inserts it gently through the nostril, directing it toward the septum and floor of the nasal cavity, without applying negative pressure. The catheter is gently twisted if any resistance in the nose is felt. If twisting does not help, the catheter is withdrawn and inserted through the other nostril.

As the catheter enters the lower pharynx, the patient should assume a "sniffing" position (Figure 36-4). This position helps align the opening of the larynx with the lower pharynx, making catheter passage through the larynx more likely. The catheter is continually advanced until the patient coughs or a resistance is felt.

Minimizing Complications and Adverse Responses

Complications of nasotracheal suctioning are as follows:

- Gagging and/or regurgitation
  - To minimize this risk, avoid suctioning soon after a meal or tube feeding; coordinate with nurse.

36-2 Nasotracheal Suctioning

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

- Need to maintain a patent airway and remove saliva, pulmonary secretions, blood, vomitus, or foreign material from the trachea in the presence of inability to clear secretions when audible or visible evidence of secretions in the large or central airways that persist despite patient's best cough effort, as evidenced by one or more of the following:
  - Visible secretions in airway
  - Chest auscultation of coarse, gurgling breath sounds, rhonchi, or diminished breath sounds
  - Feeling of secretions in the chest (increased tactile fremitus)
  - Suspected aspiration of gastric or upper airway secretions
  - Clinically apparent increased work of breathing
  - Deterioration of arterial blood gas values suggesting hypoxemia or hypercarbia
  - Chest radiographic evidence of retained secretions resulting in atelectasis or consolidation
  - Restlessness
- Stimulate cough or for unrelieved coughing
- Obtain a sputum sample for microbiologic or cytologic analysis

CONTRAINDICATIONS

Listed contraindications are relative unless noted to be absolute.

- Occluded nasal passages
- Nasal bleeding
- Epiglottitis or croup—absolute
- Acute head, facial, or neck injury
- Coagulopathy or bleeding disorder
- Laryngospasm
- Irritable airway
- Upper respiratory tract infection
- Tracheal surgery
- Gastric surgery with high anastomosis
- Myocardial infarction
- Bronchospasm

HAZARDS AND COMPLICATIONS

- Mechanical trauma
- Laceration of nasal turbinates
- Perforation of pharynx
- Nasal irritation or bleeding
- Tracheitis
- Mucosal hemorrhage
- Edema of uvula
- Hypoxia or hypoxemia
- Cardiac dysrhythmias or arrest
- Bradycardia
- Increased blood pressure
- Hypotension
- Respiratory arrest
- Uncontrolled coughing
- Gagging or vomiting
- Laryngospasm
- Bronchoconstriction or bronchospasm
- Discomfort and pain
- Nosocomial infection
- Atelectasis
- Misdirection of the catheter
- Increased intracranial pressure
- Intraventricular hemorrhage
- Exacerbation of cerebral edema
- Pneumothorax

ASSESSMENT OF NEED

Personnel should perform a baseline assessment for indications of respiratory distress and the need, as recognized by the previously listed presenting indications. This assessment should include but not be limited to the following:

- Auscultation of the chest
- Monitoring of heart rate
- Assessment of respiratory rate
- Assessment of cardiac rhythm
- Assessment of O_2 saturation
- Assessment of skin color and perfusion
- Assessment of effectiveness of cough

Prepare the patient for the procedure by providing an appropriate explanation along with adequate sedation and pain relief as needed.

ASSESSMENT OF OUTCOME

Assess the patient after suction for the following:

- Improved breath sounds
- Removal of secretions
- Improved blood gas data or pulse oximetry
- Decreased work of breathing (decreased respiratory rate or dyspnea)

MONITORING

The following should be monitored before, during, and after the procedure:

- Breath sounds
- Skin color
- Breathing pattern and rate
- Pulse rate, dysrhythmia, electrocardiogram if available
- Color, consistency, and volume of secretions
- Presence of bleeding or evidence of physical trauma
- Subjective response, including pain
- Oxygenation (pulse oximeter)
- Intracranial pressure, if equipment is available
- Arterial blood pressure, if available
- Laryngospasm

**For complete guidelines, see American Association for Respiratory Care: Clinical practice guideline: nasotracheal suctioning—2004 revision and update. Respir Care 49:1080, 2004.*

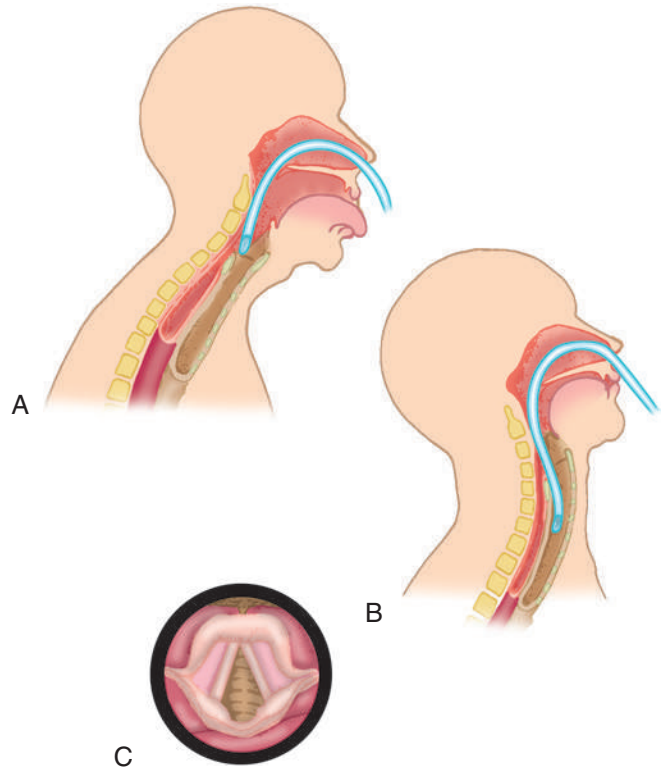

FIGURE 36-4 Nasotracheal suctioning technique. **A,** Optimal position of the head to insert catheter into the trachea. The neck is flexed, and the head is extended. The tongue is protruded (and held by a 4 × 4 gauze pad). **B,** After catheter has advanced into the trachea, the tongue is released, and the patient's head is allowed to assume a comfortable position. **C,** View of vocal cords from above. The cords are most widely separated during inspiration. (Modified from Sanderson RG: The cardiac patient: a comprehensive approach, Philadelphia, 1972, Saunders.)

- If this occurs, reposition patient and suction oropharynx if necessary.
- Airway trauma (bleeding)
  - To avoid, before suctioning, assess patient for any bleeding disorder (check platelet count and/or bleeding studies and anticoagulation medications) before suctioning.
  - To minimize, do not use excessive force when advancing catheter.
  - To minimize, lubricate catheter.
  - To minimize, use nasopharyngeal airway to protect nasal mucosa.
- Contamination of the lungs
  - Immunosuppressed patients are especially at risk.
  - To avoid, use sterile technique and gentle insertion of catheter.
- Bronchospasm or laryngospasm
  - These incidents may be stimulated by the catheter in the lower airway.
  - Patients with hyperactive airway disease are especially at risk.
  - If these occur, stop suctioning and administer aerosolized bronchodilator if needed.

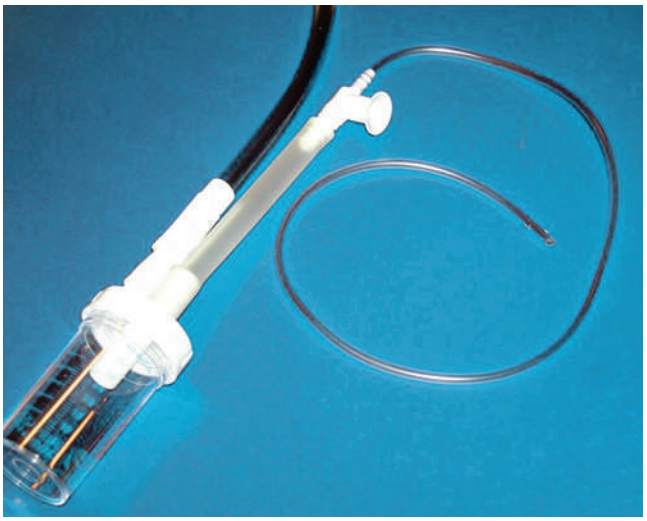

FIGURE 36-5 Specimen container placement between the suction catheter and wall suction source.

Sputum Sampling

Sputum samples are often collected to identify organisms infecting the airway. To obtain the samples, the suctioning procedures described previously should be followed. In addition to the usual equipment, a sterile specimen container is needed. This device consists of a plastic tube or cup with flexible tubing on one end to attach to the suction catheter. The other outlet is a stiff plastic nozzle that connects to the suction tubing from the wall vacuum unit (Figure 36-5).

It is important to maintain sterile technique when touching the connection points on the trap. If a closed suction system is being used, a new catheter should be placed just before suctioning the patient for the sample. When an adequate sample is obtained, the container is removed from the suction catheter and suction tubing. The flexible tubing on the container is attached to the open nozzle; this creates a closed container. The container should be labeled according to hospital or facility policy. The suctioning procedure is completed as previously described.

ESTABLISHING AN ARTIFICIAL AIRWAY

Clinical Practice Guideline

An artificial airway is required when the patient's natural airway can no longer perform its proper functions. To guide practitioners in the identification, assessment, and treatment of patients requiring artificial airways, the AARC has developed a clinical practice guideline on management of airway emergencies. Excerpts from the AARC guideline, including indications; contraindications; precautions, hazards, and possible complications; assessment of need and outcome; and monitoring, appear in Clinical Practice Guideline 36-3.[21]

36-3 Management of Airway Emergencies

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

In general, conditions requiring management of the airway are impending or actual (1) airway compromise, (2) respiratory failure, and (3) need to protect the airway. Specific conditions include but are not limited to the following:

- Airway emergency before endotracheal intubation
- Obstruction of the artificial airway
- Apnea
- Acute traumatic coma
- Penetrating neck trauma
- Cardiopulmonary arrest and unstable dysrhythmias
- Severe bronchospasm
- Severe allergic reactions with cardiopulmonary compromise
- Pulmonary edema
- Sedative/narcotic drug effect
- Foreign body obstruction
- Choanal atresia in neonates
- Aspiration
- Risk for aspiration
- Severe laryngospasm
- Self-extubation

Conditions requiring emergency tracheal intubation include but are not limited to:

- Persistent apnea
- Traumatic upper airway obstruction
- Accidental extubation of a patient unable to maintain adequate spontaneous ventilation
- Obstructive angioedema
- Massive uncontrolled upper airway bleeding
- Infection-related upper airway obstruction (partial or complete)
  - Epiglottitis in children or adults
  - Acute uvular edema
  - Tonsillopharyngitis or retropharyngeal abscess
  - Suppurative parotitis
- Coma with potential for increased intracranial pressure
- Neonatal- or pediatric-specific conditions
  - Perinatal asphyxia
  - Severe adenotonsillar hypertrophy
  - Severe laryngomalacia
  - Bacterial tracheitis
  - Neonatal epignathus
  - Obstruction from abnormal laryngeal closure owing to arytenoid masses
  - Mediastinal tumors
  - Congenital diaphragmatic hernia
  - Presence of thick or particulate meconium in amniotic fluid
  - Absence of airway protective reflexes
  - Cardiopulmonary arrest
  - Massive hemoptysis

A patient in whom airway control is not possible by other methods may require surgical placement of an airway (needle or surgical cricothyrotomy).

Conditions in which endotracheal intubation may be impossible and in which alternative techniques may be used include but are not limited to the following:

- Restriction of endotracheal intubation by policy or statute
- Difficult or failed intubation in the presence of risk factors associated with difficult tracheal intubations such as:
  - Short neck or bull neck
  - Protruding maxillary incisors
  - Receding mandible
  - Reduced mobility of atlantooccipital joint
  - Temporomandibular ankylosis
  - Congenital oropharyngeal wall stenosis
  - Anterior osteophytes of the cervical vertebrae, associated with diffuse idiopathic skeletal hyperostosis
  - Large substernal or cancerous goiters
  - Treacher Collins syndrome
  - Morquio-Brailsford syndrome
  - Endolaryngeal tumors
  - When endotracheal intubation is not immediately possible

CONTRAINDICATIONS

Aggressive airway management (intubation or establishment of a surgical airway) may be contraindicated when the patient's desire not to be resuscitated has been clearly expressed and documented in the patient's medical record or other valid legal document.

PRECAUTIONS, HAZARDS, AND COMPLICATIONS

Possible hazards or complications related to the major facets of management of airway emergencies include the following:

- Failure to establish a patent airway
- Failure to intubate the trachea
- Failure to recognize intubation of esophagus
- Upper airway trauma, laryngeal, and esophageal damage
- Aspiration
- Cervical spine trauma
- Unrecognized bronchial intubation
- Eye injury
- Vocal cord paralysis
- Problems with endotracheal tubes
  - Cuff perforation
  - Cuff herniation
  - Pilot-tube-valve incompetence
  - Tube kinking during biting
  - Inadvertent extubation
  - Tube occlusion
  - Bronchospasm
  - Laryngospasm
  - Dental accidents
  - Dysrhythmias
  - Hypotension and bradycardia secondary to vagal stimulation
  - Hypertension and tachycardia
  - Inappropriate tube size
  - Bleeding

- Tracheal damage, including tracheoesophageal fistula, tracheal innominate fistula, tracheal stenosis, and tracheomalacia
- Pneumonia
- Laryngeal damage with consequent laryngeal stenosis, laryngeal ulcer, granuloma, polyps, synechiae

- Surgical cricothyrotomy or tracheostomy specific
  - Stomal stenosis
  - Innominate erosion
- Needle cricothyrotomy specific
  - Bleeding at insertion site with hematoma formation
  - Subcutaneous and mediastinal emphysema
  - Esophageal perforation
  - Emergency ventilation
  - Inadequate O_2 delivery
  - Hypoventilation or hyperventilation
  - Gastric insufflation or rupture
  - Barotrauma
  - Hypotension owing to reduced venous return secondary to high mean intrathoracic pressure
  - Vomiting and aspiration
  - Prolonged interruption of ventilation for intubation
  - Failure to establish adequate functional residual capacity in a newborn
  - Movement of unstable cervical spine (more than by any commonly used method of endotracheal intubation)
  - Failure to exhale owing to upper airway obstruction during percutaneous transtracheal ventilation

ASSESSMENT OF NEED

The need for airway management is dictated by the clinical condition of the patient. Careful observation, implementation of basic airway management techniques, and laboratory and clinical data should help determine the need for more aggressive measures. Specific conditions requiring intervention include the following:

- Inability to protect airway adequately (e.g., coma, lack of gag reflex, inability to cough) with or without other signs of respiratory distress.
- Partially obstructed airway. Signs of a partially obstructed upper airway include ineffective patient efforts to ventilate, paradoxical respiration, stridor, use of accessory muscles, patient pointing to neck, choking motions, cyanosis, and distress. Signs of lower airway obstruction may include the above-mentioned signs and wheezing.
- Complete airway obstruction. Respiratory efforts with no breath sounds or suggestion of air movement are indicative of complete obstruction.
- Apnea. No respiratory efforts are seen; may be associated with cardiac arrest.
- Hypoxemia, hypercarbia, or acidemia seen on arterial blood gas analysis, oximetry, or exhaled gas analysis.
- Respiratory distress. Elevated respiratory rate, high or low ventilatory volumes, and signs of sympathetic nervous system hyperactivity may be associated with respiratory distress.

ASSESSMENT OF PROCESS AND OUTCOME

Timely intervention to maintain the patient's airway can improve outcomes. Under rare circumstances, maintenance of an airway by nonsurgical means may be impossible. Despite optimal airway maintenance, outcomes are affected by patient-specific factors. Lack of appropriate equipment and personnel may adversely affect outcomes. Monitoring and recording can help improve emergency airway management. Some aspects (e.g., frequency of complications of tracheal intubations or time to establishment of a definitive airway) are easy to quantify and can help improve hospital-wide systems. The patient's condition after the emergency should be evaluated from this perspective.

MONITORING

Clinical Signs

Continuous patient observation and repeated clinical assessment by a trained observer provide optimal monitoring of the airway. Special consideration should be given to the following:

- Level of consciousness
- Presence and character of breath sounds
- Ease of ventilation
- Symmetry and amount of chest movement
- Skin color and character (temperature and presence or absence of diaphoresis)
- Presence of upper airway sounds (crowing, snoring, stridor)
- Presence of excessive secretions, blood, vomitus, or foreign objects in the airway
- Presence of epigastric sounds
- Presence of retractions
- Presence of nasal flaring

Physiologic Variables

Repeated assessment of physiologic data by trained professionals supplements clinical assessment in managing patients with airway difficulties. Monitoring devices should be available, accessible, functional, and periodically evaluated for function. These data include but are not limited to:

- Ventilatory frequency, tidal volume, and airway pressure
- Presence of CO_2 in exhaled gas
- Heart rate and rhythm
- Pulse oximetry
- Arterial blood gas values
- Chest radiograph

Endotracheal Tube Position

Regardless of the method of ventilation used, the most important consideration is detection of esophageal intubation.

- Tracheal intubation is suggested but may not be confirmed by:
  - Bilateral breath sounds over the chest
  - Symmetric chest movement
  - Absence of ventilation sounds over the epigastrium
  - Presence of condensate inside the tube, corresponding with exhalation
  - Visualization of the tip of the tube passing through the vocal cords
  - Esophageal detector devices may be useful in differentiating esophageal from tracheal intubation
- Tracheal intubation is confirmed by detection of CO_2 in the exhaled gas, although cases of transient CO_2 excretion from the stomach have been reported.
- Tracheal intubation is confirmed by endoscopic visualization of the carina or tracheal rings through the tube.
- Position of the endotracheal tube (i.e., depth of insertion) should be appropriate on chest radiograph.

AIRWAY MANAGEMENT PROCESS

A properly managed airway may improve patient outcome. Continuous evaluation of the process identifies components needing improvement. These include response time, equipment function, equipment availability, practitioner performance, complication rate, and patient survival and functional status.

**For complete guidelines, see American Association for Respiratory Care: Clinical practice guideline: management of airway emergencies. Respir Care 40:749, 1995.*

Routes

Artificial airways are inserted for various reasons and involve varying degrees of invasion into the upper airway. **Pharyngeal airways** extend only into the pharynx. Artificial airways that are placed through the mouth or nose into the trachea are called **endotracheal tubes (ETTs).** The process of placing an artificial airway into the trachea is referred to as **intubation.** When the ETT is passed through the nose first, the procedure is referred to as *nasotracheal intubation*. When the tube is passed through the mouth on its way into the trachea, the procedure is called *orotracheal intubation*.

Pharyngeal Airways

Pharyngeal airways prevent airway obstruction by keeping the tongue pulled forward and away from the posterior pharynx. This type of obstruction is common in an unconscious patient as a result of a loss of muscle tone.

A *nasopharyngeal airway* (Figure 36-6) is most often placed in a patient who requires frequent nasotracheal suctioning. Although it does not ensure entry into the trachea, it minimizes damage to the nasal mucosa that can be caused by the suction catheter. A nasopharyngeal airway also may be placed in a patient who was recently extubated after facial surgery. The nasopharyngeal airway helps maintain the patency of the upper airway despite swelling.

Oropharyngeal airways (see Figure 36-6) are inserted into the mouth over the tongue. Use of oropharyngeal airways should be restricted to unconscious patients to avoid gagging and regurgitation. These airways maintain a patent airway when the tongue would otherwise obstruct the oropharynx. The airway also can be used as a bite block for patients with oral tubes.

Pharyngeal airways are used mainly in emergency life support. Further details on their use, insertion techniques, and size selection are provided in Chapter 37.

Tracheal Airways

Tracheal airways extend beyond the pharynx into the trachea. The two basic types of tracheal airways are *endotracheal (translaryngeal) tubes* and *tracheostomy tubes.* ETTs are inserted through either the mouth or the nose (orotracheal or nasotracheal), through the larynx, and into the trachea. **Tracheostomy tubes** (TTs) are inserted through a surgically created opening in the neck directly into the trachea. Table 36-1 summarizes the advantages and disadvantages of each of these three approaches.

FIGURE 36-6 Pharyngeal airways. **A,** Nasopharyngeal airway. **B** and **C,** Oropharyngeal airways.

Airway Tubes

Endotracheal Tubes

ETTs are semi-rigid tubes most often composed of polyvinyl chloride or related plastic polymers.[22] Figure 36-7 shows a typical ETT, its key components, and a stylet used for insertion. The proximal end of the tube is attached to a standard adapter with a 15-mm external diameter. The curved body of the tube usually has length markings, indicating the distance (in centimeters) from the beveled tube tip. In addition to the beveled opening at the tip, there is a side port, or "Murphy eye," that ensures gas flow if the main port should become obstructed. The angle of the bevel minimizes mucosal trauma during insertion. The tube cuff is permanently bonded to the tube body. Inflation of the cuff seals off the lower airway, either for protection from gross aspiration or to provide positive pressure ventilation. A small filling tube leads from the cuff to a pilot balloon, used to monitor cuff status and pressure when the tube is in place. Finally, a valve with a standard connector for a syringe allows inflation and deflation of the cuff. Although not shown in Figure 36-7, included with most modern ETTs is a **radiopaque** indicator that is embedded in the distal end of the tube body. This indicator allows for easy identification of tube position on the radiograph.

Specialized Endotracheal Tubes. Some standard ETTs have been modified for specific uses, including special ventilation methods, lung pathologic conditions, and surgical procedures. Some more common tubes, including double-lumen

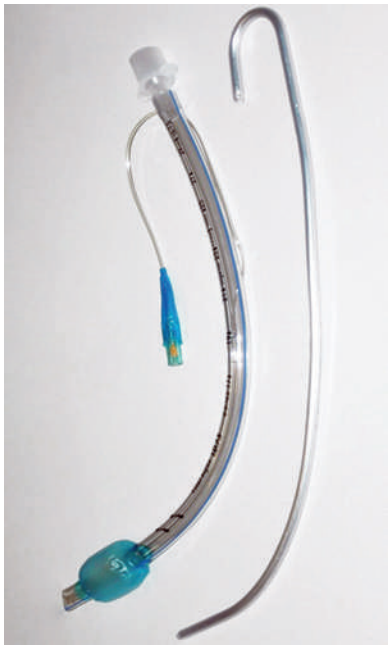

FIGURE 36-7 Typical endotracheal tube and stylet.

TABLE 36-1

Advantages and Disadvantages of Tracheal Airway Routes

Route	Advantages	Disadvantages
Oral intubation	Insertion is faster, easier, less traumatic, and more comfortable Larger tube is tolerated Easier suctioning Less airflow resistance Decreased work of breathing Easier passage of bronchoscope Reduced risk for tube kinking Avoidance of nasal and paranasal complications, including epistaxis and sinusitis	Esthetically displeasing, especially long term Greater risk for self-extubation or inadvertent extubation Greater risk for main stem intubation Risk of tube occlusion by biting or trismus Risk of injury to lips, teeth, tongue, palate, and oral soft tissues May require additional use of oral airway Great risk for retching, vomiting, and aspiration Pain and discomfort, especially with inadequate preparation
Nasal intubation	Less retching and gagging Greater comfort in long-term use Less salivation Improved ability to swallow oral secretions Improved communication Improved mouth care and oral hygiene Avoidance of occlusion by biting or trismus Easier nursing care Avoidance of oral route complications Less posterior laryngeal ulceration Better tube anchoring, less chance of inadvertent extubation Reduced risk for main stem intubation Some patients can swallow liquids, providing a means of nutritional support Blind nasal intubation does not require muscle relaxants or sedatives May avert "crash" oral intubation	Nasal and paranasal complications, including epistaxis, sinusitis, otitis More difficult to perform Spontaneous breathing required for blind nasal intubation Smaller tube is necessary Greater suctioning difficulty Increased airflow resistance Increased work of breathing Difficulty passing bronchoscope Smaller risk for transient bacteremia
Tracheotomy	Avoidance of laryngeal and upper airway complications of translaryngeal intubation Greater comfort Aids feeding, oral care, suctioning, speech Psychologic benefit (improved motivation) Easier passage of fiberoptic bronchoscope Easier reinsertion Esthetically less objectionable Facilitation of weaning from ventilator Elimination of risk for main stem intubation Reduced work of breathing Better anchoring (reduced risk for decannulation) Improved ability to place curve-tipped suction catheter in left bronchus Improved mobility (transfer out of intensive care unit to ward or extended-care facility)	Greater expense Requirement for use of operating room in most cases Need for general anesthesia in most cases Permanent scar More severe complications Greater mortality rate Delayed decannulation Increased frequency of aspiration Greater bacterial colonization rate Persistent open stoma after decannulation, reducing cough efficiency

From Stauffer JL, Silvestri RC: Complications and consequences of endotracheal intubation and tracheostomy. Respir Care 27:417, 1982.

tubes, tubes with special adapters for jet ventilation, and tubes with subglottic suction ports, are discussed.[23]

Special mechanical ventilation techniques may require unique types of ETTs. When unilateral lung disease occurs, independent lung ventilation may be needed. This ventilation requires the use of a double-lumen ETT (Figure 36-8). This tube has two proximal ventilator connectors (15-mm adapter), two inner lumens for gas flow, two cuffs, and two distal openings. The larger cuff seals the tracheal lumen and allows gas to flow into one bronchus. The smaller cuff seals the opposite bronchial lumen (Figure 36-9).

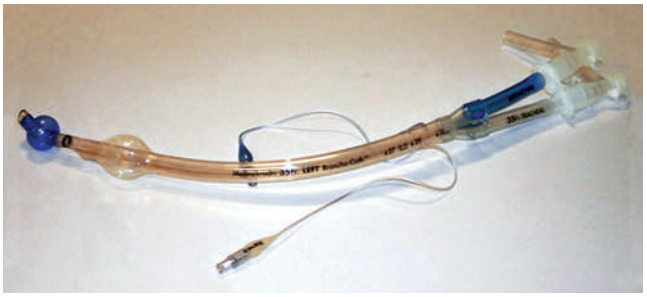

FIGURE 36-8 Double-lumen endotracheal tube for independent lung ventilation.

There are important points to consider when using double-lumen ETTs. These tubes are stiffer and bulkier to insert than standard tubes and must be rotated during insertion to align with the proper bronchus. Fiberoptic bronchoscopy should be performed to ensure proper placement. The resistance to flow through each tube is increased because each lumen is smaller than the same-size single-lumen tubes.

High-frequency jet ventilation uses a special ETT adapter (Figure 36-10). This adapter replaces the standard ETT adapter.

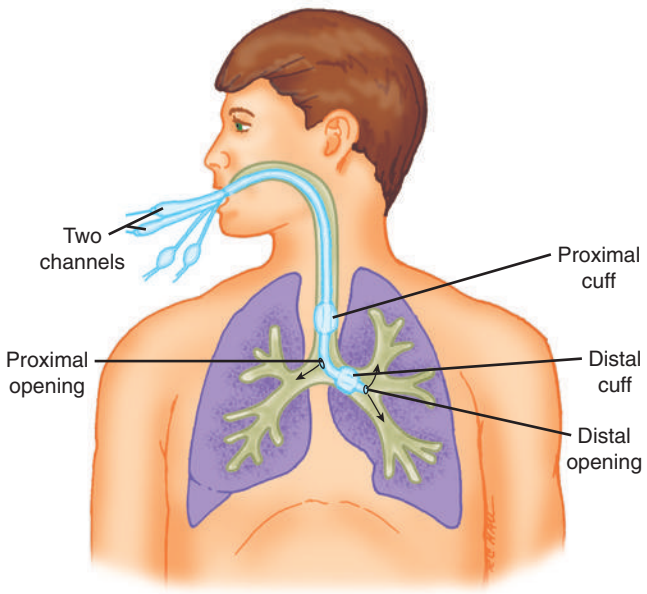

FIGURE 36-9 Correct positioning of double-lumen endotracheal tube.

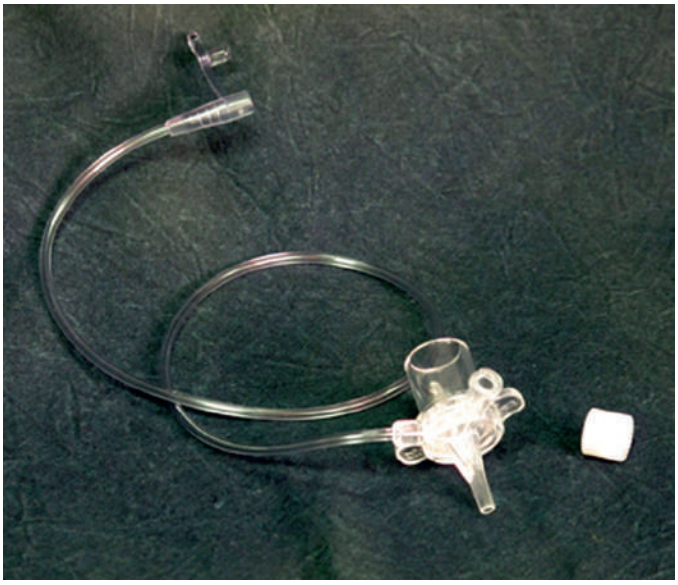

FIGURE 36-10 Endotracheal tube adapter for jet ventilation. LifePort Adapter. (Courtesy Bunnell Incorporated, Salt Lake City, Utah.)

There is a jet port for the injection of high-flow pulses from the jet ventilator and a 15-mm connection for conventional ventilation. A pressure monitoring tube also is available for monitoring airway pressures.

A specialized ETT with an attached subglottic suction port has been designed to allow for removal of secretions that often accumulate above the cuff (Figure 36-11). A separate channel in the wall of the tube attaches to a wall suction source. The suction source is run continuously at negative pressures of 20 to 30 cm H_2O. The aspirated material is collected in a small container, which is emptied on a regular basis. Every 4 hours, a small amount of air should be injected into the suction port to ensure the port and tubing are not clogged. Use of this tube has been reported to decrease the incidence of VAP.[24,25]

Tracheostomy Tubes

Tracheostomy tubes are generally made from polyvinyl chloride or silicone, although some are still made from metal.

Figure 36-12 shows a typical tracheostomy tube and its key components. The outer cannula forms the primary structural unit of the tube, to which the cuff and a flange are attached. The flange prevents tube slippage into the trachea and provides the means to secure the tube to the neck. There are single-cannula and double-cannula tracheostomy tubes. The double-cannula tube has a removable inner cannula with a standard 15-mm adapter. It is normally kept in place within the outer cannula. To prevent accidental removal, the inner cannula can be locked in place at the proximal end of the outer cannula. The inner cannula may be disposable or nondisposable. If the tube becomes occluded with very thick secretions or blood clots, the inner cannula can be easily removed and cleaned or replaced to establish a patent airway. This prevents the necessity of emergently changing the entire tracheostomy tube in this situation.

FIGURE 36-11 Endotracheal and tracheostomy tubes with subglottic suction ports.

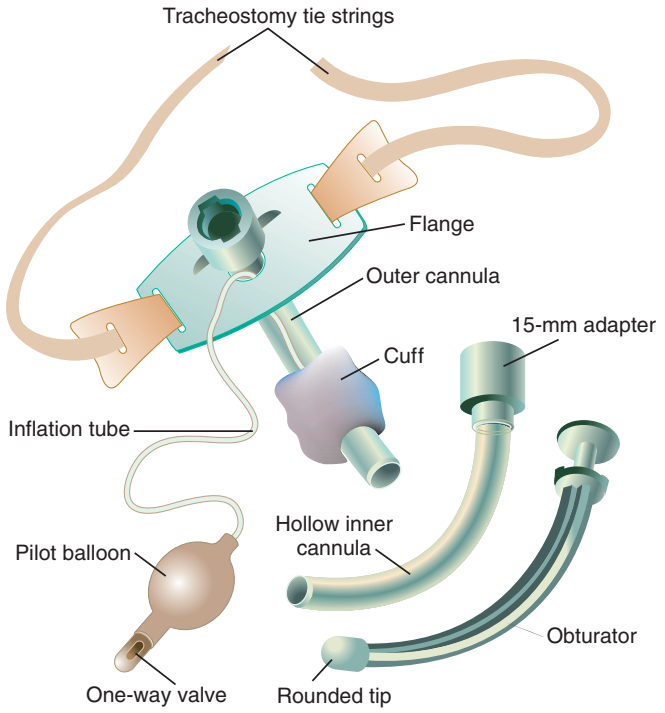

FIGURE 36-12 Parts of a tracheostomy tube.

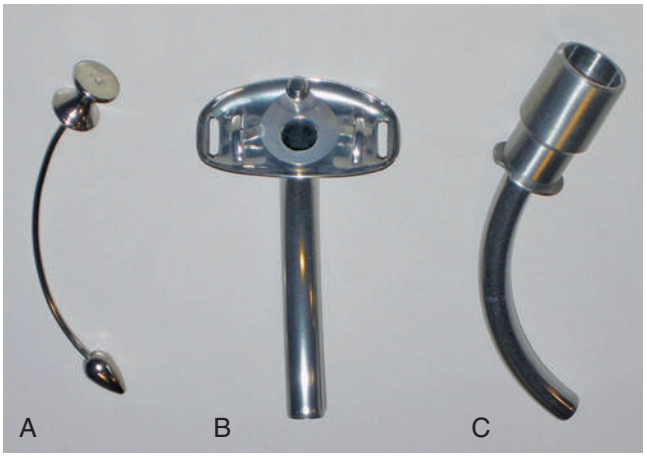

FIGURE 36-13 Jackson tracheostomy tube made from stainless steel. It has no cuff and no 15-mm adapter. **A,** Obturator. **B,** Outer cannula. **C,** Inner cannula.

FIGURE 36-14 Laryngectomy tubes.

Double cannula tubes are especially recommended for patients who are going home with a tracheostomy tube or in situations in which the humidity delivered to the airway is less than optimal. However, the inner cannula in some tracheostomy tubes can decrease the inner diameter of the tube, causing some patients to have difficulty breathing through the tube because of the increased airway resistance. In other double-cannula tubes the outer diameter is larger than the outer diameter of the same-size single cannula tube. This can decrease the room around the tube with the cuff deflated so that a patient may not be able to breathe around it with a speaking valve or cap on the tube. In this case the tube would need to be changed to a one with a smaller outer diameter.[26]

As with an ETT, an inflation tube leads from the cuff to a pilot balloon and valve. The tube is stabilized at the stoma site with cotton tape, which attaches to the flange and is tied around the neck or, more frequently, a soft tracheostomy tube holder with Velcro fasteners. An **obturator** with a rounded tip is used for tube insertion. Before insertion, the obturator is placed within the outer cannula, with its tip extending just beyond the far end of the tube; this minimizes mucosal trauma during insertion. Finally, as with ETTs, a radiopaque indicator in the distal end of the tube helps confirm tube position on a radiograph.

As with ETTs, various modified tracheostomy tubes are available. Extra-long tracheostomy tubes may be used in patients who require extra proximal or distal length because of anatomic considerations, such as a thick neck. Some extra-long tubes have an adjustable flange so that the tube, under direct vision with a bronchoscope, can be placed past an abnormality in the trachea, such as a tumor or tracheal stenosis.

The metal Jackson tracheostomy tube is made of stainless steel with an inner and outer cannula (Figure 36-13). There is no cuff at the distal end or 15-mm adapter at the proximal end. This tracheostomy tube is generally used in patients with a long-term need for an airway but who do not require a seal to protect the airway from aspiration or to facilitate positive pressure ventilation. If the patient requires manual ventilation, a 15-mm adapter should be inserted into the proximal opening. If the patient requires a sealed airway, the tube needs to be changed to the standard cuffed tube described earlier. A laryngectomy tube is a shorter tube without a cuff inserted into the stoma after a laryngectomy. The tube keeps the stoma open until it heals. There are several different types, some with a flange that can be secured with a fastener around the patient's neck and some without a flange (low profile). The tube may be easily removed to be cleaned and then reinserted (Figure 36-14).

Procedures

Orotracheal Intubation

Orotracheal intubation is the preferred route for establishing an emergency tracheal airway because the oral passage is the quickest and easiest route in most cases. Orotracheal intubation can be safely performed by an appropriately trained physician, RT,

nurse, or paramedic.[27] Typically, this training involves manikin practice and application on anesthetized patients under the guidance of an anesthesiologist or other appropriately skilled individual. The basic steps in orotracheal intubation are described here.[28] Proficiency in this technique can be developed only with extensive training and experience.

Step 1: Assemble and Check Equipment.

Box 36-3 lists the equipment necessary for intubation. All suction equipment is assembled, and the vacuum pressure is checked before intubation because vomitus or secretions may obscure the pharynx or glottis. The appropriate-size laryngoscope blade (see Box 36-3) is attached to its handle, and the light source is checked for secure attachment and brightness. If the light does not function, the bulb first should be checked to see if it is tight. If the scope still does not light, the batteries should be checked or the bulb should be replaced.

An appropriate-size tube should be selected, and other tubes should be available that are at least one size larger and one size smaller. Table 36-2 lists recommended orotracheal tube sizes according to patient weight or age. ETTs are sized by their internal diameter (in millimeters). Tube lengths given in Table 36-2 are averages after insertion, confirmed placement, and fixation (teeth to tube tip).

RULE OF THUMB

Generally, a woman is intubated with a No. 7 or No. 7.5 orotracheal tube and a man is intubated with a No. 8.0 or No. 8.5 orotracheal tube.

After selecting the correct size of tube, the RT inflates the tube cuff and checks for leaks. The RT must be sure to deflate the cuff before insertion. To ease insertion, the outer surface of the tube should be lubricated with a water-soluble gel. Finally, many clinicians insert a stylet into the tube to add rigidity and maintain shape during insertion. The tip of the stylet must never extend beyond the ETT tip.

Step 2: Position Patient.

To visualize the glottis and insert the tube, the RT aligns the patient's mouth, pharynx, and larynx. This alignment is achieved by combining moderate cervical flexion with extension of the atlantooccipital joint. Placement of one or more rolled towels under the patient's shoulders helps. Next the RT flexes the patient's neck and tilts the head backward with his or her hand, placing the patient into the sniff position (Figure 36-15).

Box 36-3 Equipment Needed for Endotracheal Intubation

- Oxygen flowmeter and tubing
- Suction apparatus
- Flexible sterile suction catheters
- Sterile gloves for endotracheal suctioning
- Yankauer (tonsillar) tip suction
- Manual resuscitation bag and mask
- Colorimetric carbon dioxide detector
- Oropharyngeal airways
- Laryngoscope (two) with assorted blades (size 2 or 3 for adults, size 1 or 2 for children, size 0 or 1 for infants)
- Endotracheal tubes (three appropriate sizes)
- Tongue depressor
- Stylet
- Stethoscope
- Tape or endotracheal tube holder
- 10- or 12-ml syringe
- Water-soluble lubricating gel
- Magill forceps
- Local anesthetic (spray)
- Towels (for positioning)
- CDC barrier precautions (gloves, gowns, masks, goggles, or face shields)

CDC, U.S. Centers for Disease Control and Prevention.

TABLE 36-2

Guideline for Infant, Pediatric, and Adult Oral Endotracheal Tube Sizes

Age	Tube Size (mm Internal Diameter)	Distance (in cm) from Incisors (Lip in Infants) to Tip of Tube
Infant, <1 kg	2.5	6.5-8
Infant, 1-2 kg	3.0	7-8
Infant, 2-3 kg	3.5	8-9
Infant, 4 kg	3.5-4.0	9-10
6 mo	3.5-4.0	10-11
18 mo	3.5-4.5	11-13
3 yr	4.5-5.0	12-14
5 yr	4.5-5.0	13-15
6 yr	5.5-6.0	14-16
8 yr	6.0-6.5	15-17
12 yr	6.0-7.0	17-19
16 yr/small women	6.5-7.0	18-20
Women (average)	7.5-8.0	19-21
Men	8.0-9.0	21-23

MINI CLINI

Indications for Artificial Airway Management

PROBLEM: A woman is admitted to the emergency department after sustaining chest trauma during a motor vehicle accident. The patient is unconscious, cyanotic, and tachypneic and has blood in the mouth and pharynx. Breath sounds are diminished on both sides. The physician requests that the RT immediately perform orotracheal intubation. Why?

DISCUSSION: This patient exhibits several indications for insertion of an artificial airway. First, being unconscious, the patient is probably unable to protect her lower airway adequately. With blood in the mouth and pharynx, there should be increased concern for protecting her lungs from aspiration. The blood also may indicate partial airway obstruction; the breath sounds, cyanosis, and respiratory distress contribute to that conclusion. Finally, the cyanosis and chest trauma indicate potential hypoxemic respiratory failure, which may require positive pressure ventilatory support via a cuffed ETT.

Step 3: Preoxygenate and Ventilate Patient.

A patient in need of intubation is often apneic or in respiratory distress. Providing ventilation and oxygenation by manual resuscitator bag and mask with 100% O_2 before intubation helps ensure the patient tolerates the intubation procedure. No more than 30 seconds should be devoted to any intubation attempt. If intubation fails, immediate ventilation and oxygenation of the patient for 3 to 5 minutes before the next attempt should occur.

Step 4: Insert Laryngoscope.

The RT should use the left hand to hold the laryngoscope and the right hand to open the mouth (Figure 36-16). The laryngoscope is inserted into the right side of the mouth and moved toward the center, displacing the tongue to the left. The tip of the blade is advanced along the curve of the tongue until the epiglottis is visualized.

RULE OF THUMB

A No. 3 curved Macintosh or straight Miller laryngoscope blade is commonly used to intubate adults.

Step 5: Visualize Glottis.

As the laryngoscope blade reaches the base of the tongue, the RT looks for the arytenoid cartilage and epiglottis (Figure 36-17). If these structures are not visible, the blade is probably advanced too far and may be in the esophagus. If this is the case, the RT should maintain upward force on the laryngoscope and slowly withdraw the blade until the larynx is seen.

Step 6: Displace Epiglottis.

The technique used to displace the epiglottis depends on the type of blade chosen (Figure 36-18). With the curved or MacIntosh blade, the epiglottis is displaced indirectly by advancing the tip of the blade into the vallecula (at the base of the tongue), and the laryngoscope is lifted up and forward (see Figure 36-18, *A*). With the straight or Miller blade, the epiglottis is displaced directly by advancing the tip of the blade over its posterior surface and the laryngoscope is lifted up and forward (see Figure 36-18, *B*).

One should avoid levering the laryngoscope against the teeth while lifting the tip of the blade because this can damage the teeth and gums. This problem can be avoided by keeping the wrist fixed and moving the handle of the laryngoscope in the direction it is pointing when visualizing the epiglottis.

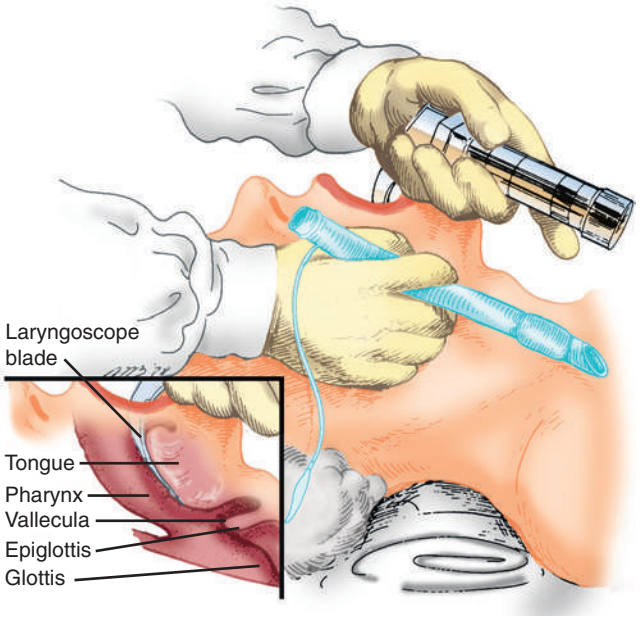

FIGURE 36-16 To achieve orotracheal intubation, the respiratory therapist holds the laryngoscope in the left hand, introduces the blade into the right side of mouth, and displaces the tongue to the left. (Modified from Ellis PD, Billings DM: Cardiopulmonary resuscitation: procedures for basic and advanced life support, St. Louis, 1980, Mosby.)

Step 7: Insert Tube.

When the epiglottis is displaced and the glottis is visualized, the tube is inserted from the right side of the mouth and advanced without obscuring the glottic opening (Figure 36-19). When the tube tip is seen passing through the glottis, it is advanced until the cuff has passed the vocal cords. When the tube is in place, the RT stabilizes it with the right hand and uses the left hand to remove the laryngoscope and stylet. The cuff is inflated to seal the airway, and ventilation and oxygenation are immediately provided.

Step 8: Assess Tube Position.

Ideally, the tip of an ETT should be positioned in the trachea about 3 to 6 cm above the carina.[29] One or more of several bedside methods can be used to assess positioning of the ETT before stabilization (Box 36-4). With the exception of fiberoptic laryngoscopy or bronchoscopy and videolaryngoscopy, none of these methods can absolutely confirm proper tube placement.

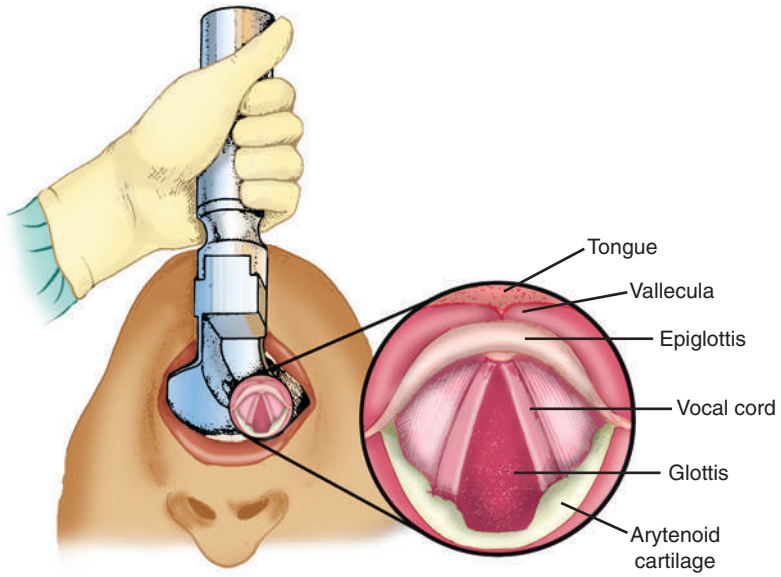

FIGURE 36-17 Visualization of vocal cords is achieved with a laryngoscope. (Modified from Ellis PD, Billings DM: Cardiopulmonary resuscitation: procedures for basic and advanced life support, St. Louis, 1980, Mosby.)

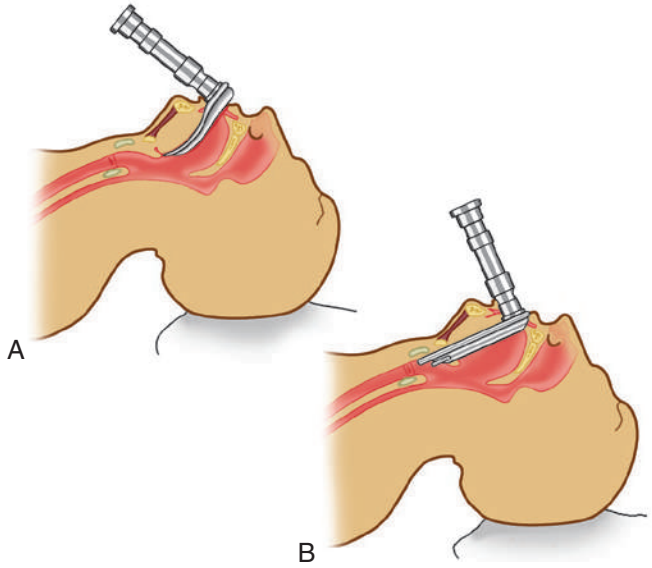

FIGURE 36-18 Placement of curved **(A)** versus straight **(B)** laryngoscope blade.

Box 36-4 Bedside Methods to Assess Endotracheal Tube Position

- Auscultation of chest and abdomen
- Observation of chest movement
- Tube length (centimeters to teeth)
- Esophageal detection device
- Light wand
- Capnometry
- Colorimetry
- Fiberoptic laryngoscopy or bronchoscopy
- Videolaryngoscopy

After tube passage and cuff inflation, the RT listens for equal and bilateral breath sounds as the patient is being ventilated. Air movement or gurgling sounds over the epigastrium indicate possible esophageal intubation. In addition, the chest wall is observed for adequate and equal chest expansion. These movements, combined with good breath sounds, are reinforcing. The combination of decreased breath sounds and decreased chest wall movement on the left side may indicate right main stem intubation. Right main stem intubation is corrected by slowly withdrawing the tube while listening for the return of left-side breath sounds. Other conditions may cause decreased breath sounds in the left lung (e.g., atelectasis, pleural effusion).

The depth of tube insertion (length from teeth to tip) is useful to help determine tube position. As indicated in Table 36-2, the average length from the teeth (incisors) to the tip of a properly positioned oral ETT in men is 21 to 23 cm. For women, this distance is approximately 2 cm less. Tube length alone cannot confirm proper placement; a tube with the 23-cm mark positioned at the teeth could just as well be in the esophagus as in the trachea.

An esophageal detection device may be used to determine whether the tube is in the esophagus or trachea.[30] This device is more commonly used outside the hospital setting. The original device consists of a squeeze-bulb aspirator attached to a standard 15-mm adapter. After a negative pressure (−80 to −90 mm Hg) is created by squeezing the bulb, the adapter is attached to the positioned ETT. If the tube is placed correctly, the bulb quickly reexpands on release because the tracheal lumen is held open by cartilaginous rings. If the tube is in the esophagus, it does not reinflate because the more pliable esophagus collapses around the tip of the ETT and prevents the bulb from reinflating. Instead of a squeeze-bulb, a large syringe with a 15-mm adapter can be used. If

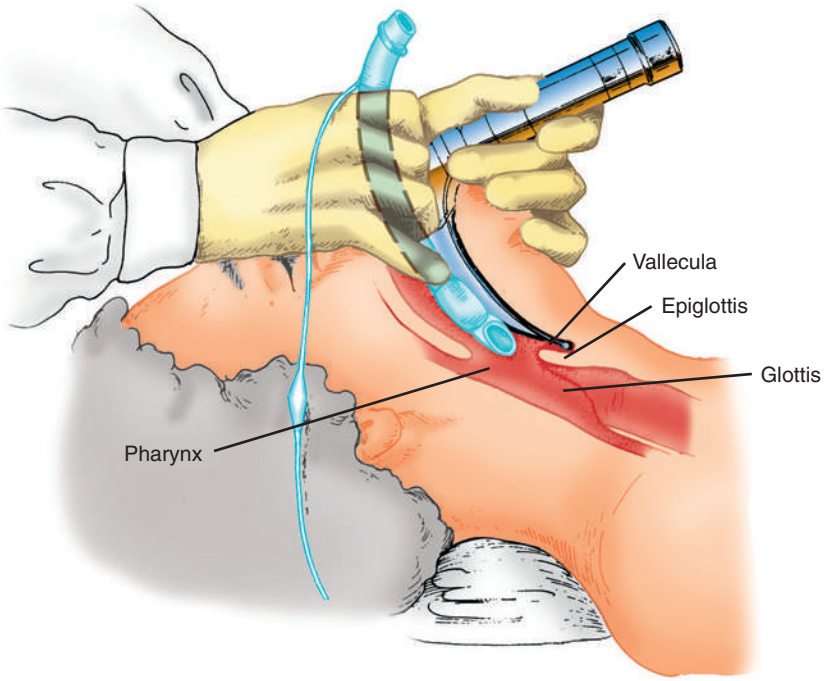

FIGURE 36-19 Insertion of endotracheal tube. (Modified from Ellis PD, Billings DM: Cardiopulmonary resuscitation: procedures for basic and advanced life support, St. Louis, 1980, Mosby.)

the ETT is in the esophagus, strong resistance is noticed when aspirating air (the barrel tends to recoil if released); if the tube is in the trachea, aspirating air into the syringe is easy. In patients with copious secretions, the esophageal detection device may become occluded and not reexpand. The esophageal detection device is not recommended for detecting esophageal intubation in children younger than 1 year.[30]

A light wand is a flexible stylet with a lighted bulb at the tip. If a light wand is used during intubation, as the stylet and ETT pass into the larynx, a characteristic glow is seen under the skin, just above the thyroid cartilage.[31] This glow is not as bright or focused if the tube is in the esophagus.

Esophageal intubation can be assessed using exhaled carbon dioxide (CO_2) analysis (capnometry). Because inspired air contains only approximately 0.04% CO_2 and end-tidal gas contains approximately 5% CO_2, placement of an ETT in the respiratory tract causes CO_2 levels to increase abruptly during expiration. This increase is evident on a capnographic display (Figure 36-20). If the tube is in the esophagus, CO_2 levels remain near zero.[32]

Colorimetric CO_2 analysis is an inexpensive alternative to capnometry. Functioning similar to pH paper, a colorimetric system has an indicator that changes color when exposed to different CO_2 levels.[33] Figure 36-21 shows a disposable colorimetric system designed specifically to confirm tube placement during intubation. Colorimetric devices are portable and disposable and are commonly used in hospitals.

Both devices are effective in detecting most esophageal intubations. However, in patients with cardiac arrest, expired CO_2 levels may be near zero because of poor pulmonary

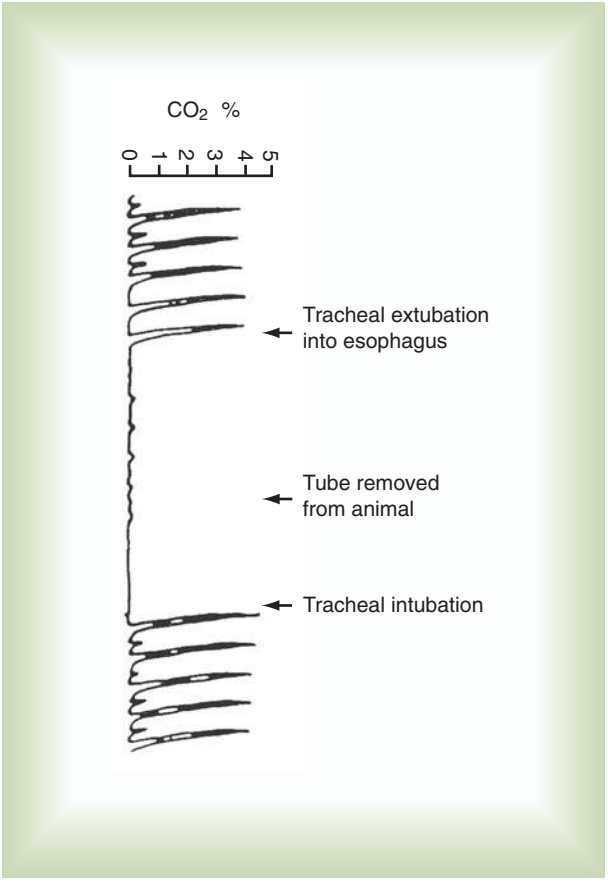

FIGURE 36-20 Capnogram tracing showing changes in expired percent carbon dioxide with proper and improper placement of endotracheal tube in test animals.

blood flow, yielding a false-negative result.[31-33] Generally, expired CO_2 levels increase with the return of spontaneous circulation. CO_2 analysis is an unreliable indicator of main stem bronchial intubation.

RULE OF THUMB

Generally, an orotracheal tube initially should be inserted to the 21- to 23-cm mark at the teeth in men and to the 19- to 21-cm mark at the teeth in women and adjusted based on the results of the patient assessment (bilateral breath sounds) and chest radiograph findings after intubation.

FIGURE 36-21 Disposable colorimetric carbon dioxide detector for confirming tracheal intubation. (Used by permission from Nellcor Puritan Bennett LLC, Boulder, Colorado, doing business as Covidien.)

Proper tube placement in the trachea can be confirmed without a chest radiograph by using a fiberoptic laryngoscope or bronchoscope[34] (Figure 36-22). After ensuring patient reoxygenation, a fiberoptic bronchoscope can be inserted directly into the ETT. Visualization of the carina distal to the tip of the ETT ensures proper placement in the trachea. More precise placement is possible by moving the bronchoscope from the tube tip to the carina, while measuring this distance. Also, a videolaryngoscope can be used to ensure proper placement of the ETT, especially in anticipated difficult intubations. It provides a better view of the airway, especially when there is limited mobility of the patient's neck or mouth. Also, other clinicians can see the airway and help if needed.[35]

MINI CLINI

Capnometry and Endotracheal Tube Placement

PROBLEM: At a code blue in the emergency department, a patient is intubated by the RT. A capnometer is attached to the ETT to confirm placement in the trachea. The end-expired CO_2 reads 0% as the patient is ventilated with a manual resuscitator. At this time, no one is performing cardiac compressions. Should the RT conclude that the ETT is not in the trachea?

DISCUSSION: No. If the patient is in cardiac arrest, no blood is perfusing the alveoli and no CO_2 is entering the alveoli. The result is an end-tidal CO_2 of 0%. When cardiac compressions begin (and they should begin immediately in confirmed cardiac arrest) and if compressions are effective, one should see an increase in end-tidal CO_2 as blood begins to perfuse the alveoli and CO_2 diffuses the blood.

There are other simple ways to assess ETT placement in the trachea, such as bilateral breath sounds on auscultation and chest excursions.[36] However, an increase in end-tidal CO_2 is a sure indication that the endotracheal tube is in the lungs because the only source of CO_2 is in the alveoli.

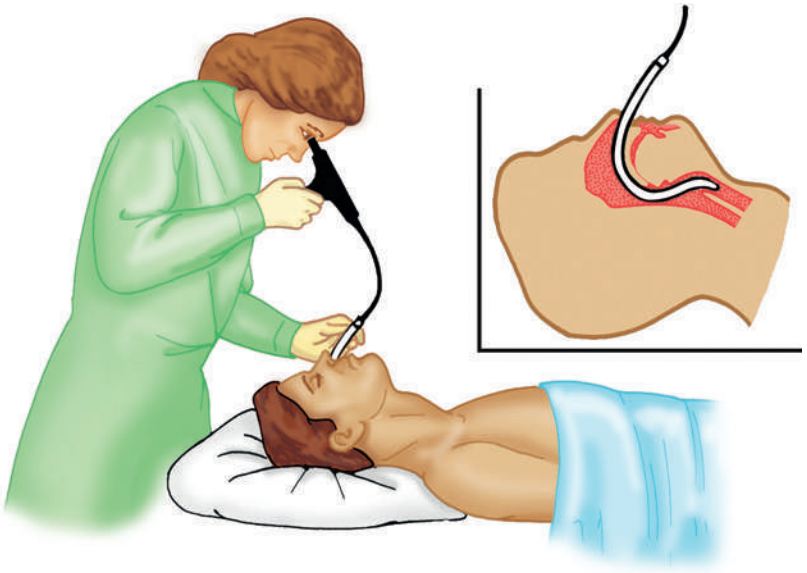

FIGURE 36-22 Fiberoptic laryngoscopy used to confirm endotracheal tube placement.

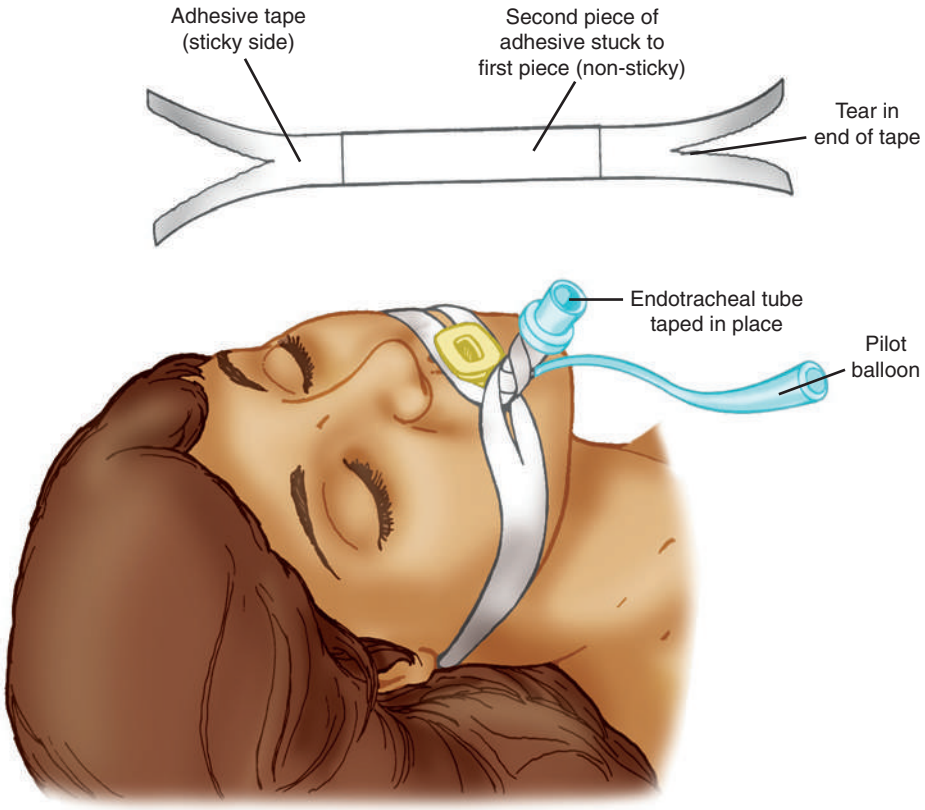

FIGURE 36-23 Securing the endotracheal tube.

Step 9: Stabilize Tube and Confirm Placement.

The tube should not be secured until correct placement has been assessed by using one or more of the previously mentioned methods. After assessing placement and while holding the tube in position, the RT secures the tube to the skin above the lip and on the cheeks using tape or an ETT holder. A bite block, oropharyngeal airway, or similar device may be needed to prevent the patient from biting down on the tube (Figure 36-23). After the tube is stabilized, a chest radiograph should be taken to confirm its position.

The most common complication of emergency airway management is tissue trauma. The most serious complications are acute hypoxemia, hypercapnia, bradycardia, and cardiac arrest.[37,38] These problems can be minimized by using proper technique, providing the patient with adequate ventilation and oxygenation (before, during, and after), and strictly adhering to intubation time limits. In addition, sedation and anesthesia can reduce complications and facilitate intubation in a semicomatose or combative patient.[27] Muscle relaxing or paralyzing agents can be used in a combative patient who cannot be controlled by sedation. A paralyzed patient has no ability to compensate for hypoxemia or hypercapnia. It is imperative that the patient can be adequately ventilated by bag and mask. Rapid-sequence induction is used with the administration of a sedative-hypnotic medication and a muscle relaxing or paralyzing agent.

Difficult intubations occur because of inability to open the patient's mouth, inability to position the patient, or unusual airway anatomy. Special intubation equipment (e.g., laryngoscope blades, videolaryngoscopy, or specialized stylets) or alternative techniques can be employed.[27,36] Additional details of these techniques are beyond the scope of this chapter.

Nasotracheal Intubation

Although nasotracheal intubation is more difficult than orotracheal intubation, it is the route of choice in certain clinical situations. Examples include intubation of patients when the oral route is unavailable, such as patients with maxillofacial injuries or undergoing oral surgery.

Nasotracheal intubation is performed either blindly or by direct visualization.[37] The direct visualization approach requires either a standard or a fiberoptic laryngoscope. For the blind technique to work, the patient must be breathing spontaneously. Equipment assembly, patient positioning, and preoxygenation are essentially the same as with oral intubation. A mixture of 0.25% phenylephrine and 3% lidocaine may be applied to the nasal mucosa with a long cotton-tipped swab to provide local anesthesia and vasoconstriction of the nasal passage.

Direct Visualization. The equipment needed for nasal intubation by direct visualization is the same as for oral intubation, with the addition of Magill forceps. A smaller ETT also may be needed. The tube should be prelubricated with water-soluble gel to aid passage. To insert the tube, the bevel is positioned toward the septum and advanced along the floor of the

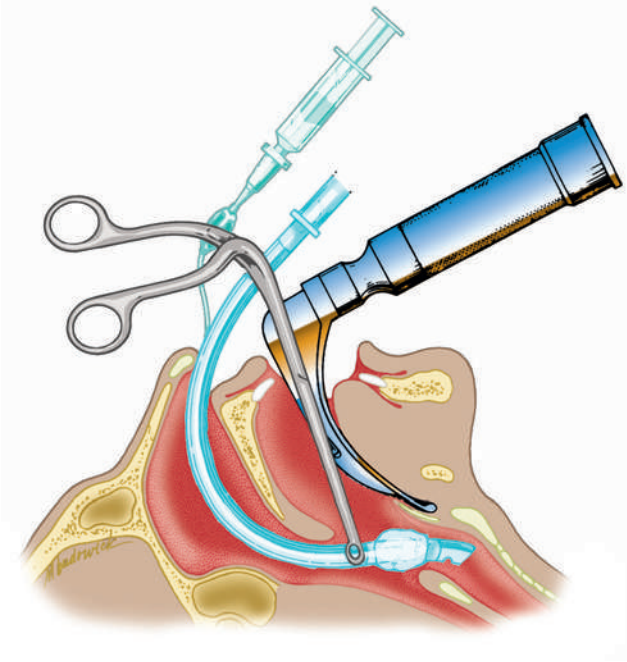

FIGURE 36-24 Nasal intubation using Magill forceps. (Modified from Finucane BT, Santora AH: Principles of airway management, Philadelphia, 1988, FA Davis.)

nasal cavity (inferiorly). When the tip of the tube is in the patient's oropharynx, the RT opens the patient's mouth, inserts the laryngoscope (with the left hand), and visualizes the glottis. The RT uses the Magill forceps with the right hand to grasp the tube just above the cuff and direct it between the vocal cords (Figure 36-24). To help advance the tube past the vocal cords, the neck may need to be flexed. Confirmation of position and stabilization follows, as with the oral route.

Alternatively, a fiberoptic bronchoscope or laryngoscope can be used to guide tube passage.[34] With the bronchoscopic method, the distal end of the scope is passed through the ETT and directly into the trachea. When placement is ensured, the RT slides the ETT down over the scope into proper position. The procedure is similar with a fiberoptic laryngoscope. However, because directional control of the scope is limited, the RT may have to reposition the patient's head and neck to help guide the tube.

Blind Passage. For blind nasal intubation, the patient is placed in either the supine or the sitting position. As with direct visualization, the tube is inserted through the nose. As the tube approaches the larynx, one can listen through the tube for air movement. The breath sounds become louder and more tubular when the tube passes through the larynx. Successful passage of the tube through the larynx usually is indicated by a harsh cough, followed by vocal silence. If the sounds disappear, the tube is moving toward the esophagus. A malpositioned tube can be corrected by manipulating the tube and repositioning the patient's head and neck. Confirmation of tube placement and stabilization should follow. As previously indicated, a light wand can help ensure proper tracheal placement during blind nasotracheal intubation.

Box 36-5 Factors to Consider in Switching from Endotracheal Tube to Tracheostomy

- Projected time the patient will need an artificial airway
- Patient's tolerance of endotracheal tube
- Patient's overall condition (including nutritional, cardiovascular, and infection status)
- Patient's ability to tolerate a surgical procedure
- Relative risks of continued endotracheal intubation versus tracheostomy

Tracheotomy

Tracheotomy is the procedure of establishing access to the trachea via a neck incision. The opening created by this procedure is called a **tracheostomy.** Tracheotomy may be performed as a regular surgical procedure or by a percutaneous dilation procedure.

Tracheotomy is the preferred, primary route for overcoming upper airway obstruction or trauma and for patients with poor airway protective reflexes. Another indication for tracheotomy is the continuing need for an artificial airway after a prolonged period of oral or nasal intubation. The patient should be assessed daily for the continued need for intubation. If the patient still needs an artificial airway after approximately 7 to 14 days, a tracheostomy is commonly considered. The benefits of a tracheostomy versus oral or nasal intubation are elimination of vocal cord injury, increased patient comfort, less need for deep sedation, easier removal of secretions, decreased work of breathing, and potentially shorter weaning time.[38] The decision when to switch from an ETT to a tracheostomy tube should be individualized. Pertinent factors that should be considered in making this decision are summarized in Box 36-5. Figure 36-25 is a decision-making algorithm useful for timing tracheotomy in critically ill patients.

Procedure. Tracheotomy should be performed as an elective procedure by a skilled physician or surgeon after the patient's airway is stabilized. Mortality and morbidity are greater when the procedure is performed on an emergency basis. The RT may be asked to assist in tracheotomy, especially if performed at the bedside. For this reason, we briefly describe both the traditional surgical procedure and the percutaneous dilation method.[38]

A local anesthetic is used, and the patient is mildly sedated if conditions permit. If an ETT is in place, it should not be removed until just before the insertion of the tracheostomy tube. Keeping the ETT in place this way ensures a patent airway and provides additional stability to the trachea during the procedure.

In traditional surgical tracheotomy, the surgeon makes an incision in the neck over the second or third tracheal ring. After the skin and subcutaneous tissue have been incised, the surgeon divides the superficial muscles and locates the underlying thyroid gland. The surgeon divides and ligates the thyroid isthmus, which overlies the second and third tracheal rings. The surgeon then enters the trachea through either a horizontal incision between rings or a vertical incision through the second

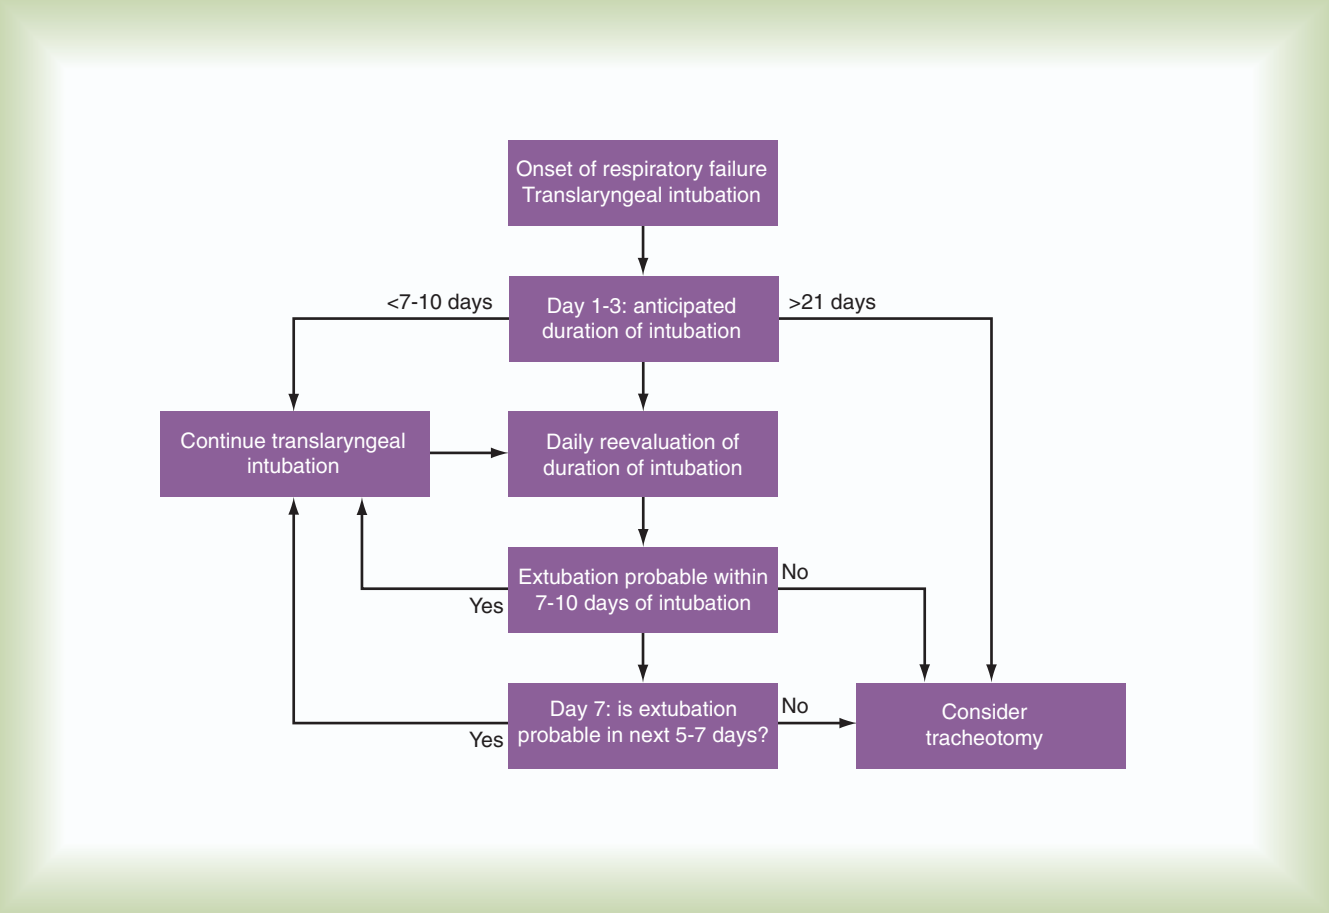

FIGURE 36-25 Approach to timing tracheotomy in patients intubated and mechanically ventilated for respiratory failure. (From Heffner JE: Timing of tracheostomy in ventilator-dependent patients. Clin Chest Med 12:611, 1991.)

and third rings. As little cartilage as possible should be removed to promote better closure after extubation.

In percutaneous dilation tracheotomy, the initial steps to prepare the patient are similar to the steps in the traditional tracheotomy procedure. After dissection to the anterior tracheal wall, the ETT is retracted to keep the tip of the tube inside the larynx. A bronchoscope can be used to reassess placement for the ETT for the duration of the procedure. A large leak around the ETT may develop, requiring adjustment of mechanical ventilation. If the patient is unable to tolerate the large leak, and adjustments to ventilatory support cannot compensate for the leak, a surgical procedure may be indicated for that patient.

The physician inserts a needle and sheath into the trachea between the cricoid and first tracheal ring or between the first and second rings. The physician then inserts a guidewire through the sheath, the sheath is removed, and a dilator is passed over the guidewire. Increasingly larger dilators are introduced until the stoma is large enough for a standard tracheostomy tube. The physician slips the tracheostomy tube over the last dilator used. An alternative to the use of multiple dilators is to use a single dilator with increasing diameter from the proximal to the distal end.

The procedure may be performed under direct vision with a bronchoscope passed through the ETT or a laryngeal mask airway (LMA). Compared with the traditional surgical procedure, a percutaneous dilation tracheotomy is rapid, with fewer complications from the surgical site, and has a better cosmetic appearance after decannulation. Contraindications for percutaneous tracheotomy are listed in Box 36-6.

Insertion of the tube, inflation of the cuff, and securing the tube follow both methods. Tracheostomy tube ties should be secure enough to prevent movement of the tube but not so tight as to cause skin ulceration. The role of the RT in the procedure may include managing the ETT, making ventilator changes as needed, assisting with the bronchoscope, and monitoring the patient. Advantages and disadvantages of percutaneous and open surgical tracheotomy are listed in Table 36-3.

Generally, the tube size is correct if it occupies two-thirds to three-quarters of the internal tracheal diameter. Tracheostomy tubes come in various sizes, lengths, and shapes depending on the manufacturer. The size marked on the flange usually indicates the internal diameter, but some tracheostomy tubes with inner cannulas use Jackson sizing. Table 36-4 lists the sizes, internal diameter, external diameter, and length of commonly used brands and styles of adult tracheostomy tubes. Table 36-5 provides guidelines for selecting a tracheostomy tube according to a patient's age. Within an age category, the exact size of tube chosen depends on the patient's height, weight, and airway

Box 36-6 Contraindications for Percutaneous Dilation Tracheostomy

ABSOLUTE
- Need for emergent surgical airway

RELATIVE
- Children younger than 12 years of age
- Poor landmarks secondary to body habitus, abnormal anatomy, or occluding thyroid mass
- Positive end expiratory pressure less than 15 cm H_2O
- Coagulopathy
- Pulsating blood vessel over tracheotomy site
- Limited ability to extend cervical spine
- History of difficult intubation
- Infection, burn, or malignancy at tracheotomy site

From Park S, Goldenberg D: Percutaneous tracheotomy: Griggs technique. Op Tech Otolaryngol 18:95, 2007.

TABLE 36-3 Comparison of Percutaneous and Open Surgical Tracheotomy

Procedure	Advantages	Disadvantages
Percutaneous tracheotomy	May be done in intensive care unit	Not done in children younger than 12 yr
	Sedation and local anesthetic given	
	Stoma usually stabilizes in 5 days	May be difficult to insert because of calcified cartilaginous rings
Open surgical tracheotomy	Done in patients with poor landmarks because of abnormal anatomy or body habitus	Usually done in operating room
	May be done emergently	General anesthesia given
	Done in children younger than 12 yr	Stoma usually takes longer to stabilize (7 to 10 days)

TABLE 36-5

Guideline for Infant, Pediatric, and Adult Tracheostomy Tube Sizes

Age/Weight*	ID (mm)
Premature <2 kg	2.5 cuffless neonatal
Infant	3.0-3.5 cuffless neonatal
6-18 mo	3.5-4.0 neonatal or pediatric
18 mo to 4-5 yr	4.0-4.5 pediatric
4-5 yr to 10 yr	4.5-6.0 pediatric
10-14 yr	5.0-6.5 pediatric or adult
14 years to adult	6.0-9.0 adult

NOTE: The difference between the same size (ID) neonatal and pediatric tube or pediatric and adult tube is the length; that is, the adult tube is longer than the pediatric tube, and the pediatric tube is longer than the neonatal tube.
ID, Inner diameter.
*Typical pediatric size = (16 + age)/4 or (age/4) + 4.

anatomy. To choose a tracheostomy tube that fits a patient properly, it is important to consider not only the internal and external diameter of the tube but also the length and shape of the tube.

Laryngectomy

Total **laryngectomy,** removal of the larynx (voice box), is usually done to treat laryngeal cancer. It also may be done to treat severe trauma, such as from a gunshot wound to the neck or damage to the larynx from radiation (radiation necrosis). Besides removing the larynx the surgeon creates a hole in the neck (stoma) and attaches the trachea to the stoma. The patient will now breathe through this permanent stoma. A laryngectomy tube may be inserted into the stoma to keep it open while it heals.

The surgeon may also do a tracheoesophageal puncture (TEP), which is a small opening between the posterior wall of the trachea and esophagus. The surgeon will insert a small device (prosthesis) that has a one-way valve. This prosthesis allows the patient to speak when the patient occludes the stoma during exhalation once the patient has been trained by a speech and language pathologist (Figure 36-26). Some patients with TEP use their thumb, and others use an attached tracheostoma adjustable valve to occlude the stoma during exhalation to be able to speak. Another way a laryngectomy patient can speak is by holding an electrolarynx against the throat. This is a battery-operated device that creates vibrations that are transmitted through the pharynx and mouth to produce a voice.[39]

The risks associated with this surgery are hematoma, wound infection, fistulas, stomal stenosis (narrowing), leaking around tracheoesophageal prosthesis, difficulty swallowing and eating, and problems speaking.

Sometimes the surgeon will perform only a partial laryngectomy to remove the cancer. A tracheotomy is also done and a tracheostomy tube is inserted while the surgical site is allowed to heal. There is still communication between the pharynx and trachea, so the patient should eventually be able to breathe using the normal upper airway and may even be able to speak once the tracheostomy tube is removed by the surgeon.[40]

It is important to know whether a patient has had a total or partial laryngectomy, in case the patient accidentally loses the artificial airway and requires manual ventilation. In the case of a total laryngectomy the RT would apply bag-mask ventilation over the stoma, ideally using a small pediatric mask that would fit more closely over the stoma than an adult mask. In a partial laryngectomy the RT would cover the stoma with a gauze pad and apply bag-mask ventilation over the nose and mouth with the standard adult mask because there is still communication between the trachea and upper airway.

AIRWAY TRAUMA ASSOCIATED WITH TRACHEAL TUBES

Artificial airways do not conform exactly to patient anatomy, which may result in pressure on soft tissues that can result in ischemia and ulceration.[41] In addition, artificial airways tend to shift position as the patient's head and neck move or as the tube is manipulated. This shifting can result in friction-like injuries. Occasional reaction to the materials composing the tube also may cause problems.

Depending on the type of tube, damage to the patient's airway can occur anywhere from the nose down into the lower trachea. Because tracheostomy tubes do not pass through the larynx, structural injury resulting from these airways is limited to tracheal sites. Laryngeal dysfunction may occur secondary to a lack of stimulation from airflow or restricted movement secondary to equipment.[14]

Because injury often cannot be assessed while an artificial airway is in place, the patient's airway should always be evaluated carefully after extubation. Techniques commonly used to diagnose airway damage include physical examination, air tomography, fluoroscopy, laryngoscopy, bronchoscopy, magnetic resonance imaging, and pulmonary function studies.[42]

Laryngeal Lesions

The most common laryngeal injuries associated with endotracheal intubation are glottic edema, vocal cord inflammation, laryngeal or vocal cord ulcerations, and vocal cord polyps or granulomas. Less common and more serious injuries are vocal cord paralysis and laryngeal stenosis.[29,41]

Glottic edema and vocal cord inflammation are transient changes that occur as a result of pressure from the ETT or trauma during intubation.[41] The primary concern with glottic edema and vocal cord inflammation occurs after extubation. Because swelling can worsen over 24 hours after extubation, patients should be evaluated periodically for delayed development of glottic edema.

The primary symptoms of glottic edema and vocal cord inflammation are hoarseness and stridor. Hoarseness occurs in most extubated patients and usually resolves quickly. Stridor is a more serious symptom than hoarseness, indicating a significant decrease in diameter of the airway. Stridor is often treated with epinephrine (2.25% racemic solution or levoepinephrine 1:1000) via aerosol.[41] The treatment goal is to reduce glottic or airway edema by mucosal vasoconstriction. A steroid also may be added to the aerosol to reduce inflammation further. Both of these techniques are more commonly used in children than in adults.

To reduce laryngeal edema in patients who have had prolonged intubation or patients who have failed prior extubation because of glottic edema, intravenous steroids may be given 24 hours before extubation.[41] If stridor continues and is unresponsive to treatment, structural changes that narrow the airway should be suspected.

Laryngeal and vocal cord ulcerations may cause hoarseness soon after extubation. Symptoms usually resolve spontaneously, and no treatment is indicated. Vocal cord polyps and granulomas develop more slowly, taking weeks or months to form.[24] Symptoms include difficulty in swallowing, hoarseness, and stridor. If symptoms are severe or persistent, the polyps or granulomas may have to be removed surgically.

Vocal cord paralysis is likely in extubated patients with hoarseness and stridor that does not resolve with treatment or time. In some patients, symptoms may resolve within 24 hours, and full movement of the vocal cords can return over several days. If the obstructive symptoms continue, tracheotomy may be indicated.

Laryngeal **stenosis** occurs when the normal tissue of the larynx is replaced by scar tissue, which causes stricture and decreased mobility. The symptoms of laryngeal stenosis are similar to symptoms of vocal cord paralysis—stridor and hoarseness. Because laryngeal stenosis does not resolve spontaneously, surgical correction is usually required. Some patients require a permanent tracheostomy.

Tracheal Lesions

Although laryngeal lesions occur only with oral or nasal ETTs, tracheal lesions can occur with any tracheal airway. These tracheal lesions include granulomas, **tracheomalacia,** and tracheal stenosis.[1,24,43] Less common, but more serious complications are tracheoesophageal and tracheoinnominate artery fistulas.

Tracheomalacia and tracheal stenosis can occur either separately or together. *Tracheomalacia* is the softening of the cartilaginous rings, which causes collapse of the trachea during inspiration and expiration. *Tracheal stenosis* is a narrowing of the lumen of the trachea, which can occur as fibrotic scarring, causes the airway to narrow. In patients with ETTs, this type of damage most often occurs at the cuff site. In patients with tracheostomy tubes, stenosis may occur at the cuff, tube tip, or stoma sites; the stoma site is the most common. Stenosis at the stoma site is associated with too large a stoma, infection of the stoma, movement of the tube, frequent tube changes, and advanced age.[44]

Signs of possible tracheal damage before extubation include difficulty in sealing the trachea with the cuff and evidence of tracheal dilation on chest radiograph.[41] Signs and symptoms of postextubation problems include difficulty with expectoration, dyspnea, and stridor. Although these findings may appear acutely, they may develop over several months and may not be present until the radius is reduced by 50% to 75%. Dyspnea at rest may not be seen until the diameter of the trachea is less than 5 mm. Symptoms are often incorrectly attributed to the development of asthma or chronic lung disease.[24]

Tomography, fluoroscopy, and pulmonary function studies (especially flow-volume loops) may be helpful in quantifying the severity of the damage. Flow-volume loops are also helpful in distinguishing between tracheomalacia and tracheal stenosis. Tracheomalacia appears as a variable obstruction with different inspiratory and expiratory patterns. Tracheal stenosis appears as a fixed obstructive pattern, with flattening of both the inspiratory and the expiratory limbs of the flow-volume loop (Figure 36-27).

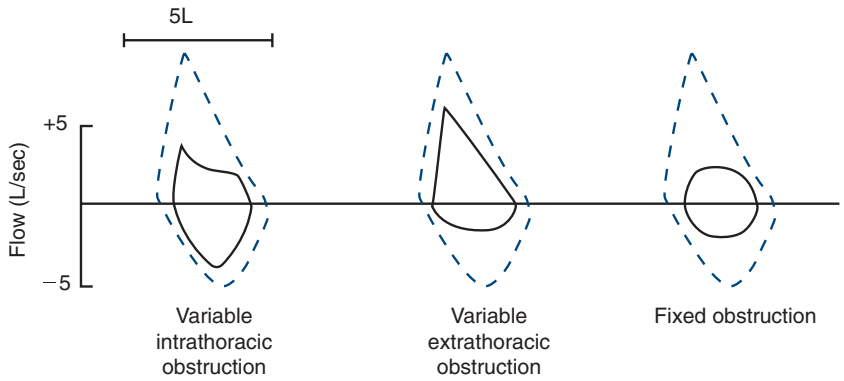

FIGURE 36-27 Patterns of pulmonary dysfunction revealed by flow-volume loops. *Dashed lines* are normal values for comparison. Tracheomalacia is typically seen as a variable obstruction, whereas stenosis most often manifests with a fixed obstruction pattern. (Modified from Mottram C: Ruppel's manual of pulmonary function testing, ed 10, Mosby, 2013, St. Louis.)

Treatment depends on the severity of the lesion, especially the length and circumference of the damage.[42] Laser therapy may be useful if the lesion is small. Resection and end-to-end anastomosis may be indicated when the damage involves fewer than three tracheal rings. More involved damage may require staged repair. Stents may be placed to maintain the patency of the airway.

A **tracheoesophageal fistula** is a direct communication between the trachea and the esophagus. Tracheoesophageal fistula is a rare complication of both tracheotomy and endotracheal intubation. If it occurs soon after a tracheotomy, incorrect surgical technique may be the cause. Later development is related to sepsis, malnutrition, tracheal erosion from the cuff and tube, and esophageal erosion from nasogastric tubes.[41] The diagnosis can be made based on a history of recurrent aspiration and abdominal distention as air is forced into the esophagus during positive pressure ventilation. Diagnosis is also made by direct endoscopic examination of the trachea and esophagus. Treatment involves surgical closure of the defect.

A **tracheoinnominate artery fistula** can occur when a tracheostomy tube causes tissue erosion through the innominate artery. The result is massive hemorrhage and, in most cases, death. Tracheoinnominate artery fistula is a rare complication, probably caused by improper low positioning of the stoma or excessive movement of the tube.[42] Pulsation of the tracheostomy tube may be the only clue before actual hemorrhage. When hemorrhage begins, hyperinflation of the cuff may slow the bleeding, but the patient still needs surgical intervention.[42] Even with proper corrective action, only 25% of patients who develop this serious complication survive.

Prevention

Several actions can minimize the trauma caused by tracheal airways. Many studies suggest that tube movement is a primary cause of injury.[41,42] Several methods can be used to limit tube movement. Sedation can help keep patients comfortable and decrease the likelihood of self-extubation. Nasotracheal tubes are easier to stabilize and may move less than orotracheal tubes. Swivel adapters can be used to minimize tube traction whenever respiratory therapy equipment is attached to patients with tracheostomies. If a patient with a tracheostomy requires O_2 therapy, tracheostomy collars are preferred to T-tubes or Briggs adapters.

Selection of the correct airway size is also important. Once in place, endotracheal and tracheostomy tubes should not be changed unless necessary. To minimize vocal cord closure around ETTs, patients should be discouraged from unnecessary coughing or efforts to talk. Tracheal wall injury from the endotracheal or tracheostomy tube cuff can be reduced by maintaining pressures of 20 to 30 cm H_2O.[13,43] If the airway is in place solely for suctioning or to bypass an obstruction, a cuff may not be needed.

Infected secretions have been implicated in the development of tracheitis and mucosal destruction, and infection of the tracheotomy stoma has been linked to tracheal stenosis.[42] Sterile techniques should be used when cleaning or suctioning tracheostomy tubes. Good tracheostomy care, including aseptic cleaning of the stoma with sterile normal saline or half-strength hydrogen peroxide, should be carried out routinely, and soiled tracheostomy dressings should be changed as needed. If there is significant drainage from the stoma, it is better to use a foam dressing, which will absorb the drainage away from the skin, rather than a standard gauze dressing, which when wet will keep the skin moist. (See discussion of tracheostomy care procedure later in the chapter.) When sutures are used to secure the trach tube flange to the patient's neck it can be very difficult to properly clean around the stoma. So if sutures are present, it is recommended to remove them as soon as possible, ideally by day 7 after the tracheostomy was performed. If there are any signs of pressure injury from the trach flange, place a hydrocolloid dressing under the flange. Sometimes because of a patient's neck anatomy, changing the tracheostomy tube to another type with a different style of flange as soon as it is safe to do so may also prevent further skin injury.

RULE OF THUMB

In adults, tracheal tube cuff pressure should be maintained at 20 to 30 cm H_2O to minimize tracheal mucosal injury and aspiration of oral secretions.

AIRWAY MAINTENANCE

The RT must attend to several aspects of airway maintenance when a tracheal airway is in place. Critical responsibilities in this area include (1) securing the tube and maintaining its proper placement, (2) providing for patient communication, (3) ensuring adequate humidification, (4) minimizing the possibility of infection, (5) aiding in secretion clearance, (6) providing appropriate cuff care, and (7) troubleshooting airway-related problems.

Securing the Airway and Confirming Placement

The most common way to secure ETTs is with tape. The tape is secured to one side of the face and then wound around the tube and airway once or twice before the end is secured to the skin again (see Figure 36-23). Silk tape is adequate if the period of intubation is short, such as during surgery; however, silk tape is easily loosened by oral secretions. Cloth tape seems to be better for longer use and may adhere better if the skin is prepared with a nonirritating medical liquid adhesive. Instead of using tape to secure the tube, practitioners can choose among several commercial ETT or stabilizers. Case reports indicate that use of these stabilizers can result in less skin damage, tube movement, and self-extubations than with traditional taping. However, of and by themselves, these stabilizing devices cannot prevent airway or skin trauma. So the skin around the mouth or nose should be checked regularly. If there is evidence of skin irritation, the tube should be moved to the other side of the mouth or the other nares and then resecured.

A tracheostomy tube can be secured by threading cloth ties through the tube flange and tying them together on the side of the patient's neck. Alternatively, a commercial tracheostomy tube holder made of soft foam with Velcro attachments threaded through the tube flange can be used. This soft tracheostomy tube holder is easier to change and does not cause skin ulceration as often as cloth ties. Whichever tube holder is used, skin damage can be minimized by keeping the ties loose enough to slip one finger underneath easily.

Proper placement of an endotracheal or tracheostomy tube normally is confirmed by radiograph. The tube tip should be approximately 3 to 6 cm above the carina in adults, or between the second and fourth tracheal rings.[29,44] Keeping the tube position in this range minimizes the chance of the tube moving down into the main stem bronchi or up into the larynx. Even so, the ETT position changes with movement of the head and neck (Figure 36-28).[45] Flexion of the neck moves the tube toward the carina, whereas extension pulls the tube toward the larynx.[46,47] When reviewing a radiograph for tube placement, the clinician should also check the position of the head and neck. If the tube is malpositioned, the old tape should be removed and the tube repositioned, using the centimeter markings as a guide. This maneuver usually requires two people to prevent extubation.

As an alternative to using chest films to confirm tube placement, a practitioner trained in fiberoptic laryngoscopy or bronchoscopy may confirm the position of the tube visually.[48] With this method, the fiberoptic scope is inserted into the tube, and the carina is directly visualized. By moving the scope from the tube tip to the carina and measuring the distance of bronchoscopy displacement, the exact distance of insertion can be determined.

Providing for Patient Communication

One of the most frustrating aspects of caring for a patient with a tracheal tube is his or her inability to talk. Phonation requires moving vocal cords, resulting in airflow between them. ETTs prevent vocal cord movement and airflow through the cords. Standard tracheostomy tubes allow vocal cord movement but prevent airflow. Without the ability to speak, the patient cannot easily inform the health care providers of changes in symptoms or make basic requests. This situation may lead to agitation and stress in the patient. If that agitation is treated with sedatives, a patient on a ventilator may wean more slowly.[47]

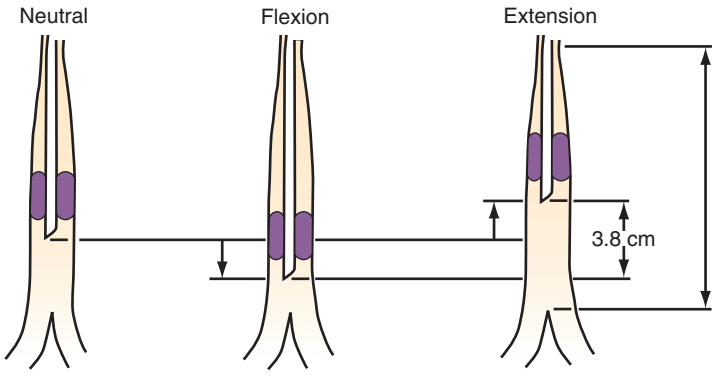

FIGURE 36-28 Effect of neck flexion and extension on endotracheal tube position. (Modified from Conrardy PA, Goodman L, Lainge F, et al: Alteration of endotracheal tube position: flexion and extension of the neck. Crit Care Med 4:8, 1976.)

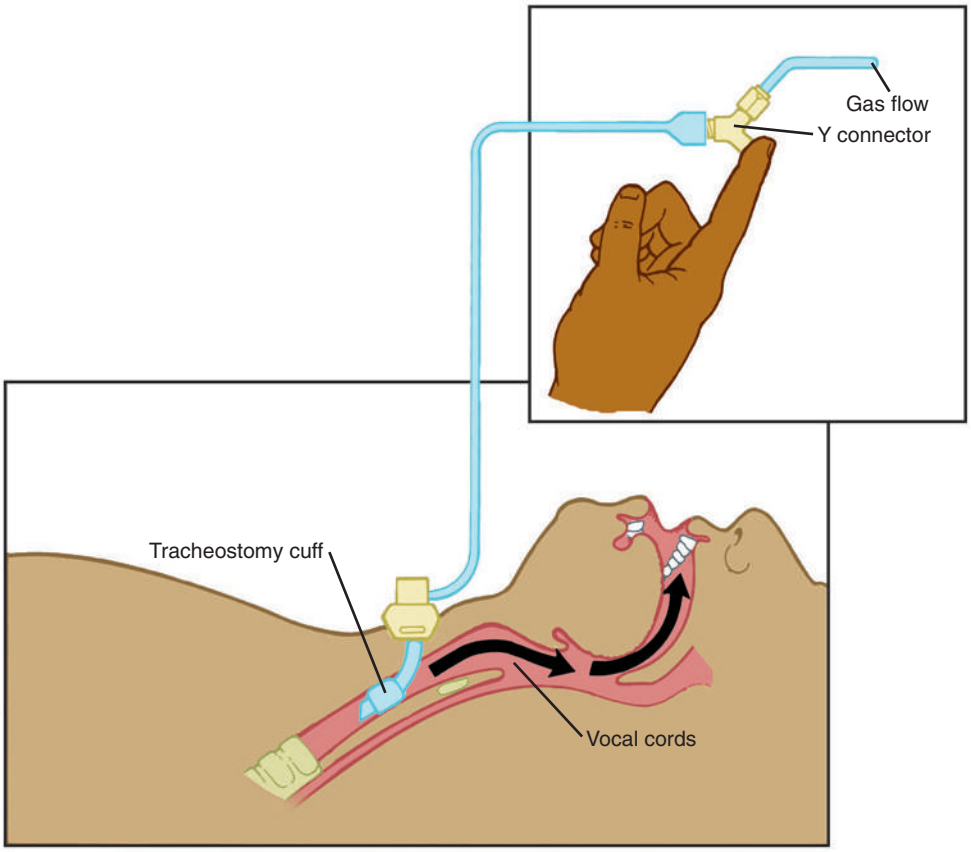

FIGURE 36-29 "Talking" tracheostomy tube.

An experienced practitioner may use lip reading, but this technique is very difficult in patients with orotracheal tubes. Alternatively, an alert patient may write messages on paper or some other writing surface. For many patients, however, restricted hand movement because of restraints or vascular catheters makes writing impossible. Some critically ill patients simply cannot hold up their heads. A better solution is a letter, phrase, or picture board.[47] These devices allow patients to communicate by simple pointing. Large and simple drawings are particularly important for patients who cannot see print clearly. Some patients may choose to use special electronic devices to communicate, especially patients who have a tracheostomy tube because of the need for chronic mechanical ventilation. Speech language pathologists often work with these patients to figure out which device will work best so an individual patient can communicate.

For conscious patients with a long-term tracheostomy who are ventilator-dependent, communication can be enhanced with a "talking" tracheostomy tube (Figure 36-29).[28] These special airways provide a separate inlet for compressed gas, which escapes above the tube, allowing phonation. There are some problems associated with these tubes, however. The continuous gas flow through a new tracheostomy may cause air leaks. High flow rates may cause mucosal drying and irritation. Finally, secretions may occlude the speaking gas outlets. Although not life-threatening, these problems can be frustrating for both the patient and the practitioner.

Another tracheostomy tube, the Blom fenestrated tracheostomy tube, has a special speech cannula that allows ventilator-dependent patients to speak with the cuff fully inflated. With the speech cannula inserted during inhalation the flap valve opens and the flexible bubble valve expands, blocking the fenestrations. During exhalation the flap valve closes and the bubble valve collapses, which allows air to pass through the fenestrations so the patient can speak.[28] (Figure 36-30)

An alternative to a speaking tracheostomy tube is to place a one-way valve (speaking valve) on the external opening of the tracheostomy tube.[28] With this device in place and the tracheostomy tube cuff deflated, the patient inhales around and through the tube and exhales only around the tube through the larynx. Speech is coordinated with exhalation through the larynx. A patient who is a good candidate for a speaking valve is one who is medically stable, is able to communicate, and has a low risk for aspiration. Several types of speaking valves are available, as shown in Figure 36-31. They can be used with spontaneously breathing or ventilator-dependent patients. When using the speaking valve, the cuff on the tube must be deflated to allow airflow around the tube. This deflation of the cuff causes a leak on inspiration and a decrease in tidal volume (V_T) delivery during mechanical ventilation. However, an increase in the set V_T on the ventilator during initial trials of the valve should compensate for this.

During the initial placement of the speaking valve, the patient's ability to exhale around the tracheostomy tube should

FIGURE 36-30 Blom fenestrated trach tube with speech cannula.

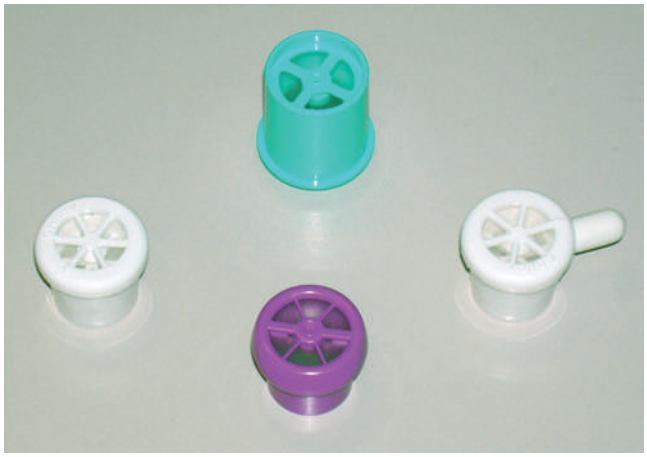

FIGURE 36-31 Speaking valves.

FIGURE 36-32 Setup to measure transtracheal pressures with speaking valve on tracheostomy tube.

be assessed by measuring the tracheal pressure during exhalation with the valve in place as shown in Figure 36-32. If the tracheal pressure is greater than 5 cm H_2O, it may indicate that there is increased resistance during exhalation. The most common causes of this problem are the size of the tracheostomy tube relative to the size of the trachea, tube position, inadequate cuff deflation, or an upper airway abnormality.[28] The tube may need to be changed to a smaller size, to a cuffless tube, or to a tube with a tight-to-shaft cuff. The speaking valve then can be placed and the tracheal pressure measured again. If an upper airway abnormality is suspected, an otolaryngologist should be consulted. A speech-language pathologist may be consulted to assist in the assessment of the patient's risk for aspiration and tolerance of the speaking valve.

Assessment of heart rate, respiratory rate, and saturation should follow initial placement of the valve for all patients. In addition to facilitating communication, other benefits of airflow over the upper airway include better function of the vocal cords, better sense of smell, and fewer secretion problems. Improved swallowing function and less aspiration have been reported with the speaking valve.[48,49]

RULE OF THUMB

The tracheostomy tube cuff must be deflated before a speaking valve is placed on the tracheostomy tube.

Ensuring Adequate Humidification

Although tracheal tubes provide an artificial airway to conduct gas to and from the lungs, they do not function as well as natural airways. Specifically, artificial tracheal airways bypass the normal humidification, filtration, and heating functions of the upper airway. The decreased humidity in the inspired air can cause secretions to thicken. Cool air also can decrease ciliary function. These conditions may impair mucociliary clearance and cause retention of secretions. If a patient is intubated to help clear secretions, failure to provide adequate humidification only worsens the problem. In the worst case, thick secretions can obstruct a tracheal tube and cause asphyxiation.

Either a heated humidifier or a large-volume jet nebulizer should be used to deliver heated humidity to nonventilated patients with a tracheostomy. However, some patients may have increased airway resistance or bronchospasm from the aerosol produced by a large-volume jet nebulizer. A heat and moisture exchanger may be used to provide humidity to patients who do not require O_2 and do not have thick secretions. For ventilated patients, a heated humidifier or heat and moisture exchanger can be used. These devices can provide saturated gas to the airway at temperatures between 32° C and 35° C.[50] The selection of a humidification device ultimately should be based on patient needs and assessment of the airway and include the volume and thickness of secretions and the history of mucous plugging or tube occlusions. More details are provided in the AARC Clinical Practice Guideline for humidification during mechanical ventilation, which is included in Chapter 38.[51]

Minimizing Nosocomial Infections

Patients with tracheal airways are very susceptible to bacterial colonization and infection of the lower respiratory tract. The presence of infection is suggested by changes in the patient's sputum (color, consistency, or amount), breath sounds (wheezes, crackles, or rhonchi), or chest radiograph (infiltrates or atelectasis).[52] Additional changes associated with bacterial infection include fever, increased heart rate, and leukocytosis.

There are several reasons why tracheal tubes increase the incidence of pulmonary infection (Box 36-7).[52,53] To guard against infection, the clinician first should avoid introducing organisms into the airway. The clinician does this by (1) adhering to sterile technique during suctioning, (2) ensuring that only aseptically clean or sterile respiratory equipment is used for each patient, and (3) consistently performing hand hygiene between patient contacts (see Chapter 4).[54]

In addition, efforts should be made to prevent retention of secretions. Suctioning, chest physiotherapy, and adequate humidification are useful to this end. Closed suction systems may be preferred to open suction systems in the prevention of infection.[54] Routinely cleaning or changing the inner cannula on tracheostomy tubes also may help minimize bacterial contamination and infection. Techniques to decrease the consequences of pharyngeal aspiration include (1) use of medications for stress ulcer prophylaxis, such as sucralfate, that maintain normal gastric pH; (2) positioning of patients with the head of the bed elevated 30 degrees or more to decrease reflux; and (3) continuous aspiration of subglottic secretions.[55]

Facilitating Secretion Clearance

The most common cause of airway obstruction in critically ill patients is retained secretions. To remove retained secretions, blood, or other semiliquid fluids from the large airways, the patient is suctioned as described previously in this chapter. Suctioning involves application of negative pressure to the large airways through a catheter. This method may be used alone or in combination with noninvasive techniques described in Chapter 43.

One noninvasive technique is the mechanical insufflator-exsufflator (Cough Assist, J. H. Emerson, Cambridge, MA). It has been shown to facilitate secretion clearance in patients with an ineffective cough, especially secondary to neuromuscular disease, such as amyotrophic lateral sclerosis and muscular dystrophy.[56,57] These patients have decreased vital capacities and expiratory flows. During inspiration, the mechanical insufflator-exsufflator delivers positive pressure usually set between 30 and 40 cm H_2O for 1 to 3 seconds to inflate the lungs. During expiration, it delivers negative pressure usually set between 30 and 40 cm H_2O for 2 to 3 seconds, which increases the expiratory flow rates mobilizing secretions upward into the larger airways.

The mechanical insufflator-exsufflator can be used with a face mask, mouthpiece, or artificial airway. The patient's oropharynx may need to be suctioned after using the mechanical insufflator-exsufflator with a face mask or mouthpiece if the patient is unable to expectorate the secretions. A patient with a tracheostomy tube may require suctioning to clear the tube of secretions after using the mechanical insufflator-exsufflator. The mechanical insufflator-exsufflator may also be used to improve secretion clearance in patients with chronic obstructive pulmonary disease (COPD) and in pediatric patients, but the evidence is unclear as to how beneficial it is in these patients.[58]

Box 36-7 Why Tracheal Airways Increase the Incidence of Pulmonary Infection

- Bypassed upper airway filtration
- Increased aspiration of pharyngeal secretions
- Contaminated equipment or solutions
- Impaired mucociliary clearance in trachea
- Increased mucosal damage owing to tube or suctioning
- Ineffective clearance via cough

Providing Cuff Care

Tracheal tube cuffs are used to seal the airway for mechanical ventilation or to prevent or minimize aspiration. As previously mentioned, tracheal stenosis and tracheomalacia are associated with cuff use. The pathogenesis of these problems is related to the amount of cuff pressure transmitted to the tracheal wall, impeding the flow of blood and lymphatic fluid. If cuff pressure exceeds the mucosal perfusion pressure, ischemia, ulceration, necrosis, and exposure of the cartilage may result (Figure 36-33).

Importance of Cuff Pressure

In the past, high-pressure tracheal tube cuffs were a major cause of airway damage. Since the 1970s, high-residual-volume, low-pressure cuffs have become the norm (Figure 36-34). The fully inflated diameter of these cuffs is greater than the diameter of the trachea. This means that the cuff does not have to be fully inflated to seal the airway, and less internal cuff pressure is needed. When properly used, these cuffs transmit less pressure to the tracheal wall than the older high-pressure designs. Although low-pressure cuffs have reduced the incidence of tracheal damage, they have not eliminated the problem entirely.

Cuff Inflation and Measuring and Adjusting Cuff Pressure

Key aspects of airway care are cuff inflation and cuff pressure measurement and adjustment. The goal is to keep cuff pressures below the tracheal mucosal capillary perfusion pressure, estimated to range from 20 to 30 mm Hg.[43] Higher pressure cuts off mucosal blood flow and causes tissue damage. However, if the cuff pressure is too low, it does not prevent silent aspiration of pharyngeal secretions, which can contribute to the development of VAP. It is recommended to inflate the cuff to 20 to 30 cm H_2O, which should prevent tracheal mucosal injury. Minimal occluding volume and minimal leak inflation techniques are no longer recommended because they increase the risk for silent aspiration.[43]

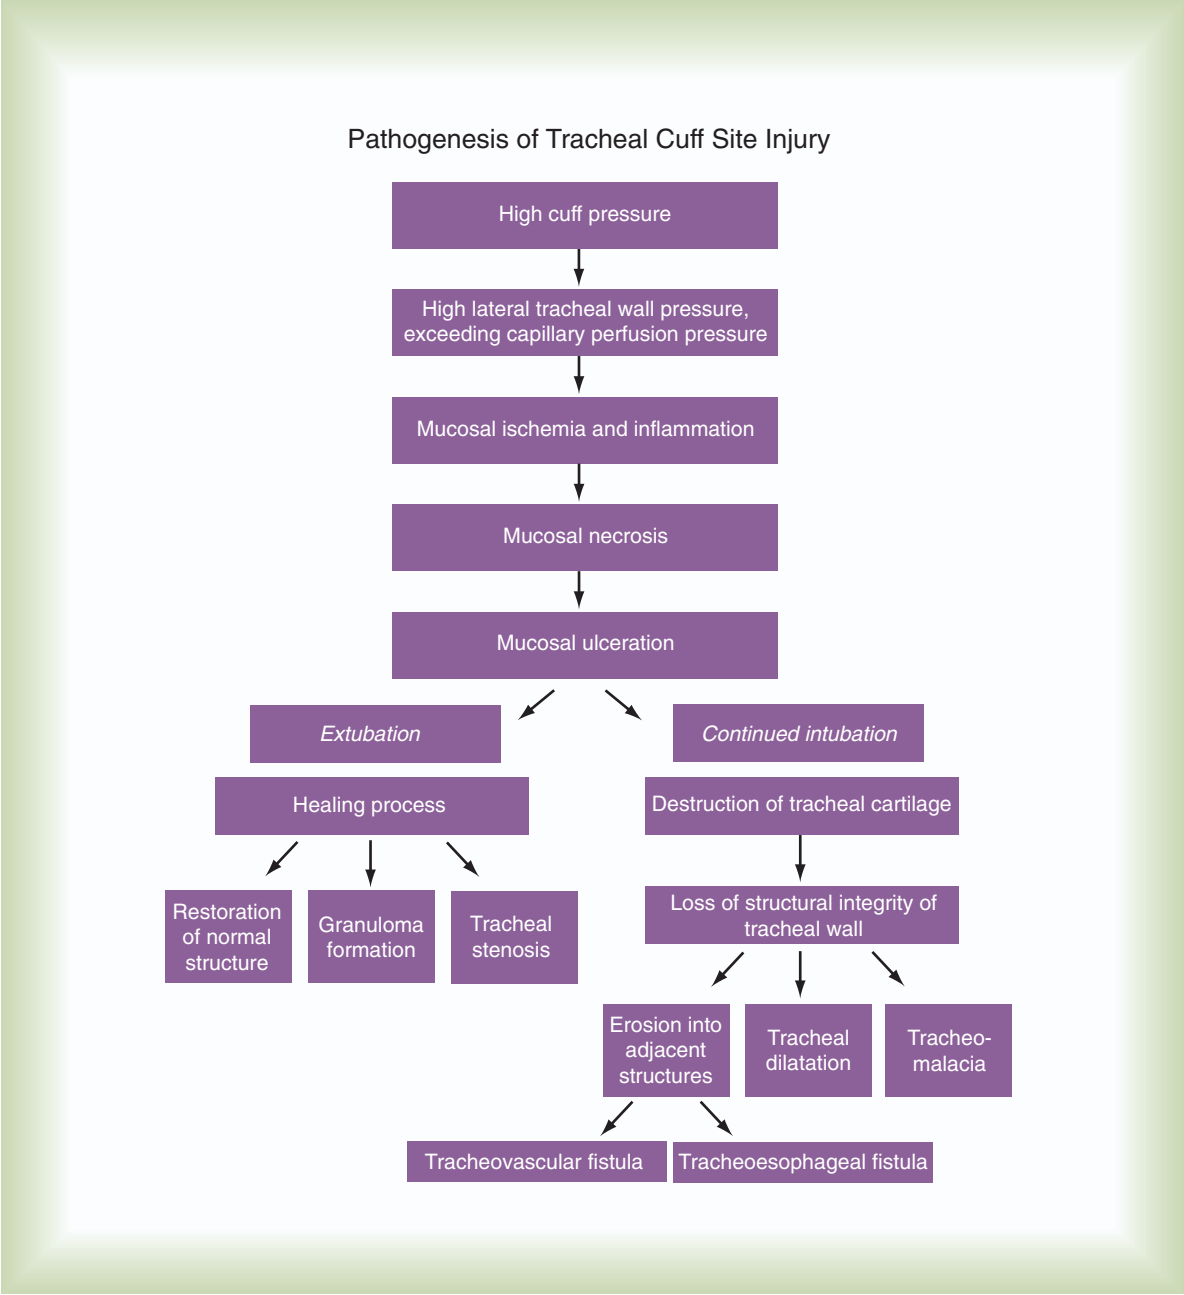

FIGURE 36-33 Tracheal injury may occur secondary to trauma from the cuff. (Modified from Stauffer JL: Complications of endotracheal intubation and tracheostomy. Respir Care 44:828, 1999.)

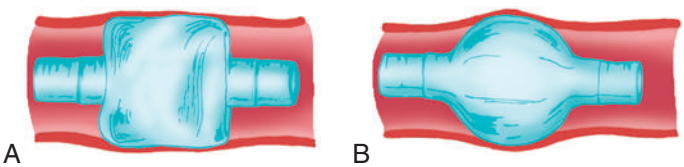

FIGURE 36-34 Comparison of shapes of high-residual-volume, low-pressure cuff **(A)** and low-residual-volume, high-pressure cuff **(B).** (Modified from McPherson SP: Respiratory therapy equipment, ed 4, St. Louis, 1989, Mosby.)

Cuff pressure can be measured with various devices designed for this purpose. These devices have the ability to measure the pressure and allow air to be added or withdrawn from the cuff. There are two key considerations when making these adjustments. First, most manometers are calibrated in centimeters of water, with the "acceptable range" of pressure 20 to 30 cm H_2O.[42] Second, attaching the measurement system to the pilot tube evacuates some volume from the cuff (and decreases its pressure). For this reason, the clinician should always adjust the pressure to the desired level and never just measure it.

High cuff pressures may be caused by the need to overinflate the cuff to seal the airway. This problem is common if the tube

chosen is too small for the patient's trachea or positioned too high in the trachea or if the patient has developed tracheomalacia (softening of the tracheal tissue). Another cause of high cuff pressures is high airway pressures generated by mechanical ventilation, which may require adding air to the cuff to maintain an adequate tracheal seal. Intracuff pressure measurements should be done regularly to maintain the cuff pressure in the safe range to avoid tracheal wall injury and minimize risk for aspiration of oral secretions.

Alternative Cuff Designs

Some different types of cuffs have been designed to minimize mucosal trauma.[24] The foam cuff is one, which is designed to seal the trachea with atmospheric pressure in the cuff (Figure 36-35). Before insertion, the foam cuff must be deflated by actively withdrawing air from the cuff with a cuff pressure device or syringe. When in position, the pilot tube is opened to the atmosphere, and the foam is allowed to expand against the tracheal wall. Expansion of the cuff stops when the tracheal wall is encountered. If too much air leak and volume loss occur around the tube, the pilot tube can be placed in line with the ETT. Foam cuff tubes are not commonly used except in patients who have already developed tracheal injury. This cuff can minimize tracheal mucosal trauma but may not minimize the risk for aspiration of oral secretions and may make mechanical ventilation difficult.

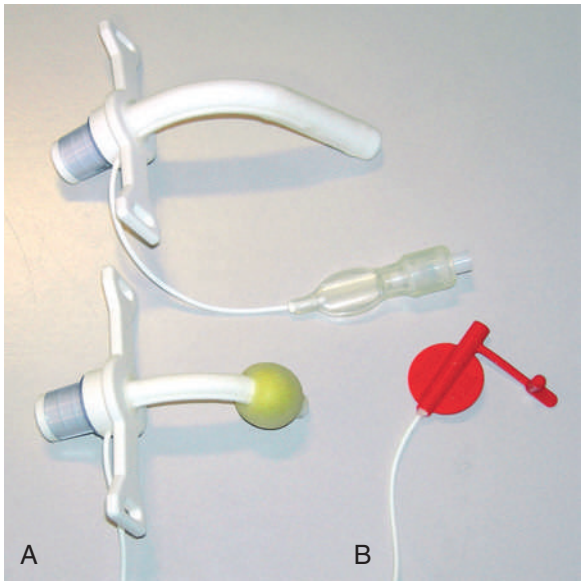

FIGURE 36-35 Tracheostomy tubes (TTs) with different types of cuffs. **A,** TTS cuff. **B,** Self-inflating foam cuff.

Another cuff design is the TTS cuff on some tracheostomy tubes (Figure 36-36). This is a low-volume, high-pressure cuff designed to maximize airflow around the tube when it is deflated. It should be inflated only intermittently for airway protection or short-term ventilation. Because the cuff is made of a porous silicone material, it can be inflated only with sterile water and not air.

Prevention of silent aspiration is difficult because the current generation of cuffs when inflated properly create channels along the cuff in which secretions from above the cuff move by capillary action. Newer tubes with longer length ultrathin polyurethane cuffs form a cylinder shape or an inverted pear shape when inflated so that they do not form channels. These newer cuff designs and material seem to minimize silent aspiration that has been implicated in the development of VAP.[59]

Minimizing Likelihood of Aspiration

When judging the adequacy of a tracheal seal, the potential for aspiration should be taken into account. Keeping the cuff pressure between 20 and 30 cm H_2O helps minimize aspiration and injury. Also, aspiration is reported to be more common in spontaneously breathing patients than in patients receiving positive pressure ventilation; this may be due to the movement of pharyngeal secretions past the cuff during the negative pressure phase of a spontaneous inspiration.

A simple swallowing test can help determine whether aspiration is occurring. These tests can be performed by various clinicians, including speech therapists, nurses, and RTs. To perform this test, blue food coloring is added to the patient's feedings or the patient swallows a small amount of blue food coloring in water. The patient's trachea is suctioned through the artificial airway. If blue-tinged secretions are obtained when performing suctioning, some aspiration is occurring. However, false-negative results can occur; the patient may still be aspirating despite no sign of blue coloring in suctioned secretions. For this reason, a modified barium swallow test may be needed to determine conclusively whether a patient is aspirating.[60]

If aspiration is confirmed, efforts must be made to minimize the aspiration. Ideally, the patient should be switched to a tube that continually aspirates subglottic secretions (see the previous

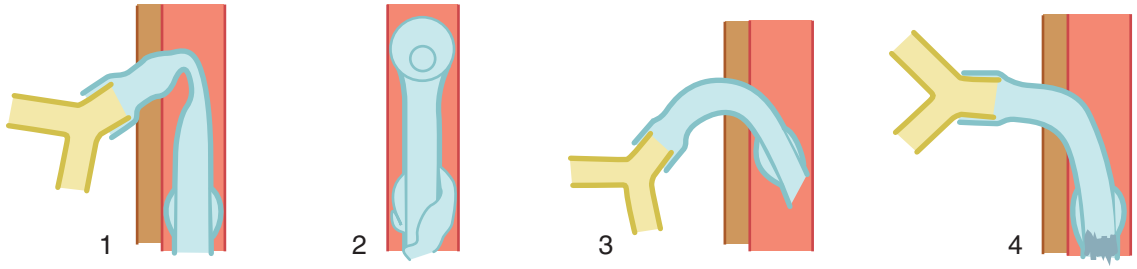

FIGURE 36-36 Causes of tube obstruction. (See text for details.) (Modified from Sykes MK, McNichol MW, Campbell EJM: Respiratory failure, Philadelphia, 1969, FA Davis.)

Box 36-8 Equipment for Tracheostomy Care

- Personal protective equipment: Goggles and mask or face shield
- Sterile gloves
- Suction equipment
- Resuscitation bag
- Oxygen
- Tracheostomy care kit (basin and brush)
  - Spare inner cannula
  - Disposable inner cannula (if appropriate)
  - Hydrogen peroxide and sterile water
  - Cotton-tipped applicators
  - Precut gauze pad or precut foam dressing (to absorb excessive drainage)
  - New tracheostomy tube tie or Velcro tracheostomy tube (TT) holder
  - Another TT of the same size as backup
  - Additional equipment needed if changing TT
  - New TT with component parts and another tube one size smaller
  - Water-soluble lubricant
  - 10- or 12-ml syringe

section on Specialized Endotracheal Tubes). If it is impossible to make this switch, oropharyngeal suctioning (above the tube cuff) should be performed as needed. To decrease the possibility of aspiration with feedings, the head of the bed should be elevated 30 degrees or more when possible.[55] Also, the feeding tube can be inserted into the duodenum, with its position confirmed by radiograph. The use of slightly higher cuff pressure during and after feedings may minimize aspiration.

Care of Tracheostomy and Tube

Tracheostomy tubes require daily care to clean the site and change the tie or holder securing the tube. The tubes also may be removed and replaced for routine cleaning or in an emergency, such as obstruction of the tube. The procedures for tracheostomy care and changing a tracheostomy tube are described in the following section.[61-63]

Tracheostomy Care

Step 1: Assemble and Check Equipment.

Box 36-8 lists the equipment needed for routine tracheostomy care. The equipment needed is for cleaning through the tube, around the tube, and the tube itself. Personal protective equipment (face shield or mask and goggles) for the clinician is needed because the stimulation of the trachea may result in coughing and expectorated secretions. Use of suction equipment to remove secretions from the tube before the procedure can decrease the possibility of secretions contaminating the environment. O_2 and a manual resuscitator are needed for the suctioning procedure and in case any problems such as desaturation occur. To clean around the tube, hydrogen peroxide (diluted to half-strength with sterile water or saline), sterile water, cotton-tipped applicators, and tracheostomy sponges are needed along with a new tie or tracheostomy tube holder to secure the tube. A tracheostomy tube kit includes a basin and brush to clean the inner cannula of the tube. Alternatively, a disposable inner cannula may be used. The function of the manual resuscitator, O_2 flow, and suction control must be checked before starting.

Step 2: Explain Procedure to Patient.

Explain the procedure and confirm the patient understands what will be done.

Step 3: Suction Patient.

The procedures previously described for endotracheal suctioning are appropriate for this situation. A tracheostomy tube is much shorter than an ETT. The catheter is inserted just to the end of the tracheostomy tube to avoid causing mucosal injury to the carina.

Step 4: Clean Inner Cannula (If Present and Nondisposable).

The inner cannula is removed and placed in the basin. If appropriate, such as in the case of a ventilator-dependent patient, the spare inner cannula is inserted. Patients with certain types of tracheostomy tubes (Portex) can be mechanically ventilated without an inner cannula in place. If the patient is not mechanically ventilated, the O_2 therapy device is reapplied as necessary. Sterile water and hydrogen peroxide are added to the basin, and the cannula is left to soak. The brush is used to remove any dried secretions from the inner lumen or the outside of the cannula. The cannula is rinsed with sterile water and allowed to air dry on sterile gauze.

Step 5: Clean and Examine Stoma Site.

The dressing (if present) is removed and disposed. Applicators that have been dipped in sterile normal saline or half-strength hydrogen peroxide are used to clean around the stoma site. After cleaning liquid, a skin barrier should be applied to protect the skin from moisture. A clean dressing, if needed to absorb drainage, is placed under the flange of the tube. Either precut gauze or an absorbent foam dressing, especially if there is excessive drainage around stoma, should be used. If the stoma site appears red or swollen, has pus around it, or is emitting a foul smell, the physician and nurse should be notified.

Step 6: Change Tie or Holder.

The clinician cuts the old tie or loosens the Velcro holder. One hand is kept on the flange of the tracheostomy tube to keep it secure. The old tie or holder is removed and discarded. The clinician replaces the tie or holder, keeping one finger-width of space between the neck and tie or holder.

Step 7: Replace Clean Inner Cannula (If Present).

If the inner cannula is marked disposable and is not to be reused, a new one is inserted.

Step 8: Reassess Patient.

The clinician checks for adequate breath sounds, checks vital signs and oxygenation, and confirms no adverse effects.

RULE OF THUMB

An extra tracheostomy tube of the same size and another, one size smaller, should be kept readily available in or near the patient's room in case of an accidental decannulation.

Changing a Tracheostomy Tube

A tracheostomy tube may need to be replaced according to schedule in the case of long-term mechanical ventilation; if the current tube develops a problem, such as a mucous plug or damage to the cuff; or if a different size or type of tube is needed.[63] If a tube needs to be replaced before the stoma heals (7 to 10 days), it is best done by a physician. Intubation equipment should also be available. Because a single cannula tube has no inner cannula to remove for cleaning, it may need to be replaced periodically.

Step 1: Assemble and Prepare Equipment.
In addition to the equipment described previously, the new tube, an extra tube one size smaller, and water-soluble lubricant are necessary.

Step 2: Explain Procedure to Patient.

Step 3: Prepare Equipment.
Sterile technique must always be maintained for the distal portion of the cannula, which goes into the trachea. The inner cannula is removed and placed on a sterile surface. The obturator is inserted. The tie or tracheostomy tube holder is attached to one side of the flange of the tube. The clinician inflates the cuff, checks for leaks, and deflates the cuff. Lubricant is applied to the distal portion of the cannula.

Step 4: Prepare Patient.
The patient should be placed with the neck extended so that the tracheal stoma is accessible. The patient is suctioned and hyperoxygenated.

Step 5: Remove Old Tube.
The tie is cut, or the Velcro tracheostomy tube holder is opened. The cuff is deflated. The clinician removes the tube by following the curve of the tube. The clinician grasps the outer portion of the tracheostomy tube with one hand and rotates the wrist toward the chest. The stoma is inspected for any bleeding or other problems, such as granuloma or ulceration.

Step 6: Insert New Tube and Assess Patient.
The new tube is picked up by the proximal portion. The surface that enters the trachea should not be touched. The tip of the obturator is inserted into the stoma, and the tube is advanced following the curve of the tube. While holding the flange of the tube against the neck, the clinician immediately removes the obturator. The clinician assesses for airflow through the tube. Coughing may reflect pressure on the outside of the trachea. The patient is assessed for proper tube placement and tolerance of the procedure. If extreme difficulty is encountered inserting the new tube, insertion of the "stand-by" tube, which is one size smaller, is attempted.

Step 7: Secure Tube.
While still holding onto the flange, the clinician secures the tracheostomy tube tie or holder without overtightening. The inner cannula, if present, is inserted. The clinician reassesses for airflow and reapplies the O_2 therapy device or ventilator.

Step 8: Reassess Patient.
Suctioning may be required again. The clinician checks vital signs and O_2 saturation (SaO_2) and assesses the patient's overall tolerance of the procedure.

Troubleshooting Airway Emergencies

The areas discussed so far are routine aspects of airway care. Three emergency situations that may occur are tube obstruction, cuff leaks, and accidental extubation. Clinical signs frequently encountered under these circumstances include various degrees of respiratory distress; changes in breath sounds; air movement through the mouth; or, if the patient is mechanically ventilated, changes in pressures.

Decreased breath sounds are a common finding in airway emergencies. The RT must try to identify specific indications of decreased breath sounds, such as the inability to pass a suction catheter (obstruction, occluded tube) or airflow around the tube (leaking cuff). Replacement airways, a manual resuscitator, mask, and gauze pads (for patients with tracheostomies) should be kept at the bedside.

Tube Obstruction

Obstruction of the tube is one of the most common causes of airway emergencies. Tube obstruction can be caused by (1) the kinking of the tube or the patient biting on the tube, (2) herniation of the cuff over the tube tip,[64] (3) obstruction of the tube orifice against the tracheal wall,[67] and (4) mucous plugging (see Figure 36-36).

Different clinical signs are present depending on whether the tube obstruction is partial or complete.[39,65] A spontaneously breathing patient with partial airway obstruction exhibits decreased breath sounds and decreased airflow through the tube. If the patient is receiving volume-controlled ventilation, peak inspiratory pressures increase, often causing the high-pressure alarm to sound; during pressure-controlled ventilation, delivered V_Ts decrease. With complete tube obstruction, the patient exhibits severe distress, no breath sounds are heard, and there is no gas flow through the tube.

If the tube is kinked or positioned against the tracheal wall, the obstruction can be reversed by moving the patient's head and neck or repositioning the tube.[39] If this action does not relieve the obstruction, a herniated cuff may be blocking the airway. Deflating the cuff relieves the obstruction in such cases. If these steps fail to overcome the obstruction, the clinician can try to pass a suction catheter through the tube. The distance the catheter inserts before stopping helps determine the site of obstruction. If the catheter does not travel much beyond the tube tip and insertion does not cause coughing, the likely problem is a herniated cuff or a mucous plug. In the case of mucous plugging, the clinician can attempt to remove the plug by suctioning the tube before considering more drastic action. Although instillation of sterile normal saline into the tube is not routinely needed during suctioning, it may facilitate mobilizing the mucous plug so that it can be more easily removed by suctioning. Also, a mucus shaving device may be used to clear thick, dried secretions from the inner lumen of the ETT. This device has a balloon at the end of the catheter. Once the catheter is inserted into the ETT, the balloon is inflated. When the catheter is withdrawn, the balloon scrapes the thick, dried mucus from the inside of the tube[66] (Figure 36-37).

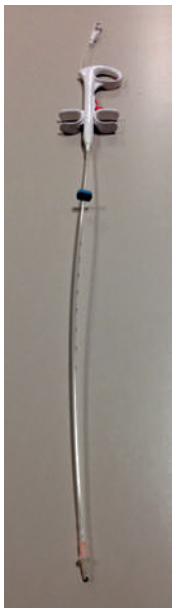

FIGURE 36-37 Mucus shaving device.

When the patient has a tracheostomy tube with an inner cannula, it should be removed and checked to see if the plug is lodged in the tube. O_2 should be provided to the patient through the outer cannula, or the inner cannula should be replaced with a spare one to facilitate manual ventilation.

If the obstruction cannot be cleared by using these techniques, the airway should be removed and replaced. In patients who have undergone recent tracheotomy (4 or 5 days earlier), the stoma may not be well established and may close when the tube is removed. If suture ties were left in place by the surgeon, they can be used to pull open the stoma.

After the obstructed airway is removed, the clinician should immediately try to restore adequate ventilation and oxygenation. For a patient with a tracheotomy stoma, the stoma may need to be covered with a gauze pad and the patient may need to be manually ventilated with a mask. Airway reinsertion by a properly trained RT or physician should be undertaken only after adequate ventilation and oxygenation are restored.

Cuff Leaks

A leak in the cuff, pilot tube, or one-way valve is a problem mostly for patients receiving mechanical ventilation. This leak causes a system leak, with a resultant loss of delivered volume or decreased inspiratory pressure or both.

A small cuff leak can be detected by noting decreasing cuff pressures over time. A large leak, such as occurs with a ruptured cuff, generally has a more rapid onset. Breath sounds are decreased, but a spontaneously breathing patient has air movement through the tube. With positive pressure breaths, airflow often is felt at the mouth. Under such circumstances, the RT should try to reinflate the cuff while checking the pilot tube and valve for leaks.[13] If the pilot tube or valve is leaking, the tube needs to be changed as soon as possible. However, a pilot valve (pilot balloon) repair kit, which permits the insertion of a replacement valve into the pilot tubing, can offer a safe and effective alternative until a replacement tube can be inserted.

A ruptured cuff requires extubation and reintubation emergently if the patient is being mechanically ventilated. This procedure can be done via the standard reintubation procedure or by using an ETT exchanger, which is a semirigid guide over which the damaged tube can be removed and the new tube promptly inserted. An ETT exchanger should be used only by an individual trained in its use, and all necessary intubation equipment and personnel should be available to perform a standard intubation if problems occur. An ETT that is positioned too high in the trachea and near the glottic opening can mimic a cuff leak. Before presuming a cuff leak, the RT should check the tube depth by noting the markings, and if the tube appears shallow, the RT should attempt to advance the tube slightly and reassess the leak. A leak around a tracheal tube can occur from a tube or cuff problem. Figure 36-38 is a diagram of the process to investigate the source of a leak around a tube.[13]

MINI CLINI

Airway Cuff Problems

PROBLEM: The RT is called to assist with a 220-lb, 6-ft, 2-inch male patient who is intubated with a 7-mm ETT and receiving positive pressure ventilation. The patient's nurse reports to the RT that over the last week it has been increasingly difficult to get a good seal with the tube cuff and that she has had to add "more and more air" to prevent gross leakage. When asked if the cuff pressures have been monitored, she says no. What is the likely problem and solution?

DISCUSSION: "Low-pressure" cuffs can exert high pressure at high inflation volumes. The need for high volumes to get a good seal usually indicates that the ETT or tracheostomy tube is too small for the patient. This large man probably should have been intubated with at least an 8-mm tube. In addition, because cuff pressures were not monitored, it is possible that tracheal damage has already occurred. The fact that the nurse reports having to add "more and more air" to get a seal suggests tracheomalacia, which could be confirmed by radiographic or bronchoscopic examination.

Tracheomalacia can cause a vicious cycle in which high pressure causes more tracheal dilation, which requires higher pressures to seal the cuff, and so on. If tracheomalacia is confirmed, and the patient still needs an artificial airway, the smaller tube should be replaced with a larger one that allows a good seal at acceptable cuff pressures. It also may be necessary to reposition the tube so that the cuff is not proximal to the original site of damage.

Accidental Extubation

Partial displacement of an airway out of the trachea can be detected by noting decreased breath sounds, decreased airflow through the tube, and the ability to pass a catheter to its full length without meeting an obstruction or eliciting a cough.

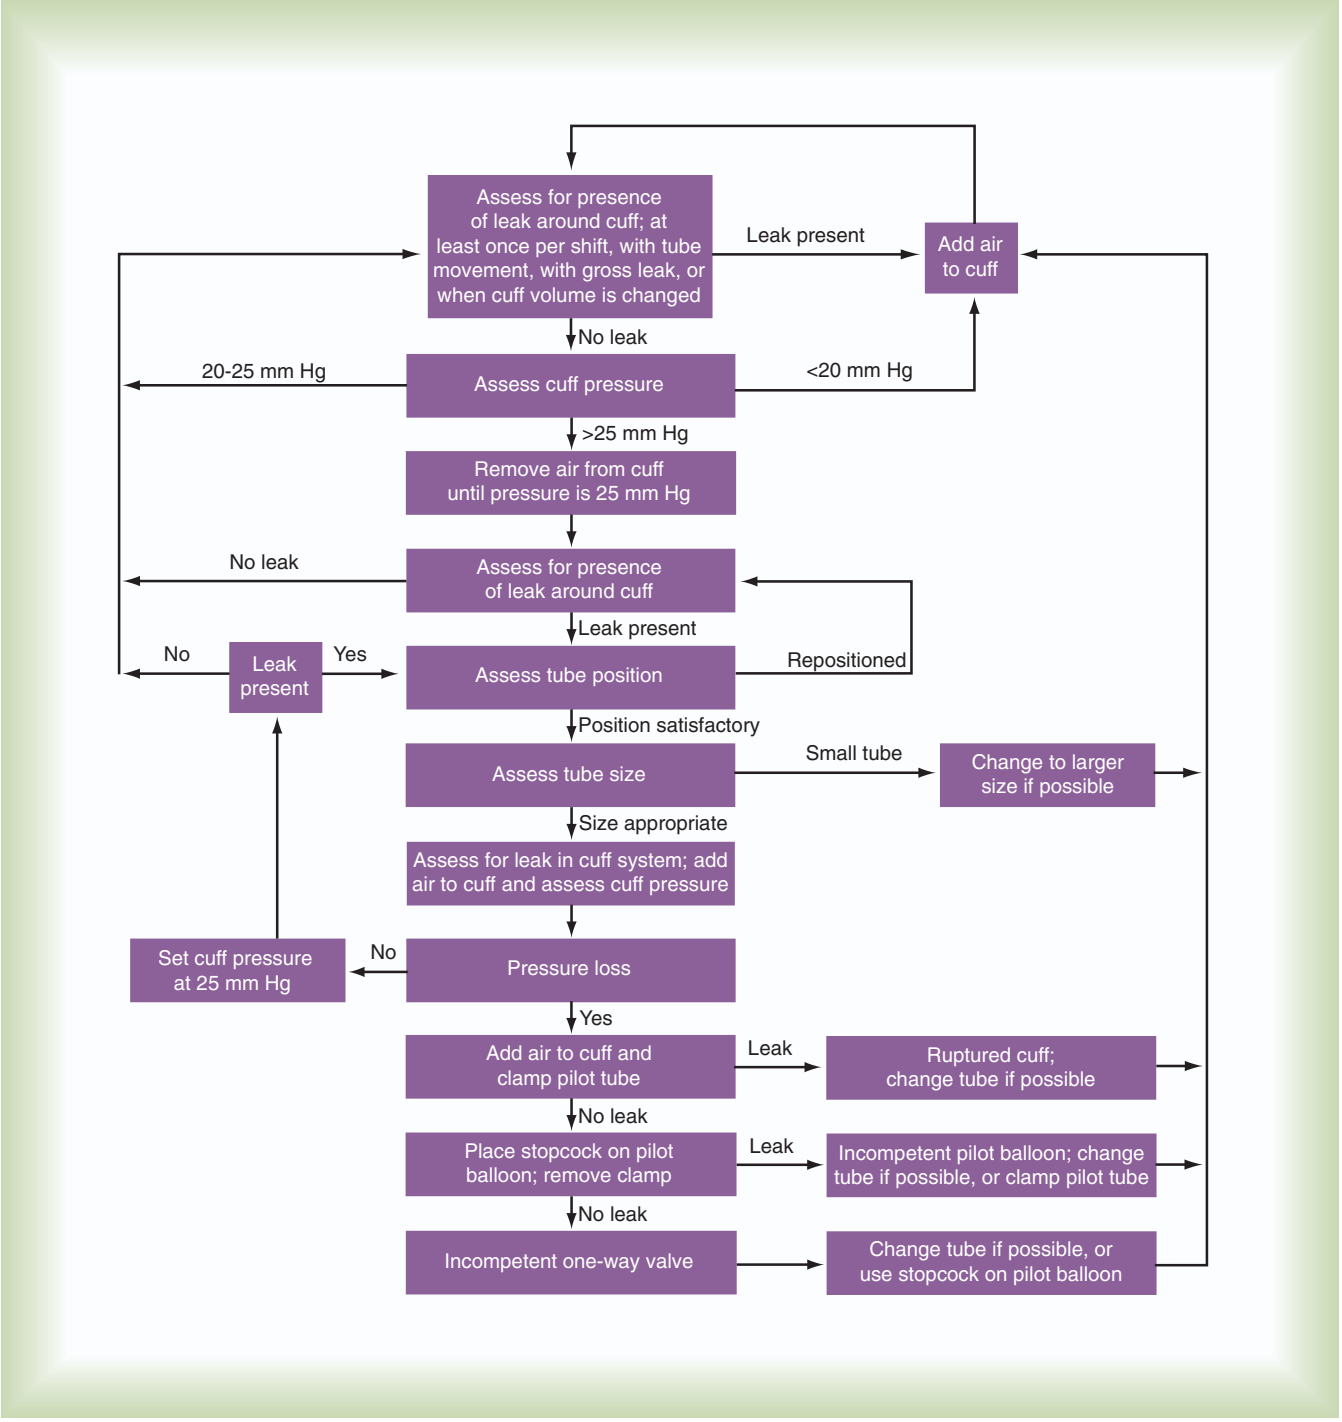

FIGURE 36-38 Algorithm for solving leaking cuff problems. (From Hess D: Managing the artificial airway. Respir Care 44:759, 1999.)

With positive pressure ventilation, airflow through the mouth or into the stomach may be heard and a decrease in delivered volumes or pressures occurs. In these cases, the tube should be completely removed and ventilatory support should be provided by manual resuscitator and mask as needed until the patient can be reintubated or the tracheostomy tube reinserted. To monitor trends and optimize quality outcomes associated with unplanned extubations, hospitals often require certain details of such incidents to be recorded.

EXTUBATION OR DECANNULATION

For most patients, tracheal intubation is a temporary measure. The artificial airway should be removed when it is no longer needed. The process of removing an artificial tracheal airway is called **extubation** (ETT) or **decannulation** (tracheostomy tube). Although most patients eventually undergo extubation, a few need to maintain a permanent artificial route, usually by tracheostomy. Permanent tracheostomies are common among

patients with surgically treated throat or laryngeal cancer and patients requiring long-term positive pressure ventilation. Advances in noninvasive mechanical ventilation have reduced the need for permanent tracheostomies in the latter group.

Assessing Patient Readiness for Extubation

A patient is ready to be extubated when the original need for the artificial airway no longer exists. Because artificial airways are inserted for many different reasons, several different criteria to establish readiness for extubation need to be considered.[67] Some basic assessments include the ability of the patient to protect the airway by the presence of a gag reflex, the ability to manage secretions based on cough strength, the quantity and thickness of secretions, and the patency of the upper airway.

MINI CLINI

Extubation Assessment

PROBLEM: A physician informs the RT that a patient recently removed from a ventilator is maintaining adequate oxygenation and ventilation via spontaneous breathing through an oral ETT. She requests that the RT evaluate the patient for extubation. What would the RT assess and why?

DISCUSSION: Because the patient is maintaining adequate oxygenation and ventilation off the ventilator, two key criteria for extubation have already been met. Further assessment is needed to determine (1) the risk for upper airway obstruction after extubation, (2) the level of protection against aspiration, and (3) the ability of the patient to clear secretions after extubation. First, the RT should perform a leak test to assess for upper airway edema. Second, the RT should determine the patient's level of consciousness and neuromuscular function by assessing the gag reflex or having the patient try to raise and hold his or her head off the bed. Third, the RT should determine the patient's ability to cough, using either subjective assessment (on suctioning) or measurement of maximum expiratory pressure or peak cough flow. Extubation should be recommended only if all three areas yield positive results.

The decision to remove the airway may not be the same as the decision to discontinue mechanical ventilation. The ventilator and airway may be removed simultaneously in the case of patients with normal lungs intubated for surgery. If a patient was intubated because of respiratory failure and has improved, but the upper airway problems remain (e.g., no gag reflex), the ventilator may be discontinued before extubation.

The cuff-leak test is designed to help predict the occurrence of glottic edema or stridor after extubation.[68,69] The clinician totally deflates the tube cuff and assesses the leak around the tube during positive pressure ventilation in a volume-controlled mode. The percent of the cuff leak should be approximately 15% or greater, as determined by the difference between the measured expiratory V_T with the cuff inflated and then deflated.[68] If the exhaled volume is 500 ml with the cuff inflated and 400 ml with the cuff deflated, the difference is 100 ml. The percent cuff leak is 20% (100 ml divided by 500 ml), which suggests that there is no significant upper airway edema or obstruction. However, some data suggest that this test may not always be predictive of the presence of upper airway obstruction or edema.[70] This test may be most useful in patients who are at greatest risk for postextubation stridor, such as children, women, and patients intubated for more than 6 days.[71] Some patients who fail the test or who have questionable results may still be extubated, but they must be closely monitored with the appropriate personnel and equipment available to reestablish the airway if needed.

Clinical Practice Guideline

To guide practitioners in safe and effective application of this procedure, the AARC has developed a clinical practice guideline on removal of the ETT. Excerpts from the AARC guideline, including indications, contraindications, hazards and complications, assessment of need, assessment of outcome, and monitoring, appear in Clinical Practice Guideline 36-4.[67]

Procedures

Because RTs play a key role in extubation and decannulation and the techniques differ, the procedures for removing orotracheal or nasotracheal (extubation) and tracheostomy tubes (decannulation) are reviewed separately.

Orotracheal or Nasotracheal Tubes

The procedure for orotracheal or nasotracheal extubation is as follows.

Step 1: Assemble Needed Equipment.
Needed equipment includes suctioning apparatus; two age-appropriate suction kits with sterile suction catheters and gloves; tonsillar suction tip (Yankauer); 10-ml or 12-ml syringe; O_2 and aerosol therapy equipment; manual resuscitator and mask; aerosol nebulizer with racemic epinephrine and normal saline (if ordered); and intubation equipment (laryngoscope blades, handle, ETTs, stylets, water-soluble lubricant, syringe to inflate cuff, tape or holder to secure tube).

Step 2: Suction Endotracheal Tube and Pharynx to Above Cuff.
Suctioning before extubation helps prevent aspiration of secretions after cuff deflation. After use, the first suction kit should be discarded, and another should be prepared for use, or a rigid tonsillar (Yankauer) suction tip should be prepared to suction the oropharynx.

Step 3: Oxygenate Patient Well After Suctioning.
Extubation is a stressful procedure that can cause hypoxemia and unwanted cardiovascular side effects. To help avoid these problems, 100% O_2 should be administered for 1 to 2 minutes.

Step 4: Deflate Cuff.
The 10- or 12-ml syringe is attached to the pilot tubing. All the air is withdrawn from the cuff while applying positive pressure to direct any pooled secretions above the cuff up into the oropharynx, where they can immediately be

36-4 Removal of the Endotracheal Tube

AARC Clinical Practice Guideline (Excerpts)*

ENVIRONMENT

The endotracheal tube should be removed in an environment in which the patient can be physiologically monitored and in which emergency equipment and appropriately trained health care providers with airway management skills are immediately available.

INDICATIONS

- The airway control afforded by the endotracheal tube is deemed to be no longer necessary for the continued care of the patient.
- Subjective or objective determination of improvement of the underlying condition impairing pulmonary function or gas-exchange capacity, or both, is made before extubation. To maximize the likelihood for successful extubation, the patient should be capable of maintaining a patent airway and generating adequate spontaneous ventilation. Generally, the patient needs to possess adequate central inspiratory drive, respiratory muscle strength, cough strength to clear secretions, laryngeal function, nutritional status, and clearance of sedative and neuromuscular blocking effects.
- Occasionally, acute airway obstruction of the artificial airway caused by mucus or mechanical deformation mandates immediate removal of the artificial airway. Reintubation or other appropriate techniques for reestablishing the airway (i.e., surgical airway management) must be used to maintain effective gas exchange.
- Patients in whom an explicit declaration of the futility of further medical care is documented may have the endotracheal tube removed despite failure to meet the previously listed indications.

CONTRAINDICATIONS

There are no absolute contraindications to extubation. However, some patients may require one or more of the following to maintain acceptable gas exchange after extubation: Noninvasive ventilation, continuous positive airway pressure (CPAP), high inspired O_2 fraction, or reintubation. Airway protective reflexes may be depressed immediately after as well as for some time after extubation. Measures to prevent aspiration should be considered.

HAZARDS AND COMPLICATIONS

- Hypoxemia after extubation may result from but is not limited to
  - Failure to deliver adequate FiO_2 through the natural upper airway
  - Acute upper airway obstruction secondary to laryngospasm
  - Development of postobstruction pulmonary edema
  - Bronchospasm
  - Development of atelectasis, or lung collapse
  - Pulmonary aspiration
  - Hypoventilation
- Hypercapnia after extubation may be caused by but is not limited to
  - Upper airway obstruction resulting from edema of the trachea, vocal cords, or larynx
  - Respiratory muscle weakness
  - Excessive work of breathing
  - Bronchospasm
- Death may occur when medical futility is the reason for removing the endotracheal tube.

ASSESSMENT OF EXTUBATION READINESS

The endotracheal tube should be removed as soon as the patient no longer requires an artificial airway. Patients should show some evidence for the reversal of the underlying cause of respiratory failure and should be capable of maintaining adequate spontaneous ventilation and gas exchange. The determination of extubation readiness may be individualized using the following guidelines:

- Patients with an artificial airway to facilitate treatment of respiratory failure should be considered for extubation when they have met established extubation readiness criteria; examples of these criteria include but are not limited to:
  - The capacity to maintain adequate arterial partial pressure of O_2 (PaO_2/FiO_2 ratio >150 to 200) on inspired O_2 fractions provided with simple O_2 devices ($FiO_2 \leq 0.4$ to 0.5) and with low levels of PEEP (≤5 to 8 cm H_2O)
  - The capacity to maintain appropriate pH (pH ≥ 7.25) and arterial partial pressure of CO_2 during spontaneous ventilation
  - Successful completion of 30- to 120-minute spontaneous breathing trial performed with a low level of CPAP (e.g., 5 cm H_2O) or low level of pressure support (e.g., 5 to 7 cm H_2O) showing adequate respiratory pattern and gas exchange, hemodynamic stability, and subjective comfort
  - In adults, respiratory rate less than 35 breaths/min during spontaneous breathing; in infants and children, acceptable respiratory rate decreases inversely with age and can be measured with good repeatability with a stethoscope
  - Adequate respiratory muscle strength
  - Maximum negative inspiratory pressure greater than –30 cm H_2O, although current clinical practice may accept greater than –20 cm H_2O
  - Vital capacity greater than 10 ml/kg ideal body weight or in neonates greater than 150 ml/m^2
  - Pressure measured across the diaphragm during spontaneous ventilation less than 15% of maximum
  - In adults, spontaneous exhaled minute ventilation less than 10 L/min
  - In adults, a rapid shallow breathing index (ratio of respiratory rate to tidal volume of ≤105); in infants and children, variables standardized by age or weight prove more useful
  - Thoracic compliance greater than 25 ml/cm H_2O
  - Work of breathing less than 0.8 J/L
  - O_2 cost of breathing less than 15% total, especially for patients with chronic respiratory insufficiency requiring long-term mechanical ventilation
  - Ratio of dead space to tidal volume (V_D/V_T) less than 0.6; in children, V_D/V_T of 0.5 or less equates to 96% successful extubation, 0.51 to 0.64 equates to 60% successful extubation, 0.65 equates to 20% successful extubation.
  - Airway occlusion pressure at 0.1 second (P0.1) less than 6 cm H_2O and when normalized for maximal inspiratory

36-4 Removal of the Endotracheal Tube—cont'd

AARC Clinical Practice Guideline (Excerpts)*

pressure (MIP), as indicated by P0.1/MIP (107 to 109) (this measurement is primarily a research tool)
  - Maximum voluntary ventilation more than twice the resting minute ventilation
  - In preterm infants, minute ventilation testing versus standard clinical evaluation resulted in shorter time to extubation.
  - Peak expiratory flow of 60 L/min or greater after three cough attempts measured with an in-line spirometer.
  - Time to recovery of minute ventilation to pre–spontaneous breathing trial baseline levels
  - Sustained maximal inspiratory pressures greater than 57.5 pressure time units predicted extubation outcome.
  - In neonates, total respiratory compliance (derived from V_T/PIP – PEEP) of 0.9 ml/cm H_2O or less was associated with extubation failure, whereas a value of 1.3 ml/cm H_2O or greater was associated with extubation success.
  - Preterm infants extubated directly from low-rate ventilation without a trial of endotracheal tube CPAP showed a trend toward increased chance of successful extubation.
  - Integrated indices of measured vital capacity (threshold value 635 ml), respiratory frequency-to-tidal volume ratio (threshold value 88 breaths/min/L), and maximal expiratory pressure (threshold value 28 cm H_2O)
- In addition to treatment of respiratory failure, artificial airways are sometimes placed for airway protection. Resolution of the need for airway protection may be assessed by but is not limited to
  - Appropriate level of consciousness
  - Adequate airway protective reflexes
  - Reduced cough strength (grade 0 to 2) measured by the white card test and increased secretion burden predicted unsuccessful extubation
  - Easily managed secretions
- In addition to resolution of the processes requiring the insertion of an artificial airway, issues that should be considered in all patients before extubation include the following:
  - No immediate need for reintubation
  - Known risk factors for extubation failure
  - Patient features of high risk for extubation failure include admission to medical intensive care unit, age older than 70 years or younger than 24 months, higher severity of illness on weaning, hemoglobin less than 10 mg/dl, use of continuous intravenous sedation, longer duration of mechanical ventilation, presence of a syndromic or chronic medical condition, known medical or surgical airway condition, frequent pulmonary toilet, and loss of airway protective reflexes.
  - Risk factors for a known history of a difficult airway include syndromic or congenital conditions associated with cervical instability (i.e., Klippel-Feil syndrome or trisomy 21); limited physical access to the airway (i.e., halo vest or anatomic hindrances); and multiple failed direct laryngoscopy attempts by an experienced laryngoscopist or a failed laryngoscopy attempt followed by tracheal intubation using fiberoptic bronchoscopy or a nasal light wand or requiring placement of a laryngeal mask airway.
  - In the pediatric patients undergoing cardiothoracic surgery, presence of one or more of these variables increases the likelihood of failed extubation: age younger than 6 months, history of prematurity, congestive heart failure, and pulmonary hypertension.
  - For pediatric patients, validated bedside measures of respiratory function identifying low risk (<10%) and high risk (>25%) threshold values of extubation failure may be useful in generating discussion but do not apply to individual risk.
  - Presence of upper airway obstruction or laryngeal edema as detected by diminished gas leak around the endotracheal tube with positive pressure breaths
  - Percent cuff leak or the difference between expiratory tidal volume measured with the cuff inflated and then deflated in a volume-controlled mode of 15.5% or greater; this test was found not to be predictive in a study of patients undergoing cardiothoracic surgery.
  - Air leak may be an age-dependent predictor of postextubation stridor in children. An air leak greater than 20 cm H_2O was predictive of postextubation stridor in children 7 years old or older but was not predictive in children younger than 7 years.
  - Air leak test has been predictive of postextubation stridor or extubation failure for children with upper airway pathology, including trauma patients, patients with croup, and patients after tracheal surgery.
  - Evidence of stable, adequate hemodynamic function
  - Evidence of stable nonrespiratory functions
  - Electrolyte values within normal range
  - Evidence of malnutrition decreasing respiratory muscle function and ventilatory drive
  - Anesthesia literature indicates the patient must have no intake of food or liquid by mouth for a time before airway manipulation; continuation of transpyloric feedings during an extubation procedure is controversial.
- Prophylactic medication before extubation to avoid or reduce the severity of postextubation complications
  - Consider use of lidocaine to prevent cough or laryngospasm in patients at risk
  - Prophylactic administration of steroids may be helpful to prevent reintubation rates in high-risk neonates but not in children.
  - Prophylactic administration of steroids may help reduce the incidence of postextubation stridor in children but not in neonates or adults.
  - Prophylactic administration of steroids for patients with laryngotracheobronchitis (croup) correlates with reduced rates of reintubation.
  - Caffeine citrate reduced the risk for apnea for infants but did not reduce the risk for extubation failure.
  - Methylxanthine treatment stimulates breathing and reduces the rate of apnea for neonates with poor respiratory drive, especially low-birth-weight infants.

■ ASSESSMENT OF OUTCOME

- Removal of the endotracheal tube should be followed by adequate spontaneous ventilation through the natural airway, adequate oxygenation, and no need for reintubation.

Continued

36-4 Removal of the Endotracheal Tube—cont'd

AARC Clinical Practice Guideline (Excerpts)*

- Clinical outcome may be assessed by physical examination, auscultation, invasive and noninvasive measurements of gas exchange, and chest radiography.
- When a patient experiences an unplanned self-extubation and does not require reintubation, this suggests that planned extubation should have been considered earlier.
- Some patients may require support after extubation or intervention to maintain adequate gas exchange independent of controlled mechanical ventilation.

Noninvasive Respiratory Support

- Nasal continuous positive airway pressure (CPAP) is used in infants.
- Routine use of noninvasive positive pressure ventilation in adults is not supported.
- In patients with chronic obstructive pulmonary disease, CPAP of 5 cm H_2O and pressure support ventilation of 15 cm H_2O have improved pulmonary gas exchange, decreased intrapulmonary shunt fraction, and reduced patient work of breathing.

Postextubation Medical Therapy

- Aerosolized levoepinephrine is as effective as aerosolized racemic epinephrine in the treatment of postextubation laryngeal edema in children.
- Heliox may alleviate symptoms of partial airway obstruction and resultant stridor, improve patient comfort, decrease work of breathing, and prevent reintubation.

Diagnostic Therapy

- For patients with postextubation complications such as stridor or obstruction, fiberoptic bronchoscopy may provide direct airway inspection and therapeutic interventions (secretion clearance, instillation of drugs, removal of aspirated foreign objects).

**For complete guidelines, see American Association for Respiratory Care: Clinical practice guideline: removal of the endotracheal tube—2007 revision and update. Respir Care 52:81, 2007.*

suctioned with the tonsillar suction tip. The RT should listen for an audible leak around the tube. If no audible leak is present, the RT should reinflate the cuff and discuss with the physician how to proceed.

Step 5: Remove Tube.

The tape or holder that is securing the tube is removed. The technique used to remove the tube should help avoid aspiration of pharyngeal secretions and maximally abduct the vocal cords. Clinicians use one of two different techniques to accomplish these goals. In the first method, a large breath is given with the manual resuscitator, and the tube is removed at peak inspiration (when the vocal cords are maximally abducted). In the second method, the patient coughs and the tube is pulled during the expulsive expiratory phase. This technique also results in maximal abduction of the vocal cords.

Step 6: Apply Appropriate Oxygen and Humidity Therapy.

Patients who have been receiving mechanical ventilation may still require O_2 therapy, usually at a higher FiO_2. Other patients may require some O_2 because this is a stressful procedure. If humidity or aerosol therapy is indicated, most clinicians suggest a cool mist immediately after extubation.

Step 7: Assess or Reassess Patient.

After extubation, auscultation is performed to check for good air movement. Stridor or decreased air movement after extubation indicates upper airway problems. Next, the patient's respiratory rate, breathing pattern, heart rate, blood pressure, and SaO_2 are checked. Mild hypertension and tachycardia immediately after extubation are common and resolve spontaneously in most cases. The patient should be monitored for nosebleed after nasotracheal extubation. The patient is encouraged to cough, with assistance as needed. Because laryngeal edema may worsen with time and stridor may develop, racemic epinephrine for nebulization should be available. Arterial blood gas (ABG) values should be sampled and analyzed as needed.

The most common problems that occur after extubation are hoarseness, sore throat, and cough.[41] These problems are benign and improve with time. A rare but serious complication associated with extubation is laryngospasm. Postextubation laryngospasm is usually a transient event, lasting several seconds. If laryngospasm occurs, oxygenation can be maintained with a high FiO_2 and the application of positive pressure. If laryngospasm persists, a neuromuscular blocking agent may need to be given, which necessitates manual ventilation or reintubation.

Because the vocal cords have had limited function during the intubation period, they may not close fully as needed when the airway has been removed. To avoid aspiration, oral feedings, especially liquids, should be withheld for 24 hours after extubation. Patients may aspirate liquids even with an intact gag reflex.[48]

Extubation failure, defined as the sudden need for reinsertion of the airway because of airway problems, often occurs within 8 hours of extubation. Aspiration and edema are the most common problems. If the patient also is

mechanically ventilated, reintubation may be required for work of breathing issues unrelated to the airway.

Tracheostomy Tube Removal (Decannulation)

Decannulation refers to removal of the tracheostomy tube. Several approaches exist to remove tracheostomy tubes. Patients who received a tracheostomy as a result of upper airway obstruction that has been resolved may have their tube removed in one step. Patients who have been on mechanical ventilation for an extended time may have problems with muscle weakness, problems adjusting to the increase in anatomic dead space, and upper airway problems with secretions and glottic closure. For these patients, a weaning process is used rather than abrupt removal of the tube. Weaning is accomplished by using fenestrated tubes, progressively smaller tubes, or tracheostomy buttons.[70]

Before decannulation, a comprehensive patient assessment is required. The patient should have sufficient muscle strength (peak expiratory pressure > 40 cm H_2O) to generate an effective cough. Ideally, there should be no active pulmonary infection, and the volume and thickness of secretions should be acceptable. Patency of the upper airway can be assessed via bronchoscopy.[71] An adequate swallow must be present to decrease the risk for aspiration. After removal of the tube, the stoma closes on its own in a few days. After cleaning around the stoma, a sterile occlusive dressing should be applied over the stoma until it closes. The particular decannulation technique used depends on the patient's needs and the experience and preferences of the attending physician.

Fenestrated Tracheostomy Tubes

A **fenestrated** tracheostomy tube is a double cannulated tube that has an opening in the posterior wall of the outer cannula above the cuff (Figure 36-39). Removal of the inner cannula opens the fenestration, allowing air to pass into the upper airway. Capping or placing a speaking valve on the proximal opening of the tube's outer cannula, accompanied by deflation of the cuff, allows for assessment of upper airway function.

FIGURE 36-39 Fenestrated tracheostomy tubes.

Removal of the cap or speaking valve allows access for suctioning. If mechanical ventilation is needed, the inner cannula can be reinserted and the cuff can be reinflated.

One problem associated with this type of tracheostomy tube is malposition of the fenestration, such as between the skin and stoma or against the posterior wall of the larynx.[43] Customizing the fenestration or trying a fenestrated tube of a different size or by a different manufacturer can help avoid this problem. Proper placement can be confirmed by using fiberoptic bronchoscopy.

Case reports have shown granular tissue formation in some patients using a fenestrated tracheostomy tube. Granular tissue tends to form on the posterior tracheal wall, above the tube fenestration. This granular tissue may occlude the fenestration, cause bleeding (especially with tube changes), or result in airway obstruction on decannulation. Given the location of this granular tissue, these problems may be due to poor positioning of the fenestration within the airway.

Progressively Smaller Tubes

A second airway weaning technique is to use progressively smaller tracheostomy tubes. Similar to fenestrated tubes, this approach maintains the airway, but it allows for increasing use of the upper airway. This technique is also indicated in patients whose airway is too small for the available fenestrated tubes. The use of progressively smaller tubes may also allow for better healing of the stoma.

The problem with these techniques is the continued presence of a tube within the lumen of the airway.[70] The presence of the tube (cuffed or uncuffed) increases airway resistance. In patients with preexisting obstructive disorders, this added airway resistance may be too much to bear, resulting in failed decannulation. These tubes also can impair coughing by preventing full compression of the inspired thoracic volume. The last factor to consider when using smaller tubes is the fit of the tube within the trachea. Smaller tubes not only have a smaller diameter but also a different length; this may result in the curve of the tube impacting the posterior tracheal wall.

Tracheal Buttons

The tracheal button also may be used to maintain a tracheal stoma.[43] In contrast to the fenestrated tube, the tracheal button fits through the skin to just inside the anterior wall of the trachea (Figure 36-40), which avoids the problem of added resistance. Because the tracheal button has no cuff, its use is limited to relieving airway obstruction and aiding the removal of secretions. When the inner cannula is removed, the clinician can suction through the outer cannula. However, when the inner cannula is removed, the clinician needs to hold the outer cannula in place to prevent it from being coughed out during suctioning.

Assessment After Tracheostomy Decannulation

After tracheostomy decannulation, the patient should be assessed for vocal cord responses.[71] Vocal cord abnormalities can result in either aspiration or acute airway obstruction.

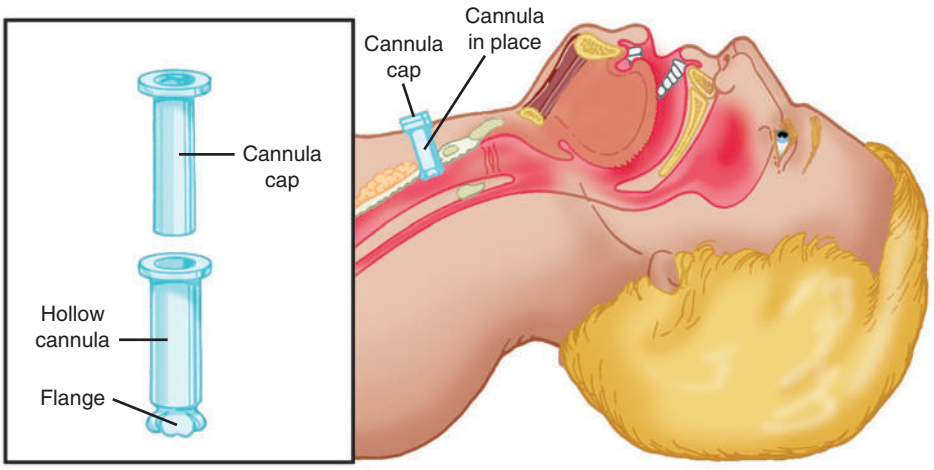

FIGURE 36-40 Tracheostomy button.

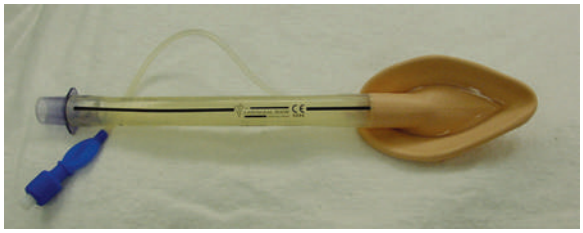

FIGURE 36-41 Largneal mask airway (LMA). (From Gartsman G: Shoulder arthroscopy, ed 2, Philadelphia, 2009, Saunders.)

Symptoms such as stridor, retractions, and inability to feel airflow through the upper airway indicate upper airway obstruction. A replacement tracheostomy tube and suctioning equipment should be available in case the patient develops any of these symptoms of obstruction.

ALTERNATIVE AIRWAY DEVICES

Placement of an ETT is a complex skill and is not always accomplished easily, even in experienced hands. Emergency medical services personnel are not always in the best situation to intubate. A patient's particular anatomy may make intubation difficult. Several alternative devices and techniques can be used in such circumstances. An algorithm for difficult intubations created by the American Society of Anesthesiologists provides extensive options.[72] Video-assisted laryngoscopy or intubating over a fiberoptic bronchoscope are alternative approaches during a difficult intubation. Two devices, the *LMA* and the *double-lumen airway* (Combitube), are referred to as *nonintermediate airways*. They can be used to ventilate a patient, but an ETT or tracheostomy tube may be needed eventually. These two devices may be inserted by respiratory care practitioners and are discussed subsequently. The advantages and disadvantages of each device are summarized in Table 36-6.

Laryngeal Mask Airway

The algorithm for management of a difficult airway has been modified to show the various uses of the LMA. The LMA consists of a short tube and a small mask that is inserted deep into the oropharynx (Figure 36-41).[72,73] The open surface of the mask faces the laryngeal opening, and the tip of the mask is just above the esophageal sphincter. The short tube has a 15-mm adapter that can be connected to a manual resuscitator bag. A

TABLE 36-6

Advantages and Disadvantages of Alternatives to Endotracheal Intubation for Maintaining Upper Airway Patency

Device	Advantages	Disadvantages
Oral and nasal airways	Little training required	Does not guarantee airway patency
	No special equipment necessary	May worsen obstruction
	Inexpensive	Poorly tolerated by awake patient
	Can be quickly placed	Does not prevent aspiration
		Short-term use
		Does not facilitate positive pressure ventilation
Double-lumen airway (Combitube) placement	Less skill than bag-valve-mask or intubation	Difficulty distinguishing tracheal versus esophageal insertion
	No special equipment necessary	Short-term use
	Protection against aspiration	Aspiration during removal
	Facilitates positive pressure ventilation	Cannot suction in esophageal position
		Only one size (adult)
		Potential for esophageal injury
Laryngeal mask airway (LMA)	Easy to insert	Short-term use
	No special equipment necessary	Aspiration not avoided
	Can intubate without removing LMA	Cannot provide high ventilation pressures if needed
	Avoids laryngeal and tracheal trauma	

small tube is used to inflate a cuff when the device is in place. LMAs range in size from size 5 for adults to size 1 for infants.

Compared with bag and mask ventilation, a greater amount of ventilation is directed to the lungs by the LMA. The ease and speed of insertion offer an advantage over intubation when the intubator is inexperienced, the patient cannot be positioned for intubation, or the intubation is difficult.

The insertion of the LMA does not require any equipment (Figure 36-42).[73] Before insertion, the posterior surface of the mask must be lubricated and the cuff must be fully deflated. The index finger is used to guide insertion of the mask along the palate and down into the oropharynx. When the cuff is in place, it is inflated to a maximum of 60 cm H_2O. Inflation causes the mask to rise slightly out of the mouth.

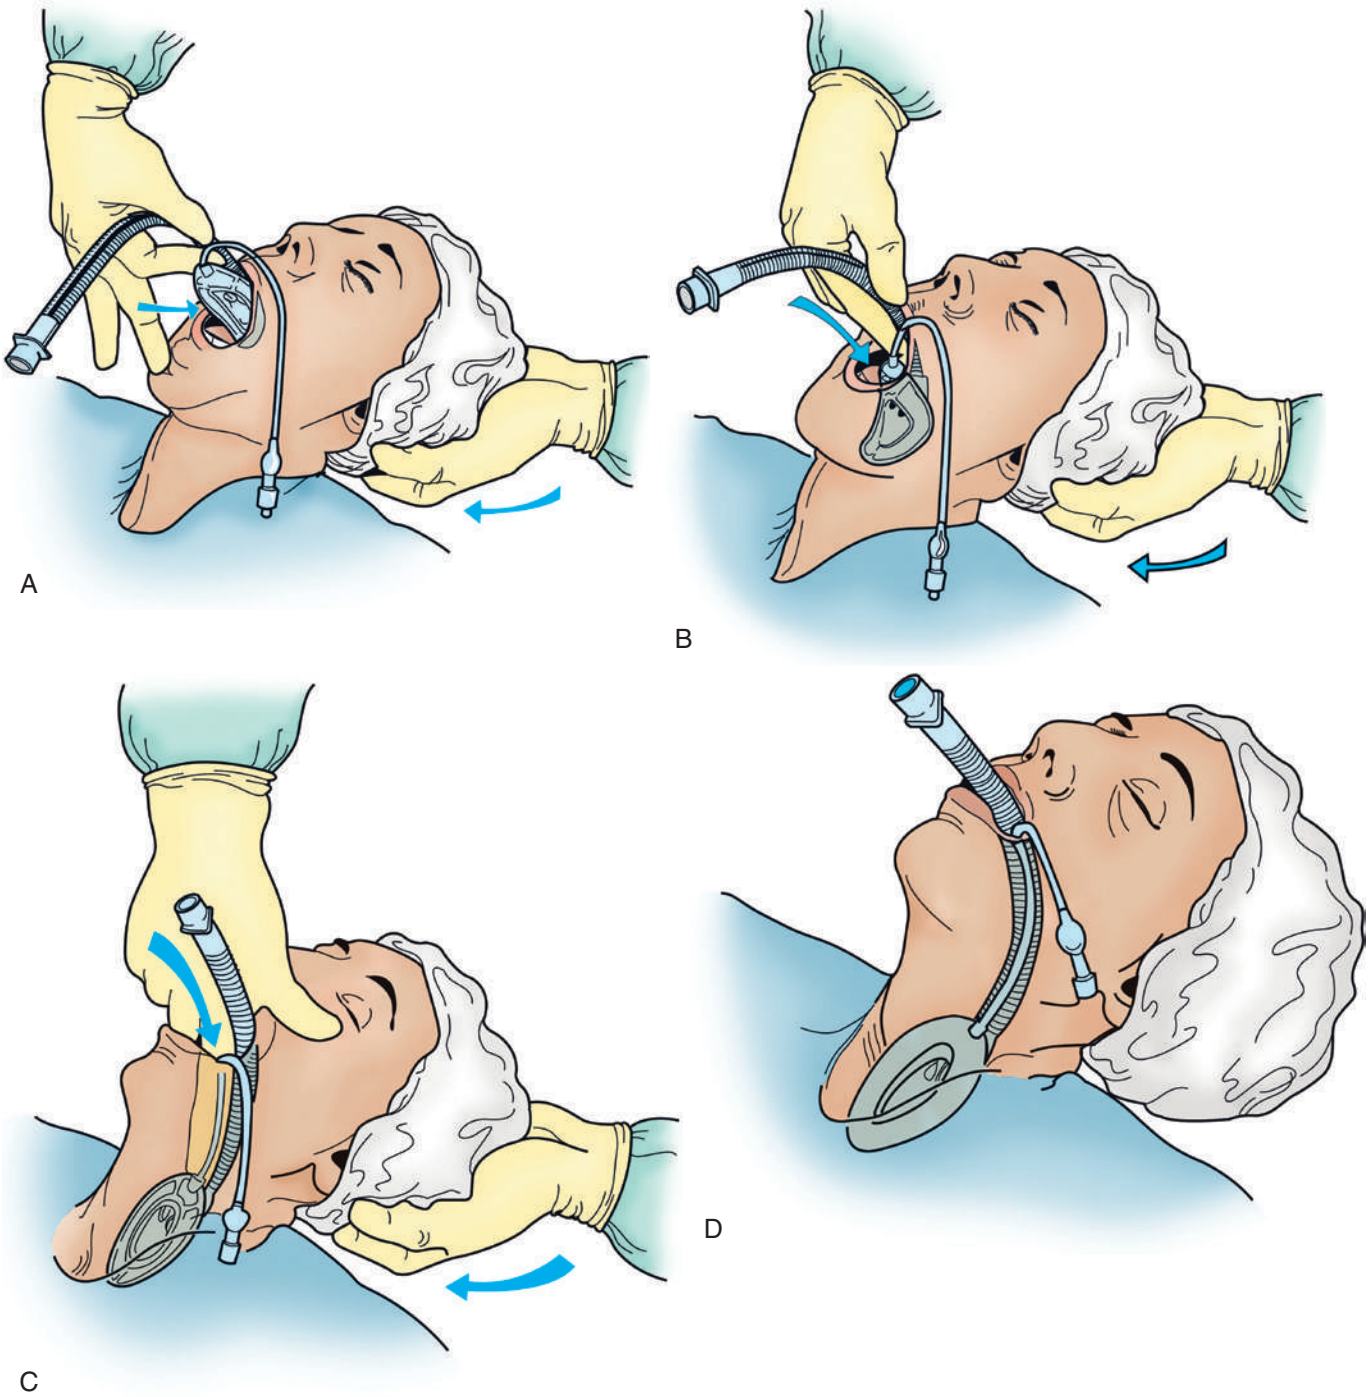

FIGURE 36-42 Insertion of largneal mask airway. (Modified from Cairo JM, Pilbeam SP: Mosby's respiratory care equipment, ed 8, St. Louis, 2010, Mosby.)

Use of the LMA has two major limitations.[73] First, it cannot be used in a conscious or semicomatose patient because of stimulation of the gag reflex. Second, if ventilating pressures greater than 20 cm H_2O are needed, gastric distention may occur. This device does not protect against aspiration should regurgitation occur.

The classic LMA can be used to facilitate intubation because the opening faces the glottis. However, because of the small size of the ventilating tube on the mask, a small ETT is needed. A specially designed LMA with a small handle facilitates intubation (Figure 36-43).

Double-Lumen Airway

The double-lumen airway (Combitube) is designed to be inserted blindly through the oropharynx and into the trachea or the esophagus (Figure 36-44).[73] Its external design is similar to that of a double-lumen ETT with two external openings, two 15-mm adapters, two lumens, and two cuffs. One cuff seals the oropharynx. The second seals the trachea or the esophagus.

If the tube is placed into the esophagus and the cuffs are inflated, ventilation is accomplished by air passing through a series of holes in the area of the hypopharynx and into the trachea. The pharyngeal cuff prevents air from leaving through the mouth. The distal cuff in the esophagus helps decrease regurgitation. If the tube is placed in the trachea, it functions like an ETT. To assess placement, the RT can manually ventilate through the external adapters and determine which gives the best breath sounds.

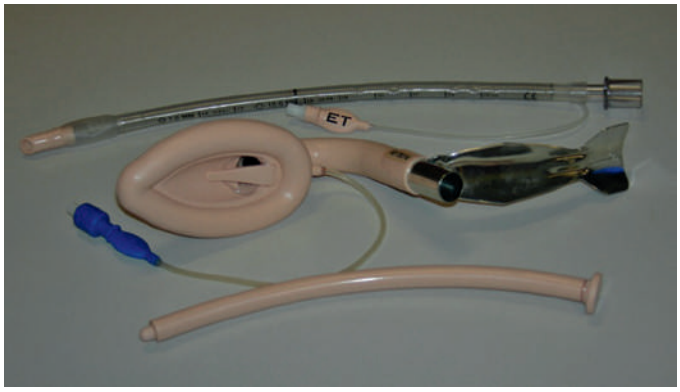

FIGURE 36-43 Intubating laryngeal mask airway.

Surgical Emergency Airways

Despite various alternatives to establish ventilation, occasionally the problem of "cannot intubate/cannot ventilate" occurs.[27] In these situations, a surgical transtracheal airway must be established. Cricothyroidotomy and percutaneous transtracheal ventilation are options. Commercial kits are available, or a series of available supplies can be used (Figures 36-45 and 36-46).[74]

Complications include bleeding, subcutaneous emphysema secondary to inspiratory airway resistance through a small lumen, and air trapping secondary to expiratory flow resistance. Nevertheless, cricothyroidotomy and percutaneous transtracheal ventilation are the preferred routes over emergent tracheotomy until a more definitive airway can be placed after the emergency has passed. A surgical transtracheal airway should be accomplished in 48 to 72 hours.[39,74]

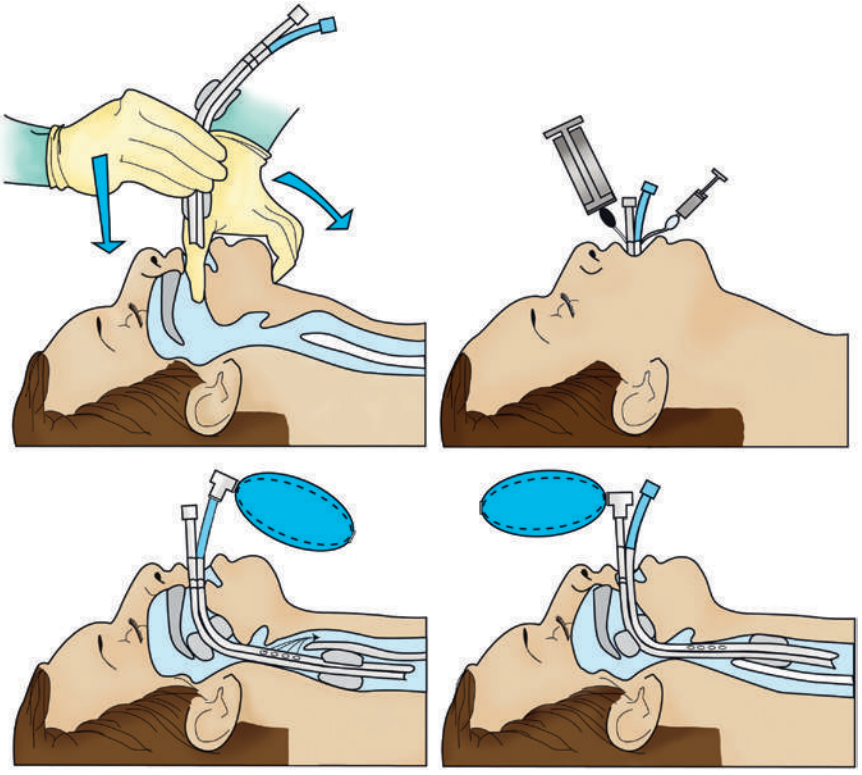

FIGURE 36-44 Insertion of a double-lumen airway (Combitube). (Modified from Cairo JM, Pilbeam SP: Mosby's respiratory care equipment, ed 8, St. Louis, 2010, Mosby.)

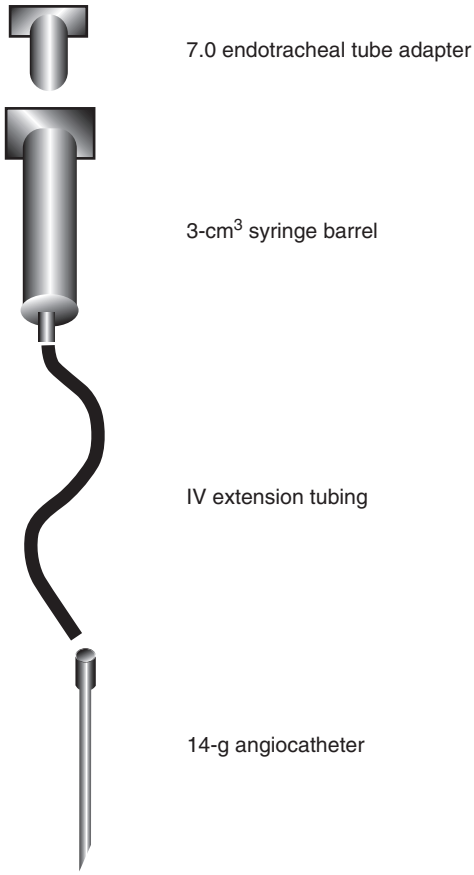

FIGURE 36-46 Percutaneous tracheal ventilation supplies. (Modified from Rodrick MB, Deutschman CS: Emergent airway management: indications and methods in the face of confounding conditions. Crit Care Clin 16:396, 2000.)

BRONCHOSCOPY

Bronchoscopy is the general term used to describe the insertion of a visualization instrument (endoscope) into the bronchi. The purposes of bronchoscopy are to inspect the airway, remove objects from the airway, collect samples from the airway, and place devices into the airway.[34] Two different bronchoscopic techniques are in use: rigid tube bronchoscopy and flexible bronchoscopy. Although RTs most often assist in flexible fiberoptic bronchoscopy, they should understand the differences between these two approaches.

Rigid Tube Bronchoscopy

A *rigid bronchoscope* is an open metal tube with a distal light source and a port for attaching O_2 or ventilating equipment. A rigid bronchoscope is used most often by otorhinolaryngologists or thoracic surgeons. The tube is passed through the mouth, down into the trachea, and as far as the bronchi. A telescoping tube with mirrors is used to advance to and view segmental bronchi. Suctioning is accomplished via a metal tube passed through the bronchoscope. The large internal diameter of this suction tube allows for aspiration of thick inspissated secretions and large mucous plugs. Grasping forceps passed through the device allow removal of foreign bodies and biopsies of airway tumors.

Rigid bronchoscopy has several disadvantages. First, it is very uncomfortable for conscious patients. It usually requires the assistance of an anesthesiologist and the use of an operating room. Last, and most important, rigid bronchoscopy cannot access the smaller airways.

Flexible Fiberoptic Bronchoscopy

Flexible fiberoptic bronchoscopy has gained popularity over the years as a result of both its versatility and its ability to access very small airways. A typical fiberoptic bronchoscope has a light transmission channel, a visualizing channel, and a multipurpose open channel (Figure 36-47). The open channel can be used for aspiration, tissue sampling, or O_2 administration. After insertion, the physician can direct the tip of the scope via the control section to the location desired. This type of bronchoscope is most often used by the pulmonologist, often with the assistance of the RT.[75]

To guide practitioners in assisting physicians performing this procedure, the AARC has developed and published a clinical practice guideline on fiberoptic bronchoscopy assisting. Excerpts from the AARC guideline, including indications, contraindications, precautions and possible complications, assessment of need, assessment of outcome, and monitoring, appear in Clinical Practice Guideline 36-5.[76]

Fiberoptic Bronchoscopy Procedure

Key factors in planning and conducting fiberoptic bronchoscopy include premedication, equipment preparation, airway preparation, and monitoring.[76,77] To reduce the risk for aspiration secondary to gagging and loss of airway reflexes, the patient should refrain from food or drink for at least 8 hours before the start of the procedure. In addition, if the intravenous route is not already available, vascular access should be obtained before the start of the procedure.

Premedication

Bronchoscopy is an uncomfortable procedure. To decrease anxiety, the patient should be premedicated 30 to 45 minutes

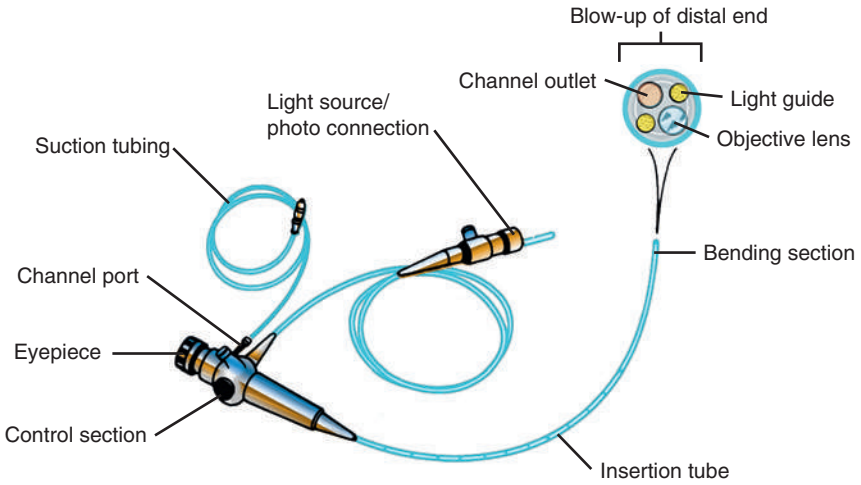

FIGURE 36-47 Flexible fiberoptic bronchoscope.

36-5 Bronchoscopy Assisting

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

- Presence of lesions of unknown cause on the chest radiograph or need to evaluate recurrent pneumonia, persistent atelectasis, or pulmonary infiltrates
- Need to assess patency or mechanical properties of the upper airway
- Need to investigate hemoptysis, unexplained cough, wheeze, or stridor
- Suspicious or positive sputum cytology results
- Suspicion that secretions or mucous plugs are causing atelectasis
- Need to obtain lower respiratory tract secretions, cell washings, and biopsy specimens for cytologic, histologic, and microbiologic evaluation
- Need to determine location and extent of injury from toxic inhalation or aspiration
- Need to evaluate problems associated with endotracheal or tracheostomy tubes (tracheal damage, airway obstruction, or tube placement)
- Need for aid in performing difficult intubations or percutaneous tracheostomies
- Suspicion that secretions or mucous plugs are responsible for lobar or segmental atelectasis
- Need to remove abnormal endobronchial tissue or foreign material by forceps, basket, or laser
- Need to retrieve a foreign body (although rigid bronchoscopy is preferred under most circumstances)
- Therapeutic management of endobronchial toilet in ventilator-associated pneumonia
- Selective intubation of a main stem bronchus
- Need to place or assess airway stent function
- Need for airway balloon dilation in treatment of tracheobronchial stenosis

CONTRAINDICATIONS

Flexible bronchoscopy should be performed only when the relative benefits outweigh the risks. Absolute contraindications include the following:

- Absence of consent from the patient or his or her representative unless a medical emergency exists and patient is not competent to give permission
- Absence of an experienced bronchoscopist to perform or supervise closely and directly the procedure
- Lack of adequate facilities and personnel to care for emergencies such as cardiopulmonary arrest, pneumothorax, or bleeding
- Inability to oxygenate the patient adequately during the procedure
- Danger of a serious complication from bronchoscopy is especially great in patients with the following disorders, and these conditions are usually considered absolute contraindications unless the risk-benefit assessment warrants the procedure:
  - Coagulopathy or bleeding diathesis that cannot be corrected
  - Severe refractory hypoxemia
  - Unstable hemodynamic status including dysrhythmias

Relative contraindications (or conditions involving increased risk), according to the American Thoracic Society guidelines for fiberoptic bronchoscopy in adults, include the following:

- Lack of patient cooperation
- Recent (within 6 weeks) myocardial infarction or unstable angina
- Partial tracheal obstruction
- Moderate to severe hypoxemia or any degree of hypercarbia

36-5 Bronchoscopy Assisting—cont'd

AARC Clinical Practice Guideline (Excerpts)*

- Uremia and pulmonary hypertension (possible serious hemorrhage after biopsy)
- Lung abscess (danger of flooding airway with purulent material)
- Obstruction of superior vena cava (possibility of bleeding and laryngeal edema)
- Debility and malnutrition
- Disorders requiring laser therapy, biopsy of lesions obstructing large airways, or multiple transbronchial lung biopsies
- Known or suspected pregnancy (safety concern of possible radiation exposure)
- Safety of bronchoscopic procedures in asthmatic patients is a concern, but the presence of asthma does not preclude use of these procedures
- Patients with recent head injury are susceptible to increased intracranial pressures
- Inability to sedate (including time constraints of oral ingestion of solids or liquids)

HAZARDS AND COMPLICATIONS

- Adverse effects of medication used before and during bronchoscopic procedure
- Hypoxemia
- Hypercarbia
- Bronchospasm
- Hypotension
- Laryngospasm, bradycardia, or other vagally mediated phenomena
- Mechanical complications such as epistaxis, pneumothorax, and hemoptysis
- Increased airway resistance
- Cross-contamination of specimens or bronchoscopes
- Nausea, vomiting
- Fever and chills
- Cardiac dysrhythmias
- Death
- Infection hazard for health care workers or other patients

ASSESSMENT OF NEED

Need is determined by bronchoscopist assessment of the patient and treatment plan in addition to the presence of clinical indications and the absence of contraindications, as described previously.

ASSESSMENT OF OUTCOME

Patient outcome is determined by clinical, physiologic, and pathologic assessment. Procedural outcome is determined by the accomplishment of the procedural goals as indicated and by appropriate quality assessment indicators.

MONITORING

The following should be monitored continuously before, during, and after bronchoscopy, until the patient returns to presedation level of consciousness.

Patient

- Level of consciousness
- Medications administered, dosage, route, and time of delivery
- Subjective response to procedure (e.g., pain, discomfort, dyspnea)
- Blood pressure, breath sounds, heart rate, rhythm, and changes in cardiac status
- SpO_2, FiO_2, and end-tidal CO_2
- Tidal volume, peak inspiratory pressure, adequacy of inspiratory flow, and other ventilator parameters if patient is mechanically ventilated
- Lavage volumes (delivered and retrieved)
- Monitor and document site of biopsies and washings; record which laboratory tests were requested on each sample
- Periodic follow-up monitoring of patient condition after the procedure is advisable for 24 to 48 hours for inpatients. Outpatients should be instructed to contact the bronchoscopist regarding fever, chest pain or discomfort, dyspnea, wheezing, hemoptysis, or any new findings manifesting after procedure has been completed. Oral instructions should be reinforced by written instructions that include names and phone numbers of persons to be contacted in emergency.
- Chest radiograph 1 hour after transbronchial biopsy to exclude pneumothorax

Technical Devices

- Bronchoscope integrity (fiberoptic or channel damage, passage of leak test)
- Strict adherence to the manufacturer's and institutional recommended procedures for cleaning, disinfection, and sterilization of the devices and integrity of disinfection or sterilization packaging
- Smooth, unhampered operation of biopsy devices (forceps, needles, brushes)

Recordkeeping

- Quality assessment indicators determined appropriate by the institution's quality assessment committee
- Documentation of patient and device monitoring
- Identification of bronchoscope used for each patient
- Annual assessment of the institutional or departmental bronchoscopy procedure, including (1) evaluation of the adequacy of bronchoscopic specimens; (2) review of infection control procedures and compliance with current guidelines for semicritical patient care objects; (3) synopsis of complications; (d) control washings to ensure that infection control and disinfection and sterilization procedures are adequate, and that cross contamination of specimens does not occur; and (e) annual review of the bronchoscopy service and all of the previously listed records with physician bronchoscopists

before the procedure. The patient should be calm but alert enough to follow commands, such as taking a deep breath. Conscious sedation is normally performed for this procedure.

Another goal of premedication is to dry the patient's airway. A dry airway promotes anesthetic deposition, aids visibility, and can reduce procedure time. An anticholinergic agent, such as atropine, may be given before the procedure. Atropine also may help decrease vagal responses (e.g., bradycardia and hypotension) that can occur during bronchoscopy.

Narcotic analgesics such as morphine or fentanyl also may be given. In addition to reducing pain, these agents help diminish laryngeal reflexes. However, narcotics should be withheld until procedures requiring patient cooperation are completed. Caution must be exercised to avoid respiratory depression. Naloxone (Narcan) must be available in the event of respiratory depression.

Additional narcotics and sedatives (e.g., propofol) may be needed for patient comfort and should be available. The need for antiarrhythmics, resuscitative drugs, narcotic antagonists, and intravenous fluids is harder to predict. Advance preparation results in a more efficient and rapid response.

Equipment Preparation

The RT is often responsible for preparing the equipment needed for bronchoscopy. Box 36-9 lists needed equipment. Special procedure rooms are often used for bronchoscopy and usually have most of the ancillary equipment already in place. All equipment must be thoroughly checked for function, tight connections, and integrity. This check is especially important for small parts and connectors, which can be aspirated if they loosen and disconnect.

Airway Preparation

The goals of airway preparation are to prevent bleeding, decrease cough and gagging, and decrease pain. Topical vasoconstrictors such as pseudoephedrine or dilute epinephrine (usually 1:10,000) may be used to prevent or treat bleeding.

Airway anesthesia is achieved by topical anesthetics or nerve block. Topical anesthetics are more common. The particular anesthetic and route of administration vary depending on experience and locale. Lidocaine (1%, 2%, or 4%) is often used. Lidocaine is commonly delivered via an atomizer to the nose, via mouthwash to the oropharynx, and via nebulizer or instillation through the bronchoscope to the lower airways. The RT will usually administer the lidocaine by nebulizer. The use of lidocaine by nebulizer before bronchoscopy may limit the need for lidocaine instillations into the lower airways and can make the procedure less unpleasant for the patient. Superior laryngeal nerve block provides anesthesia in the upper larynx, but it does not affect the vocal cords. Transtracheal block through the cricoid membrane anesthetizes both the vocal cords and the trachea.

Monitoring

The RT has an active role in monitoring the patient and should communicate any changes to the physician. Oxygenation should

Box 36-9 Equipment Needed for Bronchoscopy

EQUIPMENT FOR BRONCHOSCOPIST AND ASSISTANT
- Masks and goggles
- Gloves (sterile for bronchoscopist)
- Gown

BRONCHOSCOPIC DEVICES
- Appropriate size bronchoscope, as determined by bronchoscopist
- Bronchoscopic light source
- Bronchoscope adapter for endotracheal tube (ETT)
- Cytology brushes, flexible forceps, transbronchial aspiration needles, retrieval baskets, as determined by the bronchoscopist
- Syringes for medication delivery, normal saline lavage, and needle aspiration
- Sterile normal saline
- Specimen collection devices and fixatives as determined by institutional policies
- Bite block
- Sterile gauze pads for cleaning tip of bronchoscope, as needed
- Water-soluble lubricant
- Venous access equipment
- In case intubation is required
  - ETTs (various sizes, laryngoscope, laryngeal mask airway, thoracostomy set/tray)
  - Appropriate procedure documentation paperwork, including laboratory requisitions

FOR PATIENT SUPPORT AND MONITORING
- Pulse oximeter
- Oxygen and related delivery equipment
- Electrocardiographic monitoring equipment
- Sphygmomanometer
- Suction system with suction supplies for mouth and scope
- Resuscitation equipment, in case needed

MEDICATIONS*
- Topical anesthetics: Lidocaine 1%, 2%, 4%; lidocaine 3% with phenylephrine (for nares)
- Sedatives: Codeine, midazolam, morphine, diazepam, fentanyl, propofol
- Benzodiazepine antagonist (flumazenil), narcotic antagonist (naloxone)
- Anticholinergic agent (atropine, glycopyrrolate) to reduce secretions and minimize vasovagal reflexes
- Sterile nonbacteriostatic 0.9% sodium chloride solution for bronchial washings or lavage
- Dilute epinephrine (usually 1:10,000) for bleeding control
- Inhaled beta agonist (albuterol, levalbuterol)
- Nasal decongestants (pseudoephedrine)
- Water-soluble lubricant or combined lubricant and anesthetic (viscous lidocaine)
- Mucolytics or mucokinetics (10% or 20% acetylcysteine, 7.5% sodium bicarbonate, rhDNAse)
- Emergency and resuscitation drugs as deemed appropriate

From American Association for Respiratory Care: Clinical practice guideline: bronchoscopy assisting—2007 revision and update. Respir Care 52:74, 2007.
*Depend on institutional policy and bronchoscopist preference. Aerosolized, atomized, or instilled drugs may be administered by an appropriately trained respiratory therapist. Intravenous medications must be administered by a physician or nurse.

be monitored continuously via pulse oximetry. If desaturation occurs, FiO_2 is increased with an O_2 therapy device. Alternatively, the procedure can be temporarily halted, and O_2 can be given through the scope's open channel. The latter technique has the advantage of defogging the scope.

The respiratory rate and depth are also observed. Decreases in rate or depth may indicate oversedation. Continuous electrocardiogram and periodic blood pressure monitoring also should be routine. Arrhythmias and changes in blood pressure that occur are usually due to hypoxemia, vagal stimulation, pain, or anxiety. Prompt recognition of a problem and appropriate response aid recovery.

Assisting With the Procedure

The physician inserts the bronchoscope into the airway and guides it by directing the tip with the thumb lever. While monitoring the patient, the RT may also assist the physician by supplying syringes filled with anesthetic, vasoconstrictor, mucolytic agents, or lavage solutions. Forceps or brushes are often inserted into the bronchoscope by the RT. The physician guides these devices to the desired area. In addition, sputum or tissue samples obtained by the physician may be collected by the RT and prepared for laboratory analysis. When the goals of the procedure have been achieved, the bronchoscope is removed, and the patient's recovery period begins.

Recovery

Hypoxemia that occurs during the procedure may persist after completion. O_2 therapy should be maintained for up to 4 hours. Adequate oxygenation, via pulse oximetry, should be confirmed before therapy is discontinued.

The risk for aspiration persists as long as the airway is anesthetized. Patients should remain in a sitting position and refrain from eating or drinking until sensation returns. Patients are assessed for the development of stridor or wheezes. The physician is notified, and appropriate aerosol therapy with nebulized racemic epinephrine or bronchodilators is given in such cases.

Complications

The complications of bronchoscopy are similar to the complications associated with suctioning. However, the greater patient discomfort, longer duration, and the extent of airway penetration make bronchoscopy a more hazardous and complex procedure.

Hypoxemia is most severe in patients with underlying lung disease. To minimize this problem, all patients should receive O_2 before and during the procedure. When the nasal route is used to insert the bronchoscope, O_2 can be administered by a nasal catheter (in the opposite naris) or by a mask adapted to allow passage of the bronchoscope.

Hemodynamic changes (heart rate, blood pressure, and cardiac output) vary and may be related to differences in techniques or medications. Bronchospasm also has been reported and is most severe in patients with asthma. Premedication with albuterol and ipratropium bromide may help relieve this problem; the use of sedatives or narcotic analgesics, which do not release histamine, would also be helpful. Meperidine (Demerol) and fentanyl are better for patients with asthma.[34]

In patients with artificial airways, placing a bronchoscope through an ETT or tracheostomy tube may decrease the radius by 50%. If the patient is on a ventilator, peak inspiratory pressure may increase, or V_Ts may decrease. Inadvertent PEEP also may increase. An RT should be present during the procedure to adjust the ventilator and monitor SaO_2 and exhaled volumes.

SUMMARY CHECKLIST

- Retained secretions or other semiliquid fluids are removed from the large airways via suctioning. Removal of foreign bodies or tissue masses beyond the main stem bronchi requires bronchoscopy.
- To avoid or minimize the complications of suctioning, the RT needs to (1) preoxygenate, (2) limit negative pressure and suction time, and (3) use sterile technique.
- The primary indications for an artificial tracheal airway are (1) to relieve airway obstruction, (2) to facilitate secretion removal, (3) to protect against aspiration, and (4) to provide positive pressure ventilation.
- There are two basic types of tracheal airways: endotracheal (translaryngeal) tubes and tracheostomy tubes.
- Orotracheal intubation is the preferred route for establishing an emergency tracheal airway.
- Before intubation, adequate ventilation and 100% O_2 by manual resuscitator and mask should be provided.
- No more than 30 seconds should be devoted to any intubation attempt.
- There are many ways to assess ETT position; only laryngoscopy or bronchoscopy can confirm correct positioning.
- Serious complications of emergency airway management include acute hypoxemia, hypercapnia, bradycardia, and cardiac arrest.
- Nasotracheal intubation is the preferred route for intubation of patients with maxillofacial injuries.
- The primary indication for tracheotomy is the continuing need for an artificial airway after a prolonged period of oral or nasal intubation; the decision when to switch from ETT to tracheostomy tube should be individualized.
- The most common laryngeal injuries associated with endotracheal intubation are glottic edema, vocal cord inflammation, laryngeal or vocal cord ulcerations, and vocal cord polyps or granulomas.
- Although laryngeal lesions occur only with oral or nasal ETTs, tracheal lesions can occur with any tracheal airway. The most common tracheal lesions are granulomas, tracheomalacia, and tracheal stenosis.
- To minimize or prevent trauma secondary to tracheal airways, the RT needs to (1) select the correct size of airway, (2) avoid tube movement or traction, (3) limit cuff pressures, and (4) use sterile techniques.
- To minimize the risk for infection, the RT needs to (1) use closed suction devices, (2) use passive humidification, (3) monitor cuff pressure carefully, (4) use subglottic suction, and (5) keep the head of the bed elevated.

- ETT obstruction can be caused by (1) kinking of or biting on the tube, (2) herniation of the cuff over the tube tip, (3) obstruction of the tube orifice against the tracheal wall, and (4) mucous plugging.
- If a tracheal airway appears to be completely obstructed, the RT needs to perform the following steps in order until the obstruction is relieved: (1) Reposition the patient's head and neck, (2) deflate the tube cuff, (3) try passing a suction catheter, (4) try removing the inner cannula of the tracheostomy tube, (5) remove the airway and provide bag-valve-mask ventilation and oxygenation.
- A patient is ready for extubation if the patient (1) can maintain adequate spontaneous oxygenation and ventilation, (2) is at minimal risk for upper airway obstruction, (3) has adequate airway protective reflexes, and (4) can adequately clear secretions.
- Tracheostomy decannulation can be accomplished by using fenestrated tubes, progressively smaller tubes, or tracheostomy buttons.
- An LMA or a double-lumen airway (Combitube) can be used in a difficult intubation.
- Cricothyroidotomy is performed when a patient cannot be intubated or ventilated.
- Key factors in planning and conducting fiberoptic bronchoscopy include premedication, equipment preparation, airway preparation, and monitoring.

CHAPTER 37

Emergency Cardiovascular Life Support

THOMAS A. BARNES

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- List the causes of sudden cardiac arrest (SCA).
- List the signs of SCA, heart attack, and foreign body airway obstruction.
- Describe how to perform cardiopulmonary resuscitation (CPR) on adults, children, and infants.
- Describe how to perform defibrillation with automated external defibrillators and manual defibrillators.
- State how to administer synchronized cardioversion.
- Describe how to evaluate quality and effectiveness of CPR.
- List the complications that can occur as a result of resuscitation of SCA.
- State when not to initiate CPR.
- Describe how to apply key adjunct equipment during Advanced Cardiac Life Support (ACLS).
- State common drugs and drug routes used during ACLS.
- Describe how to monitor patients before cardiac arrest, during CPR, and after cardiac arrest.

defibrillation
gastric inflation
synchronized cardioversion

Respiratory therapists (RTs) play a vital role in emergency cardiovascular life support. In hospitals, RTs serve as key members of the medical emergency teams, also known as *rapid response teams.* In addition to managing the airway, RTs often provide ventilatory and circulatory support; drug and electrical therapy; and monitoring immediately before, during, and after a cardiac arrest.

In the community, RTs also may be certified **cardiopulmonary resuscitation** (CPR) instructors, extending their knowledge to laypeople through organizations such as the American Heart Association (AHA) and the American Red Cross. Mastery of an extensive knowledge base and the development of various, sometimes difficult, manual skills are required for teaching and performing CPR. The practitioner is encouraged to obtain further competencies by completion of formal courses in CPR, **Advanced Cardiovascular Life Support** (ACLS), pediatric advanced life support, and neonatal resuscitation program.

CAUSES AND PREVENTION OF SUDDEN DEATH

Sudden cardiac arrest (SCA) is a leading cause of death among adults over the age of 40 in the United States and many parts of the world.[1] In the United States, approximately 500,000 people per year experience SCA and receive an attempted resuscitation.[1] Pulseless ventricular rhythms are the first manifestation of 23% of emergency medical services (EMS)-treated out-of-hospital cardiac arrests.[2] Successful resuscitation depends on immediate CPR and delivery of a shock before pulseless ventricular rhythms deteriorate into asystole. In cases of SCA related to asphyxia secondary to trauma, drug overdose, or upper airway obstruction, CPR with chest compressions and ventilation before the shock is critical.

BASIC LIFE SUPPORT

The goal of **basic life support** (BLS) is to restore ventilation and circulation to victims of airway obstruction and respiratory or cardiac arrest. These skills can be used by a single practitioner to restore ventilation and circulation until the victim is revived or until ACLS equipment and personnel are available. The steps for administering BLS by a single health care practitioner are as follows:

1. Check for lack of movement or response and no normal breathing or only gasping.
2. Activate the emergency response system (get automated external defibrillator [AED] if close to your location).
3. If no AED is available, start chest compressions and rescue breathing for adult cardiac arrest (use cycles of 30 compressions to 2 ventilations).
4. Open airway and check breathing.
5. If person is not breathing, give 2 breaths that produce chest rise.
6. Immediately resume chest compressions (push hard and deep with a minimum depth of 2 inches [5 cm] and a minimum rate of 100 to 120/min. Do not exceed 120/min compressions because depth of compression and release of pressure during chest compression will be affected).
7. AED arrives with response team.

Steps 3 through 6 are referred to as the *CABDs* of resuscitation—*c*irculation, *a*irway, *b*reathing, and *d*efibrillation. Table 37-1 summarizes the CABDs of CPR for adults, children (1 year old to puberty), and infants (younger than 1 year old).

Determining Unresponsiveness

BLS begins with immediate recognition of SCA and activation of the emergency response system, based on assessment of unresponsiveness, not moving, and no normal breathing (only gasping).

Whatever the location, the victim's level of consciousness should be assessed quickly by checking for signs of life (e.g., movement and normal breathing). The rescuer should call for help and activate the EMS system if the patient is not moving or breathing or only gasping. Outside the hospital, someone may need to call 911 or the emergency number for the local EMS system. Within the hospital, specific protocols exist for "calling a code." All RTs must be familiar with the protocols of their institution for handling these emergency situations.

Restoring Circulation

Determining Pulselessness

For ease of training, the lay rescuer should be taught to assume that a cardiac arrest is present if the unresponsive victim is not breathing or gasping and not take time to check for a pulse. Health care workers also may take too long for a pulse check and have difficulty determining if a pulse is present. For this reason, health care rescuers should proceed immediately with chest compressions if no pulse is found within 10 seconds.

RULE OF THUMB

Assessment of the pulse of an unresponsive patient by health care providers should be limited to 10 seconds to avoid delaying chest compressions. Pulse checks are difficult to accomplish with any fidelity. Pulse and rhythm checks should not be done after a shock until five cycles of CPR have been completed. Pulse checks should not be done by lay rescuers.[3]

Pulselessness is evaluated by palpating a major artery. In adults and children older than 1 year, the carotid artery in the neck or femoral artery should be palpated. To locate the carotid artery, the rescuer should maintain the head-tilt with one hand while sliding the fingers of the other hand into the groove created by the trachea and the large neck muscles (Figure 37-1). The carotid artery area must be palpated gently to avoid compressing the artery or pushing on the carotid sinus. Because the pulse may be slow, weak, or irregular, the artery may need to be assessed for approximately 10 seconds for the presence or absence of a pulse to be confirmed.

For infants, the brachial artery is preferred for assessing pulselessness. To palpate the brachial artery, the rescuer must

TABLE 37-1

Steps for Cardiopulmonary Resuscitation in Adults, Children, and Infants

Procedure	Adult	Child	Infant
Compressions			
Where to check pulse (limit pulse check to <10 sec)	Carotid artery	Carotid or femoral artery	Brachial artery
Hand placement	Heel of one hand on sternum in center of chest, between nipples. Second hand on top of first with hands overlapped and parallel.	Lower half of sternum with heel of one hand or with two hands (for larger children). Do not compress over xiphoid.	Sternum with two fingers placed just below nipple line in center of chest
Compression-to-ventilation ratio	One or two rescuers 30:2	One rescuer 30:2; two rescuers 15:2	One rescuer 30:2; two rescuers 15:2 Newly born or newborn 3:1
Cycles of compression-to-ventilation	5	5	5
Depth of compressions (push in hard and fast, allow chest to recoil fully)	Minimum of 2 in (50 mm)	At least one-third anteroposterior diameter of chest or 2 inches (50 mm)	At least one-third anteroposterior diameter of chest or 1½ inch (4 cm).
Compression rate	Minimum of 100/min (do not exceed 120/min)	100/min	100/min
Breathing			
Obstructive procedure	*Responsive:* If mild, allow victim to clear the airway by coughing. If severe, repeat abdominal thrusts until foreign body is expelled, or the choking victim becomes unresponsive. Consider chest thrusts if abdominal thrusts are ineffective, if rescuer is unable to encircle victim's abdomen, or if victim is in the late stages of pregnancy. *Unresponsive:* Carefully move victim to the ground, immediately activate EMS system, and begin CPR, compressions first, then look into the mouth before giving breaths. If a foreign body is seen, it should be removed. Follow ventilation with chest compressions.	Same as for adult	*Responsive:* If mild, allow infant to clear the airway by coughing. If infant is unable to make a sound (severe obstruction), deliver five back blows (slaps) followed by chest thrusts repeatedly until object is expelled or infant becomes unresponsive. Abdominal thrusts should not be done on infants because they may damage the largely unprotected liver. *Unresponsive:* Activate EMS system and begin CPR, 30 chest compressions first, then look into the mouth before giving breaths. If a foreign body is seen, it should be removed. Follow ventilations with cycles of 30 chest compressions and 2 ventilations.
Rescue Breathing			
Palpable pulse, but no spontaneous breaths or inadequate breathing	10-12/min, 1 breath every 5-6 sec	12-20/min, 1 breath every 3-5 sec, if palpable pulse ≥60/min	20/min, 1 breath every 3 sec, if palpable pulse ≥60/min

grasp the infant's arm with his or her thumb outward, slide his or her fingers down toward the antecubital fossa, and press gently to feel for a pulse. The femoral artery also can be palpated, which may be done for an adult, a child, or an infant.

In hospital critical care settings, bedside monitoring equipment may provide supporting or confirming information regarding the respiratory or circulatory status of a patient. However, information obtained from these devices should never be a substitute for careful clinical assessment.

If the patient has a pulse but is not breathing, ventilation must be started immediately, at the appropriate rate of 8 to 10 breaths/min (every 6 to 8 seconds). If no pulse is palpable, external chest compressions must be interposed with ventilatory support. Deliver cycles of 30 compressions and 2 ventilations until an advanced airway is placed; then deliver uninterrupted chest compressions with asynchronous ventilations at a rate every 6 to 8 seconds (8 to 10/min) (see Table 37-1).

Providing Chest Compressions

Adequate circulation can be restored in a pulseless victim using external chest compressions. The rescuer manually compresses the lower half of the sternum (for an adult patient) at a minimum rate of 100 compressions/min without exceeding 120/min. The duty cycle for downstroke and upstroke (release) is 1:1 downstroke-to-upstroke ratio. It is very important to

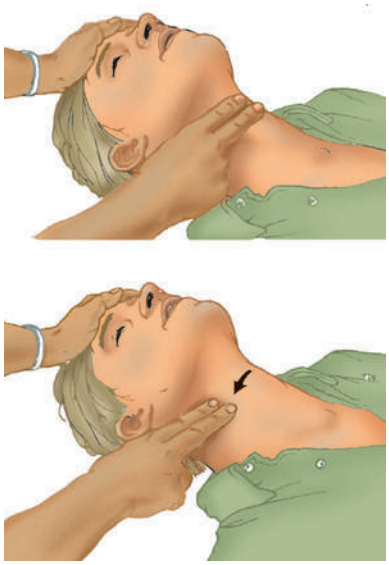

FIGURE 37-1 Determining pulselessness.

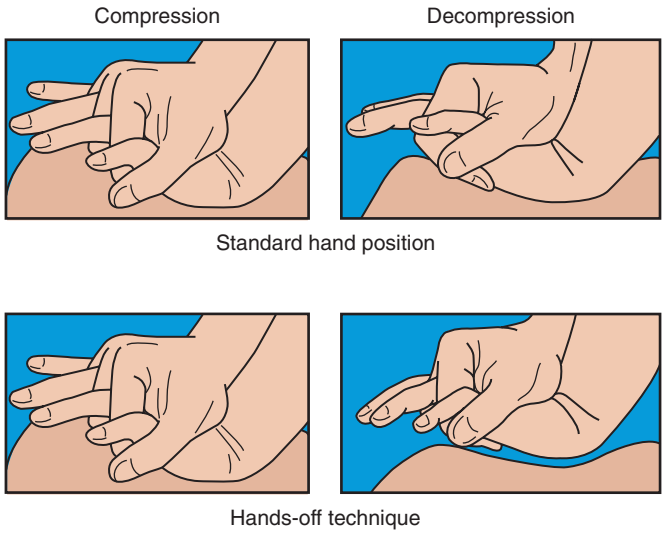

FIGURE 37-3 Techniques for hand position.

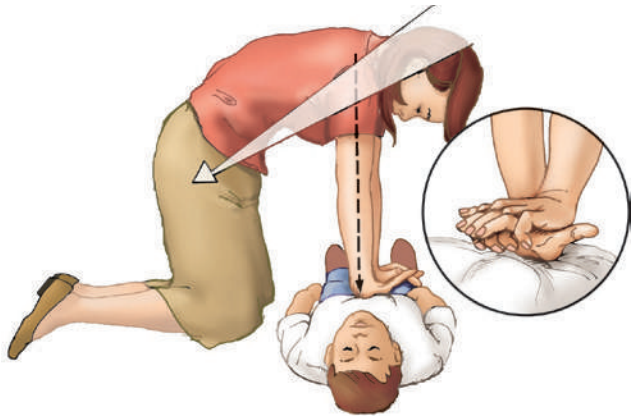

FIGURE 37-2 Position of practitioner for external cardiac compression. Note interlocked fingers to prevent pressure on rib cage.

have a complete upstroke so as not to increase intrathoracic pressure during the diastolic phase. The best way to ensure that the upstroke is complete is for the rescuer to take his or her hand slightly off the chest between compressions.[4,5] Cardiac output produced by external chest compressions is approximately one-fourth of normal cardiac output, with arterial systolic blood pressures between 60 and 80 mm Hg. Blood flow during chest compression probably results from changes in the intrathoracic pressure.

Adults. The procedure for providing chest compressions to adults is as follows (Figures 37-2 and 37-3):

1. Place the victim in a supine position on a firm surface because chest compressions are more effective when the victim is on a firm surface.
2. Choose a position close to the patient's upper chest so that the weight of your upper body can be used for compression. If the patient is on a bed or stretcher, stand next to it with the patient close to that side. If the bed is high or you are short, you may need to lower the bed, stand on a stool or chair, or kneel on the bed next to the victim. If the patient is on the ground, kneel at his or her side.
3. Identify the lower half of the victim's sternum, in the center of the chest between the nipples, place the heel of your hand on the sternum with your other hand on top, and lock your elbows.[6]
4. Perform compression with the weight of your body exerting force on your outstretched arms, elbows held straight. Your shoulders should be positioned above the patient so that the thrust of each compression goes straight down onto the sternum, using your upper body weight and the hip joints as a fulcrum (see Figure 37-2). It is acceptable to let your hands leave the victim's chest ever so slightly to ensure a complete upstroke (see Figure 37-3).
5. Compress the sternum 2 inches (5 cm) at a minimum rate of 100 compressions/min; however, do not exceed a rate of 120/min. The compression phase of the cycle should be equal in duration to the upstroke phase.
6. If CPR must be interrupted for transportation or advanced life-support measures, resume chest compressions as quickly as possible. Compressions should not cease for more than 5 seconds (30 seconds if the victim is being intubated).

Children. Children who have reached puberty should receive chest compressions as outlined for adults. The procedure for younger children (1 year old to puberty) is as follows:

1. Place the victim in the supine position on a firm surface. Small children may require additional support under the upper body; this is particularly true when chest compressions are given with mouth-to-mouth ventilation because extension of the neck raises the shoulders. The head should be no higher than the body.
2. As with an adult, identify the lower half of the sternum. Because the liver and spleen of younger children lie higher in the abdominal cavity, take special care to ensure proper

positioning as described previously. However, use only one hand to compress. Use the other hand to maintain head position and maintain an airway.

3. Compress the chest at a rate of at least 100 compressions/min. Push with enough force to depress the chest one-third of the anteroposterior diameter, approximately 1½ inch (4 cm) in infants or at least 2 inches (5 cm) in children. Generally, the heel of one hand is sufficient to achieve compression. Because children and rescuer hands come in all sizes, one or two hands can be used to deliver chest compressions to ensure that adequate compression depth and with complete release occur. The use of two hands to compress the chest of children will result in better release (less leaning) and less fatigue.[6,7] As with adults, compression and relaxation times should be equal in length and delivered smoothly.

Infants. The procedure for infants (1 year of age or younger) is as follows (Figure 37-4):

1. Use the lower half of the sternum for compression in an infant. Proper placement is determined by imagining a line across the chest connecting the nipples. Place your index finger along this line on the sternum. Then place your middle and ring fingers next to the index finger. Raise your index finger and perform compressions with the middle and ring fingers. Use the other hand to maintain the infant's head position and airway.
2. Compress the sternum approximately 1.5 inch (4 cm) at a rate of at least 100 compressions/min. Compression and upstroke phases should be equal in length and delivered smoothly. Your fingers should remain on the chest at all times.

Neonates. Chest compressions are indicated if the neonate's heart rate decreases to less than 60/min despite adequate ventilation with supplemental oxygen (O_2) for 30 seconds.[8] Before starting chest compressions, the rescuer should ensure that the neonate is being ventilated optimally.[8] Neonatal chest compressions are delivered on the lower third of the sternum to a depth of approximately one-third of the anteroposterior diameter of the chest to achieve a 3:1 ratio of 90 compressions and 30 breaths to achieve 120 events per minute.[8] Coordinated chest compressions and ventilations should continue until the spontaneous heart rate is greater than 60/min.[8] Two methods have been described. The first method uses a "wraparound" technique (Figure 37-5). To use this method, the rescuer encircles the neonate's chest with both hands and compresses the sternum with two thumbs, using the other fingers of both hands to support the neonate's back. The rescuer should position the thumbs just below the victim's intermammary line, taking care not to compress the xiphoid process. Compression should be performed smoothly, with downstroke and upstroke times approximately equal. In all infants, the chest should be allowed to expand fully after a compression. After every third compression, the neonate should receive a breath of 100% O_2, coordinated with compressions to avoid simultaneous delivery. The second method, the two-finger technique (see Figure 37-4), may have advantages when access to the umbilicus is required.

Chest Compressions Under Special Circumstances

The following unique circumstances require modification of the normal procedures for applying cardiac compressions: near drowning and electrical shock.

Near Drowning. Use the A-B-C approach instead of C-A-B because of the hypoxemia caused by near drowning. When cardiac arrest occurs as a result of drowning, the victim must be moved as quickly as possible to a firm surface. Cardiac compressions are difficult to perform while a victim is in the water and may be ineffective. Mouth-to-mouth ventilation in shallow water may be helpful when administered properly. Stabilization of the cervical spine is unnecessary unless circumstances leading to the incident indicate that trauma is likely. Manual cervical spine and spine immobilization equipment

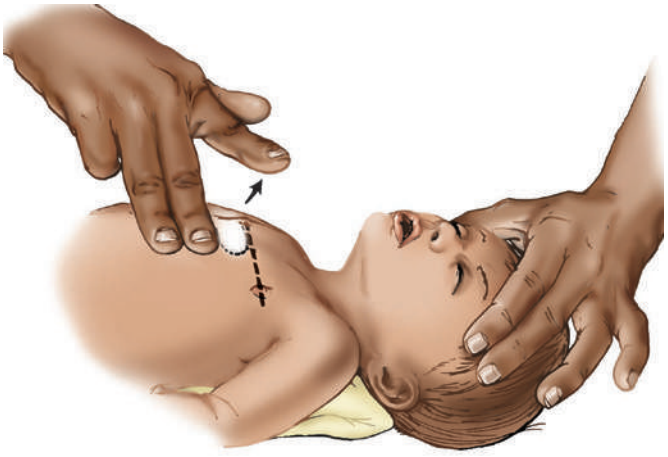

FIGURE 37-4 Position for chest compression in infants.

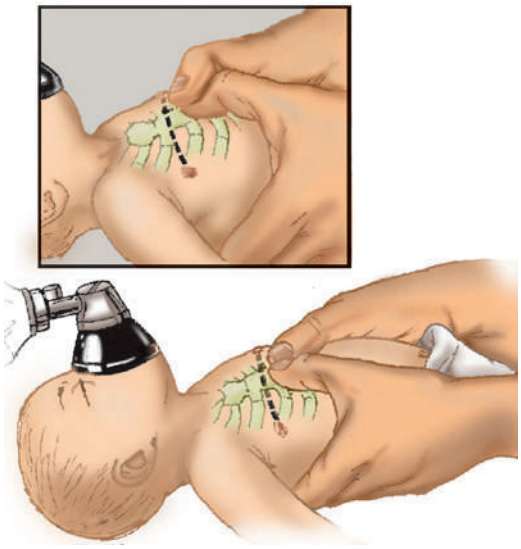

FIGURE 37-5 Neonatal chest compression using the wraparound technique.

may restrict adequate opening of the airway and may delay the delivery of adequate ventilation.

Electrical Shock. Electrical shock can cause either cardiac or respiratory arrest. Cardiac arrest is caused by ventricular fibrillation (VF). Respiratory arrest may occur secondary to paralysis of ventilatory muscles. Initially, the victim must be removed from contact with the source of electricity and evaluated. The rescuers must pay special attention to their own safety. A victim who is still connected to an electrical source must not be touched. The power must be turned off. If cardiac arrest has occurred, airway control, CPR, and attempts at defibrillation should be administered immediately.

Restoring the Airway

After calling for help and activating the EMS system, the lay rescuer providing "hands only" CPR should not use a passive airway such as hyperextending the neck. There is insufficient evidence indicating that a passive airway improves ventilation while administering chest compressions.[3]

The health care provider after activating the emergency response system and sending someone for an automatic external defibrillator should deliver 30 chest compressions and use the head-tilt/chin-lift or jaw-thrust maneuver to open the airway (Figures 37-6 and 37-7). The victim should be quickly inspected for any neck or facial trauma. If spinal cord trauma is suspected, the neck must be carefully positioned in a neutral in-line position and procedures requiring hyperextension must be modified. In addition, when a victim is found lying on his or her side or stomach, he or she should be moved to a supine position before airway procedures are begun. Manual in-line spinal motion restriction should be employed when moving the patient. The rescuer must ensure that the victim is positioned on a hard, flat surface.

One of two procedures can be used. (1) The head-tilt/chin-lift method is the primary procedure recommended when spinal trauma is not suspected. (2) The jaw thrust is used mainly by trained clinicians when spinal neck injuries are suspected. Health care providers should use the head-tilt/chin-lift procedure if the jaw-thrust maneuver does not open the airway.[4] After the airway is cleared and opened, the rescuer must immediately deliver 2 breaths.

Restoring Ventilation

Breathlessness exists if no chest movement or normal breath sounds are present or only gasping is present. This evaluation should take no longer than 3 to 5 seconds to complete. Delivery of chest compressions should always precede attempts to ventilate the patient using a ratio of 30 compressions to 2 breaths.

Providing Artificial Ventilation

During respiratory arrest, the victim must be provided with O_2 within 4 to 6 minutes, or biologic death follows. The lay rescuer can restore O_2 supply to the victim's lungs by exhaling into the victim's mouth, nose, or tracheal stoma. These procedures can be used for any victim, with appropriate modification for the patient's age. Health care providers should be able to provide bag-mask ventilation with 100% O_2.

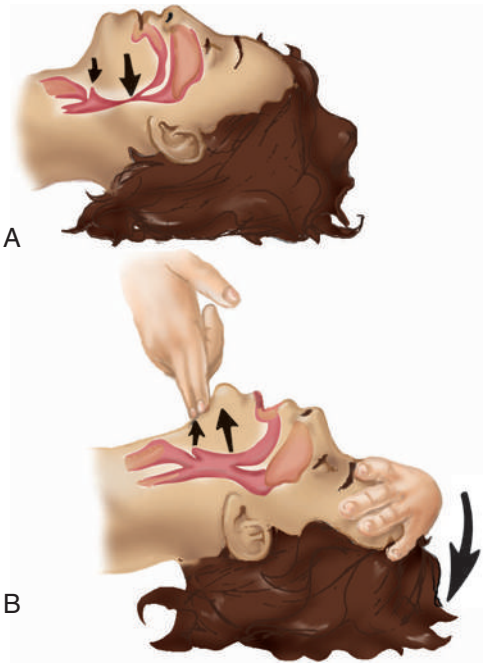

FIGURE 37-6 Opening the airway. **A,** Airway obstruction produced by tongue and epiglottis. **B,** Relief by head-tilt/chin-lift method.

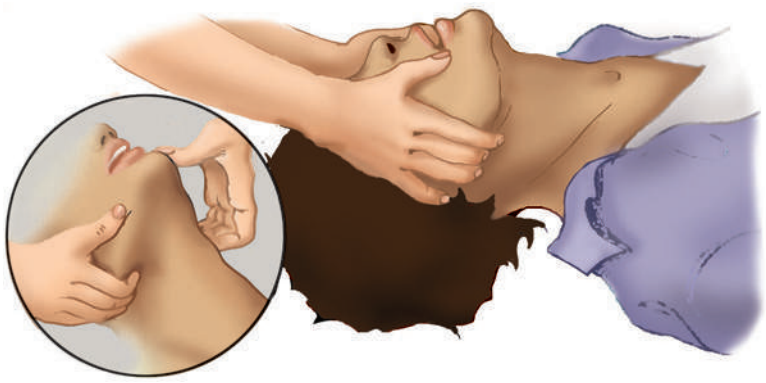

FIGURE 37-7 Jaw-thrust maneuver.

Mouth-to-Mouth Ventilation. **Untrained lay rescuers should be encouraged to deliver hands-only (chest compression only) CPR** (i.e., continuous chest compression over the middle of the chest). Trained rescuers can restore adequate oxygenation through mouth-to-mouth ventilation. To do this, the rescuer should take a normal breath (500 to 600 mL) and exhale directly into the victim's mouth over 1 second to produce visible chest rise. Exhaled air provides approximately 16% O_2, which is sufficient to achieve an arterial O_2 tension (PaO_2) of 50 to 60 mm Hg. A tidal volume (V_T) of 500 mL should be delivered when chest compressions are being administered. Children require proportionally smaller volumes.

During resuscitation of a victim of cardiac arrest, 2 breaths should be given over a period of 1 second each. Excessive volumes (>500 mL) or an inspiratory rate that is too fast (>10 breaths/min) must be avoided because this can push air into the stomach, causing **gastric inflation** and increase intrathoracic pressure. Increased intrathoracic pressure can decrease coronary and cerebral perfusion. Visible chest rise should be used to gauge the V_T needed in children and adults.

Adults. Thirty chest compressions should be delivered to unresponsive victims with apnea or abnormal breathing (gasping) before attempting mouth-to-mouth breathing. The exception would be a hypoxic event such as a near-drowning victim. The procedure for mouth-to-mouth ventilation of adults with spontaneous circulation (i.e., strong palpable pulses) is as follows (Figure 37-8).

1. Place the person on his or her back on a hard, flat surface.
2. Kneel at the person's side, and open and clear the airway as previously described. Pinch the person's nose with your thumb and index finger close to the nares to prevent air from escaping during ventilation.
3. Take a normal breath and deliver 500 mL over 1 second, while making a seal over the person's mouth and watching for chest rise. A good seal over the person's mouth is essential. If a good seal cannot be obtained using this method, attempt mouth-to-nose ventilation.
4. Remove your mouth from the person's mouth, and allow him or her to exhale passively. Provide a second breath after exhalation is complete.
5. After successfully delivering 2 breaths, immediately assess the circulatory status (take <10 seconds to accomplish).
6. Should the initial attempt to ventilate fail, reposition the person's head and repeat the effort. If a second attempt at ventilation fails, the person may have foreign body airway obstruction (FBAO), and the procedures for handling such situations described elsewhere in this chapter should be followed.
7. Assuming mouth-to-mouth ventilation is successful and the person remains apneic, continue the effort at a rate of 1 breath every 5 to 6 seconds to maintain the minimal adult rate of 10 to 12 breaths/min.[3]

Infants and Children. Airway opening maneuvers for children and infants are similar to maneuvers for adults, with several key differences. Anatomic differences in the infant's airway make it especially susceptible to occlusion by the tongue. The infant's head should be extended only slightly, or it should be tilted back gently into a neutral position when the head-tilt/chin-lift maneuver is used. The procedure for children and infants is as follows:

1. If the child is an infant (younger than 1 year), create an airtight seal by placing your mouth over the infant's nose and mouth (Figure 37-9).
2. If the patient is a child between 1 year old and puberty, ventilate the child's lungs using the same technique as would be used for an adult (see Figure 37-8).
3. Provide an initial breath (over 1 second) sufficient to cause a visible rise in the chest. In infants, small puffs of air from the rescuer's cheeks are usually sufficient to achieve adequate ventilation.
4. Remove your mouth, and allow the child to exhale passively. Provide a second breath after this deflation pause.
5. After successfully delivering 2 breaths, immediately assess the pulse (<5 seconds). Provide chest compressions if the pulse is less than 60/min despite adequate oxygenation and ventilation.
6. If the initial attempt to ventilate fails, reposition the child's head and repeat the effort. A child's head may need to be

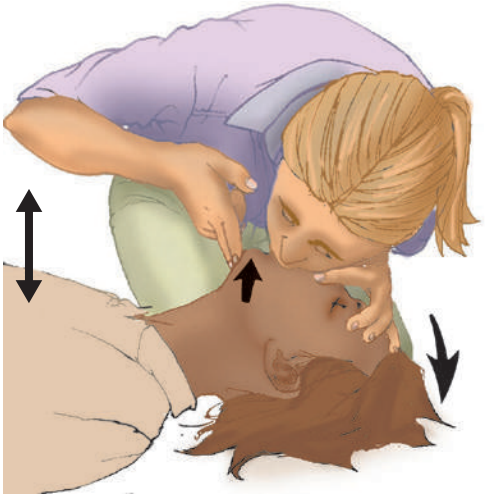

FIGURE 37-8 Adult mouth-to-mouth ventilation.

FIGURE 37-9 Mouth-to-mouth and nose seal for infants.

moved through a wide range of positions to secure an open airway. Hyperextension of a child's neck can cause obstruction and should be avoided. If a second attempt at ventilation fails, the victim may have FBAO, and the appropriate procedures outlined elsewhere in this chapter should be followed.

7. Assuming mouth-to-mouth ventilation is successful and the child remains apneic, continue to provide 1 breath every 3 to 5 seconds to maintain a rate of 12 to 20 breaths/min. Recheck pulse every 2 minutes.

Mouth-to-Nose Ventilation. Mouth-to-mouth ventilation cannot be performed in some situations; these include trismus (involuntary contraction of the jaw muscles, also known as *lockjaw*) and traumatic jaw or mouth injury. Also, sometimes it is difficult to maintain a tight seal with the lips using the mouth-to-mouth method. In these situations, mouth-to-nose ventilation should be used. The procedure is as follows (Figure 37-10):

1. Place the person in a supine position.
2. Use the head-tilt/chin-lift maneuver to establish the airway, taking care to close the mouth completely.
3. Inhale normally and exhale into the person's nose. Greater force may need to be applied than would be used with mouth-to-mouth ventilation because the nasal passageways are smaller.
4. Remove your mouth from the person's nose to allow the person to exhale passively. If the person does not exhale through the nose (because of nasopharyngeal obstruction from the soft palate), open the mouth or separate his or her lips to facilitate exhalation.
5. After successfully delivering 2 slow breaths, immediately assess the circulatory status (limit pulse check to <10 seconds).
6. If the person remains apneic, maintain ventilation at the rate appropriate for his or her age.

FIGURE 37-10 Mouth-to-nose ventilation.

Mouth-to-Stoma Ventilation. Patients with tracheostomies or laryngectomies can be ventilated directly through the stoma or tube. These patients can be identified by an obvious stoma or a tracheostomy or laryngectomy tube in place. Some patients wear a medical alert tag or bracelet indicating that a stoma is present. The procedure for mouth-to-stoma ventilation is as follows:

1. Place the person on his or her back with the neck in vertical alignment. Usually, the neck does not need to be extended and the nose or mouth does not need to be sealed because oropharyngeal structures are bypassed by the stoma.
2. Ensure that the stoma is clear of any obstructing matter and breathe directly into the stoma (or tube). If the person has a cuffed tracheostomy tube in place, inflate the cuff to prevent air from escaping around the tube. If the tube is uncuffed, the mouth and nose may need to be sealed off with your hand or a tight-fitting face mask. A pediatric face mask may be used to create an adequate peristomal seal for bag-mask ventilation to persons with stomas without artificial airways.
3. After delivering 2 breaths, immediately assess the circulatory status.
4. If the person remains apneic, maintain ventilation at the rate appropriate for his or her age.

One-Rescuer Versus Two-Rescuer Adult Cardiopulmonary Resuscitation

Outside the hospital, one-rescuer CPR is common. In such cases, the rescuer must assess the victim, call for help, and begin CPR without assistance from others. The rescuer must remain calm and remember the steps of one-rescuer CPR. The technique for performing chest compressions, opening the airway, and giving mouth-to-mouth breaths is the same, regardless of the number of rescuers.

When performing CPR alone, the lay rescuer must remember to give only compressions for adults, children, and infants until an AED arrives. When two rescuers are available, the second rescuer ventilates and evaluates the effectiveness of CPR. The other rescuer administers cardiac compressions. To facilitate movement, each rescuer should assume the appropriate rescue position on opposite sides of the victim. For an adult and child, the compression-to-ventilation ratio is the same as for a single rescuer (30:2) and the timing for compressions is "one and two and three and four and five" (a minimum rate of 100 times/min). In infants, two rescuers should use a compression-to-ventilation ratio of 3:1 with 90 compressions and 30 breaths delivered per minute (120 events/min). Each breath is delivered over a half-second with exhalation occurring on the next compression.

RULE OF THUMB

Lay rescuers should be taught to do a minimum of 100 compressions/min (do not exceed 120/min) until the AED arrives for all age groups because it is easier to remember. Emphasis should be placed on teaching lay rescuers to "push hard and fast" on the sternum.

RULE OF THUMB

Health care providers should use a 30:2 compression-to-ventilation ratio on adults and children. However, when two health care providers work together to resuscitate a child or infant the compression-to-ventilation ratio should be 15:2.[9]

When two health care providers resuscitate a patient, the individual providing compressions briefly pauses after 30 compressions so that the other person can administer two ventilations. The cycle is repeated without interruption of compressions to check for signs of circulation or response until an AED arrives or until the hospital code team take over CPR. Health care providers should limit interruptions in chest compressions to no longer than 10 seconds except for interventions such as insertion of an advanced airway or defibrillation.

To provide rest for the individual delivering cardiac compressions, the rescuers should change positions every five cycles (approximately 2 minutes). The individual doing cardiac compressions calls for the change, saying "we will change next time" in sequence with compressions. The switch should be accomplished in less than 5 seconds. The cycle continues with the two rescuers in their new positions. Alternatively, to avoid fatigue, teams of three health care providers can be assigned to do chest compression, switching every five cycles of 30:2 compression-to-ventilation ratio. The goal is to push "hard and fast" at a minimum rate of 100/min (do not exceed 120/min) without fatigue diminishing that goal.

RULE OF THUMB

The person doing chest compressions should be changed every 2 minutes. Doing chest compressions is tiring, and fatigue occurs within a few minutes, leading to a compression rate less than 100 compressions/min, shallow chest compressions (<50 mm), and incomplete chest recoil.[4]

Rescue attempts continue until advanced life support is available, the rescuers note spontaneous pulse and breathing, or a physician pronounces the victim dead. A cardiopulmonary emergency is a crisis for the victim and his or her family, and appropriate support and intervention should be provided all individuals affected. Victims who survive CPR should be transported quickly to tertiary care facilities, ideally only after advanced life support is instituted.

Automated External Defibrillation

Early Defibrillation

Since 1990 the AHA has recommended adding a fourth step to the treatment of cardiac arrest. This step involves early **defibrillation** after CPR has been initiated. The rationale is as follows:

FIGURE 37-11 Automated external defibrillator with pads attached. (From Chapleau W: Emergency first responder, making the difference, revised ed 2, St. Louis, 2011, St. Louis, Mosby JEMS.)

1. The most common initial rhythm in witnessed sudden cardiac arrest is VF.
2. The treatment for VF is electrical defibrillation.
3. The probability of successful defibrillation diminishes rapidly over time.
4. VF tends to convert to asystole within a few minutes.

Studies have shown that survival rates are highest when immediate bystander CPR is provided and defibrillation occurs within 5 minutes after SCA.[10,11]

The AHA recommendation is that **automated external defibrillators** (AEDs) be made available to individuals expected to respond to emergencies, such as police, security personnel, ski patrol personnel, flight attendants, and first-aid volunteers (Figure 37-11). Early defibrillation has already proved effective in saving lives of people who otherwise may not have been successfully resuscitated.[10,11] After appropriate training and implementation of the *CABs,* this step is inserted as the letter *D,* for defibrillation. This step should be initiated within 2 minutes of beginning CPR. If the EMS provider witnesses the collapse or for in-hospital situations, the rescuer should use the defibrillator as soon as it is available. When more than one health care provider is available, one should provide chest compressions while the other activates the emergency response system and retrieves the defibrillator. In an adult drowning victim or a victim of FBAO who becomes unconscious, a health care provider working alone may give about five cycles (approximately 2 minutes) of CPR before activating the emergency response system.[3]

Personnel employed at high-acuity hospitals may not be equipped with AEDs because access to ACLS is readily available, usually within minutes of the code being called. However, low-acuity hospitals, skilled nursing facilities, and other medical facilities that do not have a code team on the premises would benefit from AEDs. RTs working at such facilities should inquire whether one is on the premises and, if so, where it is located and how it functions. If an AED is not present, a recommendation should be made to the administration of the facility to

purchase one. The AHA recommends that an AED be available wherever CPR is likely to be performed.

VF cardiac arrest is less common in children than adults and accounts for 5% to 15% of pediatric and adolescent arrests.[12] The AHA recommends use of an AED for children older than 1 year who are in cardiac arrest and encourages the use of a pediatric dose-attenuator system if one is available. If such a system is unavailable, a standard AED is recommended. The standard doses recommended by the AHA for manual defibrillation of children are 2 J/kg for the first attempt and 4 J/kg for the subsequent attempt, increasing the dose in additional subsequent attempts not to exceed 10 J/kg.[13] Research has shown that lower energy (120 to 200 J) biphasic waveform shocks have equivalent or higher success in terminating VF than three stacked monophasic waveform shocks delivering escalating energy of 200 J, 300 J, and 360 J.[14,15] AEDs should be deployed in locations where there is a high incidence of witnessed SCA, such as airports, casinos, and sports facilities.

Automated External Defibrillators

AEDs function in a semiautomatic fashion; the device only recommends that a shock be delivered, rather than initiating one automatically. Adhesive electrodes from the AED are attached to the patient. When all of the equipment is hooked up, the "Analyze" button should be pressed to begin. A rhythm recognition program analyzes the patient's rhythm. If it detects ventricular tachycardia (VT) or VF, it advises the rescuer through voice and visual prompts that a shock should be delivered. If a shock is indicated, the rescuer should "Clear" the patient and press the "Shock" button. After pressing the shock button, the rescuer should deliver five cycles of CPR beginning with chest compressions using a compressions-to-ventilations ratio of 30:2.

The rescuer should not delay chest compressions by stopping to recheck the rhythm or pulse. The rhythm is checked by the AED after five cycles (approximately 2 minutes) of CPR have been completed. The rescuers should be prepared to initiate another five cycles of CPR immediately after a second shock has been delivered. The rescuer administering chest compressions should be changed every 2 minutes. The rescuer providing 2 minutes of chest compressions should be prepared to deliver a shock as soon as he or she removes hands from the victim's chest. The second rescuer should be in position to start chest compressions as soon as the shock is delivered. If no shock is advised by the AED, the AED voice prompt should instruct the rescuer to resume CPR immediately, starting with chest compressions. If the message reads "No shock indicated," CPR should be performed for 1 to 2 minutes and then the rhythm analysis should be repeated. A 1- to 2-minute period of CPR after a no-shock prompt from the AED delivers O_2 and metabolic substrates to the myocardium, increasing the probability that a perfusing rhythm will occur. The rescuer should not be concerned that chest compressions might trigger the return of VF in the presence of a postshock organized rhythm.[16] Figure 37-12 demonstrates how the AED is attached to the victim.

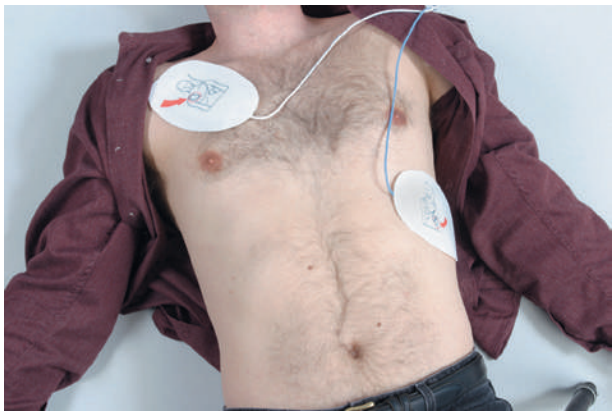

FIGURE 37-12 Positioning of rescuer and placement of pads when using automated external defibrillator. (From Chapleau W: Emergency first responder, making the difference, revised ed 2, St. Louis, 2011, St. Louis, Mosby JEMS.)

RULE OF THUMB

Patients in VF or pulseless VT cardiac arrest should receive only one shock followed immediately by five cycles of CPR before the next shock is delivered. Time should not be taken to check for a pulse or ventilate the patient before delivering the second shock if needed. Biphasic AEDs have a 90% conversion rate of VF on the first shock, so it is unlikely there will be a need for a second shock. However, chest compressions immediately after the first shock increase O_2 delivery and increase the chance of VF conversion to a normal rhythm.[13]

Evaluating Effectiveness of Cardiopulmonary Resuscitation

CPR providers need to judge continuously both the effectiveness of CPR and the victim's response. Ventilation can be evaluated by observing visible rise and fall of the victim's chest during mouth-to-mouth resuscitation. Air that is escaping can be heard and felt during exhalation. A consensus statement from the AHA on the quality of CPR reached the following conclusions on five quality metrics of CPR performance.[17]

1. Minimize the frequency and duration of interruptions in chest compressions.
2. Compress the adult chest at a rate of 100 to 120 compressions/min.
3. Ensure chest compression depth of 50 mm or greater (≥2 inches) in adults and at least one-third the anteroposterior dimension of the chest in infants and children.
4. Allow the chest to recoil completely after each compression, that is, no residual leaning.
5. Avoid excessive ventilation: rate less than 12 breaths/min (minimal chest rise).

The time to deliver 30 compressions is 18 seconds or less if the compression rate is at least 100 compressions/min. It takes a rescuer 4 seconds to deliver 2 breaths with a 1-second

inspiratory time and a 1-second expiratory time. Assuming 2 seconds are lost switching from compressions to ventilations, the total ventilation time is 6 seconds. The CPR cycle time is 24 seconds or less; 2.5 cycles/min would optimally deliver a minimum of 75 compressions and five breaths. The AHA has encouraged the use of CPR prompts after studies showed compression and ventilation rates are frequently too fast or slow.[17] Every effort possible must be made to decrease the number of interruptions in chest compressions.

Hazards and Complications

The most common complications that occur with CPR are worsening of existing neck or spine injuries, gastric inflation and vomiting, trauma to internal structures during chest compressions, and problems associated with the removal of foreign objects to clear an obstructed airway.

Neck and Spine Injuries

Health care providers can aggravate neck or spinal injuries by inappropriately moving the victim's head. However, only approximately 2% to 5% of victims with blunt trauma have a spinal injury. Spinal injury risk is greatest if the victim has craniofacial injury or a Glasgow Coma Scale score of less than 8.[18] The victim should be carefully assessed for head, neck, or spinal injuries. If this type of injury is apparent, the head should be carefully supported, and side-to-side motion must be avoided. In such situations, using the jaw thrust maneuver rather than the head-tilt/chin-lift method to open the airway is recommended by the AHA.[3] If jaw thrust is unsuccessful in establishing an airway, the rescuer should try a slight head-tilt.[3]

Gastric Inflation

During prolonged mouth-to-mouth ventilation, air enters the esophagus and stomach. Some gastric inflation is not unusual, particularly in children, and occurs in approximately 17% of cases.[19,20] Severe gastric inflation puts pressure on the diaphragm, restricting lung expansion. Gastric inflation also can increase vagal tone and cause reflex bradycardia and hypotension.

RULE OF THUMB

The best way to avoid gastric inflation during bag-mask ventilation is to deliver breaths with low to moderate flow (<30 L/min) over 1 second.[21] V_T size should be only large enough to cause visible chest rise. The health care provider should not ventilate and compress the chest simultaneously with a bag-mask device.

However, most important is the fact that severe gastric inflation prompts regurgitation. Because an unconscious patient lacks normal upper airway reflexes, regurgitated stomach contents can be aspirated easily into the lungs. Aspiration of stomach contents into the lungs may cause death by making ventilation virtually impossible or lead to severe lung injury such as aspiration pneumonia that may cause death days or weeks later.

Vomiting

Vomiting is another complication associated with **abdominal thrusts**, and it is impossible to avoid in some victims. Vomiting itself is a minor problem. The hazard is the aspiration of vomitus into the lung. Aspiration can be prevented only by using advanced airway devices such as an endotracheal tube, laryngeal mask airway, or esophageal-tracheal double-lumen airway (Combitube, Medtronic, Minneapolis, MN).

Internal Trauma

External cardiac compression is hazardous, and every attempt should be made to minimize trauma by using the correct technique. Complications associated with chest compression include rare incidents of gastric perforation, laceration of the liver, pneumothorax, hemothorax, cardiac tamponade, and soft tissue emphysema. More common complications are contusion of the lung and fractured ribs or sternum.[22,23] These complications most often are linked to improper hand position. Placement of the hands too far to either the left or the right can cause fractured ribs or lacerated lung. Incorrect placement on the left can injure the heart. Placing the hands too high on the sternum can fracture the sternum; placing the hands too low can cause a fractured xiphoid process or a lacerated liver. Correct identification of landmarks and proper hand placement minimize the likelihood of these complications.

Foreign Body Airway Obstruction

Manual removal of FBAO from the upper airway also can be hazardous because of the possibility of forcing the object deeper into the airway or traumatizing the airway. This hazard can be minimized by attempting to remove an FBAO only when the provider can see solid material obstructing the airway in an unresponsive patient and using extreme care in removing it.[3]

Contraindications to Cardiopulmonary Resuscitation

A pulseless, apneic patient dies within 4 to 6 minutes without intervention. Fear of further harm should never influence the decision to begin CPR. CPR is contraindicated only when the patient is obviously biologically dead (as noted by such findings as rigor mortis). In the hospital, CPR is contraindicated when a valid "do-not-resuscitate" order is in effect or when a properly executed living will (advance directive) specifically requests that CPR not be initiated.

Health Concerns and Cardiopulmonary Resuscitation

The actual risk for disease transmission during mouth-to-mouth ventilation is very small. However, the reluctance to initiate CPR poses a clear threat to the effectiveness of early intervention in life-threatening emergencies, which affects the public as a whole. A bystander should provide hands-only

(chest compression only) CPR, with an emphasis on "push hard and fast," or follow the directions of the emergency medical dispatcher.[4]

RULE OF THUMB

Rescuers of adult VF cardiac arrest should provide chest compressions at a rate of at least 100 compressions/min, with an emphasis on "push hard and fast." Periodic gasps and chest recoil in adult cardiac arrest may provide some ventilation if the airway is open. Most children and infants with cardiac arrest require both prompt ventilations and chest compressions.

Health care providers with a duty to provide CPR should follow the guidelines established by the U.S. Centers for Disease Control and Prevention (CDC) and the Occupational Safety and Health Administration. These recommendations include the use of latex gloves, masks, and goggles. Mechanical barrier aids to ventilation (e.g., masks, filters, valves, bag-mask) also have been suggested to allay fear and protect the rescuer. However, these devices require training to be used properly.

Equipment contaminated with blood or other body fluids during a resuscitation effort always should be discarded in appropriate receptacles or thoroughly cleaned and disinfected according to hospital protocols.

Treating Foreign Body Airway Obstruction

Early recognition of FBAO is critical. Foreign bodies may cause partial or complete obstruction. Partial obstruction may allow nearly adequate air exchange, in which case the patient remains conscious and coughing. As long as air exchange is present, the patient should be reassured and allowed to clear his or her own airway by coughing. If partial obstruction persists, or air exchange worsens, the EMS system should be activated. Poor air exchange exists when the patient has a weak or ineffective cough, increased inspiratory difficulty, or cyanosis.

With a completely obstructed airway, the patient commonly clutches at his or her throat. This is known as the *universal distress signal for foreign body obstruction.* A person with a complete obstruction cannot talk, cough, or breathe and is in dire need of emergency intervention using abdominal thrusts, chest thrusts, back blows, or a combination of two or more maneuvers.

Several procedures can be used to obtain a clear passageway if attempts to open a victim's airway are unsuccessful or if a foreign body is observed but cannot be removed from the mouth or pharynx. For adults and children, the procedure for health care providers for clearing a foreign body is the *abdominal thrust.* The rescuer should attempt back blows first for infants with an obstructed airway; if these are unsuccessful, the rescuer should try chest thrusts. *Chest thrusts* may be used in place of abdominal thrusts on women in advanced stages of pregnancy and on markedly obese individuals. Both abdominal thrusts and chest thrusts normally are followed by a visual check and manual removal of any observed obstructing foreign material.

Abdominal Thrusts (Heimlich Maneuver)

Forceful thrusts applied to the epigastrium can dislodge an obstruction caused by a food bolus, vomitus, or other foreign body. Quick thrusts to the abdomen rapidly displace the diaphragm upward, increasing intrathoracic pressure and creating expulsive expiratory airflow. As with a normal cough, this expulsive airflow may be sufficient to expel the foreign body from the airway. The procedure for performing abdominal thrusts on adults and children is as follows (Figure 37-13). If the victim is sitting or standing, stand behind the victim and wrap your arms around his or her waist. Make a fist with one hand, and place the thumb side midline on the abdomen slightly above the navel and well below the tip of the xiphoid process (see Figure 37-13). Grasp the fist with the other hand and deliver a quick upward and inward thrust. Each thrust should be a separate and distinct movement. Repeat the process until the obstruction is removed or the victim loses consciousness.

If an adult victim with FBAO becomes unresponsive, the rescuer should move the patient to the ground, activate the EMS system, and begin CPR. Each time the mouth is opened during cycles of compressions and ventilation, the rescuer should look into the victim's mouth for FBAO and remove it; this should be done without increasing the time to deliver 2 breaths (approximately 6 seconds). The routine use of blind finger sweeps to remove FBAO in adults, children, and infants is not recommended by the AHA.[3,8]

A conscious victim who is alone can attempt to dislodge the foreign body with self-administered abdominal thrusts, performed by pressing his or her fist into the abdomen or pushing the abdomen against a firm surface such as a counter top, sink, chair back, railing, or tabletop.

FIGURE 37-13 Abdominal thrusts, adult victim standing. (From Chapleau W: Emergency First Responder, Making the Difference, Revised 2nd edition, 2011, St. Louis, Mosby JEMS.)

Internal Organ Damage. The major hazard associated with abdominal thrusts that are performed when an individual has choked and lost consciousness is possible damage to internal organs, such as laceration or rupture of abdominal or thoracic viscera.[24] The body of clinical data regarding choking is largely retrospective and anecdotal. Abdominal thrusts have been recommended for relief of FBAO in adults and children since 1975, based mostly on early anecdotal case reports. Abdominal thrusts are recommended by the AHA and several other resuscitation councils for use for *unresponsive* adult and child (but not infant) victims. Abdominal thrusts are not recommended for infants younger than 1 year of age because of their relatively unprotected abdomens and large livers. Rational conjecture and common practices suggest that back blows may loosen obstruction so that subsequent abdominal or chest thrusts may relieve obstruction. The risk for internal organ damage from abdominal thrusts in a conscious patient can be minimized by the rescuer placing his or her arms and fist below the victim's xiphoid process and the lower margin of the ribs.

Back Blows and Chest Thrusts

Because an abdominal maneuver can easily cause abdominal injury when applied to infants, a combination of back blows and chest thrusts should be used to clear foreign bodies from the upper airway. Back blows alone may create sufficient force to dislodge trapped objects, but if this is ineffective, the back blows should be followed with five chest thrusts. The rescuer should continue inspecting the airway until the airway is restored. This procedure is as follows:

1. Back blows can be administered to infants more efficiently if the child is held straddled over one arm with the head lower than the body (Figure 37-14).
2. Use the flat portion of your hand to deliver gently, but quickly, five back blows between the shoulder blades.
2. If the back blows do not clear the infant's airway, turn the infant over and institute a series of five chest thrusts (see Figure 37-14). Similar to abdominal thrust, chest thrust creates a rapid increase in intrathoracic pressure, aiding expulsion of the foreign body. Chest thrusts for infants are performed in the same manner and at the same location as cardiac compressions but at a slower rate.
3. Try to clear the airway between attempts to expel the foreign body. First, visually inspect the oral cavity and remove any foreign matter that can be seen. Deep blind finger sweeps of the mouth of an infant, child, or adult are not recommended.

Evaluating Effectiveness of Foreign Body Removal

After each airway restoration maneuver, the rescuer must determine whether the foreign body has been expelled and the obstructed airway cleared. If the foreign body has not been dislodged, the appropriate sequence (abdominal thrusts or chest thrusts for adults and children, back blows and chest thrusts for infants) should be repeated until successful. Successful removal of an obstructing body is indicated by the following:

FIGURE 37-14 Use of back blows and chest thrusts to clear foreign bodies from infant airway.

- Confirmed expulsion of foreign body
- Clear breathing and ability to speak
- Return of consciousness
- Return of normal color

If successive attempts to clear the airway fail, more aggressive techniques are indicated, if available. These include direct laryngoscopy and foreign body removal with Magill forceps, transtracheal catheterization, cricothyrotomy, and tracheotomy. These methods require specially trained health care professionals and equipment, and they are aptly categorized as advanced life-support techniques. Transtracheal catheterization and cricothyrotomy are discussed later in this chapter, and laryngoscopy, bronchoscopy, and tracheotomy are described in Chapter 36.

ADVANCED CARDIOVASCULAR LIFE SUPPORT

ACLS extends BLS capabilities by providing additional measures beyond immediate ventilatory and circulatory assistance. These measures include using accessory equipment to support ventilation and oxygenation, monitoring the electrocardiogram (ECG), establishing an intravenous (IV) route for drug administration, and applying selected pharmacologic agents and electrical therapies (Figure 37-15). The AHA claims that "the

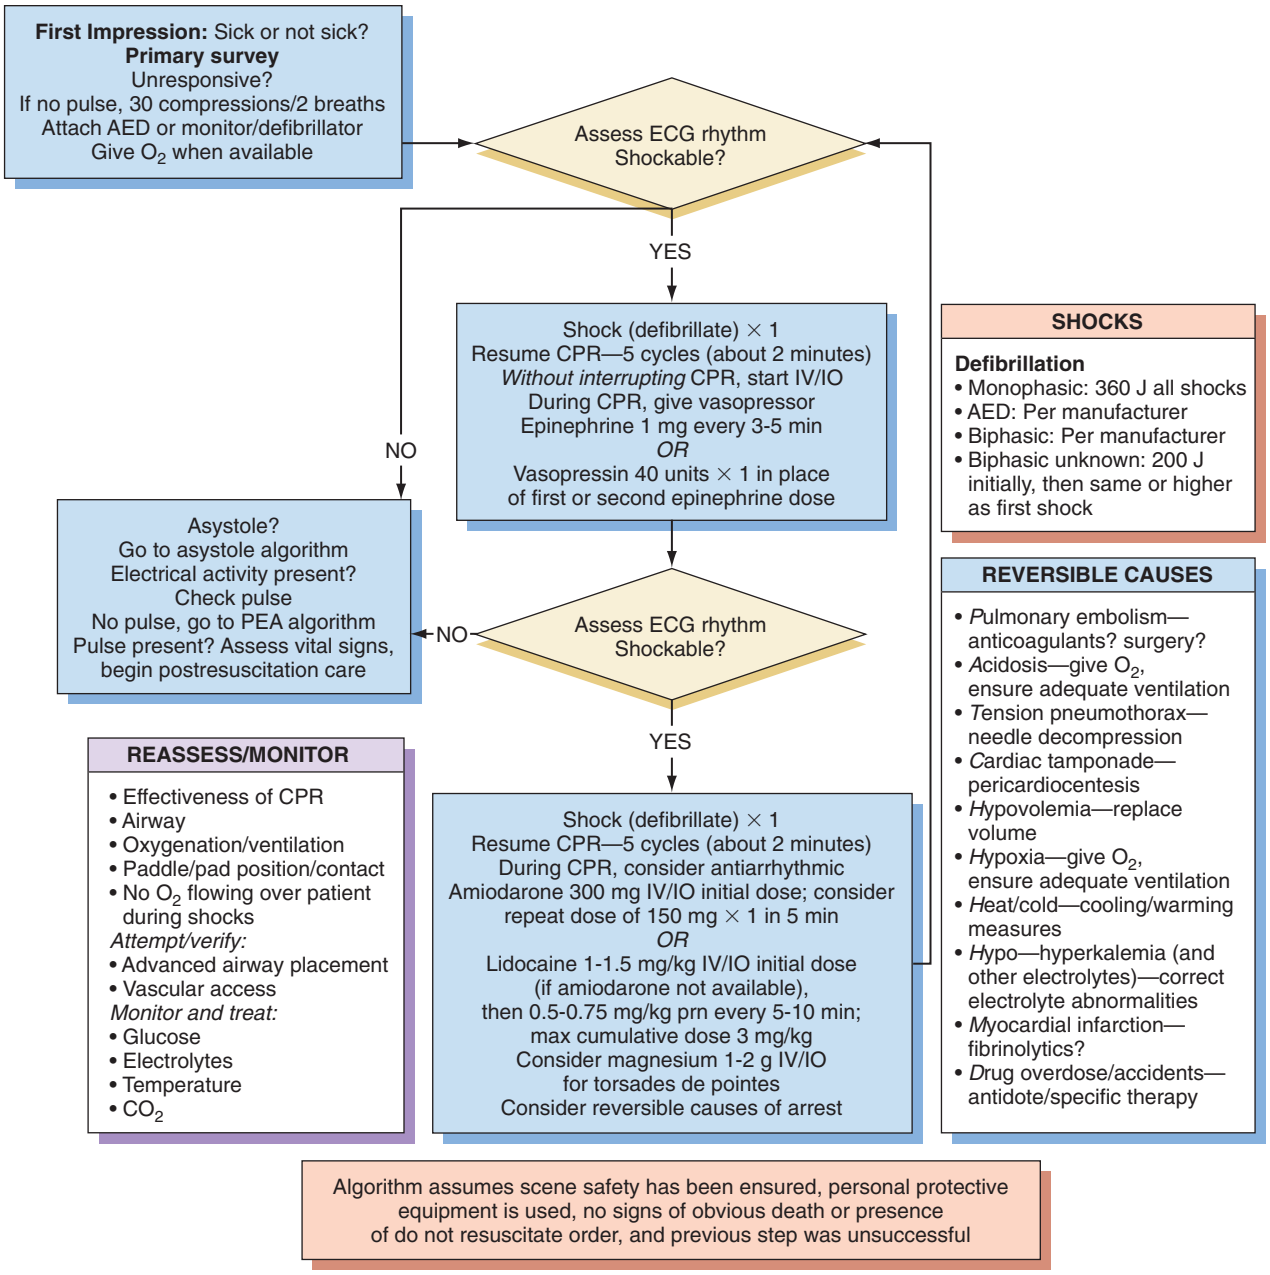

FIGURE 37-15 Pulseless VT/VF algorithm. (From Aehlert B: ACLS study guide, ed 4, St. Louis, 2012, Mosby.)

foundation of ACLS is good BLS care, beginning with prompt high-quality bystander CPR and, for pulseless ventricular rhythms, attempted defibrillation within minutes of collapse."[25]

During ACLS in the hospital, the RT assumes primary responsibility for supporting oxygenation, establishing and maintaining the airway, and providing ventilation. RTs must demonstrate high levels of proficiency in these advanced life-support skills and other ACLS skills that may be assigned by the resuscitation team leader.

Support for Oxygenation

Although expired air ventilation provides an acceptable level of oxygenation, low cardiac output, pulmonary shunting, and abnormalities during CPR lead to hypoxia. Hypoxia results in anaerobic metabolism and metabolic acidosis. Metabolic acidosis impedes the action of certain drugs and can diminish the effectiveness of electrical therapies. For these reasons, the highest possible concentration of O_2 should be administered as soon as possible to adults and children. Concerns about O_2 toxicity are not valid during this period of resuscitation. Less than 100% O_2 may be used during neonatal resuscitation at birth.

During ACLS, supplemental O_2 is normally given through accessory devices designed to support ventilation. The ability of these devices to provide high fractional inspired O_2 (F_IO_2) is a key factor in judging their performance.

Airway Management

Accessory equipment designed to provide airway management during ACLS includes a variety of masks and artificial airways.

Pharyngeal Airways

Pharyngeal airways can help restore airway patency and maintain adequate ventilation, in particular, when using a bag-mask device. A properly placed pharyngeal airway also may help provide access for suctioning. Pharyngeal airways should be used only after BLS methods have successfully opened and cleared the airway.

Pharyngeal airways restore airway patency by separating the tongue from the posterior pharyngeal wall. Two types of pharyngeal airways are used in clinical practice: the oropharyngeal airway and the nasopharyngeal airway.

Oropharyngeal airways come in many different sizes to fit adults, children, and infants. Figure 37-16 shows the two most common oropharyngeal airway designs: the Guedel airway (Flexicare, Irvine, CA; see Figure 37-16, *A*) and the Berman airway (Medline, Mundelein, IL; see Figure 37-16, *B*). Both types have an external flange, a curved body that conforms to the shape of the oral cavity, and one or more channels. The Guedel airway has a single center channel, whereas the Berman airway uses two parallel side channels.

To choose the correct size airway, the clinician should place the devices on the side of the patient's face with the flange even with the patient's mouth. The correct size airway measures from the corner of the patient's mouth to the angle of the jaw following the natural curve of the airway.

Because insertion of an oropharyngeal airway can provoke a gag reflex, vomiting, or laryngeal spasm, these devices generally are contraindicated for conscious or semiconscious patients. They also are contraindicated when there is trauma to the oral cavity or the mandibular or maxillary areas of the skull. These airways should never be placed when either a space-occupying lesion or a foreign body obstructs the oral cavity or pharynx.

Two techniques may be used to insert an oropharyngeal airway. In the first method, the tongue is displaced away from the roof of the mouth with a tongue depressor. The curved portion of the airway is slipped over the tongue, following the curve of the oral cavity.

In the second approach, the jaw-lift technique is used to help displace the tongue. The oropharyngeal airway is rotated 180 degrees before insertion. In this manner, the airway itself helps separate the tongue from the posterior wall of the pharynx. As the tip of the airway reaches the hard palate, it is rotated 180 degrees, aligning it in the pharynx.

In either approach, incorrect placement can displace the tongue, pushing it farther back into the pharynx and worsening the obstruction. Oropharyngeal airways must be inserted carefully and by trained personnel only. As shown in Figure 37-16, *C*, when properly inserted, the tip of an oropharyngeal airway lies at the base of the tongue above the epiglottis, with the flange portion extending outside the teeth. Only in this position can the device properly maintain airway patency.

Nasopharyngeal Airways

Nasopharyngeal airways are inserted through the nose instead of the mouth. A properly inserted nasopharyngeal airway provides a passageway from the external nares to the base of the tongue. As with the oropharyngeal airway, the nasopharyngeal airway helps restore airway patency by separating the tongue from the posterior pharyngeal wall.

The nasopharyngeal airway generally is indicated when placement of an oropharyngeal airway is impossible. The nasopharyngeal airway also is used when the jaws of a victim cannot be separated, as may occur with seizures. A nasopharyngeal airway should not be used when there is trauma to the nasal region or when space-occupying lesions or foreign objects block

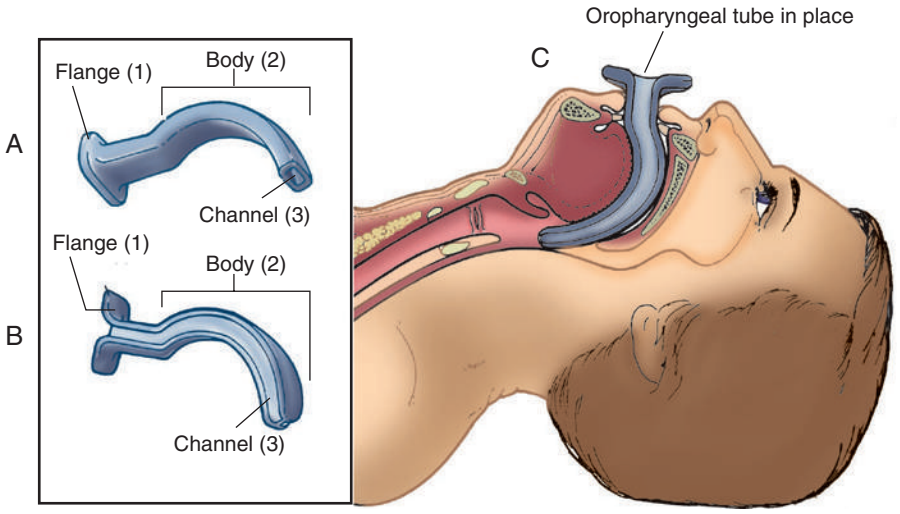

FIGURE 37-16 Oropharyngeal airways. **A,** Guedel airway. **B,** Berman airway. **C,** Airway in place.

the nasal passages. Because the nasal passageway in children and infants is small, the use of nasal airways is generally limited to adults.

Most nasal airways are made from either rubber or plastic polymers and sized by external diameter according to the French scale, with 26F to 32F being the usual range for adults. Anatomically, the length of the airway is more critical than the diameter. The appropriate length can be estimated by measuring the distance from the patient's earlobe to the tip of the nose.

To insert a nasopharyngeal airway, the victim's head is tilted slightly backward. The airway is lubricated with a water-soluble agent to ease insertion, and it is positioned perpendicular to the frontal plane of the victim's face. The airway is advanced slowly through the inferior meatus of either the right or the left nasal cavity, with the bevel edge facing the septum. If an obstruction is felt during insertion, gentle twisting may facilitate placement. If the resistance continues, the most likely cause is a deviated nasal septum. In this case, attempt to insert the airway through the other naris or try a smaller diameter tube.

After the airway is inserted, try to visualize and confirm its correct position quickly, using a tongue depressor if necessary. When properly positioned, a nasopharyngeal airway is usually stabilized by its own flange.

Masks

A mask that fits the patient is a useful tool for the application of artificial ventilation by appropriately trained rescuers. An ideal mask should be made of transparent material, be capable of sealing tightly against the face, provide an inlet for supplemental O_2, and have a standard 22-mm port for connection to a bag-mask device. The mask should be available in various sizes to accommodate adults, children, and infants. Infant masks often have a 15-mm male connector instead of a 22-mm port. The use of masks to support ventilation presumes that the airway can be maintained by conventional BLS techniques. Which mask should be used in a given situation depends on careful assessment of the status of the victim and an in-depth knowledge of the capabilities and limitations of the equipment at hand.

Endotracheal Intubation

An advanced airway allows the rescuer to achieve one or more of the following goals:

1. Deliver ventilations that are not synchronous with chest compressions
2. Restore airway patency
3. Maintain adequate ventilation
4. Isolate and protect the airway from aspiration
5. Provide access for clearance of secretions

Endotracheal intubation is the preferred method for securing the airway during CPR. When positioned properly, an endotracheal tube can maintain a patent airway, prevent aspiration of stomach contents, permit suctioning of the trachea and main stem bronchi, facilitate ventilation and oxygenation, and provide a route for drug administration.

Attempts to intubate the trachea must never interfere with providing adequate ventilation and oxygenation by other means. Only highly trained personnel should perform endotracheal intubation, and each attempt ideally should not exceed 10 seconds because chest compressions will not be possible during the procedure. Continuous waveform capnography is recommended by the AHA Guidelines in addition to physical assessment as the initial method for confirming and monitoring correct placement of an endotracheal tube.[25] When capnometry is not available, auscultation and direct visualization should be used to confirm tracheal position of the endotracheal tube. Adequate ventilation and oxygenation must be provided between attempts. Figure 37-17 shows a cuffed orotracheal tube properly positioned in the trachea. It is being used with a manual bag-mask device to provide ventilation and oxygenation. Adequate ventilation and oxygenation can be provided with 10 to 12 breaths/min.

RTs should be trained in endotracheal intubation techniques, as applied in both emergency life support and mechanical ventilation situations. Details about the necessary equipment,

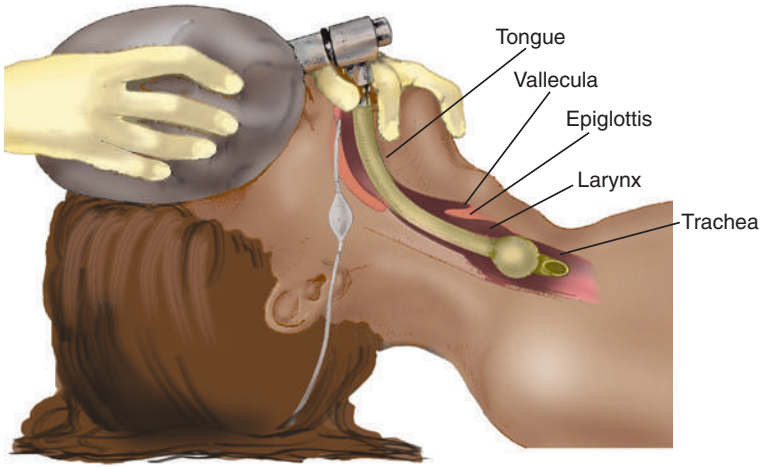

FIGURE 37-17 Orotracheal tube in place, being used with a bag-valve resuscitator.

FIGURE 37-18 T-tube resuscitator used to ventilate newly born neonates. (Courtesy Mercury Medical, Clearwater, FL.)

procedures, and short-term and long-term complications of endotracheal intubation are provided in Chapter 36.

Ventilation

Accessory equipment used to support ventilation in advanced life support includes manual and O_2-powered resuscitators. Manual resuscitators, also called *bag-mask devices,* are available for adults, children, and infants. Conversely, O_2-powered resuscitators are strictly limited to adult application and are not discussed in this chapter. T-tube devices have been used successfully to ventilate and oxygenate neonates at birth (Figure 37-18).

Bag-Mask Devices

One-way valves on bag-mask devices should be simple, dependable, and jam-free. All health care professionals responding to a cardiac arrest call should be familiar and skilled in the use of such a device for support of ventilation and oxygenation. Application of the bag-mask device is best performed with the practitioner positioned at the head of the victim, using the head-tilt maneuver to maintain the airway (Figure 37-19). The rescuer delivers V_T adequate to produce visible chest rise (6 to 7 mL/kg predicted body weight or 400 to 500 mL) over 1 second. Using this smaller V_T decreases airway pressure and minimizes risk for gastric inflation.

It is important to deliver the 2 breaths during CPR over only 3 seconds so that the optimal number of chest compressions per minute can be delivered (75 compressions/min, rate of delivery 100 to 120 compressions/min). The ratio of 30 compressions to 2 ventilations allows for only 5 breaths to be delivered per minute. All 5 breaths should be delivered with no more than visible chest rise.[17] After an advanced airway replaces the face mask, the ventilatory rate should be 8 to 10 breaths/min during CPR. Slower rates of 6 to 8 breaths/min might be needed for patients with chronic obstructive pulmonary disease (COPD) to prevent air trapping and the development of auto–positive end expiratory pressure (PEEP). Ventilatory rates greater than 12 breaths/min are not recommended during CPR because they lead to increased intrathoracic pressure, impeding venous return to the heart during chest compressions,[26] and hyperventilation.

FIGURE 37-19 Ventilation using a bag-mask device and head-tilt/chin-lift method to open the airway. (From Henry MC, Stapleton ER: EMT prehospital care, revised ed 4, St. Louis, 2009, Mosby.)

The rescuer delivers each breath over 1 second and should not attempt to synchronize ventilations with the chest compressions. Nonsynchronized delivery of ventilation and compressions allows the number of chest compressions delivered per minute to increase from 75 to 100 (33% increase) and breaths delivered per minute increase from 5 to 10 (100% increase). After restoration of a perfusing rhythm, the ventilation rate should be 10 to 12 breaths/min delivered over 1 second.

RULE OF THUMB

Rescuers should not hyperventilate victims of cardiac arrest. Once an advanced airway is placed, ventilations should be delivered over 1 second at a rate of 8 to 10 breaths/min (every 6 to 8 seconds). Do not attempt to synchronize ventilations with chest compressions. Ventilation for patients with a perfusing rhythm should be at a rate of 10 to 12 breaths/min (1 breath every 5 to 6 seconds). Patients with COPD may need ventilation rates of 6 to 8 breaths/min to prevent auto-PEEP.

Bag-mask devices combine a mask with a self-inflating bag and a nonrebreathing valve mechanism. These devices may be used to ventilate patients by applying the mask over the patient's mouth and nose or by attaching the self-inflating bag directly to an endotracheal tube or other advanced airways. All devices are capable of providing ventilation with air or with supplemental O_2. Bag-mask devices can provide 100% O_2 when properly applied. Although initially designed as adjuncts for emergency life support, they are used extensively in other respiratory care settings, particularly in the areas of airway management and continuous mechanical ventilation.

Design

Figure 37-20 is a schematic of a typical bag-mask device, showing gas movement and valve action during both the inhalation-compression and exhalation-relaxation phases. The key components shown in this schematic are the nonrebreathing valve *(left)*, the bag itself, the O_2 inlet and bag inlet valve *(to the right of the bag)*, and the O_2 reservoir tube *(far right)*.

During exhalation (see Figure 37-20, *A*), gas flows out from the patient's lungs through the nonrebreathing valve into the atmosphere. At the same time (while the bag expands), the intake valve opens and 100% O_2 flows into the bag from both the reservoir and the O_2 inlet.

During the inhalation phase (see Figure 37-20, *B*), the bag is compressed manually, causing bag pressure to increase. This increase in bag pressure simultaneously closes the inlet valve and opens the nonrebreathing valve, forcing gas into the patient. While the bag inlet valve is closed, O_2 coming in through the O_2 inlet goes into the reservoir tube, where it is stored for the next breath.

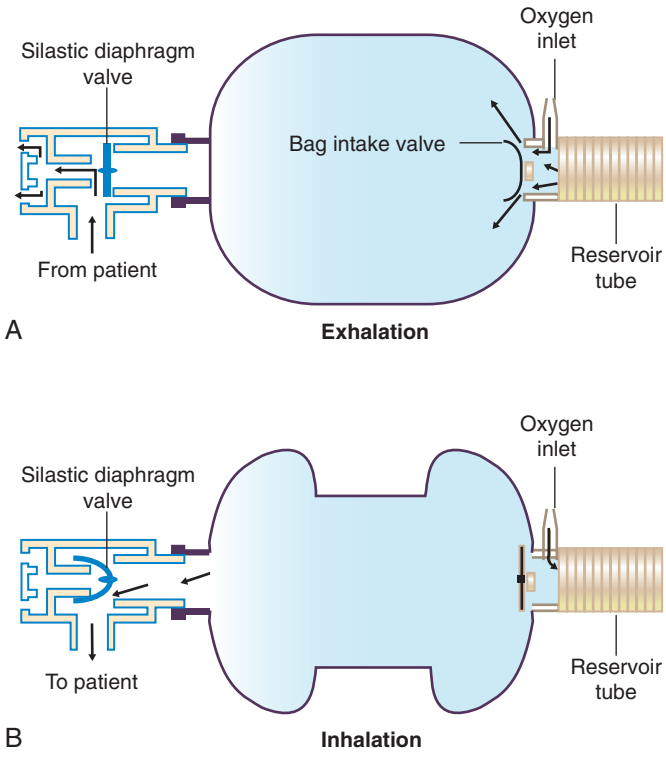

FIGURE 37-20 Components of bag-mask device.

Use

To use a bag-mask device, the health care provider is positioned at the head of the patient's bed. Ideally, an oral airway is inserted, and the head-tilt method is used to keep the airway open (assuming there are no neck injuries). While using one hand to keep the patient's head extended and the mask tightly sealed to the patient's face, the health care provider uses the other hand to compress the bag (see Figure 37-19).

In addition to providing adequate ventilation, bag-mask devices can provide high FiO_2. Theoretically, all such devices on the market can deliver 100% O_2; however, the actual FiO_2 provided at the bedside depends on several factors, including O_2 input flow, reservoir volume, delivered volume and rate, and bag refill time. As a guideline to achieve the highest possible FiO_2 with a bag-mask device, the following always should be done:

1. Use an O_2 reservoir of adequate size.
2. Set the O_2 input flow at 10 to 15 L/min.
3. Deliver appropriate V_T for a 1-second period (when using a mask).
4. Ensure the longest possible bag refill time.

Hazards and Troubleshooting

Bag-mask devices are simple and safe advanced life-support devices. However, several major hazards are associated with their use. The first and most common problem is unrecognized equipment failure. Knowledge of how such devices operate can help clinicians understand the operational testing of and troubleshooting for these devices. Gastric inflation is another common hazard encountered when using a bag-valve device with a face mask. Gastric inflation can be minimized by providing low to moderate inspiratory flows (<30 L/min).[23] For an adult, a full 1 second should be used to deliver V_T of 500 mL.

Barotrauma has long been recognized as a potential hazard of bag-mask device use. However, with the full-bag volume of adult-size devices (generally ≤2000 mL), the potential for barotrauma is small if the nonrebreathing valve is working properly and a bronchial intubation has not occurred. The average mask leak with bag-mask devices ranges from 20% to 40% of stroke volume and substantially reduces the risk for barotrauma, especially if no more than visible chest rise is used to determine adequate V_T. Some pediatric bag-mask devices have bag volumes of more than 500 mL, and rescuers may cause barotrauma to small children or infants if they do not adjust stroke volume by squeezing the bag so that only half to one-third of the volume is delivered to the mask.

Hyperventilation during resuscitation of a cardiac arrest victim markedly decreases coronary perfusion pressure and survival rates.[26] Overzealous ventilation with high rates (>12 breaths/min) during resuscitation of cardiac arrest increases intrathoracic pressure, impedes venous return, decreases cardiac output, decreases coronary artery perfusion pressure, increases gastric inflation, and provides more ventilation than is needed.

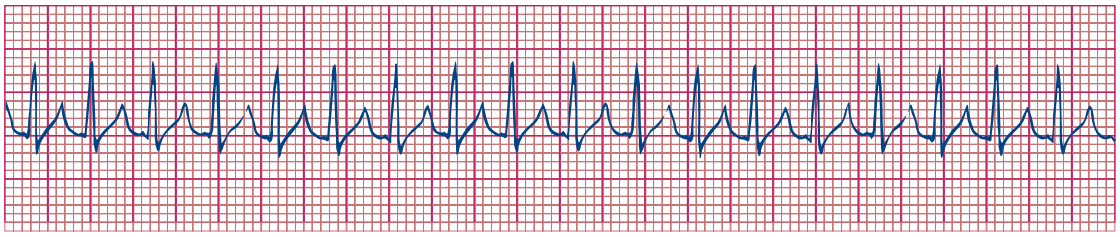

FIGURE 37-21 Supraventricular tachycardia, lead II.

MINI CLINI

Ventilation During Cardiopulmonary Resuscitation

PROBLEM: A student is observing a code blue in progress in the intensive care unit. The patient has had a cardiac arrest, and CPR is being administered. The student notices that the RT is ventilating the patient's lungs with a bag-valve device through an endotracheal tube at a considerably higher rate and minute ventilation than would normally be established on a mechanical ventilator for a patient of this size. Is this increased minute ventilation needed?

SOLUTION: No, it is not. The ventilation rate should be 8 to 10 breaths/min, and V_T should be limited to achieve no more than a visible chest rise to avoid excessive ventilation.[17] Ventilation rates greater than 12 breaths/min and large V_T (>6 to 7mL/kg) increase intrathoracic pressure and impede venous return to the heart during chest compressions.[26] During CPR, hyperventilation reduces cardiac output and decreases coronary and cerebral perfusion. Increases in central venous pressure, as a result of increased intrathoracic pressure, can decrease cerebral blood flow. Increased airway pressures and auto-PEEP generated by hyperventilation should be avoided. The AHA guidelines for CPR and emergency cardiovascular care state that "routine hyperventilation during and after cardiac arrest is detrimental and it is considered a Class III procedure" (i.e., the risk is greater than the benefit).[3,17] Ventilation with V_T of 400 to 500 mL at rates of 1 breath every 6 to 8 seconds is all that is needed to maintain a normocarbic level during CPR.

Restoring Cardiac Function

Perfusion support techniques, such as chest compressions, can restore circulation only temporarily. ACLS must go beyond simple perfusion support to identify, remove, or relieve the underlying cause of cardiac failure; this is done by combining ECG monitoring with pharmacologic and electrical therapies.

Electrocardiogram Monitoring

Because most cases of cardiac arrest are caused by arrhythmias, ECG monitoring should be started as soon as the necessary equipment and personnel arrive. Monitoring may be done with either standard electrocardiographic equipment or the quick-look paddles now available on most defibrillators.

Given their important role in ACLS, RTs must be skilled in recognizing arrhythmias. Although an RT may be able to quickly interpret gross arrhythmias appearing on electrocardiographic monitors at the bedside, these skills develop only after much practice with actual rhythm strips. Chapter 18 presents a review of ECG interpretation. The reader should focus on the following arrhythmias:

- VT
- VF
- Sinus tachycardia
- Sinus bradycardia
- Sinus arrest
- Premature atrial contractions
- SVT—a classification of arrhythmias, including but not limited to sinus tachycardia, atrial flutter, and atrial fibrillation
- Atrioventricular blocks—first degree, second degree types I and II, and third degree
- Premature ventricular contractions
- Pulseless electrical activity (PEA)
- Systole

This section briefly discusses the arrhythmias closely associated with CPR conditions, including SVT, VT, VF, and PEA.

Supraventricular Tachycardia. The term *supraventricular tachycardia* is commonly used to describe any tachycardia not of ventricular origin. This grouping can include sinus tachycardia, atrial tachycardia, junctional tachycardia, atrial flutter, and atrial fibrillation (with rates >100 beats/min). These individual supraventricular arrhythmias are identified by ECG and treated accordingly (Figure 37-21).

A more specific form of SVT involves rapid impulse formation caused by a reentry mechanism that develops in the atria or atrioventricular junction. Normally, a single impulse from the sinoatrial node traverses the atria and continues down into the ventricles, causing depolarization and contraction. In reentry, an ectopic focus disrupts this normal conduction. The impulse not only moves down to the ventricles but also returns to the atria. This pattern repeats in a self-perpetuating, or circular, manner.

Typically, this form of SVT results in heart rates between 160 and 220 beats/min. The rhythm is regular, which distinguishes it from rapid atrial fibrillation. However, because of its rapid rate, P waves may not be seen. If identifiable, the P waves appear abnormal. In addition to the rate and regular rhythm, SVT is characterized by a normal QRS complex. At very high

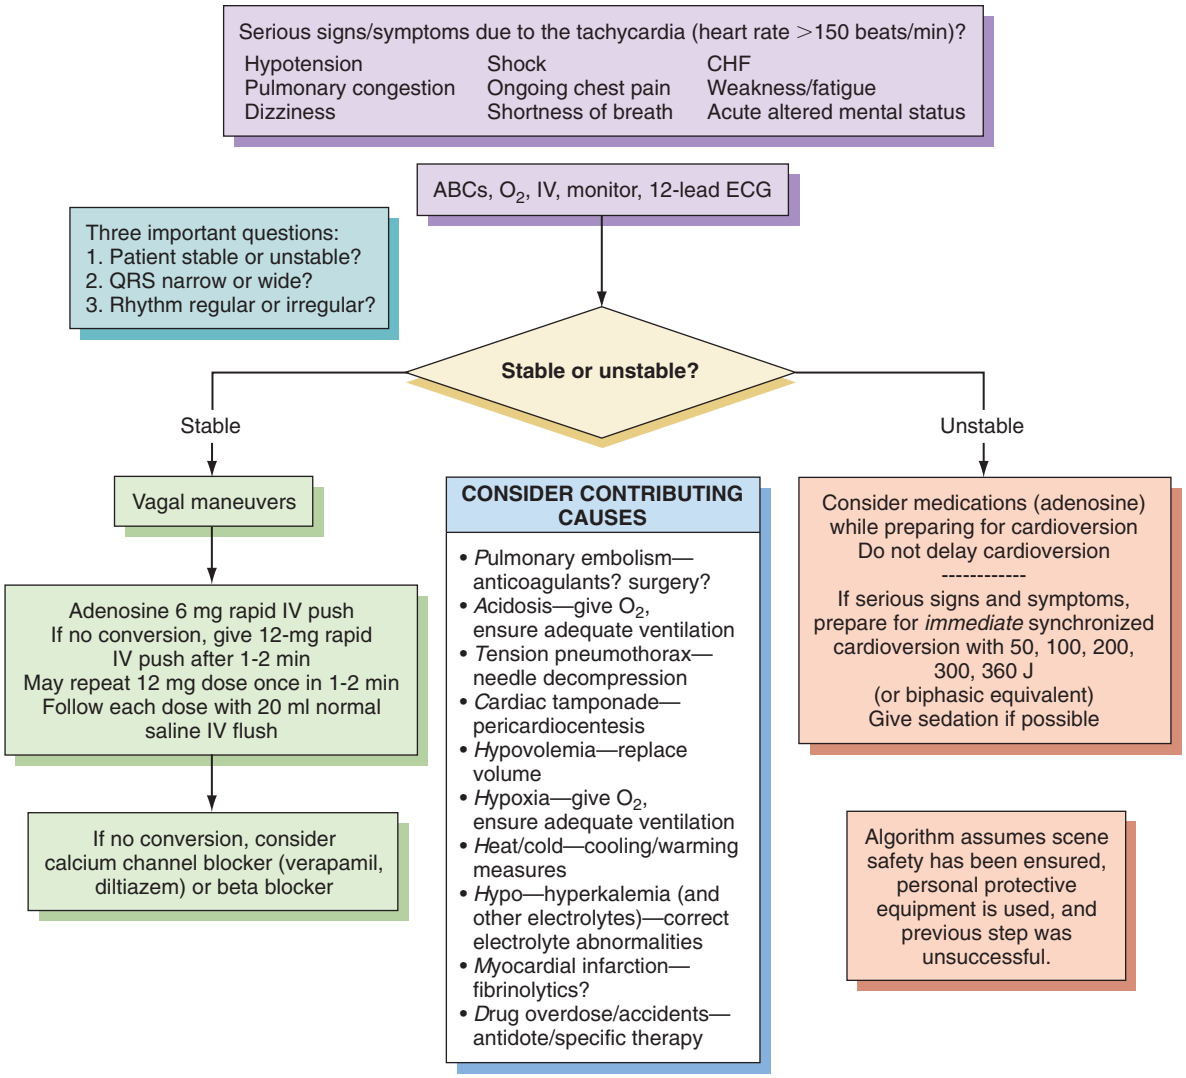

FIGURE 37-22 Narrow-complex QRS tachycardia. (From Aehlert B: ACLS study guide, ed 4, St. Louis, 2012, Mosby.)

rates, the ventricles may not have enough time to fill completely. Incomplete ventricular filling can result in decreased cardiac output, congestive heart failure, and tissue hypoxia. SVT may deteriorate to VT if it is not recognized and treated in a timely manner.

The treatment of SVT varies according to the clinical situation (Figure 37-22). If a patient with SVT is ill or unstable, the treatment of choice is immediate synchronized electrical cardioversion, as described elsewhere in this chapter. If the patient is stable, other interventions are tried before cardioversion is considered. The most common nonelectrical treatment for SVT is vagal stimulation by carotid artery massage or Valsalva maneuver. If these attempts are ineffective and the patient remains stable, drugs such as adenosine, diltiazem, verapamil, or beta blockers (as a second-line agent) may halt SVT. These drugs work primarily on the nodal tissue by slowing ventricular response to atrial arrhythmias, or they block the reentry SVT that travels through the atrioventricular node.[25]

Ventricular Tachycardia. VT occurs when one or more irritable foci within the ventricle discharge at rapid rates, creating the appearance of a prolonged chain of premature ventricular contractions. Rates typically range from 140 to 220 beats/min and usually are regular (Figure 37-23). Although VT may come and go in brief episodes, or *paroxysms,* it is always a sign of a serious underlying pathologic condition and should be treated immediately. In stable patients, VT is managed with amiodarone, procainamide, and/or sotalol.[25] Procainamide and sotalol should be avoided in patients with prolonged QT.[25] For patients with sustained VT who exhibit hypotension, ischemic chest pain, shortness of breath, decreased consciousness, or signs of pulmonary edema, immediate **synchronized cardioversion** is indicated (Figure 37-24). Patients with sustained VT in full cardiac arrest are treated similarly to patients with VF.

Ventricular Fibrillation. VF is a rapid, sustained, and uncontrolled depolarization of the ventricles. During VF, the ECG is characterized by irregular, widened, and poorly defined

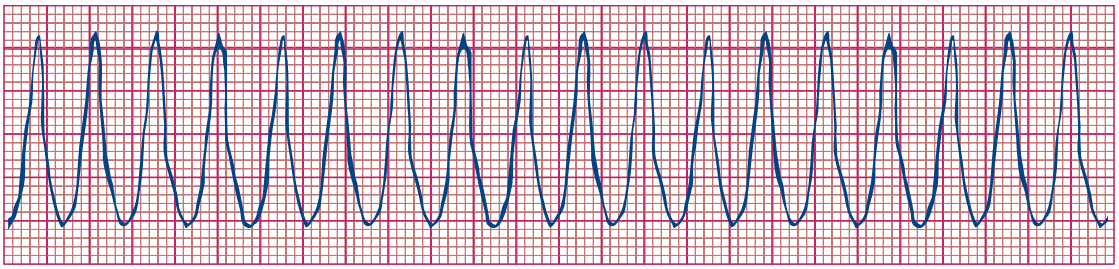

FIGURE 37-23 Ventricular tachycardia, lead II.

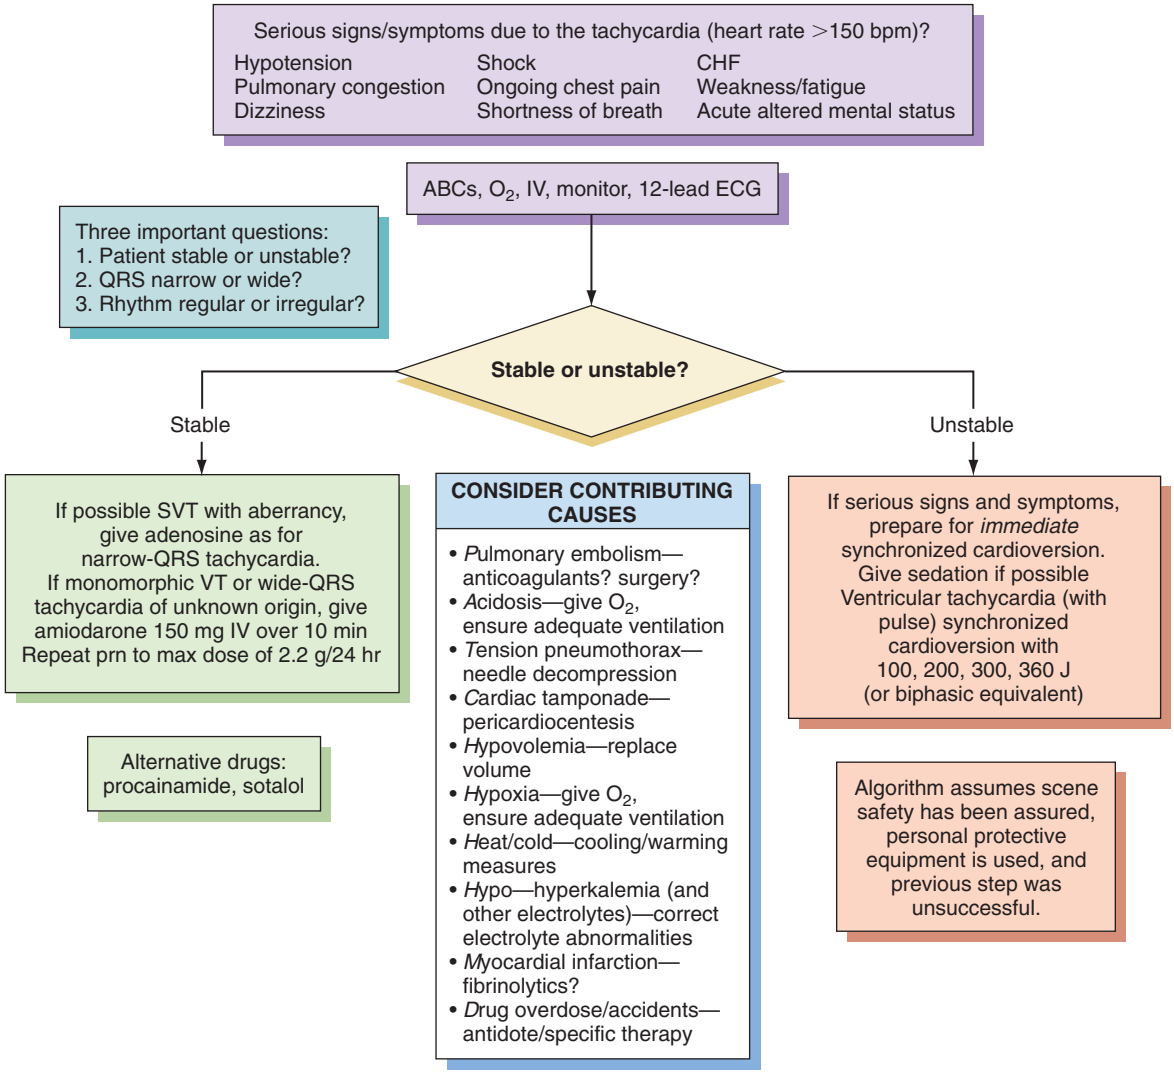

FIGURE 37-24 Wide-complex QRS tachycardia. (From Aehlert B: ACLS study guide, ed 4, St. Louis, 2012, Mosby.)

QRS complexes, known as *coarse* VF (Figure 37-25, *A*). These complexes widen farther and lose amplitude, resembling a coarse asystole, which now is defined as *fine* VF (see Figure 37-25, *B*). Rather than exhibiting coordinated contractions, the ventricles quiver in a totally disorganized manner. Cardiac output during VF is zero. The rapid decrease in cardiac output produces acute cerebral hypoxia, often manifested by seizures. VF is uniformly fatal if not corrected immediately.

Many conditions cause VF. The most common causes include hypoxia, hypovolemia, acidosis, hypokalemia and hyperkalemia, hypothermia, toxins, cardiac tamponade, tension pneumothorax, pulmonary thrombosis, and coronary thrombosis.[25] Regardless of the cause, VF constitutes a true emergency. Patient survival depends on immediate provision of ACLS, especially electrical defibrillation. Early defibrillation is the major determinant of survival in cardiac arrest caused by VF.

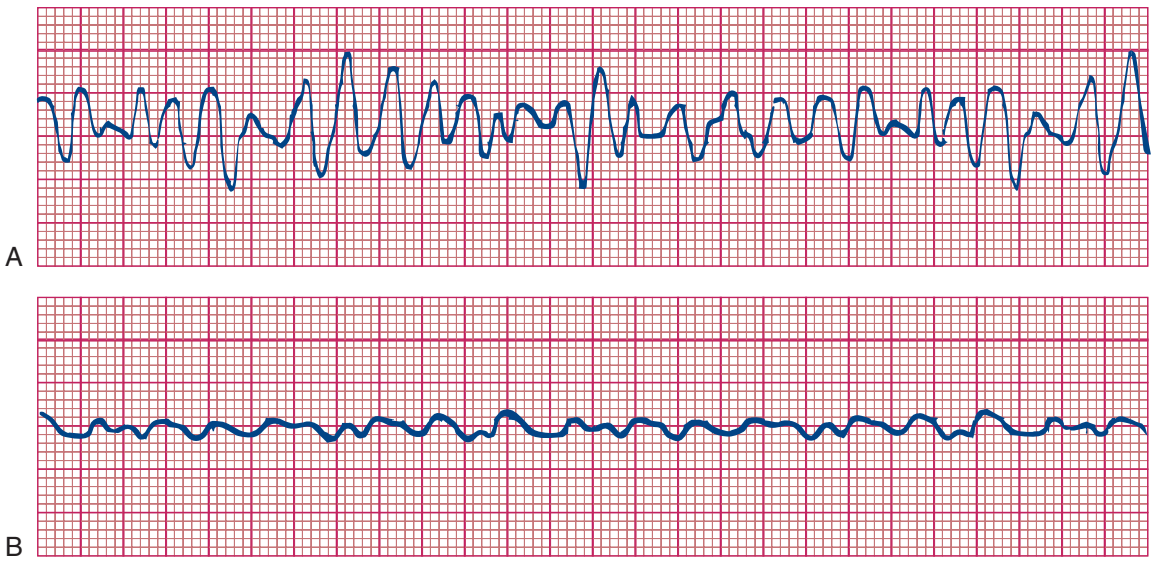

FIGURE 37-25 Ventricular fibrillation (VF). **A,** Coarse VF. **B,** Fine VF, lead II.

Pulseless Electrical Activity. PEA that is not shockable can result from several reversible causes (Figure 37-26). The immediate primary treatment is uninterrupted CPR for approximately 2 minutes with vasopressor given simultaneously. The best secondary approach is to identify and treat reversible causes (e.g., for hypovolemia, replace volume; for tension pneumothorax, needle decompression). In asystole or slow PEA, vasopressin administration should be considered (see Figure 37-26).[25]

Pharmacologic Intervention

Although the full range of drug use in ACLS is beyond the scope of this chapter, RTs must have a general knowledge of both the various drug categories and the specific agents used in emergency situations.[27] Table 37-2 summarizes the major drug categories and primary agents currently used in ACLS.

Routes of Administration. Unless a central vein is already cannulated, the ideal route for drug administration in emergency situations is a peripheral IV line. IV drugs should be given by rapid bolus injection, followed by a 20-mL bolus of IV fluid and elevation of the extremity.

Selected drugs, such as epinephrine, vasopressin, lidocaine, and atropine, also may be given through intraosseous access when IV access is not readily available.[28]

The intraosseous route always is an option, especially in small children or infants.[29] Chapter 35 provides information about pharmacologic agents often used in ACLS.

Electrical Therapy

The following three general types of electrical therapy are used in emergency cardiac care: (1) unsynchronized countershock, or defibrillation; (2) synchronized countershock, or cardioversion; and (3) electrical pacing.

Unsynchronized Countershock (Defibrillation). When an electrical shock of appropriate strength is applied to the myocardium, all myocardial fibers simultaneously depolarize. Theoretically, when all cells depolarize, the cells that spontaneously fire at the fastest rate should be able to regain control and pace the heart. Normally, the sinus node spontaneously depolarizes most rapidly. After electrical shock, the sinus node should discharge first and capture all parts of the myocardium as the depolarization wave travels through the still, silent heart.

MINI CLINI

Route of Drug Administration During Advanced Cardiovascular Life Support

PROBLEM: An RT working in a small, rural hospital is called to the emergency department, where a patient is in cardiac arrest. The RT is able to intubate and ventilate the patient, using a bag-valve device with 100% O_2.

Nurses are performing cardiac compressions and attempting unsuccessfully to start a peripheral IV line. The ECG monitor reveals a fine VF pattern. Electrical defibrillation is unsuccessful on the first attempt, and five cycles of 30 compressions to 2 ventilations are in progress. Immediate administration of epinephrine without interrupting CPR is indicated before or after the next shock. Attempts to secure an IV line continue to be unsuccessful. What action is appropriate at this time?

SOLUTION: Because of its strong inotropic and alpha-adrenergic effects, epinephrine should be the first drug during resuscitation of cardiac arrest and it should be administered as soon as possible. Drugs given via a peripheral vein require 1 to 2 minutes to reach the central circulation. Epinephrine can convert fine VF to coarse VF and improves the chance for successful electrical defibrillation. In this case, because IV routes are unavailable, epinephrine should be administered using the intraosseous route, which can be quickly established with minimal complications by providers with varied levels of training.[25,28,29]

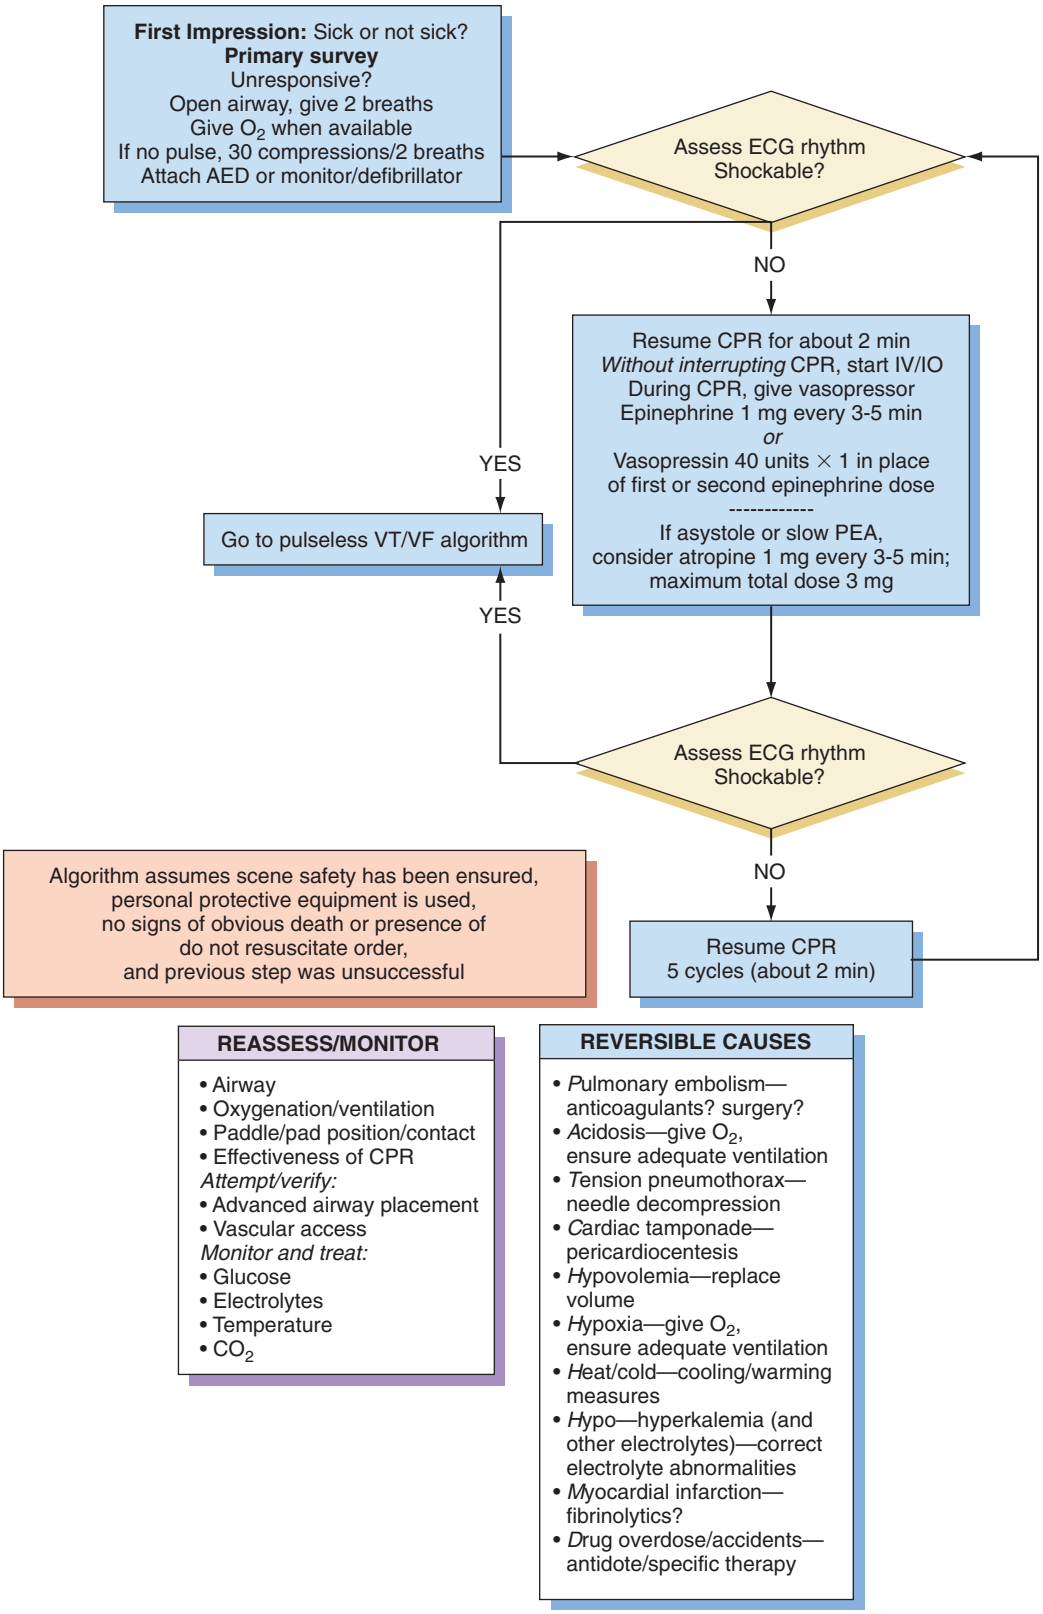

FIGURE 37-26 Asystole or pulseless electrical activity algorithm. (From Aehlert B: ACLS study guide, ed 4, St. Louis, 2012, Mosby.)

TABLE 37-2

Drugs Used in Advanced Cardiovascular Life Support

Drug	Indications	Contraindications	Route	Dosage[26]	Pharmacologic Effects
Adenosine	PSVT	Use with caution if patient has asthma; may precipitate atrial fibrillation; poison-induced or drug-induced tachycardia; second-degree or third-degree heart block	IV bolus	6 mg IV for 1-2 sec followed by 20-mL saline bolus; repeat twice with 12 mg in 1-2 min if needed	Decrease in AV node conduction
Amiodarone	Stable regular narrow-complex tachycardia to control rapid ventricular rate secondary to accessory pathway conduction in preexcited atrial arrhythmias	Prolonged QT interval	IV; IO	150 mg IV over 10 min; may repeat every 10 min to maximum of 2.2 g in 24 hr	Multichannel blocker (calcium, potassium); inhibited alpha- and beta-adrenergic responses
Atropine sulfate	Acute symptomatic bradycardia	Sinus, atrial, and ventricular tachycardia; hypothermic bradycardia; infranodal (type II) AV block; new third-degree with wide QRS complexes	IV bolus; IO	0.5-1 mg IV repeated every 3-5 min to total dose of 3 mg	Increased heart rate; increased force of atrial contractions
Dopamine	Hypotension with signs and symptoms of shock; second-line drug for symptomatic bradycardia	Use with caution in cardiogenic shock with accompanying CHF	IV infusion	2-20 mcg/kg/min	Increased renal and splenic flow at low doses (1-5 mcg/kg/min); beta-adrenergic effects at moderate doses (5-10 mcg/kg/min); alpha-adrenergic effects at high doses (>10 mcg/kg/min)
Epinephrine	Cardiac arrest; VF; pulseless tachycardia; asystole; PEA; symptomatic bradycardia; severe hypotension; anaphylaxis; severe allergic reaction	VT and frequent PVCs	IV bolus; IO; endotracheal* use only if IV or IO cannot be established; IV infusion	1 mg every 3-5 min in cardiac arrest, up to 0.2 mg/kg; 2-10 mcg/min infusion, titrate to patient response	Increased heart rate; increased force of contractions; vasoconstriction; increased coronary perfusion pressure; increased myocardial irritability; increased myocardial O_2 consumption
Isoproterenol	Alternative when a bradyarrhythmia is unresponsive to or inappropriate for treatment with atropine, or as a temporizing measure while awaiting the availability of a pacemaker. Refractory torsades de pointes unresponsive to magnesium sulfate	Cardiac arrest; VT; frequent PVCs	IV infusion	2-10 mcg/min, titrate to adequate heart rate	Increased heart rate; increased force of contractions; vasodilation

Continued

TABLE 37-2

Drugs Used in Advanced Cardiovascular Life Support—cont'd

Drug	Indications	Contraindications	Route	Dosage[26]	Pharmacologic Effects
Lidocaine	Second-line antiarrythmic therapy for monomorphic VT. Alternative to procainamide, sotalol, and amiodarone in cardiac arrest from VF/VT	Signs of lidocaine toxicity; prophylactic use in acute MI	IV bolus; IV infusion; IO; endotracheal†	1-1.5 mg/kg bolus every 5-10 min up to 3 mg/kg	Increased electrical stimulation threshold; depressed ventricular electrical activity
Magnesium sulfate	Cardiac arrest only if torsades de pointes or hypomagnesemia is present; life-threatening arrhythmias caused by digitalis toxicity	Routine administration in hospitalized patients with acute MI; use with caution in renal failure	IV infusion; IO infusion	Cardiac arrest: 1-2 g (2-4 mL of 50% solution) diluted in 10 mL of 5% dextrose in water over 20 min	Hypomagnesemia hinders replenishment of intracellular potassium
Procainamide	Stable monomorphic VT with normal QT interval and preserved left ventricular function; treatment of PSVT uncontrolled by adenosine and vagal maneuvers if blood pressure is stable; stable wide-complex tachycardia of unknown origin; AF with Wolff-Parkinson-White syndrome	Heart block, asystole, PEA, proarrhythmic especially in setting of acute MI, hypokalemia, or hypomagnesemia; avoid with in patients with CHF and prolonged QT interval	IV bolus; IV infusion	20 mg/min, 50 mg/min in urgent situations up to maximum dose of 17 mg/kg;	Sodium and potassium channel blocker
Propranolol	Suspected MI and unstable angina; SVTs	Bronchospastic disease; severe bradycardia; hypotension; second-degree or third-degree heart block; cocaine-induced acute coronary syndrome	IV	Total dose: 0.1 mg/kg by slow IV push, divided into 3 equal doses at 2- to 3-min intervals. Do not exceed 1 mg/min, repeat in 2 min to a total dose of 0.1 mg/kg if required	Reduce heart rate; decreased stroke volume; decreased myocardial O_2 consumption; increased LVEDP
Vasopressin	Alternative pressor to epinephrine in treatment of adult shock-refractory VF; alternative to epinephrine in asystole and PEA, hemodynamic support in vasodilatory shock	Responsive patients with coronary artery disease	IV bolus; IO bolus; if IV or IO access cannot be established, vasopressin or epinephrine may be administered via endotracheal tube	40-unit push may replace either first or second dose of epinephrine	Potent peripheral vasoconstrictor

TABLE 37-2

Drugs Used in Advanced Cardiovascular Life Support—cont'd

Drug	Indications	Contraindications	Route	Dosage[26]	Pharmacologic Effects
Verapamil, diltiazem	Alternative drug (after adenosine or vagal maneuvers) to terminate PSVT with narrow QRS complex, adequate blood pressure, and preserved left ventricular function; control ventricular rate in patients with atrial fibrillation or atrial flutter	Wide-complex QRS tachycardias of uncertain origin, Wolff-Parkinson-White syndrome and AF, sick sinus syndrome, second-degree or third-degree block without pacemaker, concurrent IV administration with IV beta blockers	IV bolus	*First dose:* Verapamil: 2.5- to 5-mg IV bolus over 2 min (over 3 min in older patients) *Second dose:* 5-10 mg, if needed, every 15-30 min; maximum dose 20 mg *Alternative:* 5-mg bolus every 15 to 30 min to a total dose of 20 to 30 g *Diltiazem:* initial dose 15 to 20 mg (0.25 mg/kg) IV over 2 min; an additional 20 to 25 mg (0.35 mg/kg) IV in 15 min if needed; 5-15 mg/hr IV titrated maintenance infusion titrated AF heart rate (if given for rate control)	Decreased sinoatrial node automaticity; slowed AV node conduction

AF, Atrial fibrillation; *AV,* atrioventricular; *CHF,* congestive heart failure; *IO,* intraosseous; *LVEDP,* left ventricular end-diastolic pressure; *MI,* myocardial infarction; *PSVT,* paroxysmal supraventricular tachycardia; *PEA,* pulseless electrical activity; *PVC,* premature ventricular contraction; *SVT,* supraventricular tachycardia; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia.

*Endotracheal tube dosage is usually double IV dosage.

†Dose of lidocaine via an endotracheal tube is 2.0 to 2.5 times the normal IV dose diluted in 10 mL of normal saline or sterile water to be used only when IV and IO access is unavailable.

Defibrillation is an unsynchronized shock used to depolarize the myocardial fibers simultaneously. It is the definitive treatment for both VF and pulseless VT. If one of these arrhythmias is present, and the proper equipment and trained personnel are available, defibrillation of the patient should be performed immediately.

If a biphasic defibrillator is available, the AHA recommends an initial energy level of 120 to 200 J for defibrillation of adults and 2 to 4 J/kg for defibrillation of children and infants.[13] For children older than 1 year, if a shockable rhythm persists after five cycles of CPR, the rescuer should give one shock (4 J/kg) and resume compressions immediately. Use a 360-J shock for monophasic defibrillators for the first and subsequent shocks for adults.[13] If VF recurs, the previously successful energy level should be used for subsequent shocks and compressions should be resumed immediately.

Electrode paddle size and placement are important in ensuring that the full energy of the countershock is applied. For adults, paddles should be 8 to 12 cm in diameter to decrease resistance; adult paddles are adequate size for children older than 1 year. Normally, one paddle is placed below the clavicle and just to the right of the upper portion of the sternum, with the other positioned on the midaxillary line to the left of the left nipple. Alternatively, one paddle may be placed on the left precardium, with the other positioned posteriorly under the patient, behind the heart. Paddles should be prepared with conducting gel and applied with firm pressure (approximately 25 lb).

Synchronized Countershock (Cardioversion). **Cardioversion** is similar to defibrillation, with two major exceptions. First, the countershock is synchronized with the heart's electrical activity (the R wave). Synchronization is necessary because electrical stimulation during the refractory phase (part of the T wave) can cause VF or VT. Second, the energy used during cardioversion usually is less than the energy applied during defibrillation.

Cardioversion is considered when a patient with an organized arrhythmia producing a high ventricular rate exhibits signs or symptoms of cardiac decompensation. These so-called *tachyarrhythmias* include SVT, atrial flutter, atrial fibrillation, and monomorphic VT with pulses. Cardioversion is ineffective for treatment of junctional tachycardia or multifocal atrial tachycardia.[13]

If the arrhythmia is not causing serious signs or symptoms, drug therapy is used first. However, if the patient is hypotensive, exhibits signs of decreased consciousness or pulmonary congestion, or complains of chest pain, cardioversion is indicated.

Electrical Pacing. Another application of electrical therapy uses intermittently timed, low-energy discharges to replace or supplement the natural pacemaker of the heart. There are two primary types of electrical pacing. First, the electrical discharge can be delivered from an external power pack through wires

inserted into the patient's chest wall (transcutaneous, or transthoracic, pacing). Alternatively, wire electrodes may be floated through the large veins and implanted directly inside the heart (transvenous pacing). Because it can be started quickly, transcutaneous pacing is the method used most often in emergency cardiac care.

Pacemaker therapy is used to treat sinus bradycardias that produce serious signs and symptoms and that do not respond to atropine (Figure 37-27). Electrical pacing also is used to manage second-degree type II and third-degree heart block.

Because defibrillation can cause damage to permanent pacemakers, care should be taken not to place the electrode paddles near these devices. After a patient with a permanent pacemaker undergoes either cardioversion or defibrillation, the device should be checked for proper functioning. Pacing is not recommended by the AHA for patients in asystolic cardiac arrest because it is ineffective and may delay or interrupt the delivery of chest compressions.[13]

Monitoring Provider Team Performance During Advanced Cardiac Life Support

1. Five main components of high-performance CPR have been identified by an AHA consensus statement for inside and outside the hospital.[17] Minimize interruptions in chest compressions to less than 20% of the time chest compressions are performed during cardiac arrest.

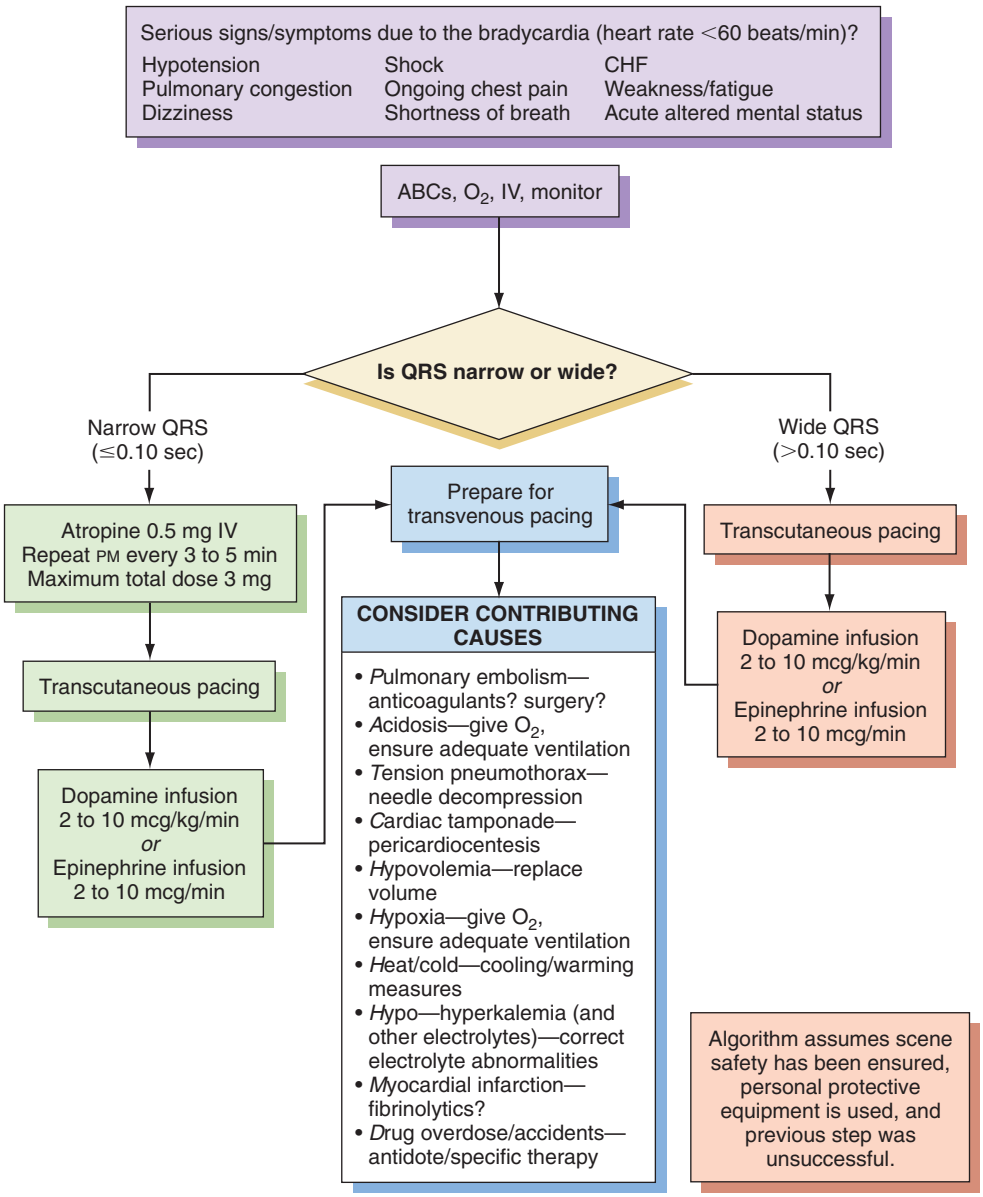

FIGURE 37-27 Symptomatic bradycardia algorithm. (From Aehlert B: ACLS study guide, ed 4, St. Louis, 2012, Mosby.)

2. Maintain a chest compression rate of 100 to 120/min.
3. Chest compression depth should be 50 mm (2 inches) or greater in adults and at least one-third of the anterior to posterior chest diameter in children and infants.
4. Allow the chest to recoil completely during chest compressions (i.e., no residual leaning).
5. Avoid excessive ventilation by keeping the rate to less than 12/min and use a rate of 8 to 10 with an advanced airway.

MINI CLINI

Cardiopulmonary Resuscitation Quality Control

PROBLEM: The RT is part of a code team resuscitating a patient in VF cardiac arrest. The RT notices several quality control issues. Another therapist is providing bag-mask ventilation with breaths that are too large and delivered with a fast inspiratory flow and rate. Another member of the team is administering chest compressions at rate of 80 compressions/min and appears to be tiring. A house-staff member has failed to place an endotracheal tube on the first attempt and is preparing for a second attempt. What steps can the RT take to improve the quality of CPR?

SOLUTION: The RT providing ventilations should be asked to deliver breaths that are large enough only to create visible chest rise and to deliver them over 1 second at a rate of 10 to 12/min. The RT should say silently "one-one thousand" to estimate a 1-second delivery time. The team member doing chest compression should be asked to push "hard and fast" at a rate of 100 to 120 compressions/min at a depth greater than 50 mm and allow complete chest recoil. The hands of the person doing chest compressions should be lifted slightly off the chest on each upstroke to ensure complete chest recoil. Interruptions in chest compressions should be held to less than 20% of CPR time and should not be interrupted by a second attempt to place an advanced airway (endotracheal tube, laryngeal mask airway, double-lumen airway [Combitube]) until five cycles (approximately 2 minutes) of CPR have been completed using a 30:2 compression-to-ventilation ratio. Postponing the second intubation attempt assumes that the victim can be ventilated with a bag-mask device. The team members doing chest compressions should be rotated every 2 minutes to prevent fatigue from affecting performance. One cycle of CPR takes approximately 24 seconds with 30 compressions delivered in 18 seconds and 2 breaths delivered in 6 seconds (1 second for inspiration and 1 second for exhalation × 2, with 2 seconds lost to transitioning between compressions and ventilation). Perfect CPR would result in 75 compressions and five breaths being delivered each minute. Code team members should not stop CPR to check the rhythm or a pulse immediately after shock delivery. After the shock, they should immediately administer five cycles of uninterrupted CPR beginning with chest compressions and should check the rhythm and pulse after about 2 minutes.

The ECG is the most common and one of the most useful types of monitoring used during ACLS. The ECG provides the basis for selecting various drug and electrical therapies during CPR and helps indicate patient response to these interventions. However, an acceptable ECG rhythm does not mean that cardiac output is adequate. Other indices of perfusion, such as pulse, blood pressure, and skin temperature, are needed to confirm adequate cardiac output.

Patient Care After Resuscitation

After cardiac arrest, a patient may exhibit an optimal response, in which case the patient regains consciousness, is responsive, and breathes spontaneously. More often, however, the patient requires support of one or more organ systems. Acidemia associated with cardiac arrest usually improves when normal ventilation and perfusion are restored.

If the patient is conscious and breathing spontaneously after resuscitation, supplemental O_2, maintenance of an IV infusion, and continuous cardiac and hemodynamic monitoring may be all that is necessary. A 12-lead ECG, chest x-ray, arterial blood gas (ABG) analysis, and clinical chemistry profile should be performed as soon as possible. Providers of care after cardiac arrest should do the following: "(1) control body temperature to optimize survival and neurologic recovery; (2) identify and treat acute coronary syndromes; (3) optimize mechanical ventilation to minimize lung injury; (4) reduce the risk for multiorgan injury and support organ function if required; (5) objectively assess prognosis for recovery; and (6) assist survivors with rehabilitation services when required."[30] The patient should be closely supervised in an intensive care or coronary care unit, especially during the first 24 hours after a cardiac arrest.

Only in this setting can underlying organ system insufficiency or failure be properly identified and managed. The organs most likely to exhibit failure after resuscitation are the lung, heart, and vasculature, and kidneys. Central nervous system failure is an ominous sign and generally indicates a failed resuscitation attempt.

Respiratory Management

If the patient remains apneic or exhibits irregular breathing after resuscitation, mechanical ventilation is instituted through a properly positioned endotracheal tube, with an initial O_2 concentration of 100%. ABGs, preferably obtained through an arterial line, are analyzed as needed until the oxygenation and acid-base status of the patient stabilize. ABG analysis also helps differentiate between pulmonary and nonpulmonary (or cardiac) causes of hypoxemia and tissue hypoxia. Mechanical ventilation is adjusted to maintain a normal $PaCO_2$ level. Hyperventilation is detrimental and should be avoided. Higher ventilatory rates and larger V_T may cause hyperventilation. This hyperventilation may generate increased airway pressures and auto-PEEP, leading to an increase in cerebral venous and intracranial pressures and a decrease in coronary artery and cerebral arterial pressures.[31] Cerebral blood flow may decrease, causing increased brain ischemia, if hyperventilation results in increased intrathoracic pressure. For details of the selection and use of mechanical ventilators and appropriate patient monitoring procedures, see Chapters 44 to 49, 51, and 52.

Cardiovascular Management

The 12-lead ECG, chest radiograph, clinical chemistry profile, cardiac enzyme results, and current and past drug histories should be reviewed. Invasive hemodynamic monitoring may be needed to monitor blood pressure and cardiac output. This monitoring provides needed data on the adequacy of vascular volumes, left ventricular performance, and overall tissue perfusion. Based on these data, judgments can be made regarding the need for fluid therapy and the selection and use of appropriate drugs.

SUMMARY CHECKLIST

- The most common cause of sudden death in adults is coronary artery disease; accidents are the most common cause of death in young people.
- The fundamental steps of basic CPR of health care providers for a witnessed cardiac arrest are as follows:
  1. Confirm unresponsiveness.
  2. Call for help and activate the EMS system.
  3. Check for a pulse (<10 seconds).
  4. Perform 30 cardiac compressions.
  5. Give two 1-second breaths to produce visible chest rise.
  6. Initiate automated external defibrillation immediately (perform defibrillation as soon as possible).
- Five cycles of 30 compressions to 2 ventilations CPR for adults should be given between attempts at defibrillation using only one shock followed immediately by chest compressions.
- Evaluating the effectiveness of CPR is important and requires rescuers to watch for visible chest rise and fall with ventilation and to push hard and fast when delivering chest compression.
- Complications of CPR include worsening of potential neck injuries, gastric inflation and vomiting, and internal trauma during chest compressions. Correct technique minimizes the risk for such complications.
- The RT is most often called on to establish an airway and ventilation with elevated FiO_2 during ACLS of hospitalized patients. Most often, knowledge and skill with bag-valve devices and oropharyngeal airways are required. Special care should be taken not to hyperventilate the patient during or after cardiac arrest.
- Common pharmacologic agents used during ACLS include atropine for bradycardia, epinephrine and amiodarone or lidocaine for ventricular arrhythmias, and epinephrine or vasopressin for cardiac arrest and hypotension.
- The RT is often involved in care after cardiac arrest of a victim who responds favorably to CPR. In the postresuscitative phase, the RT may need to maintain normal ventilation and oxygenation and assist the physician and nurses in monitoring the patient's condition.

CHAPTER 38

Humidity and Bland Aerosol Therapy

JAMES B. FINK AND ARZU ARI

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe how airway heat and moisture exchange normally occurs.
- State the effect dry gases have on the respiratory tract.
- State when to humidify and warm inspired gas.
- Describe how various types of humidifiers work.
- Describe how to enhance humidifier performance.
- State how to select and use humidifier heating and feed systems safely.
- Identify the indications, contraindications, and hazards that pertain to humidification during mechanical ventilation.
- Describe how to monitor patients receiving humidity therapy.
- Describe how to identify and resolve common problems with humidification systems.
- State when to apply bland aerosol therapy.
- Describe how large-volume aerosol generators work.
- Identify the delivery systems used for bland aerosol therapy.
- Describe how to identify and resolve common problems with aerosol delivery systems.
- Describe how to perform sputum induction.
- State how to select the appropriate therapy to condition a patient's inspired gas.

Vapors and mists have been used for millenia to treat respiratory disease. Modern respiratory care still uses these treatments at the bedside, in the form of water vapor (humidity) and bland water aerosols. Concepts of absolute and relative humidity are essential for understanding humidity therapy and are covered in Chapter 6. This chapter reviews the principles, methods, equipment, and procedures for using these concepts appropriately.

HUMIDITY THERAPY

Humidity therapy involves adding water vapor and (sometimes) heat to the inspired gas. To understand the need for humidity therapy, clinicians must understand the normal control of heat and moisture exchange.

Physiologic Control of Heat and Moisture Exchange

Heat and moisture exchange is a primary function of the upper respiratory tract, mainly the nose.[1] The nose heats and humidifies gas on inspiration and cools and reclaims water from gas that is exhaled. The nasal mucosal lining is kept moist by secretions from mucous glands, goblet cells, transudation of fluid through cell walls, and condensation of exhaled humidity. The nasal mucosa is very vascular, actively regulating temperature changes in the nose and serving as an active element in promoting effective heat transfer. Similarly, the mucosa lining the sinuses, trachea, and bronchi aid in heating and humidifying inspired gases.

During inspiration through the nose, the tortuous path of gas through the turbinates increases contact between the inspired air and the mucosa. As the inspired air enters the nose, it warms *(convection)* and picks up water vapor from the moist mucosal lining *(evaporation),* cooling the mucosal surface.

During exhalation, the expired gas transfers heat back to the cooler tracheal and nasal mucosa by convection. As the saturated gas cools, it holds less water vapor. Condensation occurs on the mucosal surfaces during exhalation, and water is reabsorbed by the mucus *(rehydration).* In cold environments, the formation of condensate may exceed the ability of the mucus to reabsorb water (resulting in a "runny nose").

The mouth is less effective at heat and moisture exchange than the nose because of the low ratio of gas volume to moist and warm surface area and the less vascular squamous epithelium lining the oropharynx and hypopharynx. When a person inhales through the mouth at normal room temperature, pharyngeal temperatures are approximately 3° C less than when the person breathes through the nose, with 20% less relative humidity. During exhalation, the relative humidity of expired gas varies little between mouth breathing and nose breathing, but the mouth is much less efficient in reclaiming heat and water.[2]

As inspired gas moves into the lungs, it achieves BTPS conditions (i.e., body temperature, 37° C; barometric pressure; saturated with water vapor [100% relative humidity at 37° C]) (Figure 38-1). This point, normally approximately 5 cm below the carina, is called the **isothermic saturation boundary** (ISB).[3]

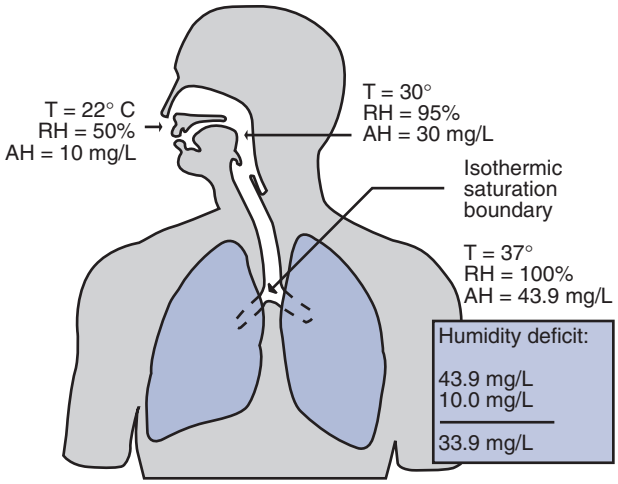

FIGURE 38-1 As a person breathes typical ambient air, the upper airway adds 20 mg/L of water vapor and the lower airway adds 13.9 mg/L. If all of that humidity were exhaled, this would represent a 33.9 mg/L humidity deficit. *AH,* Absolute humidity; *RH,* relative humidity; *T,* temperature. (From Fink J: Humidity and aerosol therapy. In Cairo J, Pilbeam S, editors: Mosby's respiratory equipment, ed 8, St. Louis, 2010, Mosby.)

Above the ISB, temperature and humidity decrease during inspiration and increase during exhalation. Below the ISB, temperature and relative humidity remain constant (BTPS).

Numerous factors can shift the ISB deeper into the lungs. The ISB shifts distally when a person breathes through the mouth rather than the nose; when the person breathes cold, dry air; when the upper airway is bypassed (breathing through an artificial tracheal airway); or when the minute ventilation is higher than normal. When this shift of ISB occurs, additional surfaces of the airway are recruited to meet the heat and humidity requirements of the lung. This recruitment of airways that do not typically provide this level of heat and humidity can have a negative impact on epithelial integrity. These shifts of the ISB can compromise the body's normal heat and moisture exchange mechanisms, and humidity therapy is indicated.

Indications for Humidification and Warming of Inspired Gases

The primary goal of humidification is to maintain normal physiologic conditions in the lower airways. Proper levels of heat and humidity help ensure normal function of the mucociliary transport system. Humidity therapy is also used to treat abnormal conditions. Box 38-1 summarizes the indications and contraindications for humidity therapy.

Administration of dry medical gases at flows greater than 4 L/min to the upper airway causes immediate heat and water loss and, if prolonged, causes structural damage to the epithelium. As the airway is exposed to relatively cold, dry air, ciliary motility is reduced, airways become more irritable, mucus production increases, and pulmonary secretions become **inspissated** (thickened owing to dehydration).

As listed in Box 38-2, the hazard of breathing dry gas is even greater when the normal heat and water exchange capabilities

Box 38-1 Indications for Humidification Therapy

PRIMARY
- Humidifying dry medical gases
- Overcoming humidity deficit created when upper airway is bypassed

SECONDARY
- Treating bronchospasm caused by cold air
- Contraindications for humidification therapy

There are no contraindications to providing physiologic conditioning of inspired gas during mechanical ventilation. However, a heat and moisture exchanger (HME) is contraindicated for patients:
- With thick, copious, or bloody secretions
- With an expired tidal volume (V_T) less than 70% of the delivered V_T (e.g., patients with large bronchopleural fistulas or incompetent or absent endotracheal tube cuffs)
- With body temperature less than 32° C
- With high spontaneous minute volumes (>10 L/min)
- Receiving noninvasive ventilation with large mask leaks, because the patient does not exhale enough V_T to replenish heat and moisture to adequately condition the inspired gas. Also, the resistance and dead space of the HME may negate the effects of the noninvasive positive pressure and add additional work of breathing.
- Receiving lung protective ventilation strategies such as in acute respiratory distress syndrome (additional dead space of HME may increase the ventilation requirement and $PaCO_2$).
- Receiving in-line aerosol drug treatments (a standard HME must be removed from the patient circuit during treatments. An HME designed for aerosol delivery must be switched to the aerosol bypass mode)

Box 38-2 Hazards and Complications for Humidification Therapy

Hazards and complications associated with the use of heated humidifier (HH) and HME devices during mechanical ventilation include the following:
- Potential electrical shock (HH)
- Potential for burns to caregivers from hot metal (HH)
  - Hypothermia (HME or inadequately set HH)
  - Hyperthermia (HH)
  - Thermal injury (HH)
- Underhydration and mucous impaction (HME or HH)
  - Hypoventilation and/or alveolar gas trapping resulting from mucus plugging of airways (HME or HH)
  - Hypoventilation secondary to hypercapnia caused by the increase in dead space (HME)
  - Increased work of breathing (HME)
  - Possible hypoventilation resulting from hypercapnia caused by the increase in dead space (HME)
  - Inadvertent overfilling or pooled condensate resulting in unintentional tracheal lavage (HH)
  - High flow rates during disconnect may aerosolize contaminated condensate (HH)
  - Elevated airway pressures caused by condensation (HH)
  - Ineffective low-pressure alarm during disconnection (HME)
  - Patient-ventilator dyssynchrony and improper ventilator function caused by condensation in the circuit (HH)
  - Airway burns or tubing meltdown if heated wire circuits are covered or incompatible with humidifier (HH)

of the upper airway are lost or bypassed, as occurs with endotracheal intubation. Breathing dry gas through an endotracheal tube (ETT) can cause damage to tracheal epithelium within minutes. However, as long as the inspired humidity is at least 60% of BTPS conditions, no injury occurs in normal lungs.[4,5] Prolonged breathing of improperly conditioned gases through a tracheal airway can result in **hypothermia** (reduced body temperature), inspissation of airway secretions, mucociliary dysfunction, destruction of airway epithelium, and atelectasis.[6] Box 38-3 summarizes the signs and symptoms associated with breathing cold, dry gases. A reduction of 20 mg/L below BTPS (44 mg/L) is less than 60% relative humidity at BTPS.

The amount of heat and humidity that a patient needs depends on the site of gas delivery (e.g., nose or mouth, hypopharynx, trachea). Table 38-1 summarizes the recommended levels based on standards.[7]

Warmed, humidified gases are used to prevent or treat various abnormal conditions. For treatment of hypothermia, heating and humidifying the inspired gas is one of several techniques used to raise core temperatures back to normal.[8,9] Heated humidification is used to prevent intraoperative hypothermia.[10] Of possibly greater clinical significance, warming and humidifying the inspired gas can help alleviate bronchospasm in patients who develop airway narrowing after exercise or when they breathe cold air. Although the cause of this condition is not known for certain, the primary stimulus is probably a combination of airway cooling and drying, which leads to hypertonicity of airway lining fluid and the release of chemical mediators.[11] The incidence of cold air–induced bronchospasm can be reduced by wearing a scarf over the nose and mouth in cold weather; the scarf becomes a crude passive heat and moisture exchanger.

TABLE 38-1
Recommended Heat and Humidity Levels

Delivery Site	Temperature Range (° C)	Relative Humidity (%)	Absolute Humidity (mg/L)
Nose/mouth	20-22	50	10
Hypopharynx	29-32	95	28-34
Trachea	32-35	100	36-40

From Chatburn R, Primiano F: A rational basis for humidity therapy. Respir Care 32:249, 1987.

Box 38-3 Clinical Signs and Symptoms of Inadequate Airway Humidification

- Atelectasis
- Dry, nonproductive cough
- Increased airway resistance
- Increased incidence of infection
- Increased work of breathing
- Patient complaint of substernal pain and airway dryness
- Thick, dehydrated secretions

The delivery of cool humidified gas is used to treat upper airway inflammation resulting from croup, epiglottitis, and postextubation edema. This technique is used most often in conjunction with bland aerosol delivery (see the section on Bland Aerosol Delivery).

Equipment

A **humidifier** is a device that adds molecular water to gas. This process occurs by evaporation of water from a surface (see Chapter 6), whether the water is in a reservoir, a wick, or a sphere of water in suspension (aerosol).

Physical Principles Governing Humidifier Function

The following four variables or principles affect the quality of performance of a humidifier: (1) temperature, (2) surface area, (3) time of contact, and (4) thermal mass. These factors are exploited to various degrees in the design of humidification devices (Box 38-4).

Temperature. Temperature is an important factor affecting humidifier performance. The greater the temperature of a gas, the more water vapor it can hold (increased capacity). As gas expansion and evaporation cool water in unheated humidifiers to 10° C below ambient temperature, the humidifiers become less efficient.

Figure 38-2 shows this concept, where, owing to evaporative cooling, the unheated humidifier on the left is operating at 10° C. Although the humidifier fully saturates the gas, the low operating temperature limits total water vapor capacity to approximately 9.4 mg/L water vapor, equivalent to approximately 21% of **body humidity.** Simply heating the humidifier to 40° C (Figure 38-2, right) increases its output to 51 mg/L, which is sufficient to meet BTPS conditions.

Surface Area. The greater the area of contact between water and gas, the more opportunity there is for evaporation to occur. Passover humidifiers pass gas over a large surface area of water. More space-efficient ways to increase the ratio of water to gas surface area include bubble diffusion, aerosol, and wick technologies.

Bubble-diffusion directs a stream of gas underwater, where it is broken up into small bubbles. As the gas bubbles rise to the surface, evaporation increases the water vapor content within the bubble. The smaller the bubble, the greater is the ratio of water to air surface area.

Box 38-4 Physical Principles Governing Humidifier Function

Temperature: The higher the temperature of a gas, the more water vapor it can hold (increased capacity) or vice versa.
Surface area: The greater the surface area of contact between water and gas, the more opportunity there is for evaporation to occur.
Contact time: The longer a gas remains in contact with water, the greater is the opportunity for evaporation to occur.
Thermal mass: The greater the mass of water or the core element of a humidifier, the greater is its capacity to hold and transfer heat.

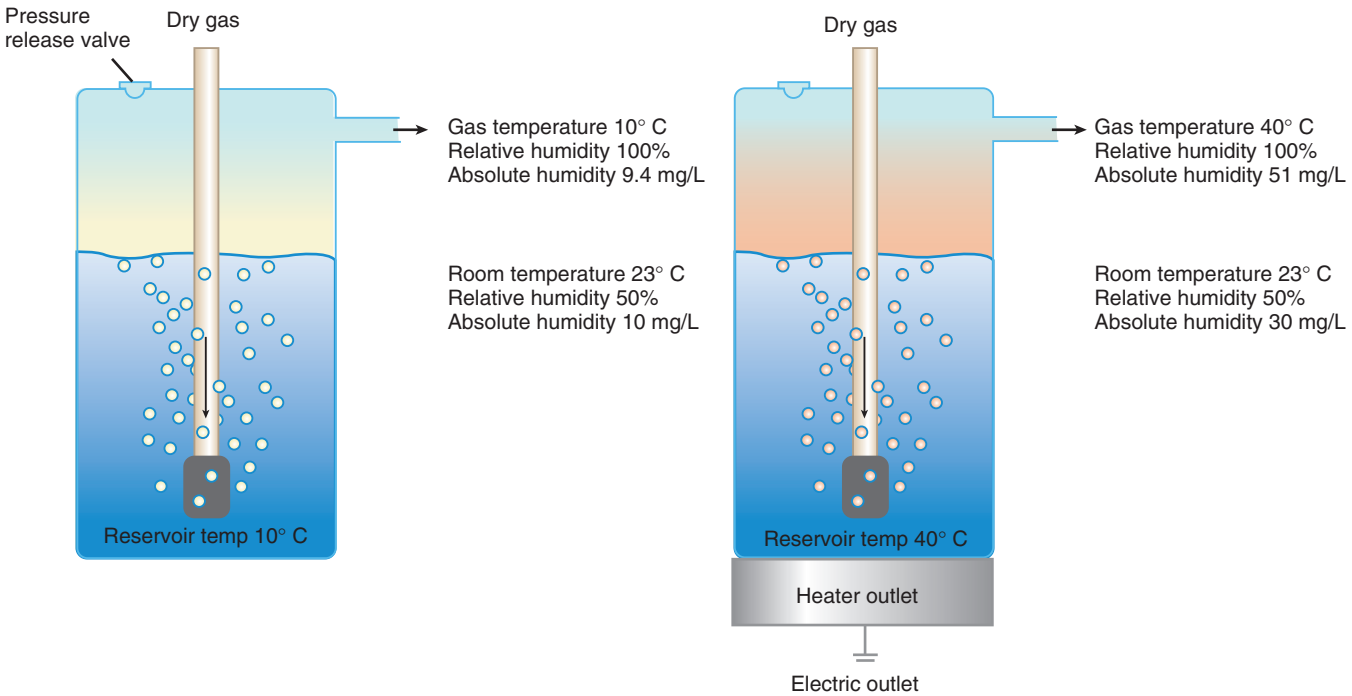

FIGURE 38-2 Effects of reservoir temperature on humidity output with unheated *(left)* and heated *(right)* bubble-type humidifiers. (Modified from Fink J, Cohen N: Humidity and aerosols. In Eubank D, Bone R, editors: Principles and applications of cardiorespiratory care equipment, St. Louis, 1994, Mosby.)

An alternative to dispersing gas bubbles in water is spraying water particles (aerosol) into the gas. The higher the aerosol density (number of particles per volume of gas), the greater is the gas to water surface area available for evaporation.

Wicks use porous water-absorbent materials to draw water (similar to a sponge) into its fine honeycombed structure by means of capillary action. The surfaces of the wick increase the area of contact between the water and gas, which aids evaporation.

Contact Time. The longer a gas remains in contact with water, the greater the opportunity is for evaporation to occur. For bubble humidifiers, contact time depends on the depth of the water column; the deeper the column, the greater is the time of contact as the bubbles rise to the surface. In passover and wick-type humidifiers, the flow rate of gas through the humidifier is inversely related to contact time, with high flow rates reducing the time available for evaporation to occur. Aerosols suspended in a gas stream have extended contact time (and opportunity for evaporation) as the aerosol and gas travel to the patient.

Thermal Mass. The greater the amount of water in a humidifier, the greater is the thermal mass. Increased thermal mass equates to increased capacity to hold and transfer heat to therapeutic gases. Larger reservoir humidifiers can provide more consistent heat and humidification with a broader range of gas flow.

Types of Humidifiers

Humidifiers are either *active* (actively adding heat or water or both to the device-patient interface) or *passive* (recycling exhaled heat and humidity from the patient). Active humidifiers typically include (1) bubble humidifiers, (2) passover humidifiers, (3) nebulizers of bland aerosols, and (4) vaporizers. Passive humidifiers refer to typical **heat and moisture exchangers** (HMEs). Specifications covering the design and performance requirements for medical humidifiers are established by the **American Society for Testing and Materials** (ASTM).[12]

Active Humidifiers

Bubble. A bubble humidifier breaks (diffuses) an underwater gas stream into small bubbles (Figure 38-3). Use of a foam or mesh diffuser produces smaller bubbles than an open lumen, allowing greater surface area for gas/water interaction. Unheated bubble humidifiers are commonly used with oxygen (O_2) delivery systems (see Chapter 41) to raise the water vapor content of the gas to ambient levels.

As indicated in Table 38-2, unheated bubble humidifiers can provide absolute humidity levels between approximately 15 mg/L and 20 mg/L.[13,14] At room temperature, 10 mg/L absolute humidity corresponds to approximately 80% relative humidity but only approximately 25% body humidity (see Chapter 6). As gas flow increases, the reservoir cools and contact time is reduced, limiting effectiveness at flow rates greater than 10 L/min. Heating the reservoirs can increase humidity content,

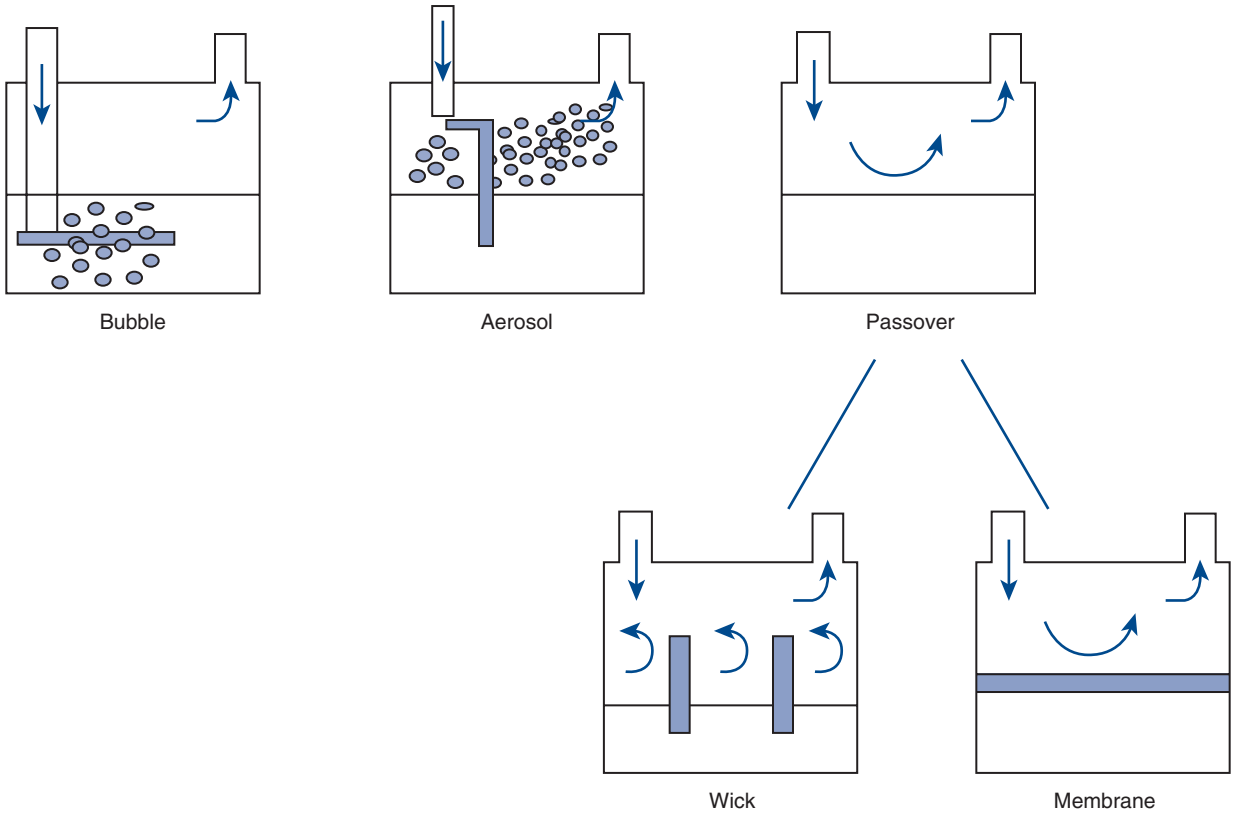

FIGURE 38-3 Primary types of active humidifiers. Gas passes through the water (bubble), around drops of water (aerosol) or over the surface of water (Passover), a saturated material (wick) or a semipermeable membrane (membrane). (From Fink J: Humidity and aerosol therapy. In Cairo J, Pilbeam S, editors: Mosby's respiratory equipment, ed 8, St. Louis, 2010, Mosby.)

TABLE 38-2

Absolute Humidity (mg/L) Provided by Unheated Bubble Humidifiers

L/min	Aquapak 301 (Hudson RCI, Dunham, NC)	Traveral 500 (Baxter-Travenol, Deerfield, IL)
2	17.6	20.4
4	17.7	19.5
6	16.9	16.2
8	14.9	15.7

Modified from Darin J, Broadwell J, MacDonell R: An evaluation of water-vapor output from four brands of unheated, prefilled bubble humidifiers. Respir Care 27:41, 1982.

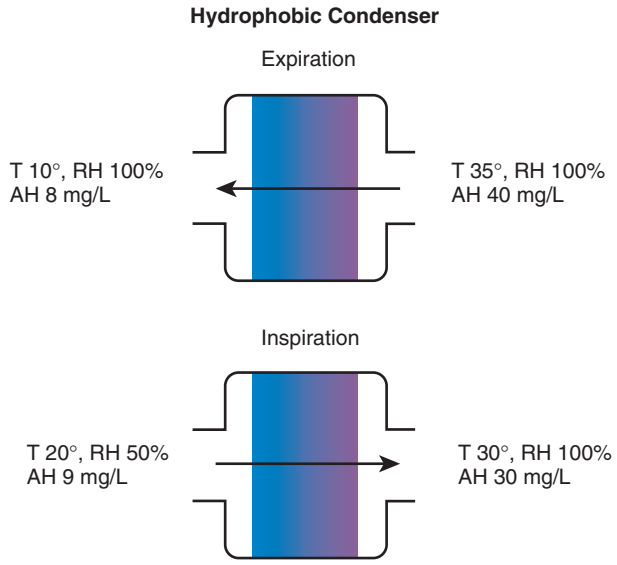

FIGURE 38-4 Process of humidification with a hydrophobic condenser humidifier. *AH,* Absolute humidity; *RH,* relative humidity; *T,* temperature.

but this is not recommended because cooling produces condensate that obstructs small-bore delivery tubing.

To warn of flow-path obstruction and prevent bursting of the humidifier bottle, bubble humidifiers incorporate a simple pressure-relief valve, or *pop-off*. The pop-off is commonly a gravity or spring-loaded valve that releases pressures greater than 2 psi. Humidifier pop-offs should provide both an audible and a visible alarm and resume normal position when pressures return to normal.[12] The pop-off can be used to test an O_2 delivery system for leaks by obstructing delivery tubing at or near the patient interface. If the pop-off sounds, the system is leak-free; failure of the pop-off to sound may indicate a leak (or a faulty pop-off valve).

As gas flow increases, bubble humidifiers can produce aerosols. Although invisible to the naked eye, these water droplet suspensions can transmit pathogenic bacteria from the humidifier reservoir to the patient.[15] Because any device that generates an aerosol poses a high risk for spreading infection, strict infection control procedures must be followed when using these systems (see Chapter 4).

Passover. Passover humidifiers direct gas over a surface containing water. There are three common types of passover humidifiers: (1) simple reservoir type, (2) wick type, and (3) membrane type (see Figure 38-3).

The simple reservoir device directs gas over the surface of a volume of water (or fluid). The surface for gas-fluid interface is limited. Typically used with heated fluids with invasive mechanical ventilation, room temperature fluids may be used with noninvasive ventilatory support (nasal continuous positive airway pressure or bilevel ventilation).

A wick humidifier uses an absorbent material to increase the surface area for dry air to interface with heated water. Typically, a wick is placed upright with the gravity-dependent end in a heated water reservoir. Heating elements might be below or surrounding the wick. Capillary action draws water up from the reservoir and keeps the wick saturated. As dry gas enters the chamber, it flows around the wick, quickly picking up heat and moisture and leaving the chamber saturated with water vapor. No bubbling occurs, so no aerosol is produced.

A membrane-type humidifier separates the water from the gas stream by means of a **hydrophobic** membrane (Figure 38-4). Water vapor molecules can easily pass through this membrane, but liquid water (and pathogens) cannot. As with a wick humidifier, bubbling does not occur. If a membrane-type humidifier were to be inspected while it was in use, no liquid water would be seen in the humidifier chamber.

Compared with bubble humidifiers, passover humidifiers offer several advantages.[15,16] First, in contrast to bubble devices, passover humidifiers can maintain saturation at high flow rates. Second, they add little or no flow resistance to spontaneous breathing circuits. Third, they do not generate any aerosols, and they pose a minimal risk for spreading infection.

Vaporizer Humidifiers. Simple vaporizers heat water to the point of expansion as a gas. Simple room vaporizers have been used in ambulatory settings for years as room humidifiers. A capillary force vaporizer is a thin-film, high-surface-area boiler that combines capillary force and phase transition to impart pressure onto an expanding gas (water vapor) and ejects it into the gas stream.

Heat and Moisture Exchangers. An HME is a passive humidifier, also described as an "artificial nose." Similar to the nose, an HME captures exhaled heat and moisture and returns up to 70% of the heat and humidify to the patient during the next inspiration. In contrast to the nose, with its rich vasculature and endothelium, most HMEs do not actively add heat or water to the system.[6]

Traditionally, use of HMEs has been limited to providing humidification to patients receiving ventilatory support via endotracheal or tracheostomy tubes. More recently, HMEs have been used successfully in meeting the short-term humidification needs of spontaneously breathing patients with tracheostomy tubes.[17-22] Reports of increased incidence of blocked tracheal tubes associated with long duration of HME use in the intensive care unit,[23] are in contrast with evidence supporting long-term use of HMEs for spontaneously breathing patients.[24]

The three basic types of HMEs are (1) simple condenser humidifiers, (2) hygroscopic condenser humidifiers, and (3) hydrophobic condenser humidifiers. Simple condenser HMEs contain a condenser element with high thermal conductivity, usually consisting of metallic gauze, corrugated metal, or parallel metal tubes. Inspired air cools the condenser element, and expired water vapor condenses directly on its surface and rewarms it. On the next inspiration, cool, dry air is warmed and humidified as its passes over the condenser element. Simple condenser humidifiers are able to recapture only approximately 50% of a patient's exhaled moisture.

Hygroscopic condenser HMEs provide higher efficiency by (1) using a condensing element of low thermal conductivity (e.g., paper, wool, or foam) and (2) impregnating this material with a hygroscopic salt (calcium or lithium chloride). By using an element with low thermal conductivity, hygroscopic condenser HMEs can retain more heat than simple condenser systems while hygroscopic salt helps capture extra moisture from the exhaled gas. The lower water vapor pressure in the inspired gas liberates water molecules directly from the hygroscopic salt, without cooling. Figure 38-5 depicts the overall process of humidification with a hygroscopic condenser humidifier, showing the changes in temperature and the relative and absolute humidity occurring during the cycle of breathing. As shown, these devices typically achieve approximately 70% efficiency (40 mg/L exhaled, 27 mg/L returned).

Hydrophobic condenser HMEs use a water-repellent element with a large surface area and low thermal conductivity (see Figure 38-4). During exhalation, the condenser temperature increases to approximately 25° C because of conduction and the latent heat of condensation. On inspiration, cool gas and evaporation reduce the condenser temperature down to 10° C. This large temperature change results in the conservation of more water to be used in humidifying the next breath. The efficiency of these devices is comparable to that of hygroscopic condenser HMEs (approximately 70%). However, some hydrophobic HMEs that provide bacterial filtration may reduce the risk for pneumonia but be unsuitable for patients with limited respiratory reserve or who are prone to airway blockage because they may increase artificial airway occlusion.[25,26] HMEs that deliver at least 30 mg H_2O/L should be used because they are associated with a lower incidence of ETT occlusion.[18]

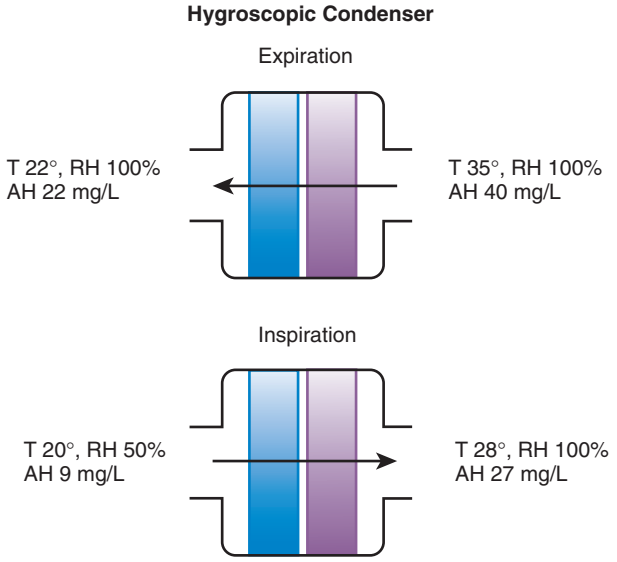

FIGURE 38-5 Process of humidification with a hygroscopic condenser humidifier. *AH,* Absolute humidity; *RH,* relative humidity; *T,* temperature.

Design and performance standards for HMEs are set by the **International Organization for Standardization** (ISO).[27] The ideal HME should operate at 70% efficiency or better (providing at least 30 mg/L water vapor); use standard connections; have a low compliance; and add minimal weight, dead space, and flow resistance to a breathing circuit.[28] HME performance varies from brand to brand and may differ from manufacturers' specifications.[29] Insufficient heat and humidification can occur with some HMEs causing complications.[30,31] Table 38-3 compares performance of several commercially available HMEs

Modified from Lellouche F, Taille S, Lefrancois F, et al: Humidification performance of 48 passive airway humidifiers: comparison with manufacturer data. Chest 135:276, 2009.
AH, Absolute humidity; *NA,* not available.

according to their moisture output, flow resistance, and dead space.[29]

As shown in Table 38-3, the moisture output of HMEs tends to decrease at high volumes and rates of breathing. In addition, high inspiratory flows and high FiO_2 levels can decrease HME efficiency.[28] Flow resistance through the HME also is important. When an HME is dry, resistance across most devices is minimal. However, because of water absorption, HME flow resistance increases after several hours of use.[32] For some patients, the increased resistance imposed by the HME may not be well tolerated, particularly if the underlying lung disease already causes increased work of breathing. An increase in work of breathing through the HME may lead to elevated airway pressures and possible disconnect.[33]

Because HMEs eliminate the problem of breathing circuit condensation, many clinicians consider these devices (especially hydrophobic filter HMEs) to be helpful in preventing nosocomial infections and ventilator-associated pneumonia (VAP).[34] Compared with active humidification systems, HMEs reduce bacterial colonization of ventilator circuits.[35] However, circuit colonization plays a minor role in the development of nosocomial infections, provided that usual maintenance precautions are applied.[36] Although there is no evidence of an overall difference between HMEs and heated humidifiers in preventing mortality and other complications in patients who are mechanically ventilated,[26] and previous research indicates no difference in incidence of ventilator-associated infections, with HMEs and heated humidifiers.[26,29,30,35,37-39] The position of the HME relative to the patient's airway can affect its ability both to heat and to humidify inhaled gas. Secretions can foul HMEs attached directly to the airway. The use of devices such as closed suction catheters and airway monitor ports requires placement of the HME closer to the ventilator. Previous research tested performance of HMEs placed directly at the airway, 10 cm away from ETT and proximal to the ventilator circuit.[40] It was reported that HME performance was best at the airway (Figure 38-6).[40]

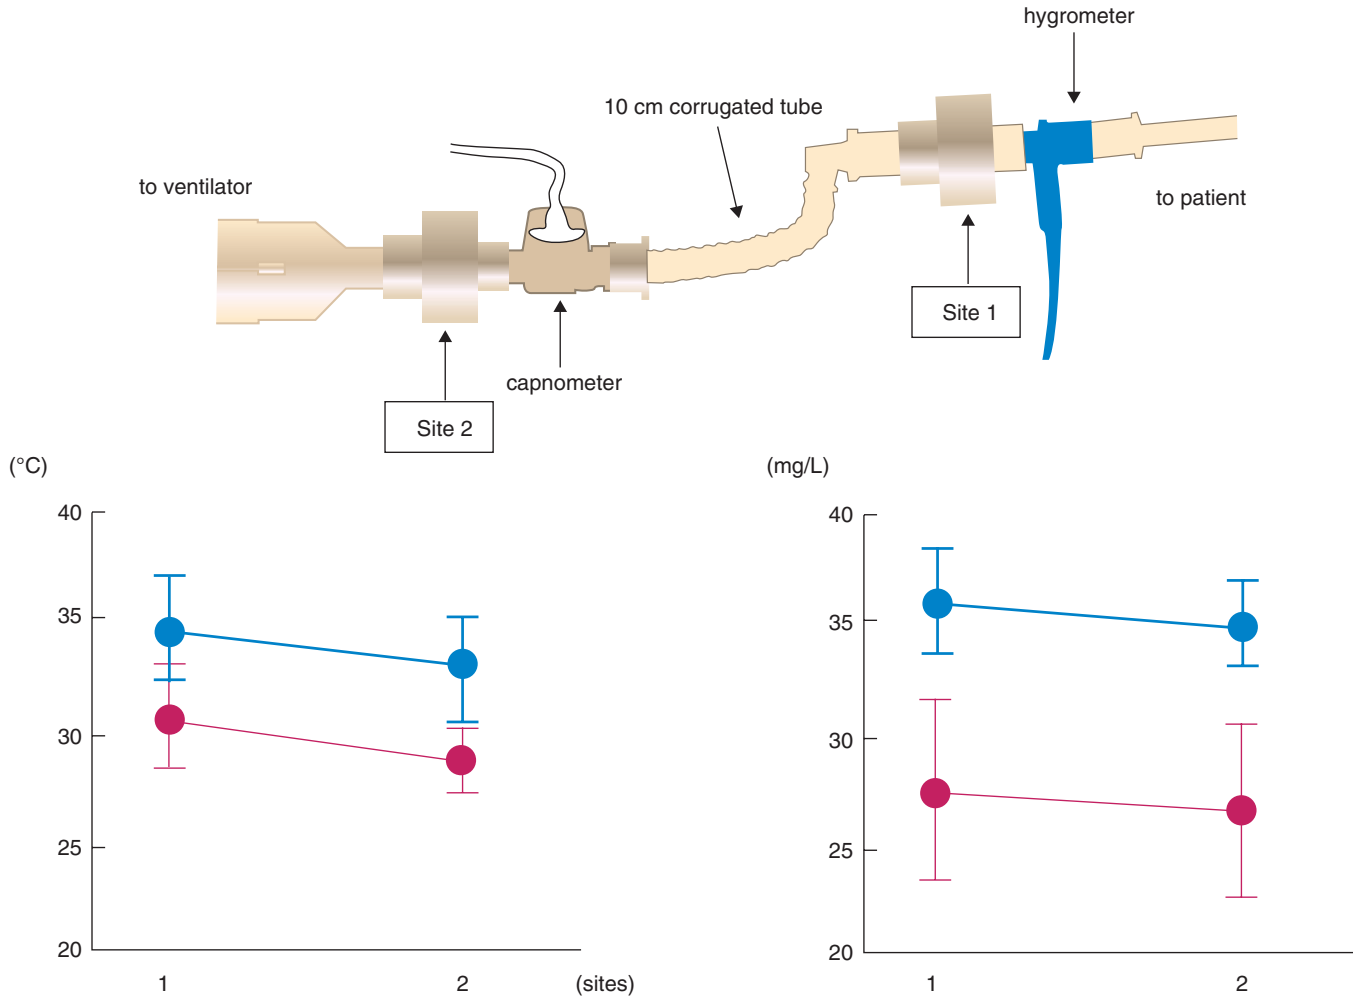

FIGURE 38-6 Placement of heat and moisture exchangers (HMEs) (Hygrobac S [Mallinckrodt-Dar, Mirandola, Italy, *blue circle*] or Thermovent HEPA [Smiths Medical International, Kent, U.K., *red circle*]) at the airway *(site 1)* or proximal to the ventilator circuit *(site 2)*. Temperature mean ± SD (TEMP; *left*) and absolute humidity were significantly higher with both HMEs. $P < .05$ placed at *site 1* compared with *site 2*. (Modified from Inui D, Oto J, Nishimura M: Effect of heat and moisture exchanger [HME] positioning on inspiratory gas humidification. BMC Pulm Med 6:19, 2006.)

Clinicians should select HMEs that perform adequately when placed at the intended position. Although use of HMEs has been associated with thickened and increased volume of secretions in some patients, the incidence of ETT occlusion when HMEs are used is equivalent to that with heated humidifiers.[38,41]

HMEs are not recommended for use with infants and small children for several reasons. First, HMEs add 30 to 90 ml of mechanical dead space, exceeding the tidal volume of the infant. In addition, infants are commonly ventilated through uncuffed ETTs, which allow exhaled gas to leak around the tube and bypass the HME reducing recovered heat and humidity.

Active Heat and Moisture Exchangers. Active HMEs add humidity or heat or both to inspired gas by chemical or electrical means.[42] The Humid-Heat (Louis Gibeck AB, Upplands Väsby, Sweden) consists of a supply unit with a microprocessor, water pump, and humidification device, which is placed between the Y-piece and the ETT. The humidification device is based on a hygroscopic HME, which absorbs the expired heat and moisture and releases it into the inspired gas. External heat and water are added to the patient side of the HME, so the inspired gas should reach 100% humidity at 37° C (44 mg H_2O/L air). The external water is delivered to the humidification device via a pump onto a wick and evaporated into the inspired air by an electrical heater. The microprocessor controls the water pump and the heater by an algorithm using the minute ventilation (which is fed into the microprocessor) and the airway temperature measured by a sensor mounted in the flex-tube on the patient side of the humidification device. The HME Booster (King Systems, Noblesville, IN) has a T-piece containing an electrically heated element that was designed for use as an adjunct to a passive HME. The heating element heats water so that water vapor passes into the airway between the artificial airway and ETT, via a Gore-Tex membrane and aluminum. Using a gravity feedbag via a flow regulator that limits flow to 10 mL/hr, water is fed to the heater, which operates at 110° C and adds 3 to 5.5 mg/L of humidity and 3° C to 4° C to inspired gas compared with the HME alone. The Humid-Booster was designed for patients with minute volumes of 4 to 20 L, and it is not appropriate for use with pediatric patients or infants. Active HMEs add weight and complexity at the patient airway.

RULE OF THUMB

HMEs should be replaced if secretions have contaminated the filter and/or if flow resistance has increased causing an increase in the work of breathing.

Heated Humidifiers

Heat improves the water output of humidifiers. Heated humidifiers are used to increase the heat and water content of inspired gas for patients with bypassed upper airways and patients receiving noninvasive mechanical ventilatory support.[6] Humidifier heating systems generally have a controller that regulates the power to the heating element by monitoring the heating element, which matches a preset or adjustable temperature. They also may use a thermistor placed at the outlet of the humidifier, with a heater set to control output temperature. Servo-controlled heating systems monitor the temperature at the humidifier's outlet and at the patient's airway using a thermistor probe. The controller adjusts the heater power to reach the desired airway temperature and incorporates alarms and an alarm-activated heater shutdown function.

An electrical heating element provides the needed energy. Five types of heating elements are common: (1) a hotplate element at the base of the humidifier; (2) a wraparound type that surrounds the humidifier chamber; (3) a yolk, or collar, element that sits between the water reservoir and the gas outlet; (4) an immersion-type heater, with the element placed in the water reservoir; (5) a heated wire in the inspiratory limb warming a saturated wick or hollow fiber; and (6) a thin-film, high surface area broiler.

Humidifier heating systems have a controller that regulates the element's electrical power. In the simplest systems, the controller monitors the heating element, varying the delivered current to match either a preset or an adjustable temperature. In these systems, the temperature of the patient's airway has no effect on the controller. Conversely, a **servo-controlled heating system** monitors temperature at or near the patient's airway using a thermistor probe. The controller adjusts heater power to achieve the desired airway temperature. Systems usually have alarms and alarm-activated heater shutdown. Box 38-5 outlines key features of modern heated humidification systems.

RULE OF THUMB

Place heated humidifier thermistor probes in the inspiratory limb of a ventilator circuit far enough from the patient Y adaptor to ensure that warm exhaled gas does not fool the controller system. Never place a thermistor probe in an isolette or a radiant warmer, where the probe is warmed externally and the humidifier is fooled into shutting down, reducing the humidity available to the patient.

Reservoir and Feed Systems

Heated humidifiers operating continuously in breathing circuits can evaporate more than 1 L of water per day. An ideal reservoir or feed system should be safe, dependable, easy to set up, and use allowing continuity of therapy, even when the reservoir is being replenished.

Manual Systems. Simple large-reservoir systems are manually refilled (with sterile or distilled water). If a manual system is used, momentary interruption of humidifier operation and mechanical ventilation is required for refilling. Because the system must be "opened" for refilling, cross contamination can occur. Water levels in manually filled systems are constantly changing, and changes in the humidifier fill volume alter the gas compression factor and the delivered volume during mechanical ventilation.

Box 38-5 Key Features for Heated Humidification Systems

- Gas temperature delivered to the patient should not be greater than 40° C. When temperatures greater than 40° C are reached, audible and visual alarms should indicate an overly high temperature condition and interrupt power to the heater.
- Audible and visual alarms should indicate when remote temperature sensors are disconnected, absent, or defective, and power to the heater should be interrupted to prevent overheating.
- Temperature overshoot should be minimized. Overshoot can occur when servo-controlled units warm up without flow through the circuit, when the temperature probe is not inserted in the circuit (or becomes dislodged), or when flow changes during normal operation. Non–servo-controlled units can overshoot when temperature controls are set too high or when gas flow is abruptly reduced.
- Indicators for delivered gas temperature should be accurate to ± 3° C of the indicated value.
- Humidifier temperature output should not vary more than 2° C from the set value (proximal to the patient).
- Warmup time should not exceed 15 minutes.
- The water level should be readily visible in either the humidifier or the remote reservoir.
- Humidifiers should be able to withstand ventilation pressures greater than 100 cm H_2O.
- Internal compliance should be low and stable so that changes in the water level do not significantly alter the delivered tidal volume.
- The exposed surface of a humidifier should not be too hot to touch during operation. Readily accessible surfaces should not be greater than 37.5° C. A warning label is needed for hotter surfaces.
- Operator, or feed, systems must not be able to overfill the humidifier to the point that water can block gas flow through the humidifier or ventilator circuit. Humidifiers should not be damaged by spilled fluids.
- Electromagnetic interference from other devices should not affect humidifier performance. The unit should not be damaged by 95 to 135 Volts.
- Fuses or circuit breakers should be clearly labeled and easily reset or replaced. The unit should have adequate overcurrent protection to prevent ventilator shutdown or loss of power to other equipment on the same branch circuit because of internal equipment failures.
- It should be impossible to assemble the unit in a way that would be hazardous to the patient. The direction of gas flow should be indicated on interchangeable components, for which proper direction is essential.
- The humidifier should be assembled and filled in a manner that minimizes the introduction of infectious materials or foreign objects.
- Service and operation manuals should be provided with the humidifier and should cover all aspects of its use and service.

Modified from Emergency Care Research Institute: Heated humidifiers, Health Devices. 1987. http://www.fda.gov/oc/po/firmrecalls/Vapotherm2000i_01_06.html. Accessed March 2, 2011.

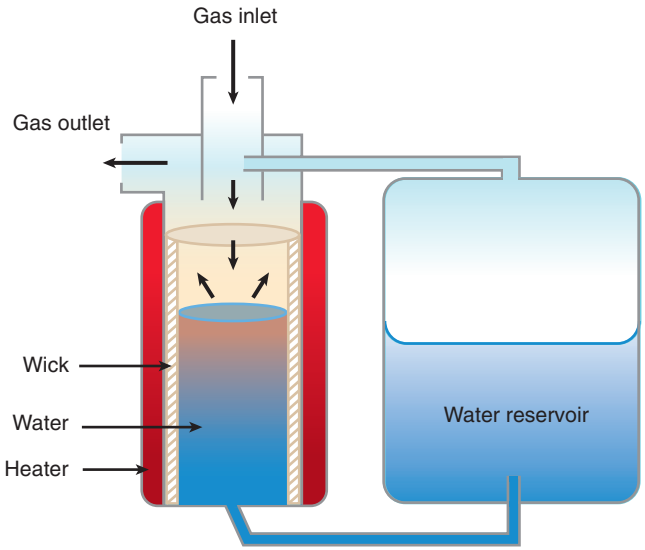

FIGURE 38-7 Schematic of the Concha-Column wick-type humidifier with level-compensated reservoir feed system (Hudson RCI, Temecula, CA). (Modified from Fink J, Cohen N: Humidity and aerosols. In Eubank D, Bone R, editors: Principles and applications of cardiorespiratory care equipment, St. Louis, 1994, Mosby.)

A small inlet that can be attached to a gravity-fed intravenous bag and line allows refilling without interruption of ventilation. Such systems still require constant checking and manual replenishment by opening the line valve or clamp. If not checked regularly, the reservoir in these systems can go dry, placing the patient at considerable risk.

Automatic Systems. Automatic feed systems avoid the need for constant checking and manual refilling of humidifiers. The simplest type of automatic feed system is the level-compensated reservoir (Figure 38-7). In these systems, an external reservoir is aligned horizontally with the humidifier, maintaining relatively consistent water levels between the reservoir and the humidifier chamber.

With flotation-type systems, a float rises and falls with the water level. As the water level falls below a preset value, the float opens the feed valve; as the water rises back to the set fill level, the float closes the feed valve. Alternatively, optical sensors can be used to sense water level, driving a solenoid valve to allow refilling of the humidifier reservoir.

RULES OF THUMB

Humidification of inspired gas is mandatory in mechanically ventilated patients with ETT or tracheostomy tube. During noninvasive ventilation, active humidification is suggested to improve comfort.

Setting Humidification Levels

The American National Standards Institute (ANSI) recommends *minimum* levels of humidity for intubated patients (>30 mg/L). However, optimum humidity targets the temperature and humidity for normal conditions at the point that the

MINI CLINI

Selecting the Appropriate Therapy to Condition a Patient's Inspired Gas

PROBLEM: A survivor of near drowning has just been intubated and placed on mechanical ventilatory support. Her body temperature is 31° C, and her minute ventilation is high. What would be the appropriate humidification system to recommend for this patient?

SOLUTION: Normally, patients without pulmonary disease supported by mechanical ventilation can be started with an HME, unless its use is contraindicated. Using an HME with this patient is contraindicated because (1) she is hypothermic and (2) she has a high minute ventilation. Based on this assessment, the best choice is a heated humidifier, preferably with servo-controlled airway temperature.

Membrane-type humidifiers require no flow control system because the liquid water chamber underlying the membrane cannot overfill and they require only an open gravity feed system. Two examples are the Vapotherm (Vapotherm, Stevensville, MD) membrane cartridge system and the Hummax II (Metran Medical Instruments, Saitama, Japan), which uses a heated wire to warm the polyethylene microporous hollow fiber placed in the inspiratory circuit.

A capillary force vaporizer is driven by software that controls a heater element and water flow. The 19-mm diameter disc can deliver 2.2 mg of water vapor/min at 37° C. Data from prototypes suggest temperature control from 33° C to 41° C for flows 2 to 40 L/min (Figure 38-8).[43]

A gas temperature above 41° C may lead to a potential thermal injury to the patient; over-temperature alarms protect the patient from thermal injury.[6]

FIGURE 38-8 The capillary force vaporizer (CFV) is a thin-film, high-surface-area boiler that combines capillary force and phase transition. **A,** Inducing phase transition in a capillary environment, the CFV imparts pressure onto the expanding gas and ejects it. **B,** The CFV is incorporated to provide controlled heated humidity in the Hydrate (Pari, Midlothian, VA). **C,** Temperature probe. (Courtesy Pari.)

gas is entering the airway. For example, the humidity of air entering the carina is typically 37 to 40 mg/L. When humidifiers run too cold (<32° C), humidity can be reduced to the point of increased airway plugging. Not all active heated humidifiers perform the same under all conditions.[40] Previous research emphasized the need to set humidifiers to maintain airway temperatures between 35° C and 37° C.[44]

Controversy exists regarding the appropriate temperature and humidity of inspired gas delivered to mechanically ventilated patients with artificial airways. The current AARC Clinical

Practice Guideline recommends 33° C, within 2° C, with a minimum of 30 mg/L of water vapor. (see Clinical Practice Guideline 38-1). In a comprehensive review, Williams[45] suggested that inspired humidity be maintained at an optimal level, 37° C with 100% relative humidity and 44 mg/L, to minimize mucosal dysfunction. Theoretically, optimal humidity offers improved mucociliary clearance. The benefits of this strategy are theory based but have yet to be shown conclusively in the clinical setting. Further controlled studies are needed to support better the need for optimal humidity.

38-1 Humidification During Invasive and Noninvasive Mechanical Ventilation

AARC Clinical Practice Guideline (Excerpts)*

INDICATIONS

Humidification of inspired gas during mechanical ventilation is mandatory when an endotracheal or a tracheostomy tube is present. Humidification of inspired gas during mechanical ventilation is mandatory when an endotracheal or tracheostomy tube is present but optional with noninvasive ventilation.

CONTRAINDICATIONS

There are no contraindications to providing physiologic conditioning of inspired gas during mechanical ventilation. However, a heat and moisture exchanger (HME) is contraindicated in the following circumstances:

- For patients with thick, copious, or bloody secretions
- For patients with an expired tidal volume less than 70% of the delivered tidal volume (e.g., patients with large bronchoneural fistulas or incompetent or absent endotracheal tube cuffs)
- For patients whose body temperature is less than 32° C
- For patients with high spontaneous minute volumes (>10 L/min)
- For patients receiving in-line aerosol drug treatments (an HME must be removed from the patient circuit during treatments)

HAZARDS AND COMPLICATIONS

Hazards and complications associated with the use of heated humidifier (HH) and HME devices during mechanical ventilation include the following:

- High flow rates during disconnect may aerosolize contaminated condensate (HH)
- Underhydration and mucous impaction (HME or HH)
- Increased work of breathing (HME or HH)
- Hypoventilation caused by increased dead space (HME)
- Elevated airway pressures caused by condensation (HH)
- Ineffective low-pressure alarm during disconnection (HME)
- Patient-ventilator dyssynchrony and improper ventilator function caused by condensation in the circuit (HH)
- Hypoventilation or gas trapping caused by mucous plugging (HME or HH)
- Hypothermia (HME or HH)
- Potential for burns to caregivers from hot metal (HH)
- Potential electrical shock (HH)
- Airway burns or tubing meltdown if heated wire circuits are covered or incompatible with humidifier (HH)
- Possible increased resistive work of breathing caused by mucous plugging (HME or HH)
- Inadvertent overfilling resulting in unintended tracheal lavage (HH)
- Inadvertent tracheal lavage from pooled condensate in circuit (HH)

ASSESSMENT OF NEED

- Either an HME or an HH can be used to condition inspired gases:
- HMEs are better suited for short-term use (≤96 hours) and during transport.
- HHs should be used for patients requiring long-term mechanical ventilation (>96 hours) or for patients for whom HME use is contraindicated.

ASSESSMENT OF OUTCOME

Humidification is assumed to be appropriate if, on regular, careful inspection, the patient exhibits none of the listed hazards or complications.

MONITORING

The humidifier should be inspected during the patient-ventilator system check, and condensate should be removed from the circuit as needed. HMEs should be inspected and replaced if secretions have contaminated the insert or filter. The following should be recorded during equipment inspection:

- During routine use on an intubated patient, an HH should be set to deliver inspired gas at 33° C ± 2° C and should provide a minimum of 30 mg/L of water vapor.
- Inspired gas temperature should be monitored at or near the patient's airway opening (HH).
- Specific temperatures may vary with the patient's condition; airway temperature should never exceed 37° C.
- For heated wire circuits used with infants, the probe must be placed outside the incubator or away from the radiant warmer.
- The high-temperature alarm should be set no higher than 37° C, and the low setting should not be less than 30° C.
- The water level and function of automatic feed system (if applicable) should be monitored.
- Quantity, consistency, and other characteristics of secretions should be noted and recorded. When using an HME, if secretions become copious or appear increasingly tenacious, an HH should replace the HME.

**For the complete guideline, see Restrepo RD, Walsh BK: Humidification during invasive and noninvasive mechanical ventilation: 2012. Respir Care 57:782–788, 2012.*

Problem Solving and Troubleshooting

Common problems with humidification systems include condensation, avoiding cross contamination, and ensuring proper conditioning of the inspired gas.

Condensation

In standard heated humidifier systems, saturated gas cools as it leaves the point of humidification and passes through the delivery tubing en route to the patient. As gas cools, water vapor capacity decreases, resulting in condensation or "rain out." Factors influencing the amount of condensation include (1) the temperature difference across the system (humidifier to airway); (2) the ambient temperature; (3) the gas flow; (4) the set airway temperature; and (5) the length, diameter, and thermal mass of the breathing circuit.

Figure 38-9 illustrates the condensation process. Because cooling occurs as gas transits the circuit, the humidifier is set to a higher temperature (50° C) than desired at the airway. At 50° C, saturated gas has an absolute humidity level of 84 mg/L of water. As cooling occurs along the tubing, the capacity of the gas to hold water vapor decreases as temperature decreases to 37° C, and holds only 44 mg/L of water vapor. Although BTPS conditions have been achieved, 40 mg/L, half the total output of the humidifier (84 mg/L − 44 mg/L = 40 mg/L), condenses in the inspiratory limb of the circuit.

This condensation poses risks to patients and caregivers and can waste a lot of water. Condensation can disrupt or occlude gas flow through the circuit, potentially altering ventilator function. Because condensate can enter the patient airway and be aspirated, circuits must be positioned to drain condensate away from the patient and checked often, with condensate drained from breathing circuits frequently.

Patients contaminate ventilator circuits within hours, with condensate colonized with bacteria posing an infection risk.[46] Health care personnel should treat all breathing circuit condensate as infectious waste. See Chapters 4 and 46 for more detail on control procedures used with breathing circuits, including the American Association for Respiratory Care (AARC) Clinical Practice Guideline on changing ventilator circuits (see Clinical Practice Guideline 4-1).

RULES OF THUMB

Always treat breathing circuit condensate as infectious waste. Use standard precautions, including wearing gloves and goggles. Always drain the tubing away from the patient's airway into an infectious waste container, and dispose of the waste according to the policies and procedures of the institution.

A common method to minimize problems with condensate is to place water traps at low points in the circuit (both the inspiratory and the expiratory limbs of ventilator circuits) to collect condensate and reduce the likelihood of gas flow obstruction. Water traps should have little effect on circuit compliance, allow emptying without disrupting ventilation, and not be prone to leakage.

Nebulizers, with medication reservoirs positioned below the ventilator circuit, can act as a "water trap," collecting contaminated condensate. This creates a risk that contaminated aerosols can be generated and pathogens delivered to deep into the lung. To minimize this risk, nebulizers should be placed in a superior position so that any condensate travels downstream from the nebulizer. In addition, these nebulizers should be rinsed and air dried, washed, and sterilized or disposed of and replaced between treatments.

One way to avoid condensation problems is to prevent condensation from forming. Because the decrease in temperature

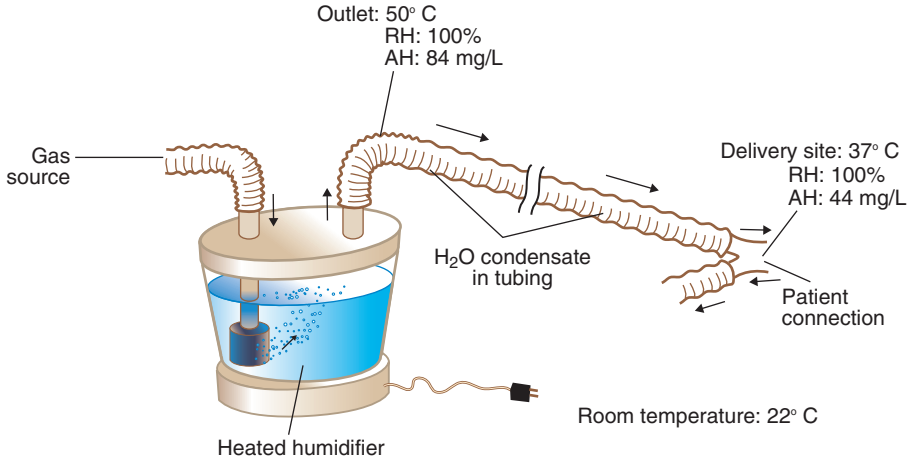

FIGURE 38-9 Gases leaving a standard heated humidifier are cooled en route to the patient. Although the gas remains saturated (100% relative humidity *[RH]*), cooling reduces its water vapor capacity, and condensation forms. Almost half of the original water (500 ml/day) is lost to condensation. The temperature at the patient connection (37° C) shown here is for illustrative purposes only. Heated humidifiers should be set to deliver inspired gas at 35° C ± 2° C. *AH,* Absolute humidity.

in gas traveling from the humidifier to the airway causes condensation, maintaining heat in the circuit can prevent formation of condensate. Several methods, such as insulation or increasing the thermal mass of the circuit, can reduce circuit cooling by keeping the circuit at a constant temperature. The most common approach uses wire heating elements inserted into the ventilator circuit.

Most heated wire circuits use dual controllers with two temperature sensors: one monitoring the temperature of gas leaving the humidifier and the other placed at or near the patient's airway[47-50] (Figure 38-10). The controller regulates the temperature difference between humidifier output and patient airway. When heated wire circuits are used, the humidifier heats gas to a lower temperature (32° C to 40° C) than with conventional circuits (45° C to 50° C). Reduction in condensate in the tubing results in less water use, reduced need for drainage, and less infection risk for patients and health care workers.

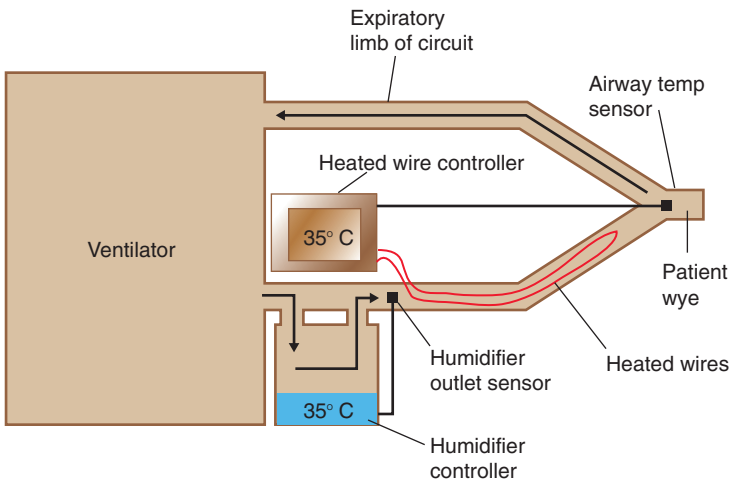

FIGURE 38-10 Heated wire humidifier system. The dual sensor system keeps the temperature constant throughout the inspiratory limb of the ventilator circuit, minimizing condensation. Cooling of exhaled gas in the expiratory limb can cause condensation unless it also is heated.

RULES OF THUMB

Heated humidifiers should be set to deliver an inspired gas temperature of 34° C or greater but less than 41° C at the inspiratory limb near the Y adaptor during invasive mechanical ventilation. Gas temperatures in patients receiving noninvasive ventilation should be selected based on patient comfort, tolerance, adherence, and underlying pulmonary condition.

Unwanted levels of condensate can still occur with heated wires. Absorptive material in the inspiratory limb of the ventilator circuit acts as a wick warmed by the heated wire system (Fisher & Paykel Healthcare, Irvine, CA).

Use of heated wire circuits in neonates is complicated by the use of incubators and radiant warmers. Incubators provide a warm environment surrounding the infant and radiant warmers use radiant energy to warm objects that intercept radiant light. In both cases, a temperature probe placed in the heated environment would affect humidifier performance, resulting in reduced humidity received by the patient. Figure 38-11 shows the impact of temperature probe placement, in or out of the incubator, on absolute humidity delivered to the neonate. Consequently, temperature probes always should be placed outside of the radiant field or incubator (Figure 38-12).

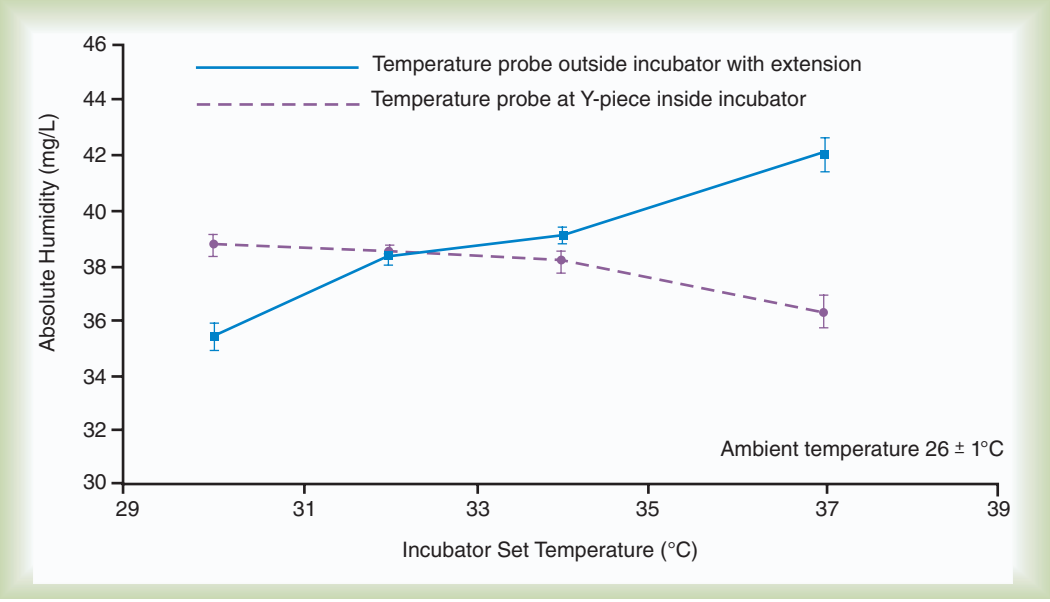

FIGURE 38-11 Humidity achieved at the Y-piece of a neonatal humidification system when used inside an incubator *(dotted line)* and outside or under an incubator *(solid line)*.

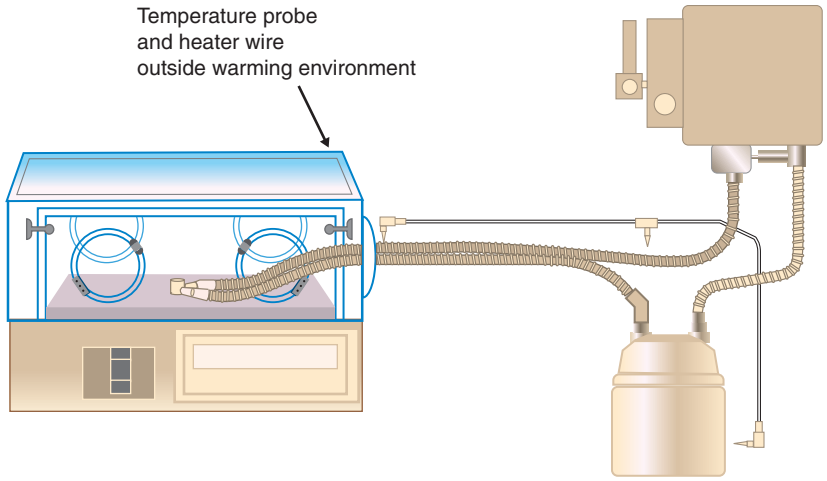

FIGURE 38-12 Neonatal breathing circuit configuration used with an incubator, with the temperature probe placed outside of the warming environment and an unheated portion of the inspiratory circuit delivering the gases to the Y-piece.

Cross Contamination

Aerosol and condensate from ventilator circuits are known sources of bacterial colonization.[46] However, advances in both circuit and humidifier technology have reduced the risk for nosocomial infection when these systems are used. Wick-type or membrane-type passover humidifiers prevent formation of bacteria-carrying aerosols. Heated wire circuits reduce production and pooling of condensate within the circuit. In addition, the high reservoir temperatures in humidifiers are bactericidal.[51] In ventilator circuits using wick-type humidifiers with heated wire systems, circuit contamination usually occurs from the patient to the circuit, rather than vice versa.

For decades, the traditional way to minimize the risk for circuit-related nosocomial infection in critically ill patients receiving ventilatory support was to change the ventilator tubing and its attached components daily.[52] It is now known that frequent ventilator circuit changes increase the risk for nosocomial pneumonia.[45] There is minimal risk for VAP with weekly circuit changes and there may be no need to change circuits at all unless visibly soiled.[35,36,53,54] In addition, substantial cost savings can accrue with decreased frequency of circuit changes.

Proper Conditioning of Inspired Gas

All respiratory therapists (RTs) are trained to measure patient inspired FiO_2 levels regularly and, in ventilatory care, to monitor selected pressures, volumes, and flows. However, few clinicians take the steps needed to ensure proper conditioning of the inspired gas received by patients.

The most accurate and reliable way to ensure that patients are receiving gas at the expected temperature and humidity level is to measure these parameters. Portable battery-operated digital **hygrometer**-thermometer systems are available for less than $300 and are invaluable in ensuring proper conditioning of the inspired gas. When measuring high-humidity environments, hygrometers become saturated and nonresponsive over time and so should be used for spot checks only.

Many heated wire humidification systems have a humidity control. This control does not reflect either absolute or relative humidity but only the temperature differential between the humidifier and the airway sensor. If the heated wires are set warmer than the humidifier, less relative humidity is delivered to the patient. To ensure that the inspired gas is being properly conditioned, clinicians always should adjust the temperature differential to the point at which a few drops of condensation form near the patient connection, or "wye." Lacking direct measurement of humidity, observation of this minimal condensate is the most reliable indicator that the gas is fully saturated at the specified temperature. If condensate cannot be seen, there is no way of knowing the level of relative humidity without direct measurement—it could be anywhere between 99% and 0%. HME performance can be evaluated in a similar manner.[55]

RULES OF THUMB

You can estimate whether an HME is performing well at the bedside by visually confirming condensation in the flex tube between the airway and HME. Lack of condensate may be a clue that humidification is inadequate and that alternative systems may be appropriate for use with the patient.

BLAND AEROSOL THERAPY

Humidity is simply water in the gas phase, whereas a bland aerosol consists of liquid particles suspended in a gas (see Chapter 39 for details on aerosol physics). Bland aerosol therapy involves the delivery of sterile water or hypotonic, isotonic, or hypertonic saline aerosols. Bland aerosol administration may be accompanied by O_2 therapy. To guide practitioners in applying this therapy, the AARC has published Clinical Practice Guideline: Bland Aerosol Administration; excerpts appear in Clinical Practice Guideline 38-2.[56]

38-2 Bland Aerosol Administration

AARC Clinical Practice Guideline (Excerpts)

INDICATIONS
- Presence of upper airway edema—cool, bland aerosol
- Laryngotracheobronchitis
- Subglottic edema
- Postextubation edema
- Postoperative management of the upper airway
- Presence of a bypassed upper airway
- Need for sputum specimens or mobilization of secretions

CONTRAINDICATIONS
- Bronchoconstriction
- History of airway hyperresponsiveness

HAZARDS AND COMPLICATIONS
- Wheezing or bronchospasm
- Bronchoconstriction when artificial airway is used
- Infection
- Overhydration
- Patient discomfort
- Caregiver exposure to airborne contagions produced during coughing or sputum induction
- Edema of the airway wall
- Edema associated with decreased compliance and gas exchange and with increased airway resistance
- Sputum induction by hypertonic saline inhalation can cause bronchoconstriction in patients with chronic obstructive pulmonary disease, asthma, cystic fibrosis, or other pulmonary diseases.

ASSESSMENT OF NEED
The presence of one or more of the following may be an indication for administration of a water or isotonic or hypotonic saline aerosol:
- Stridor
- Brassy, crouplike cough
- Hoarseness after extubation
- Diagnosis of laryngotracheobronchitis or croup
- History of upper airway irritation and increased work of breathing (e.g., smoke inhalation)
- Patient discomfort associated with airway instrumentation or insult
- Bypassed upper airway
- Need for sputum induction (e.g., *Pneumocystis* pneumonia or tuberculosis) is an indication for administration of hypertonic saline aerosol.

ASSESSMENT OF OUTCOME
With administration of water or hypotonic or isotonic saline, the desired outcome is one or more of the following:
- Decreased work of breathing
- Improved vital signs
- Decreased stridor
- Decreased dyspnea
- Improved arterial blood gas values
- Improved O_2 saturation, as indicated by pulse oximetry
- With administration of hypertonic saline, the desired outcome is a sputum sample that is adequate for analysis.

MONITORING
The extent of patient monitoring should be determined based on the stability and severity of the patient's condition:
- Patient subjective response—pain, discomfort, dyspnea, restlessness
- Heart rate and rhythm, blood pressure
- Respiratory rate, pattern, mechanics; accessory muscle use
- Sputum production—quantity, color, consistency, odor
- Skin color
- Breath sounds
- Pulse oximetry (if hypoxemia is suspected)
- Spirometry equipment (if adverse reaction is a concern)

From Kallstrom T, American Association for Respiratory Care: Clinical practice guideline: bland aerosol administration, 2003 revision and update. Respir Care 5:529–533, 2003.

Equipment

The equipment needed for bland aerosol therapy includes an aerosol generator and a delivery system. Devices used to generate bland aerosols include large-volume jet nebulizers and **ultrasonic nebulizers** (USNs). Delivery systems include various direct airway appliances and enclosures (mist tents).

Aerosol Generators

Large-Volume Jet Nebulizers. A large-volume jet nebulizer is the most common device used to generate bland aerosols. As depicted in Figure 38-13, these devices are pneumatically powered, attaching directly to a flowmeter and compressed gas source. Liquid particle aerosols are generated by passing gas at a high velocity through a small "jet" orifice. The resulting low pressure at the jet draws fluid from the reservoir up to the top of a siphon tube, where it is sheared off and shattered into liquid particles. The large, unstable particles fall out of suspension or impact on the internal surfaces of the device, including the fluid surface (**baffling**). The remaining small particles leave the nebulizer through the outlet port, carried in the gas stream. A variable air-entrainment port allows air mixing to increase flow rates and to alter FiO_2 levels (see Chapter 41).

Similar to humidifiers, if heat is required, a hot plate, wrap-around, yolk collar, or immersion element can be added. These devices rarely have sophisticated servo-controlled systems to control delivery temperature. They may not shut down when the reservoir empties, resulting in the delivery of hot, dry gas to the patient. Failure of the heating element also can cause a loss of heating capacity, without warning to the clinician.

Depending on the design, input flow, and air-entrainment setting, the total water output of unheated large-volume jet

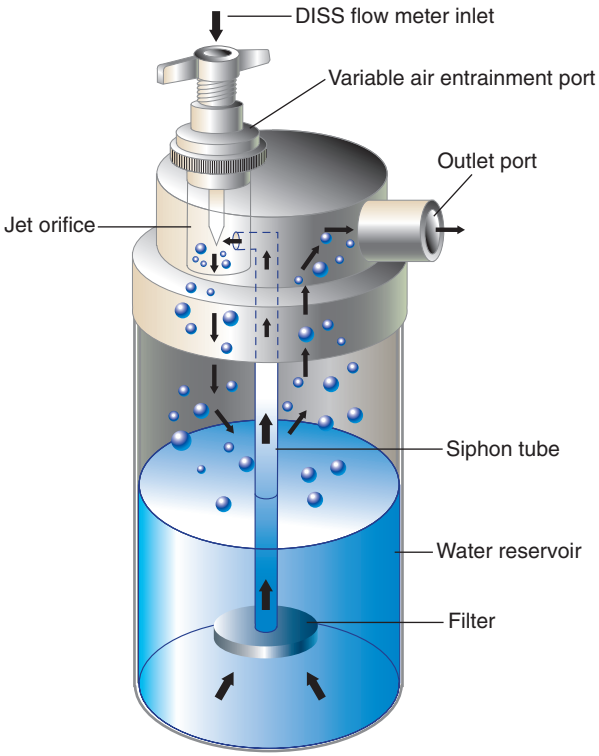

FIGURE 38-13 All-purpose large-volume jet nebulizer.

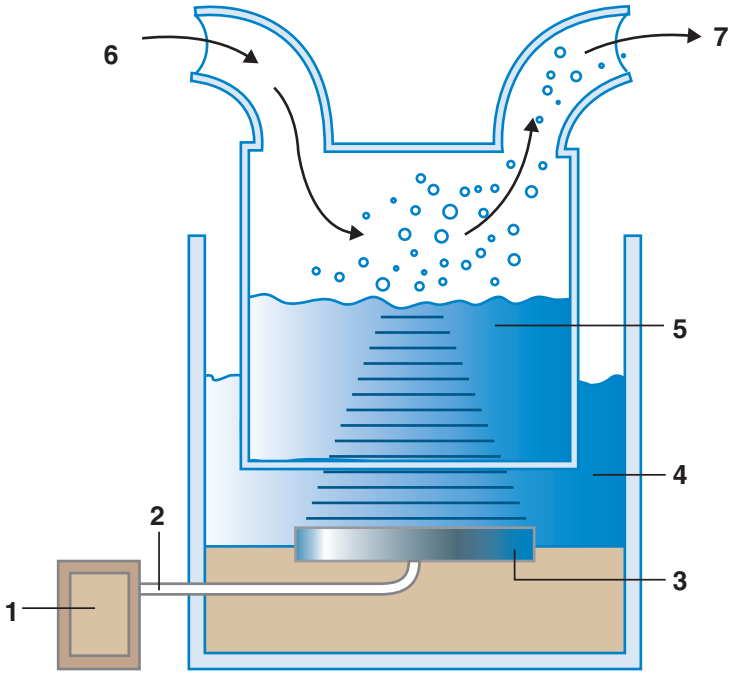

FIGURE 38-14 Functional schematic of a typical large-volume ultrasonic nebulizer. *1,* Radiofrequency generator; *2,* shielded cable; *3,* piezoelectric crystal transducer; *4,* water-filled couplant reservoir; *5,* solution chamber; *6,* chamber inlet; and *7,* chamber outlet. (Modified from Barnes TA: Core textbook for respiratory care practice, ed 2, St. Louis, 1994, Mosby.)

nebulizers varies between 26 mg H_2O/L and 35 mg H_2O/L. When heated, output increases to between 33 mg H_2O/L and 55 mg H_2O/L, mainly because of increased vapor capacity.[56,57] Larger versions of these devices (with 2-L to 3-L reservoirs) are used to deliver bland aerosols into mist tents. These enclosure systems can generate flow rates greater than 20 L/min, with water outputs of 5 ml/min (300 ml/hr). Because heat buildup in enclosures is a problem, these systems are always run unheated.

Ultrasonic Nebulizers. A USN is an electrically powered device that uses a **piezoelectric crystal** to generate aerosol. This crystal transducer converts radiowaves into high-frequency mechanical vibrations (sound). These vibrations are transmitted to a liquid surface, where the intense mechanical energy creates a cavitation in the liquid, forming a standing wave, or "geyser," that sheds aerosol droplets. Figure 38-14 provides a schematic of a large volume USN. Output from a radiofrequency generator is transmitted over a shielded cable to the piezoelectric crystal. Vibrational energy is transmitted either indirectly through a water-filled couplant reservoir or directly to a solution chamber. Gas entering the chamber inlet picks up the aerosol particles and exits through the chamber outlet.

The properties of the ultrasonic signal determine the characteristics of the aerosol generated by these nebulizers. The frequency at which the crystal vibrates, preset by the manufacturer, determines aerosol particle size. Particle size is inversely proportional to signal frequency. A USN operating at a frequency of 2.25 MHz may produce an aerosol with a mass median aerodynamic diameter (MMAD) of approximately 2.5 µm, whereas another nebulizer operating at 1.25 MHz produces an aerosol with MMAD between 4 and 6 µm. Signal amplitude directly affects the amount of aerosol produced; the greater the amplitude, the greater is the volume of aerosol output. In contrast to frequency, signal amplitude may be adjusted by the clinician.

Particle size and aerosol density delivered to the patient also are affected by the source and flow of gas through the aerosol-generating chamber. Some large-volume USNs have built-in fans that direct room air through the solution chamber conducting the aerosol to the patient. The airflow may be adjusted by changing the fan speed or use of a simple damper valve. Alternatively, compressed anhydrous gases can be delivered to the chamber inlet through a flowmeter. For precise control over delivered O_2 concentrations, clinicians can attach a flowmeter with an O_2 blender or air-entrainment system to the chamber inlet.

The flow and amplitude settings interact to determine aerosol density (mg/L) and total water output (ml/min). Amplitude affects water output. At a given amplitude setting, the greater the flow through the chamber, the less the density of the aerosol. Conversely, low flows result in aerosols of higher density. Total aerosol output (ml/min) is greatest when both flow and amplitude are set at the maximum. Using these settings, some units can achieve total water outputs of 7 ml/min.

Particle size, aerosol density, and output are also affected by the relative humidity of the carrier gas (see Chapter 39). In contrast to jet nebulizers, the temperature of the solution placed in a USN increases up to 10° C during use. Although this

increase in temperature affects water vapor capacity, its impact on aerosol output is minimal.

RULES OF THUMB

To produce a high-density aerosol using a USN (useful for sputum induction), set the amplitude high and the flow rate low. To maximize aerosol delivery per minute (when trying to help mobilize secretions), set the flow rate to match and slightly exceed patient inspiratory flow rate, and set the amplitude at the maximum.

Although USNs have some unique capabilities, in most cases of bland aerosol administration, their relative advantages over jet nebulizers are outweighed by their high cost and erratic reliability. Exceptions include the use of a USN for sputum induction, where the high output (1 to 5 ml/min) and aerosol density seem to yield higher quantity and quality of sputum specimens for analysis, although at some cost in increased airway reactivity.[58] Although a major manufacturer of USNs (DeVilbiss) discontinued their product line, other companies in both the United States and Europe still manufacture units for clinical use.

Commercially available USNs (usually marketed as "cool" mist devices) have found a place in the home, being used as room humidifiers. As with any nebulizer, the reservoirs of these devices can easily become contaminated, resulting in airborne transmission of pathogens. Care should be taken to ensure that these units are cleaned according to the manufacturer's recommendations and that water is discarded from the reservoir periodically between cleanings. In the absence of a manufacturer's recommendation, these units should undergo appropriate disinfection at least every 6 days.[59] Generally, passover and wick-type humidifiers present less risk than the USN as a room humidifier.

Airway Appliances

Airway appliances used to deliver bland aerosol therapy include the aerosol mask, face tent, T-tube, and tracheostomy mask (Figure 38-15). The aerosol mask and face tent are used for patients with intact upper airways. The T-tube is used for patients who are orally or nasally intubated or who have a tracheostomy. The tracheostomy mask is used only for patients who have a tracheostomy. In all cases, large-bore tubing is required to minimize flow resistance and prevent occlusion by condensate.

For short-term therapy to patients with intact upper airways, the aerosol mask is the device of choice. However, some patients cannot tolerate masks and may do better with a face tent. No data support preferential use of an open aerosol mask versus a face tent.

Although the T-tube is the most common application for tracheostomy patients, unless moderate to high FiO_2 levels are needed, a tracheostomy mask is a better choice. In contrast to T-tubes, tracheostomy masks exert no traction on the airway and they allow secretions and condensate to escape from the airway, reducing airway resistance.

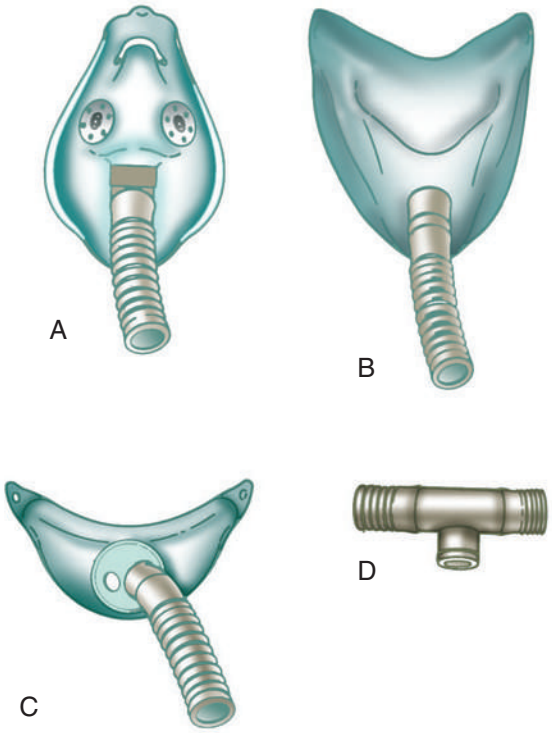

FIGURE 38-15 Airway appliances used to deliver bland aerosol therapy. *A,* Aerosol mask. *B,* Face tent. *C,* Tracheostomy mask. *D,* T-tube.

Enclosures (Mist Tents and Hoods)

Infants and small children may not readily tolerate direct airway appliances such as masks, so enclosures such as mist tents and aerosol hoods are used to deliver bland aerosol therapy to these patients. More recent studies have shown that aerosol hoods can provide aerosol delivery with similar efficiency to a properly fitted aerosol mask in infants, with less discomfort for the patient.[60]

Mist tents were used for more than 40 years mainly to treat croup and thus called *croup tents*. The cool aerosol provided through these enclosures promotes vasoconstriction, decreases edema, and reduces airway obstruction.

Any body enclosure poses two problems: carbon dioxide (CO_2) buildup and heat retention. CO_2 buildup can be reduced by providing sufficiently high gas flow rates. These high flows of fresh gas circulate continually through the enclosure and "wash out" CO_2 while helping maintain desired O_2 concentrations. Heat retention may be handled with high fresh gas flows to prevent heat buildup or use of a separate cooling device such as a simple ice compartment to cool the aerosol. The Ohmeda Ohio Pediatric Aerosol Tent (Ohmeda Ohio, Gurnee, IL) and other similar units use electrically powered refrigeration units to cool the circulating air.

The cooling produces a great deal of condensation, which must be drained into a collection bottle outside of the tent. Units such as the Mistogen CAM-3M (Mercury Medical, Clearwater, FL) have overcome some of these problems with a thermoelectric cooling system, in which an electrical current passing through a semiconductor augments heat absorption and release. As warm air is taken from the tent, heat is transferred and released in the room, and cool air is returned to the tent.

Sputum Induction

As a diagnostic procedure, sputum induction (Box 38-6) warrants separate attention from other modes of bland aerosol therapy. Sputum induction is a useful, cost-effective, and safe method for diagnosing tuberculosis, pneumocystis pneumonia (caused by *Pneumocystis jiroveci* [formerly *Pneumocystis carinii*]), and lung cancer.[61,62]

Sputum induction involves short-term application of high-density hypertonic saline (3% to 10%) aerosols to the airway to assist in mobilizing pulmonary secretions for evacuation and recovery. These high-density aerosols are often made using ultrasonic nebulization. Box 38-7 outlines a procedure for sputum induction using a 3% saline solution.[63]

To ensure a good sputum sample, every effort must be made to separate saliva from true respiratory tract secretions.[62] Some protocols have patients brush their teeth and tongue surface thoroughly and rinse their mouths before sputum induction. Although the distinction between saliva and sputum can be made in the diagnostic laboratory, care during the collection procedure reduces the need for repeat inductions.

Problem Solving and Troubleshooting

The most common problems with bland aerosol delivery systems are cross contamination and infection, environmental safety, inadequate mist production, overhydration, bronchospasm, and noise.

Box 38-6 Sputum-Induction Procedure

- Gather the necessary equipment: Ultrasonic nebulizer, aerosol mask, large-bore tubing, specimen container, 3% sterile saline, and stethoscope.
- Check the chart for order or protocol, diagnosis, history, and other pertinent information.
- Wash your hands and follow applicable standard, airborne, and tuberculosis precautions.
- Introduce yourself and identify your department, verify the patient's identity, and explain the procedure and verify that the patient understands it.
- Have the patient assume an upright, seated position if possible.
- Have the patient rinse his or her mouth with water, blow his or her nose, and clear any excess saliva.
- Perform pretreatment assessment, including vital signs, muscle tone, ability to cough, and auscultation.
- Assemble the nebulizer; fill the couplant chamber with tap water; plug the unit into a grounded electrical outlet; and attach the delivery tubing and mask.
- Aseptically fill the medication chamber of the nebulizer with 3% sterile saline.
- Turn the unit on and adjust the output control to achieve adequate flow and high density.
- Place the mask comfortably on the patient's face, and instruct the patient to take slow, deep breaths, with occasional inspiratory hold as tolerated.
- Periodically reassess the patient's condition (including breath sounds) throughout the application.
- Modify the technique and reinstruct the patient as needed, based on his or her response.
- Terminate the treatment after 15 to 30 minutes, if significant adverse reactions occur, or when sputum specimen has been obtained.
- Encourage the patient to cough and expectorate sputum into specimen cup; observe for volume, color, consistency, odor, and presence or absence of blood.
- Label the specimen container with patient identification and required information, and deliver to the appropriate personnel.
- Chart the therapy according to departmental and institutional protocol.
- Notify the appropriate personnel of any adverse reactions or other concerns.

Modified from Butler TJ: Laboratory exercises for competency in respiratory care, ed 2, Philadelphia, 2009, FA Davis.

Box 38-7 Monitoring

The humidifier should be inspected during the patient-ventilator system check, and condensate should be removed from the circuit as needed. HMEs should be inspected and replaced if secretions have contaminated the insert or filter. The following should be recorded during equipment inspection:

- *Humidifier settings*: During routine use on an intubated patient, a heated humidifier (HH) should be set to deliver inspired gas at 34° C or greater but less than 41° C at the Y adaptor in the circuit and should provide a minimum of 33 mg/L of water vapor.
- *Inspired gas temperature*: Inspired gas temperature should be monitored at or near the patient's airway opening (HH).
- *Location of probe:* For heated wire circuits used with infants, the probe must be placed outside the incubator or away from the radiant warmer.
- *Temperature:* High-temperature alarm should be set no higher than 41° C, and the low-temperature alarm should be set no lower than 2° C below the desired temperature at the circuit Y piece.
- *Water level and feed system:* Water level and function of automatic feed system (if applicable) should be monitored.
- *Quantity and consistency of secretions:* Quantity, consistency, and other characteristics of secretions should be noted and recorded. When using an HME, if secretions become copious or appear increasingly tenacious, an HH should replace the HME.
- *Airway obstruction:* The presence of copious secretions increases the resistance of airflow through the HME. This even may increase peak pressures and induce changes of the flow waveforms consistent with those observed with airway obstruction. If these changes persist after changing the HME because of copious secretions, an HH should be used instead.

Cross Contamination

Rigorous adherence to the infection control guidelines detailed in Chapter 4, especially guidelines covering solutions and equipment processing, should help minimize the cross contamination and infection risks involved in using these systems. In addition, the water should be changed regularly and the couplant compartments and nebulizer chambers of USNs should be disinfected or replaced regularly.

Environmental Exposure

Environmental safety issues from secondhand and exhaled aerosol arise mainly when aerosol therapy is prescribed for immunosuppressed patients or for patients with tuberculosis. A survey suggested that RTs may be at increased risk for developing asthma-like symptoms, attributed partly to secondhand exposure to aerosols such as ribavirin or albuterol.[64] To minimize problems in this area, all clinicians should strictly follow U.S. Centers for Disease Control and Prevention standards and airborne precautions, including precautions specified for control of exposure to tuberculosis (see Chapter 4). Additional methods for dealing with environmental control of drug aerosols are described in Chapter 39.

Inadequate Aerosol Output

Inadequate mist production is a common problem with all nebulizer systems. With pneumatically powered jet nebulizers, poor mist production can be caused by inadequate input flow of driving gas, siphon tube obstruction, or jet orifice misalignment. With the exception of inadequate driving gas flow, these problems require unit repair or replacement. If a USN is not functioning properly, the electrical power supply (cord, plug, and fuse or circuit breakers) should be checked first. The clinician next should check to confirm that (1) carrier gas is flowing through the device and (2) the amplitude, or output, control is set above minimum. If there is still no visible mist output, the clinician should inspect the couplant chamber to confirm proper fill level and the absence of any visible dirt or debris. Finally, the clinician must ensure that the couplant chamber solution meets the manufacturer's specifications (most units do not function properly with distilled water).

Overhydration

Overhydration is a problem with continuous use of heated jet nebulizers and USNs. With USNs capable of such extraordinarily high water outputs, they should never be used for continuous therapy. The risk for overhydration is highest for infants, small children, and patients with preexisting fluid or electrolyte imbalances. Even if used only to meet BTPS conditions, bland aerosol therapy effectively eliminates insensible water loss through the lungs and should be equated to a daily water gain (approximately 200 ml/day for an average adult). In addition to overhydration of the patient, inspissated pulmonary secretions can swell after high-density aerosol therapy, worsening airway obstruction. Careful patient selection and monitoring can prevent most potential problems with overhydration. Box 38-6 Lists variables that should be recorded during inspection and monitoring of humidification devices.

Bronchospasm

Bland water aerosols are irritating and can cause bronchospasm in some patients. Ultrasonic nebulization of distilled water is used in some pulmonary function laboratories to provoke bronchospasm and to assess bronchial hyperactivity.[63] Always carefully review the patient's history and diagnosis before administering any bland aerosol, especially a hypotonic water solution. As indicated in the AARC practice guideline (see Clinical Practice Guideline 38-2), patients receiving continuous bland aerosol therapy should be initially monitored carefully (including breath sounds and subjective response) and reevaluated every 8 hours or with any change in clinical condition.[56] If bronchospasm occurs during therapy, treatment must be stopped immediately, O_2 provided, and appropriate bronchodilator therapy initiated as soon as possible. If the physician still requests bland aerosol therapy, pretreatment with a bronchodilator may be needed. Isotonic solutions (0.9% saline) may be better tolerated by these patients than water.

A problem unique to large-volume, air-entrainment jet nebulizers is the noise they generate, especially at high flows. The American Academy of Pediatrics recommends that sound levels remain less than 58 dB to avoid hearing loss for infants being cared for in incubators and O_2 hoods. Because many commercial nebulizers exceed this noise level when in operation, careful selection of equipment is necessary. However, the best way to avoid this problem and minimize infection risks further is to use heated passover humidification instead of nebulization.

SELECTING THE APPROPRIATE THERAPY

Figure 38-16 provides a basic algorithm for selecting or recommending the appropriate therapy to condition a patient's inspired gas. Key considerations include (1) gas flow, (2) presence or absence of an artificial tracheal airway, (3) character of the pulmonary secretions, (4) need for and expected duration of mechanical ventilation, and (5) contraindications to using an HME.

Regarding delivery of O_2 to the upper airway, the American College of Chest Physicians advises against using a bubble humidifier at flow O_2 rates of 4 L/min or less.[65] For the occasional patient who complains of nasal dryness or irritation when receiving low-flow O_2, a humidifier should be added to the delivery system. Conversely, the relative inefficiency of unheated bubble humidifiers means that the clinician may need to consider heated humidification for patients receiving long-term O_2 at high flow rates (>10 L/min without air entrainment).

HMEs provide an inexpensive alternative to heated humidifiers when used for ventilation of patients who do not have complex humidification needs. However, passive HMEs may not provide sufficient heat or humidification for long-term management of certain patients. When an HME is to be used, it should be selected based on individual patient need and

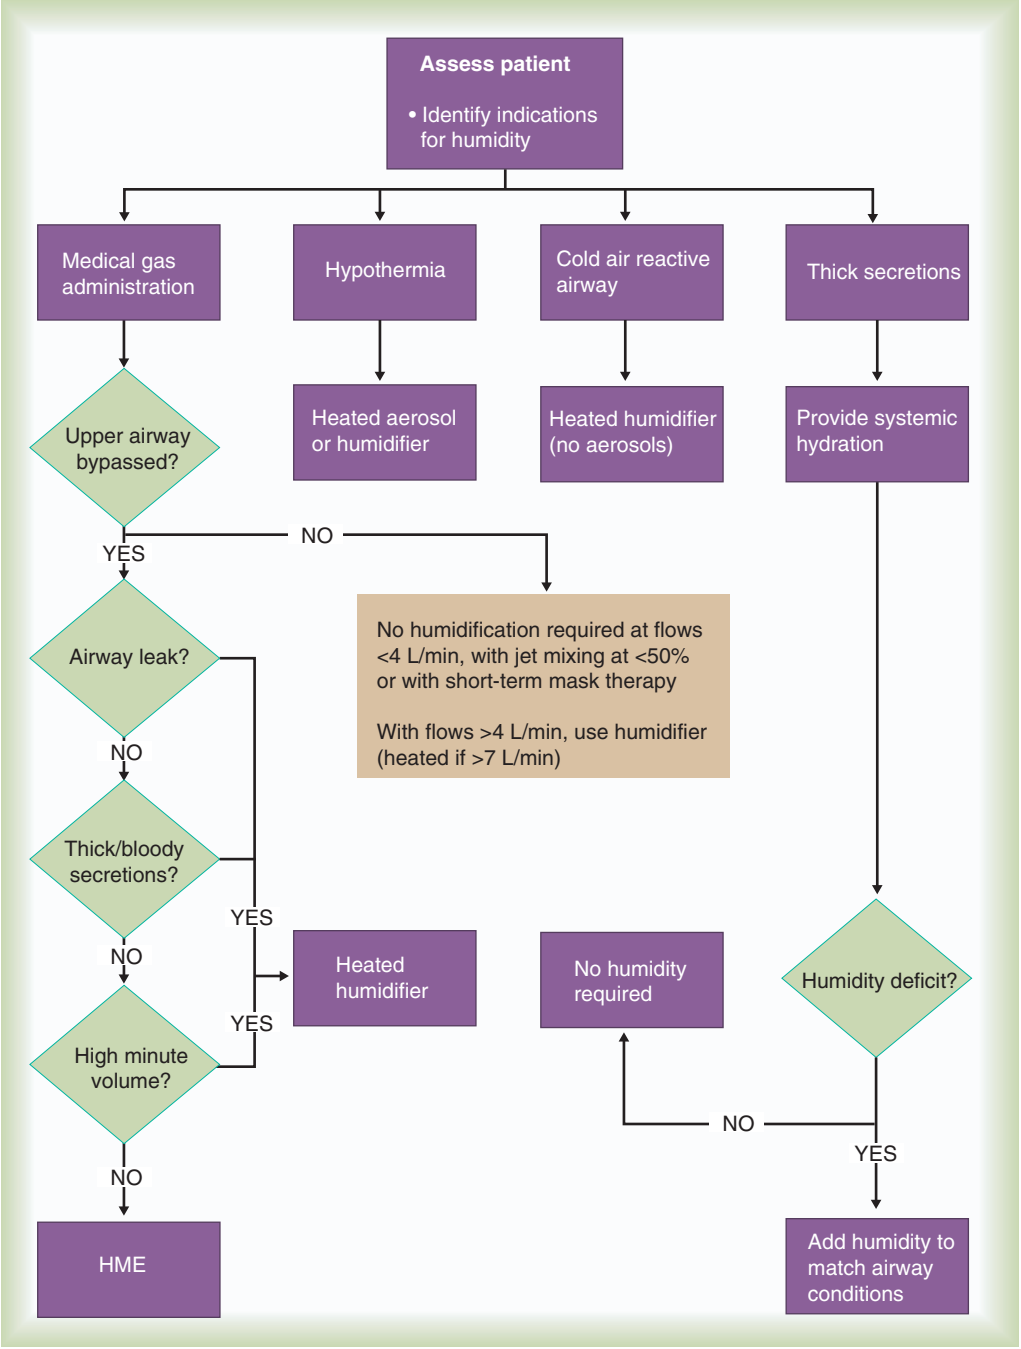

FIGURE 38-16 Selection algorithm for humidity and bland aerosol therapy. *HME,* Heat and moisture exchanger.

ventilatory pattern and the unit's performance, efficiency, and size. All patients using HMEs should be reevaluated regularly to confirm the appropriateness of continued use.

RULES OF THUMB

HMEs are better suited for short-term use and during transport, and heated humidifiers should be used for patients requiring long-term mechanical ventilation (>96 hours) or for patients for whom HME use is contraindicated.

MINI CLINI

Cost-Effectiveness of Humidification Systems

PROBLEM: There is a lot of controversy over which is more cost-effective—heated water humidifiers or HMEs. How can the cost of passover humidifiers, with standard circuit and heated wire circuits, be compared with the cost of HMEs?

SOLUTION: First, determine the frequency of circuit setup and component changes for each type of humidification system. Second, determine supplies and time required to set up the system and operate the system on a daily basis.

The following table compares illustrative costs associated with three humidification strategies in terms of circuit setup costs, water usage, and labor for a typical patient requiring 12 days of mechanical ventilation at a large, comprehensive acute care hospital. Labor costs were calculated as the time required to perform setup or maintenance multiplied by the average salary. This example assumes no circuit changes for a patient over 14 days and that the HME is changed daily.

Components of Circuit Setup and Operating Costs	Heated Humidifier With Standard Circuit	Heated Humidifier With Heated Wire Circuit	Heat Moisture Exchanger
Vent circuit	$3.00	$11.00	$3.00
Humidifier/water feed system	$12.00	$12.00	—
HME filter	—	—	$5.00
Setup cost (labor)	$18.00	$23.00	$8.00
Daily cost (labor)	$11.00	$1.50	$5.00
Total costs (5 days)	$62.00	$29.00	$28.00
Total costs (12 days)	$139.00	$39.50	$63.00

In this example, the standard circuit costs less than the heated wire circuit but has twice the daily water usage, with an additional labor cost of $9.50 per day for adding and removing water from the system. The HME has the lowest setup cost, but after ventilator day 5, total costs of daily filter replacement exceed the cost associated with operation of the heated wire circuit. However, most modern ventilator humidification systems require the purchase of their prepackaged water. This can markedly increase the cost of both unheated and heated wire circuits. Although different component costs may shift the analysis, in general there is not a significant cost difference associated with the use of HME, unheated wire, and heated wire systems. The decision to use each is generally based on the clinical needs of the patient.

SUMMARY CHECKLIST

- Conditioning of inhaled and exhaled gas is accomplished primarily by the nose and upper airway. Bypassing the upper airway without providing similar levels of heat and humidity to inhaled gas can cause damage to the respiratory tract.
- Gases delivered to the nose and mouth should be conditioned to 20° C to 22° C with 10 mg/L water vapor (50% relative humidity).
- When being delivered to the trachea, gases should be warmed and humidified to 32° C to 40° C with 36 to 40 mg/L water vapor (>90% relative humidity).
- A humidifier is a device that adds invisible molecular water to gas.
- A nebulizer generates and disperses liquid particles in a gas stream.
- Water vapor cannot carry pathogens, but aerosols and condensate can carry pathogens.
- Temperature is the most important factor affecting humidifier output. The higher the temperature, the greater is the water vapor content of the delivered gas.
- Bubble humidifiers, passover humidifiers, wick humidifiers, and HMEs are the major types of humidifiers. Active humidifiers incorporate heating devices and reservoir and feed systems.
- At high flow rates, some bubble humidifiers can produce microaerosol particles, which can carry infectious bacteria.
- Most HMEs are passive, capturing both heat and moisture from expired gas and returning it to the patient, at approximately 70% efficiency. HMEs are not recommended for use with infants because of the increased mechanical dead space and use of uncuffed ETTs, which allow some exhaled gas to bypass the HME.
- Common problems with humidification systems include condensation, cross contamination, and ensuring proper conditioning of the inspired gas.
- Breathing circuit condensate must always be treated as infectious waste.
- Bland aerosol therapy with sterile water or saline is used to (1) treat upper airway edema, (2) overcome heat and humidity deficits in patients with tracheal airways, and (3) help obtain sputum specimens.
- Large-volume jet nebulizers and USNs are used to generate bland aerosols. Delivery systems include various direct airway appliances and mist tents.
- Common problems with bland aerosol therapy are cross contamination and infection, environmental safety, inadequate mist production, overhydration, bronchospasm, and noise.

CHAPTER 39

Aerosol Drug Therapy

JAMES B. FINK AND ARZU ARI

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Define the term *aerosol*.
- Describe how particle size, motion, and airway characteristics affect aerosol deposition.
- Describe how aerosols are generated.
- List the hazards associated with aerosol drug therapy.
- Describe how to select the best aerosol drug delivery system for a patient.
- Describe how to initiate and modify aerosol drug therapy.
- State the information patients need to know to self-administer drug aerosol therapy properly.
- Describe how to assess patient response to bronchodilator therapy at the point of care.
- Describe how to apply aerosol therapy in special circumstances.
- Describe how to protect patients and caregivers from exposure to aerosolized drugs.

CHAPTER OUTLINE

KEY TERMS

aerosol
aerosol output
aging
atomizer
baffle
breath-actuated nebulizer
breath-enhanced nebulizer
chlorofluorocarbons (CFCs)
deposition
emitted dose
fine-particle fraction
geometric standard deviation (GSD)
heterodisperse
hydrofluoroalkane (HFA)
hygroscopic
inertial impaction
inhaled mass
mass median aerodynamic diameter (MMAD)
monodisperse
nebulizer
propellant
residual drug volume
respirable mass
scintigraphy
sedimentation
therapeutic index
volume median diameter (VMD)

An **aerosol** is a suspension of solid or liquid particles in gas. Aerosols occur in nature as pollens, spores, dust, smoke, smog, fog, and mist.[1] The upper airway and respiratory tract filter out larger particles to protect the lungs from invasion by these aerosols. In the clinical setting, medical aerosols are generated with **atomizers**, **nebulizers**, and inhalers. Aerosols can be used to deliver bland water solutions to the respiratory tract (see Chapter 38) or to administer drugs to the lungs, throat, or nose for local and systemic effect. This chapter focuses on the principles of medical aerosol drug therapy.

The aim of aerosol therapy is to deliver a therapeutic dose of the selected agent (drug) to the desired site of action (nose, throat, airways, or deep lung). The indication for any specific aerosol is based on the need for the specific drug.[1] Administration of drugs by aerosol offers higher local drug concentrations in the lung with lower systemic levels compared with other forms of administration. Improved therapeutic action with fewer systemic side effects provides a higher **therapeutic index**.[2]

CHARACTERISTICS OF THERAPEUTIC AEROSOLS

Effective use of medical aerosols requires an understanding of the characteristics of aerosols and their effect on drug delivery to the desired site of action. Key concepts include aerosol output, particle size, deposition, and changes in the aerosol over time (*aging*).

Aerosol Output

Aerosol output is the mass of fluid or drug produced by an aerosol generator. Output is described as the mass of drug or liquid emitted (leaving) from the aerosol generator. For nebulizers the output rate is the mass of aerosol generated per unit of time. Output varies greatly among different nebulizers and inhalers. For drug delivery systems, **emitted dose** describes the mass of drug leaving the mouthpiece of a nebulizer or inhaler as aerosol.

Aerosol output can be measured by collecting the aerosol that leaves the nebulizer on filters and measuring either their weight (gravimetric analysis) or quantity of drug (assay). Gravimetric measurements of aerosols are easier but less reliable than drug assay techniques because weight changes with water evaporation while drug mass does not. A drug assay provides the most reliable measure of aerosol output.

A large proportion of particles that leave a nebulizer may never reach the lungs. The ability of aerosols to travel through the air, enter the airways, and become deposited in the lungs is based on numerous variables ranging from particle size to breathing pattern. Understanding and skillful manipulation of these variables can greatly improve pulmonary delivery of aerosols.

Particle Size

Aerosol particle size depends on the substance for nebulization, the method used to generate the aerosol, and the environmental conditions surrounding the particle.[3] It is impossible to determine visually whether a nebulizer is producing an optimal particle size. The unaided human eye cannot see particles less than 50 to 100 μm in diameter (equivalent to a small grain of sand). The only reliable way to determine the characteristics of an aerosol suspension is laboratory measurement. The two most common laboratory methods used to measure medical aerosol

particle size distribution are cascade impaction and laser diffraction. *Cascade impactors* are designed to collect aerosols of different size ranges on a series of stages or plates. The mass of aerosol deposited on each plate is quantified by drug assay, and a distribution of drug mass across particle sizes is calculated. In *laser diffraction,* a computer is used to estimate the range and frequency of droplet volumes crossing the laser beam.

Because medical aerosols contain particles of many different sizes (**heterodisperse**), the average particle size is expressed with a measure of central tendency, such as **mass median aerodynamic diameter (MMAD)** for cascade impaction or **volume median diameter (VMD)** for laser diffraction. These measurement techniques of the same aerosol may report different sizes, so it is important to know which measurement is used. The MMAD and VMD both describe the particle diameter in micrometers (μm). In an aerosol distribution with a specific MMAD, 50% of the particles are smaller and have less mass, and 50% are larger and have greater mass.

The **geometric standard deviation (GSD)** describes the variability of particle sizes in an aerosol distribution set at 1 standard deviation above or below the median (15.8% and 84.13%). Most aerosols found in nature and used in respiratory care are composed of particles of different sizes, described as heterodisperse. The greater the GSD, the wider the range of particle sizes, and the more heterodisperse the aerosol. Aerosols consisting of particles of similar size (GSD ≤1.2) are referred to as **monodisperse**. Nebulizers that produce monodisperse aerosols are used mainly in laboratory research and in nonmedical industries.

Deposition

When aerosol particles leave suspension in gas, they deposit on (attach to) a surface. Only a portion of the aerosol generated and emitted from a nebulizer (emitted dose) may be inhaled (inhaled dose). A fraction of the inhaled dose is deposited in the lungs (respirable dose). **Inhaled mass** is the amount of drug inhaled. The proportion of the drug mass in particles that are small enough **(fine-particle fraction)** to reach the lower respiratory tract is the **respirable mass**. Not all aerosol particles delivered to the lung are retained, or deposited. A small percentage (1% to 5%) of inhaled drug may be exhaled. Whether aerosol particles that are inhaled into the lung are deposited in the respiratory tract depends on the size, shape, and motion of the particles and on the physical characteristics of the airways and breathing pattern. Key mechanisms of aerosol **deposition** include inertial impaction, gravimetric sedimentation, and brownian diffusion.[1,3]

Inertial Impaction

Inertial impaction occurs when suspended particles in motion collide with and are deposited on a surface; this is the primary deposition mechanism for particles larger than 5 μm. The greater the mass and velocity of a moving object, the greater its inertia, and the greater the tendency of that object to continue moving along its set path (Figure 39-1). When a particle of sufficient (large) mass is moving in a gas stream and that stream changes direction, the particle tends to remain on its initial path and collide with the airway surface.

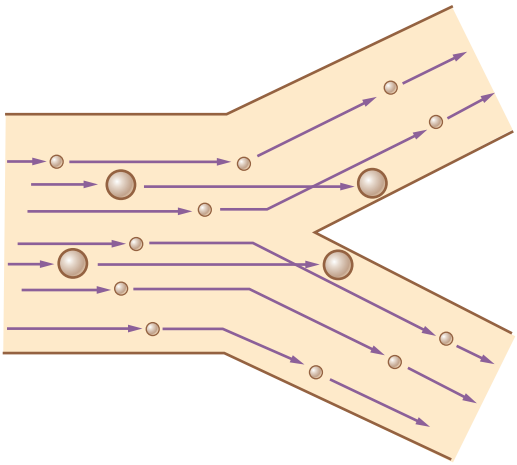

FIGURE 39-1 Inertial impaction of large particles, the masses of which tend to maintain their motion in straight lines. As airway direction changes, the particles are deposited on nearby walls. Smaller particles are carried around corners by the airstream and fall out less readily.

Because inertia involves both mass and velocity, the higher the flow of a gas stream, the greater the tendency for particles to impact and be deposited in the airways. Turbulent flow patterns, obstructed or tortuous pathways, and inspiratory flow rates greater than 30 L/min are associated with increased inertial impaction. Turbulent flow and convoluted passageways in the nose cause most particles larger than 10 μm to impact and become deposited. This process produces an effective filter that protects the lower airway from particulates such as dust and pollen. However, particles 5 to 10 μm tend to become deposited in the oropharynx and hypopharynx, especially with the turbulence created by the transition of air as it passes around the tongue and into the larynx.

Sedimentation

Sedimentation occurs when aerosol particles settle out of suspension and are deposited owing to gravity. The greater the mass of the particle, the faster it settles (Figure 39-2). During normal breathing, sedimentation is the primary mechanism for deposition of particles 1 to 5 μm. Sedimentation occurs mostly in the central airways and increases with time, affecting particles 1 μm in diameter. Breath holding after inhalation of an aerosol increases the residence time for the particles in the lung and enhances distribution across the lungs and sedimentation. A 10-second breath hold can increase aerosol deposition 10% and increase the ratio of aerosol deposited in lung parenchyma to central airway by fourfold.[4]

Diffusion

Brownian diffusion is the primary mechanism for deposition of small particles (<3 μm), mainly in the respiratory region where bulk gas flow ceases and most aerosol particles reach the alveoli by diffusion. These aerosol particles have very low mass and are

easily bounced around by collisions with carrier gas molecules. These random molecular collisions cause some particles to contact and become deposited on surrounding surfaces. Particles 1 to 0.5 μm are so stable that most remain in suspension and are cleared with the exhaled gas, whereas particles smaller than 0.5 μm have a greater retention rate in the lungs.

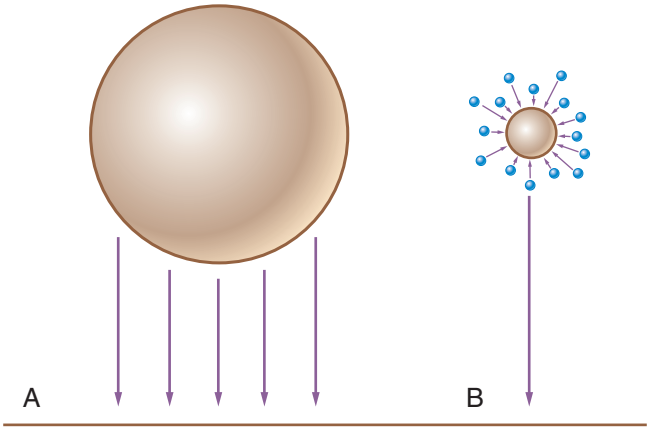

FIGURE 39-2 Effect of mass on particle size. Large particles **(A)** are more susceptible to the force of gravity than smaller particles **(B),** which are more affected by the bombardment of molecules deposited by diffusion.

Figure 39-3 summarizes the relationships between particle size and aerosol deposition in the respiratory tract. The depth of penetration and deposition of a particle in the respiratory tract tend to vary with size and tidal volume (V_T).[5] With this knowledge, it may be possible to target aerosol deposition to specific areas of the lung by using the proper particle size and breathing pattern.

RULE OF THUMB

The site of deposition in the respiratory tract varies with the size of the particle. Use of nebulizers that produce particles in a specific size range improves the targeting of aerosols for deposition to a desired site in the respiratory tract, as follows:

Desired Location	Recommended MMAD
Upper airway: nose, larynx, trachea	5 to >50 μm
Lower airways	2 to 5 μm
Parenchyma: alveolar region	1 to 3 μm
Parenchyma	<0.1 μm

Aging

Aerosols are dynamic suspensions. Individual particles constantly grow, shrink, coalesce, and fall out of suspension. The

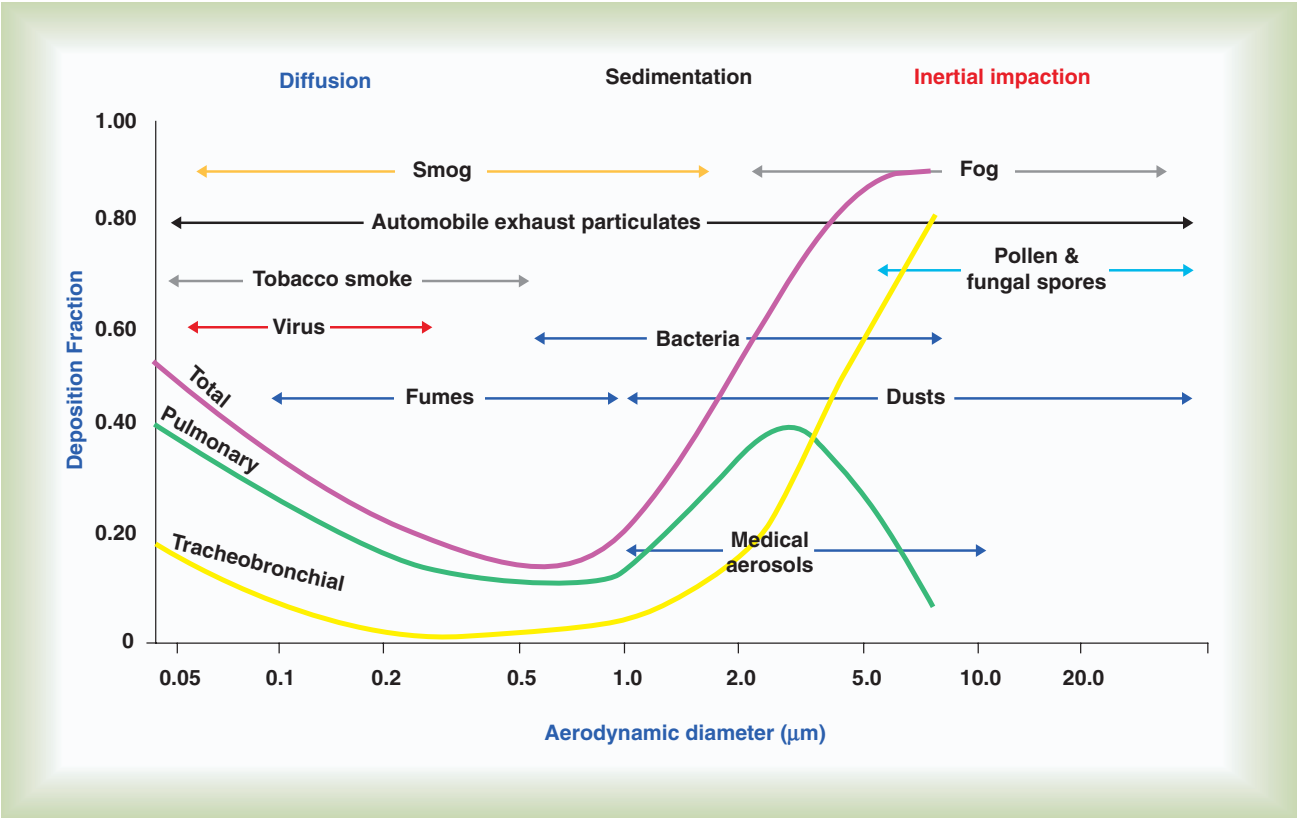

FIGURE 39-3 Range of particle size for common aerosols in the environment and the influence of inertial impactions, sedimentation, and diffusion. (Modified from Yu CP, Nicolaides P, Soong TT, et al: Effect of random airway sizes on aerosol deposition. Am Ind Hyg Assoc J 40:999, 1979.)

process by which an aerosol suspension changes over time is called **aging**. How an aerosol ages depends on the composition of the aerosol, the initial size of its particles, the time in suspension, and the ambient conditions to which it is exposed.

Aerosol particles can change size as a result of either evaporation or **hygroscopic** water absorption. The relative rate of particle size change is inversely proportional to the size of a particle, so small particles grow or shrink faster than large particles. Small water-based particles shrink when exposed to relatively dry gas. Aerosols of water-soluble materials, especially salts, tend to be hygroscopic, absorbing water and growing when introduced into a high-humidity environment.[5]

Particle size is not the only determinant of deposition. Inspiratory flow rate, flow pattern, respiratory rate, inhaled volume, ratio of inspiratory time to expiratory time (I : E ratio), and breath holding all influence where a particle of any specific size is deposited. The presence of airway obstruction is one of the greatest factors influencing aerosol deposition. It has been shown that total pulmonary deposition is greater in smokers and patients with obstructive airway disease than in healthy persons (Figure 39-4). Similarly, when inspiratory flow rates are constant, the deposition fraction of monodisperse aerosols increases with increased V_T, length of inspiration, and particle size (Figure 39-5).

These dynamic variables make it difficult to predict exactly what occurs to aerosol particles when they enter a gas stream and are inhaled. For this reason, prediction of actual aerosol deposition for an individual patient is difficult.

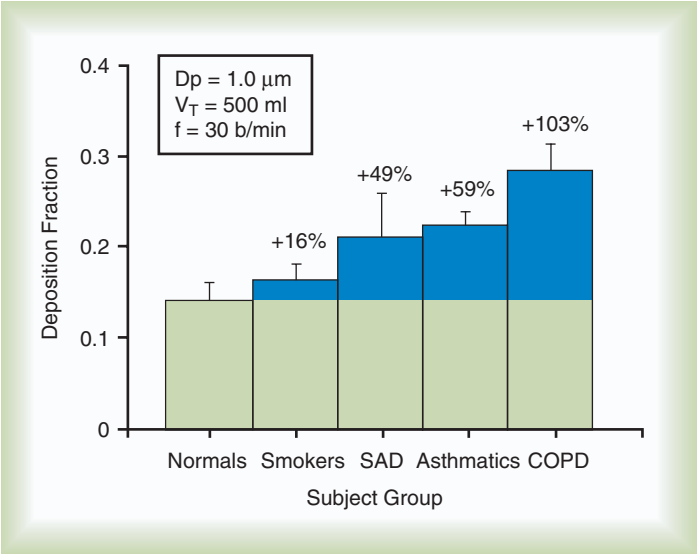

FIGURE 39-4 Total lung deposition of a fine aerosol of particles 1 µm in diameter in healthy adults and in subjects with obstructive airway disease. Numbers over the bar indicate the percentage increase above normal value. *COPD,* Patients with chronic obstructive pulmonary disease; *Dp,* particle diameter; *SAD,* smoker with symptoms of small airways disease; *f,* respiratory rate; V_T, tidal volume. (Modified from Kim CS: Methods of calculating lung delivery and deposition of aerosol particles. Respir Care 45:695, 2000.)

Quantifying Aerosol Delivery

As mentioned in the preceding sections, many characteristics of aerosols can account for the variances in quantity of aerosolized medication delivered to the patient. Although the precise amount of drug delivered to the patient's airways can be difficult to determine, it can be measured in terms of the patient's clinical response to aerosol drug therapy, including the desired therapeutic effects and any unwanted adverse effects. The amount of aerosol deposited to a patient's airways can be quantified using specialized equipment and tests.

One approach used to quantify aerosol deposition (in vivo) involves **scintigraphy**, in which a drug is "tagged" with a radioactive substance (e.g., technetium), aerosolized, and inhaled. A scanner (similar to scanners used in nuclear medicine) measures the distribution and intensity of radiation across the device and the patient's head and thorax. The result is a radiation map of aerosol deposition in the upper airway, the lungs (central and peripheral airways), and the stomach. This information is used to calculate the percentage of drug retained by the device and delivered to various areas in the patient.[6]

A less direct approach relates the systemic pharmacokinetic profile of a drug delivered by aerosol to an assay of the drug in a patient's blood or urine over time. This method does not estimate actual lung delivery, but it provides insight into systemic drug levels achieved after aerosol administration. Care must be taken to differentiate drug absorbed through the lungs from drug absorbed through the gastrointestinal tract. Simple laboratory, or in vitro, models, which simulate a range of V_T values, inspiratory flow rates, I : E ratios, and respiratory rates, have been useful in predicting inhaled mass of drug and relative performance of nebulizers.[7]

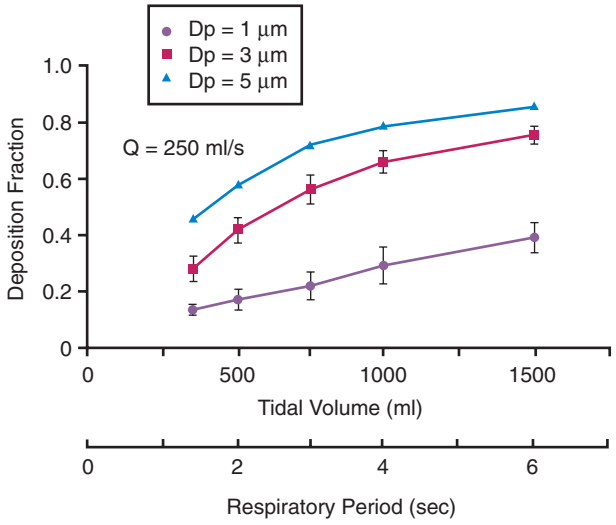

FIGURE 39-5 Total lung deposition versus V_T and respiratory time at a fixed flow: respiratory flow (Q) = 250 ml/sec. *Dp,* Particle diameter. (Modified from Kim CS: Methods of calculating lung delivery and deposition of aerosol particles. Respir Care 45:695, 2000.)

HAZARDS OF AEROSOL THERAPY

The primary hazard of aerosol drug therapy is an adverse reaction to the medication being administered (see Chapter 35). Other hazards to the patient include infection, airway reactivity, systemic effects of bland aerosols, drug concentration, and eye irritation. Care providers and bystanders risk these hazards as a result of exposure to secondhand aerosol drugs.

Infection

Aerosol generators can contribute to nosocomial infections by spreading bacteria by the airborne route.[8] The most common sources of bacteria are patient secretions, contaminated solutions (i.e., multiple-dose drug vials), and caregivers' hands. Offending organisms are primarily gram-negative bacilli, in particular, *Pseudomonas aeruginosa* and *Legionella pneumophila* (the cause of the highly virulent legionnaires' disease).[9]

Various procedures can help reduce contamination and infection associated with respiratory care equipment. Guidelines from the U.S. Centers for Disease Control and Prevention (CDC) state that nebulizers should be sterilized between patients, frequently replaced with disinfected or sterile units, or rinsed with sterile water (not tap water) and air dried every 24 hours (see Chapter 4). In addition, some recommend one nebulizer for one treatment. The cystic fibrosis foundation recommends that standard small volume nebulizers should be discarded after each treatment to prevent infection in cystic fibrosis patients.

Airway Reactivity

Cold air and high-density aerosols can cause reactive bronchospasm and increased airway resistance, especially in patients with preexisting respiratory disease.[10] Medications such as acetylcysteine, antibiotics, steroids, cromolyn sodium, ribavirin, and distilled water have been associated with increased airway resistance and wheezing during aerosol therapy. Administration of bronchodilators before or with administration of these agents may reduce the risk or duration of increased airway resistance.

The risk of inducing bronchospasm always should be considered when aerosols are administered. Monitoring for reactive bronchospasm should include auscultation for adventitious breath sounds; observation of the patient's breathing pattern and overall appearance before and after therapy; and, most essential, communicating with the patient during therapy to determine the perceived work of breathing.

Pulmonary and Systemic Effects

Pulmonary and systemic effects are associated with the site of delivery and the drug being administered. Preliminary assessment should balance the need versus the risk of aerosol therapy, especially among patients at high risk, such as infants, patients who are prone to fluid and electrolyte imbalances, and patients with atelectasis or pulmonary edema. For patients unable to clear their own secretions, suctioning or other airway clearance techniques may be indicated as an adjunct to aerosol therapy. Care must be taken to ensure that patients are capable of clearing secretions when the secretions are mobilized by aerosol therapy. Appropriate airway clearance techniques should accompany any aerosol therapy designed to help mobilize secretions (see Chapter 43).

Drug Concentration

During nebulization, the evaporation, heating, baffling, and recycling of drug solutions undergoing jet or ultrasonic nebulization increase solute concentrations.[11] This process can expose the patient to increasingly higher concentrations of the drug over the course of therapy and result in a larger concentration of drug remaining in the nebulizer at the end of therapy. This increase in concentration usually is time-dependent; the greatest effect occurs when nebulization of medications occurs over extended periods, as in continuous aerosol drug delivery.

Eye Irritation

Aerosol administration via a face mask may deposit drug in the eyes and cause eye irritation. In very rare cases, anticholinergic medications (see Chapter 35) have been suspected to worsen preexisting eye conditions, such as forms of glaucoma. Caution should be exercised when a face mask is used during aerosol drug therapy. In addition, special mask designs that have been shown to reduce drug deposition in the eyes or mouthpieces should be considered for at-risk patients.[12,13]

Secondhand Exposure to Aerosol Drugs

Workplace exposure to aerosols may be detectable in the plasma of bystanders and health care providers. Repeated secondhand exposure to bronchodilators is associated with increased risk of occupational asthma. Institutions should develop and implement an occupational health and safety policy to minimize the risk of secondhand aerosol exposure for care providers and bystanders.[14-16] Implementation of an occupational health and safety policy could include using systems that introduce less aerosol to the atmosphere (pressurized metered dose inhalers [pMDIs], dry powder inhalers [DPIs], and breath-actuated nebulizers), filtering exhalation to contain aerosol, and using environmental controls. Unless filters are placed in the expiratory limb, 40% of aerosols produced during mechanical ventilation are exhausted to the air of the intensive care unit.[17]

AEROSOL DRUG DELIVERY SYSTEMS

Effective aerosol therapy requires a device that quickly delivers sufficient drug to the desired site of action with minimal waste and at a low cost.[18] Aerosol generators in use include pMDIs with or without spacers or VHCs, DPIs, small and large volume (jet) nebulizers, hand-bulb atomizers (including nasal spray pumps), ultrasonic nebulizers (USNs), and vibrating mesh (VM) nebulizers as well as numerous emerging technologies.[2]

Pressurized Metered Dose Inhalers

The pMDI is the most commonly prescribed method of aerosol delivery in the United States. The pMDI is portable, compact,

and easy to use and provides multidose convenience. A uniform dose of drug is dispensed within a fraction of a second after actuation and is reproducible throughout the canister life. The pMDI and actuator are designed for the specific drug formulation and dose volume to be delivered. The pMDI is used to administer bronchodilators, anticholinergics, and steroids. More formulations of these drugs are available for use by pMDIs than for use with nebulizers. When properly used, pMDIs are at least as effective as other nebulizers for drug delivery. For this reason, pMDIs often are the preferred method for delivering bronchodilators to spontaneously breathing patients and patients who are intubated and undergoing mechanical ventilation.[19,20]

Although pMDIs have a relatively easy-to-use design, patients commonly misuse them during therapy. Most pMDIs are "press and breathe," but there is increasing presence of a variation known as *breath-actuated pMDIs*. The basic components of pMDI are similar regardless of type, manufacturer, or active ingredient; commonly used pMDIs are shown in Figure 39-6.

FIGURE 39-6 Examples of commonly used pMDIs. **A,** Albuterol inhaler **B,** The ASMANEX TWISTHALER. (**A,** Courtesy Hemera, Thinkstock. **B,** Reproduced with permission of Schering Corporation, subsidiary of Merck & Co. All rights reserved. ASMANEX and TWISTHALER are registered trademarks of Schering Corporation.)

The pMDI appears to be a simple device, but it represents sophisticated technology and engineering. A pMDI is a pressurized canister that contains the prescribed drug (a micronized powder or aqueous solution) in a volatile **propellant** combined with a surfactant and dispersing agent (Figure 39-7). When the canister is inverted (nozzle down) and placed in its actuator, or "boot," the volatile suspension fills a metering chamber that controls the amount of drug delivered. Pressing down on the canister aligns a hole in the metering valve with the metering chamber. The high propellant vapor pressure quickly forces the metered dose out through this hole and through the actuator nozzle.

Aerosol production takes approximately 20 msec. As the liquid suspension is forced out of the pMDI, it forms a plume, within which the propellants vaporize. Initially, the velocity of this plume is high (approximately 15 m/sec). However, within 0.1 second, the plume velocity decreases to less than half its maximum as the plume moves away from the actuator nozzle. At the same time, propellant evaporation causes the initially large particles (35 µm) generated at the actuator orifice to decrease rapidly in size.

The output volume of pMDIs ranges from 30 to 100 mcl. Approximately 60% to 80% by weight of this spray consists of the propellant, with only approximately 1% being active drug (50 mcg to 5 mg, depending on the drug formulation). For a

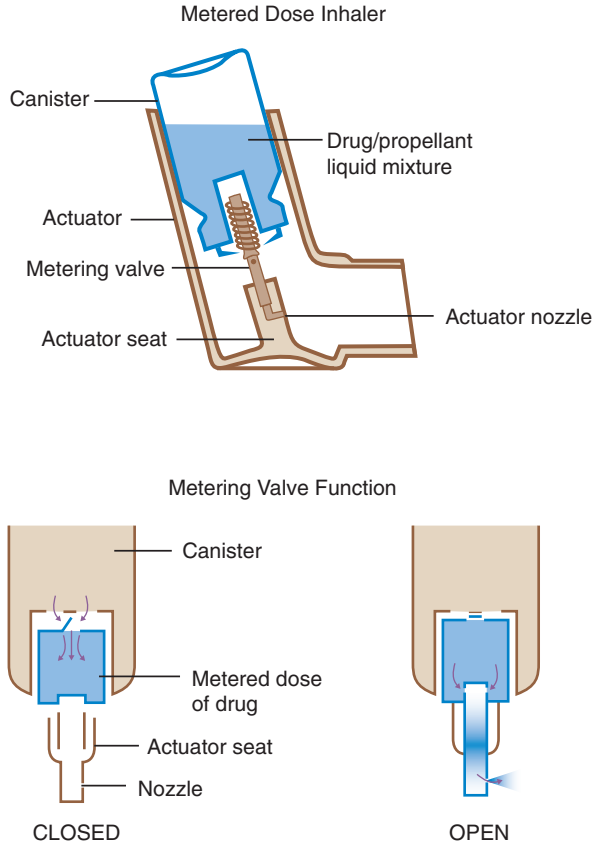

FIGURE 39-7 Components of a pMDI, including function of the metering valve. (From Gardenhire DS: Rau's respiratory care pharmacology, ed 8, St. Louis, 2012, Mosby.)

chlorofluorocarbon (CFC) pMDI used in a standard actuator, loss of drug in the valve stem housing and on the actuator mouthpiece amounts to 10% to 15% of the nominal dose from the metering valve.

From their inception in the mid-1950s to the beginning of the twenty-first century, **chlorofluorocarbons (CFCs)** such as Freon were the propellants used in pMDIs. Manufacture of CFCs for most applications has now been prohibited because of the effect of these compounds on global warming, with a period of transition provided for pMDIs. A consortium of eight pharmaceutical companies developed **hydrofluoroalkane (HFA)**-134a to be more environment-friendly and possibly clinically safer than CFCs.[21] Redesign of key components of the pMDI has resulted in improved performance.[22]

In addition to the propellant, pMDIs use dispersal agents to improve drug delivery by keeping the drug in suspension. The most common dispersal agents are surfactants, such as soy lecithin, sorbitan trioleate, and oleic acid. These agents help keep the drug suspended in the propellant and lubricate the valve mechanism but may also cause adverse responses (coughing or wheezing) in some patients.

Every pMDI should be primed by shaking and actuating the device to atmosphere one to four times (see label for the specific device) before initial use and after storage. Without priming, the initial dose actuated from a new pMDI canister contains less active substance than subsequent actuations.[23] This "loss of dose" from a pMDI occurs when drug particles rise to the top of the canister over time ("cream"). A reduction in emitted dose with the first actuation commonly occurs with a pMDI after storage, particularly with the valve pointed in the downward position. Loss of prime is related to valve design and occurs when propellant leaks out of the metering chamber during periods of nonuse (e.g., 4 hours). The result is reduced pressure and drug released with the next actuation.[23] Improved designs of metering valves developed for use with HFA propellants reduce these losses. It is recommended that a single dose be wasted before the next dose is inhaled when a CFC pMDI has not been used for 4 to 6 hours. An HFA pMDI requires no wasting of dose for periods exceeding 2 days.

New Pressurized Metered Dose Inhaler Technologies

Aerospan™. The Aerospan™ (Meda Pharmaceuticals, Somerset, New Jersey) was developed to deliver flunisolide hemhydrate as an HFA formulation (Figure 39-8). It has a built-in valveless spacer that improves hand-breath coordination. Also, it does not have a built-in dose counter. According to the manufacturer, the Aerospan™ does not need to be cleaned on a regular basis to maintain proper orientation.

Breath-Actuated Pressurized Metered Dose Inhaler

A variation of a pMDI is a **breath-actuated nebulizer**, which incorporates a trigger that is activated during inhalation. The trigger theoretically reduces the need for the patient or caregiver to coordinate pMDI actuation with inhalation.[24] Evaluation of the efficacy of breath-actuated pMDIs in children younger than 6 years is limited, and their use should be restricted to older children and adults. Oropharyngeal deposition of steroids using these devices is still very high.

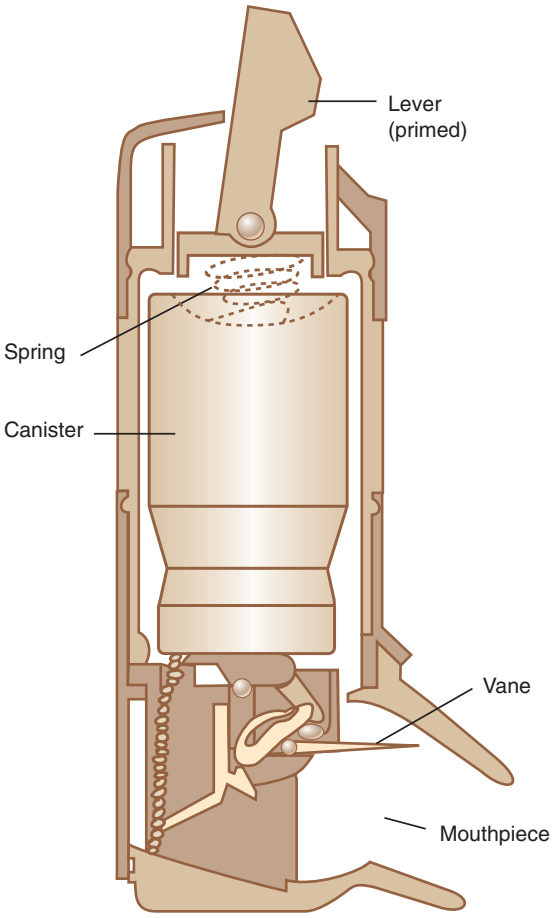

FIGURE 39-8 New pressurized metered dose inhaler (pMDI) technologies.

New Breath-Actuated pMDIs

Tempo Inhaler. A new generation of pMDIs such as the Tempo (MAP Pharmaceuticals, Mountain View, CA) have been designed to be breath actuated with lower force of the plume exiting the mouthpiece, reducing oropharyngeal deposition and increasing lung dose. It is used for the treatment of migraines and is seeking approval from the U.S. Food and Drug Administration (FDA).

RULE OF THUMB

- A pMDI has a press-and-breath design; a breath-actuated pMDI incorporates a trigger that is activated with inspiration.
- Before initial use and after storage, every pMDI should be primed by shaking and actuating the device to atmosphere one to four times, depending on the label.

FIGURE 39-9 Dose counters may be mounted on the top of a pMDI canister integrated in the actuator boot.

MINI CLINI

Using Universal Pressurized Metered Dose Inhaler Actuator or Boot

PROBLEM: The association of CFCs with degradation of the earth's atmosphere and the ozone layer has resulted in an international treaty banning use of these compounds. As HFAs become the propellants of choice, a problem arises. If the CFC and HFA drug formulations are bioequivalent, can these compounds be used with the same (universal) pMDI actuator, or boot?

Discussion: In the case of HFA-based albuterol (e.g., Proventil HFA), the operating pressure and stem orifice differ from those used for the CFC formulation. The result is different plume geometries. When HFA albuterol is used in a universal adapter designed for CFC albuterol, the MMAD and GSD are greatly increased. The result is that significantly less drug is available to the patient. When possible, accessory devices that are used in the manufacturer's boot with the pMDI should be selected. If these devices are unavailable, the universal adapter device that is available should be evaluated to determine how much additional dose may be required to provide an equivalent dose through a third-party adapter.

Dose Counters

A serious limitation of pMDIs is the lack of a "counter" to indicate the number of doses remaining in the canister. After the number of label doses has been administered, the pMDI may seem to give another 20 to 60 doses, which may deliver little or no medications as the doses "tail-off." The *tail-off effect* refers to variability in the amount of drug dispensed toward the end of the life of the canister. The result of tail-off is swings from normal to almost no dose emitted from one breath to the next with no reliable indicator to the user. Without a dose counter, there is no viable method to determine remaining drug in a pMDI other than manually keeping a log of every dose taken. The FDA is requiring all new pMDIs to have counter technology to track pMDI actuations remaining. Third-party dose counters may be added to older pMDI models but may not have the accuracy of built-in technology (Figure 39-9).

Factors Affecting Pressurized Metered Dose Inhaler Performance and Drug Delivery

Temperature. Low temperature (<10° C) decreases the output of CFC pMDIs. Patients with cold air–induced bronchospasm who keep their pMDIs in outer coat pockets when outside in cold winter weather may receive only a small percentage of drug compared with that administered with the same pMDI at 25° C. This problem has been less serious with the newer HFA pMDIs.[23]

Nozzle Size and Cleanliness. Aerosol drug delivery is influenced by nozzle size and cleanliness. Nozzle size is pMDI-specific. As debris builds up on the nozzle or actuator orifice, the emitted dose is reduced.[24] Manufacturer recommendations should be followed for cleaning. pMDI canisters should never be placed under water.

Priming. Priming is defined as shaking the device and releasing one or more sprays into the air when the pMDI is new or has not been used for awhile. It is done to mix the drug and the propellant, which can separate in the canister over time. Priming is required to provide an adequate dose, according to the manufacturer's guidelines.

Timing of Actuation Intervals. Manufacturers recommend 30 seconds to 1 minute between actuations. When propellants are released, the device cools, changing aerosol output. The pause allows the device to return to room temperature and recover normal output. However, previous research[25] showed that pMDI output is similar at 15-second intervals. Very rapid actuation of multiple puffs per breath reduces inhaled drug per puff.

Aerosol Delivery Characteristics

Although pMDIs can produce particles in the respirable range (MMAD 2 to 6 μm),[23] the initial velocity and dispersion of the aerosol plume generate larger particles that decrease in size as they leave the pMDI, resulting in approximately 80% of the dose leaving the actuator to impact and become deposited in the oropharynx. A significant proportion of this oropharyngeal deposition is swallowed and may be a factor in systemic absorption of some drugs. Pulmonary deposition ranges from 10% to 20% in adults and larger children (less in infants).[26] The exact amount of drug delivered to an individual patient is unpredictable because of high variability between patients and because pMDI drug administration is technique-dependent.

Box 39-1 Optimal Technique for Use of a Pressurized Metered Dose Inhaler

1. Warm the pMDI canister to hand or body temperature, and shake it vigorously.
2. Before first use of a new pMDI and when the pMDI has not been used for several days, prime the pMDI by pointing it into the air (away from people) and actuating a couple of times.
3. Assemble the apparatus and uncap the mouthpiece, ensuring there are no loose objects in the device.
4. Open-mouth technique: Open your mouth wide, keeping tongue down. Hold the pMDI with the canister oriented downward and the outlet aimed at your mouth. Position the pMDI approximately 4 cm (two fingerbreadths) away from your mouth.
5. Closed-mouth technique: Place mouthpiece between lips, with tongue out of the path of the outlet.
6. Breathe out normally.
7. As you slowly begin to breathe in (<0.5 L/sec), actuate the pMDI.
8. Continue inspiration to total lung capacity.
9. Hold your breath for up to 10 seconds. Then relax and breathe normally.
10. Wait 1 minute between puffs.
11. Disassemble the apparatus, and recap the mouthpiece.

Technique

The successful administration of aerosol drugs by pMDI is highly technique-dependent. Two-thirds of patients and health care professionals who teach pMDI use do not perform the procedure properly.[27] Box 39-1 outlines the recommended steps for self-administering a bronchodilator by pMDI. Patient instruction should last 10 to 30 minutes and should include demonstration, practice, and confirmation of patient performance (demonstration pMDIs with placebo are available from manufacturers for this purpose). Repeated instruction improves performance; repeat instruction is done most appropriately with follow-up clinic or home visits. Demonstration and return demonstration must occur several times for best patient adherence to device use.

For best effect, the pMDI should be actuated once at the beginning of inspiration. Common hand-breath coordination problems include actuating the pMDI before or after the breath. Some patients, especially infants, young children, elderly adults, and patients in acute distress, may be unable to coordinate actuation of the pMDI with inspiration. Some patients exhibit a "cold Freon effect," which occurs when the cold aerosol plume reaches the back of the mouth and the patient stops inhaling. All of these problems reduce aerosol delivery to the lung to the point that the patient does not benefit from the medication, but they can be corrected entirely or in part by use of the proper pMDI accessory device.

Most pMDI labels call for placing the mouthpiece between the lips. However, positioning the outlet of the pMDI approximately 4 cm (two fingerbreadths) in front of the mouth improves lung deposition by decreasing oropharyngeal impaction.[28] Holding the canister outside the open mouth (at two fingerbreadths) provides a space for the particles to decelerate while evaporating, allowing particle size to reduce to respirable size. Use of the open-mouth technique with a low inspiratory flow rate can result in a doubling of the dose delivered to the lower respiratory tract of an adult from approximately 7% to 10% to 14% to 20%. However, this technique is more difficult for patients to perform reliably than the closed-mouth technique. Although it may reduce oropharyngeal deposition, the technique has not been shown to improve the clinical response to pMDI bronchodilators.

Concerns have been raised about use of the open-mouth technique with ipratropium bromide because poor coordination can result in drug being sprayed into the eyes. Use of anticholinergic agents has been associated with increased ocular pressure, which could be dangerous for patients with glaucoma. For avoidance of ocular exposure, the drug manufacturer recommends patients use the closed-mouth technique with ipratropium.

The high percentage of oropharyngeal drug deposition with use of steroid pMDIs can increase the incidence of oral yeast infection (thrush) and changes in the voice (dysphonia). Rinsing the mouth after steroid use can help avoid this problem, but most pMDI steroid aerosol impaction occurs deep in the hypopharynx, which cannot be easily rinsed with gargling. For this reason, steroid pMDIs should not be used alone but always in combination with a spacer or valved holding chamber. See Box 39-2 for instructions for determining dosage left in the pMDI.

Pressurized Metered Dose Inhaler Accessory Devices

Various pMDI accessory devices have been developed to overcome the two primary limitations of these systems: hand-breath coordination problems and high oropharyngeal deposition. Accessory devices include spacers, and valved holding chambers.

Spacers and Valved Holding Chambers. Spacers and valved holding chambers (VHCs) are designed to reduce both oropharyngeal deposition and the need for hand-breath coordination. A spacer is a simple valveless extension device that adds distance between the pMDI outlet and the patient's mouth. This distance allows the aerosol plume to expand and the propellants to evaporate before the medication reaches the oropharynx. Larger particles leaving the pMDI tend to impact on the spacer walls. In combination, this phenomenon reduces oropharyngeal impaction and increases pulmonary deposition. VHCs incorporate one or more valves that prevent aerosol in the chamber from being cleared on exhalation. This allows patients with a small V_T to empty the aerosol from the chamber over two or more successive breaths. Generally, holding chambers provide less oropharyngeal deposition, higher respirable drug dosages, and better protection from poor hand-breath coordination than simple spacers. VHCs protect the patient from poor hand-breath coordination, with exhaled gas venting to the atmosphere, allowing aerosol to remain in the chamber

Box 39-2 Determining Dose Left in Pressurized Metered Dose Inhaler

Tracking the number of actuations (puffs) remaining in a pMDI can be done with or without dose counters (see Figure 39-9).

WITH DOSE COUNTERS

The user should[29]:

1. Determine how many puffs of drug the pMDI has when full.
2. Learn to read the counter display because each dose counter has a different way of displaying doses left in the canister.
3. Check the counter display to track the pMDI actuations remaining in the canister.
4. Reorder the pMDI when there are a few days of drug remaining.
5. Dispose of the pMDI properly, after the last dose is dispensed.

WITHOUT DOSE COUNTERS

The user should[29]:

1. Read the label to determine how many puffs of drug the pMDI has when full.
2. Calculate how long the pMDI will last by dividing the total number of puffs in the pMDI by the total puffs used per day. If the pMDI is used more often than planned, it will run out sooner.
3. Identify the date that the medication will run out, and mark it on the canister or on a calendar.
4. For drugs that are prescribed to be taken as needed, track the number of puffs of drug administered on a daily log sheet and subtract them from the remaining puffs to determine the amount of medication left in the pMDI.
5. Keep the daily log sheet in a convenient place, such as taped to the bathroom mirror.
6. Refill the pMDI prescription when there are a few days of use remaining in the pMDI.
7. Dispose of the pMDI properly when the last dose is dispensed.

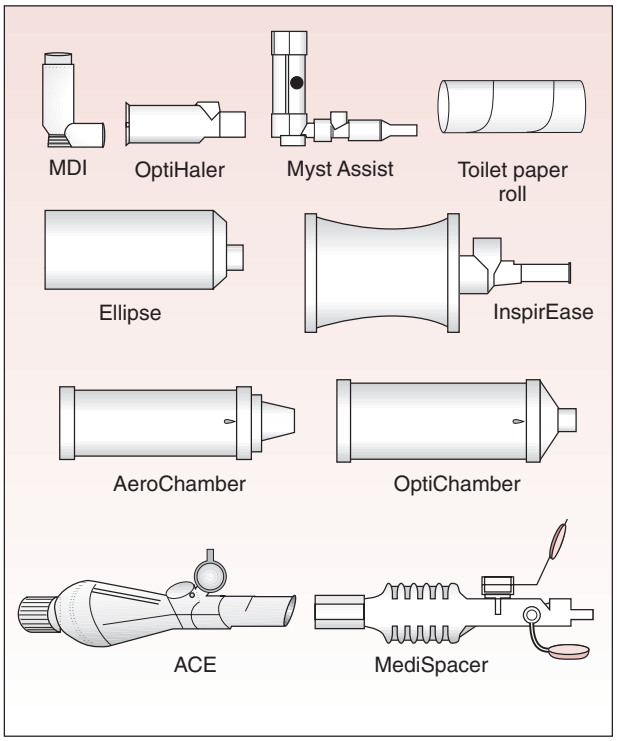

FIGURE 39-10 pMDI and accessory devices consisting of spacer and holding chambers. All of the accessory devices reduce oropharyngeal deposition. Small volume spacers (e.g., Optihaler [Philips Respironics, Murrysville, PA] and Myst Assist [Philips Respironics, Murrysville, PA]) offer no additional advantage, but large volume spacers (e.g., toilet paper roll and Ellipse [Ellipse Technologies, Irving, CA]) improve inhaled aerosol with delay between actuation and inspiration. Only the bag (e.g., Inspirease [Schering Plough, Kenilworth, NJ]) and valved holding chambers (VHCs) (e.g., Aerochamber [Invicare, Elyria, OH], Optichamber [Philips Respironics, Murrysville, PA], Ace [Smiths Medical, Kent, UK], and Medispacer [Cardinal Health, Dublin, OH]) protect the patient from blowing the dose away when the pMDI is actuated during expiration. (Modified from Wilkes W, Fink J, Dhand R: Selecting an accessory device with a metered-dose inhaler: variable influence of accessory devices on fine particle dose, throat deposition, and drug delivery with asynchronous actuation from a metered dose inhaler. J Aerosol Med 14:351, 2001.)

available to be inhaled with the next breath. VHCs allow infants, small children, and adults who cannot control their breathing pattern to be treated effectively with pMDIs.

Types of Accessory Devices. Basic concepts for spacer devices include (1) small volume adapters, (2) open tube designs, (3) bag reservoirs, and (4) valved holding chambers (Figure 39-10). More than a dozen different devices with volumes ranging from 15 to 750 ml have been developed over the past 30 years. Despite differences in design, all spacers add distance between the pMDI and the mouth, reducing the initial forward velocity of the pMDI droplets, which occurs with partial evaporation of propellant in the time the aerosol traverses the length of the spacer. The reduction in initial forward velocity decreases the number of nonrespirable particles reaching the airway. The same drug used with different accessory devices may produce differences in MMAD, GSD, and fine-particle fraction. The quantity of respirable drug available at the spacer or valved holding chamber depends on spacer volume and design and formulation. The placement of a valve between the pMDI, the chamber, and the mouthpiece works like a baffle reducing the size of particles inhaled. A simple tube spacer may reduce oral deposition by 90%, whereas a valved holding chamber can reduce oral deposition by 99%.

It is increasingly common practice to provide asthmatic patients an accessory device to use with the pMDI and to teach them how to use the pMDI with and without the accessory device. Patients are instructed to use the device with the pMDI whenever they feel short of breath. Many of these patients find that they get much better relief from the pMDI with an accessory device than with the pMDI alone.

Proper use of a simple open-tube spacer still requires some hand-breath coordination because a momentary delay between triggering and inhaling the discharged spray results in a substantial loss of drug and reduced lung delivery. Exhalation into a simple spacer after pMDI actuation clears the aerosol from the device and wastes most of the dose to the atmosphere. This

reduction in dose also occurs with small volume reverse-flow design spacers if there is no provision for "holding" the aerosol in the device.[29]

The MMAD of the aerosol emitted from the pMDI exiting a spacer decreases approximately 25%, whereas the fraction containing particles less than 5 µm in diameter increases. This change is largely due to rapid evaporation of propellant in the spacer. With valved holding chambers, in addition to evaporation of the plume, the valves act as baffles of larger particles, increasing the respirable fraction further.

VHCs produce a finer, slower moving, more "respirable" aerosol with less impaction of drug in the oropharyngeal area (1% of dose) than simple spacers (10%) or a pMDI alone (80% of dose). Research suggests that a properly used pMDI and aerochamber can significantly reduce oropharyngeal deposition versus an open-mouth technique while maintaining drug dose delivery to the lungs. This finding was true for both healthy subjects and patients with chronic obstructive pulmonary disease (COPD).[30] The advantage of reduced oropharyngeal deposition is fewer side effects from steroid aerosols. Multiple actuations of one or more drugs into a spacer reduce both the total dose and the respirable dose of drug available for inhalation. The extent of these losses may vary for different drugs and spacer designs.[23]

VHCs with masks are available for use in the care of infants, children, and adults. These units allow effective administration of aerosol from a pMDI to patients who are unable to use a mouthpiece device (because of their size, age, coordination, or mentation). VHCs are helpful in administration of pMDI steroids because deposition of the drug in the mouth is largely eliminated, and systemic side effects can be minimized.

Even with a VHC, respirable particles containing drug settle out and become deposited within the device, causing a whitish buildup on the inner chamber walls. This residual drug poses no risk to the patient but should be be rinsed out periodically. Plastic spacers decrease drug output due to the presence of an electrostatic charge. With these devices, a buildup of material can be seen on the walls of the chamber. As more material builds up on the wall of the chamber, the charge is dissipated, and more drug is inhaled by the patient. Washing the chamber with water (without soap) causes the electrostatic charge to be reestablished, making the device less effective for the next few puffs, until the static charge in the chamber (which attracts small particles) is again reduced.[32] Optimal technique is outlined in Box 39-3.

Use of conductive metal or nonelectrostatic plastic chambers or washing the plastic chamber periodically with deionizing detergent (liquid dishwashing soap) can overcome the loss of fine-particle mass owing to electrostatic charge and increase the inhaled mass from 20% to 50% of the emitted dose of the pMDI, even in children (Figure 39-11).[31] The effect of washing the chamber with conventional dishwashing soap reduces this static charge for up to 30 days. All manufacturers recommend that VHCs and spacers should be cleaned regularly, typically monthly using dilute liquid dishwashing soap, with or without rinsing, and allowing them to air dry.

Box 39-3 Optimal Technique for Use of a Metered Dose Inhaler With a Valved Holding Chamber

1. Warm the pMDI to hand or body temperature.
2. Assemble the apparatus, ensuring there are no objects or coins in the chamber that could be aspirated or obstruct outflow.
3. Hold the canister vertically, and shake it vigorously. Prime if necessary.
4. Place the pMDI in the holding chamber inlet, position chamber outlet in the mouth (or place the mask over nose and mouth), and encourage the patient to breathe through the mouth. Visually inspect for proper valve function.
5. With normal breathing, actuate the pMDI once and have the patient breathe through the device for three to seven breaths (three breaths for adults and seven breaths for infants).*
6. Allow 30 to 60 seconds between actuations.

*For a cooperative patient, synchronizing actuation at the beginning of larger breaths with breath holding may be encouraged. However, this maneuver has not been shown to increase clinical response to inhaled bronchodilators.

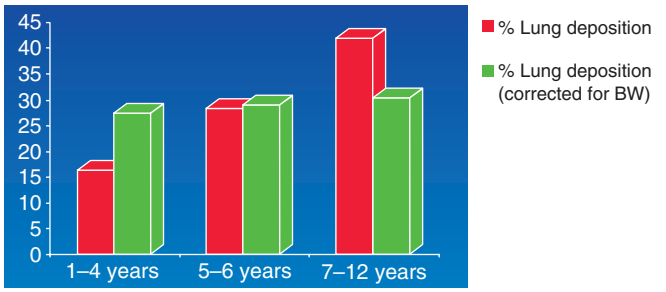

FIGURE 39-11 Although the percentage of drug deposited in the lung varies with age *(red bars)*, the percentage of lung deposition corrected for body weights is consistent across age groups. (Modified from Wildhaber JH, Janssens HM, Piérart F, et al: High percentage lung delivery in children from detergent-treated spacers. Pediatr Pulmonol 29:389-393, 2000.)

The addition of a one-way valve to convert an open tube into a reservoir for the aerosol, the incorporation of the actuator in the pMDI, the shape of the device, flow of air through the device, edge effects, masks, and manufacturing materials all affect aerosol characteristics. The inhalation valve, which is used to contain the aerosol, also acts as a baffle to reduce oropharyngeal deposition. This valve must be able to withstand the initial pressure from the pMDI when the device is triggered to retain aerosol and have sufficiently low resistance to open readily when the user inhales, in particular, when the user is a child or an infant. Exhalation valves in a face mask attached to a spacer device must also provide low resistance. Issues of spacer volume, V_T, frequency of breathing, and mechanical dead space between the spacer and mouth are of particular concern when these devices are used by children.[32] There are twofold to threefold differences in the amount of drug available at the mouth when different spacers are used to treat infants. Clinicians should

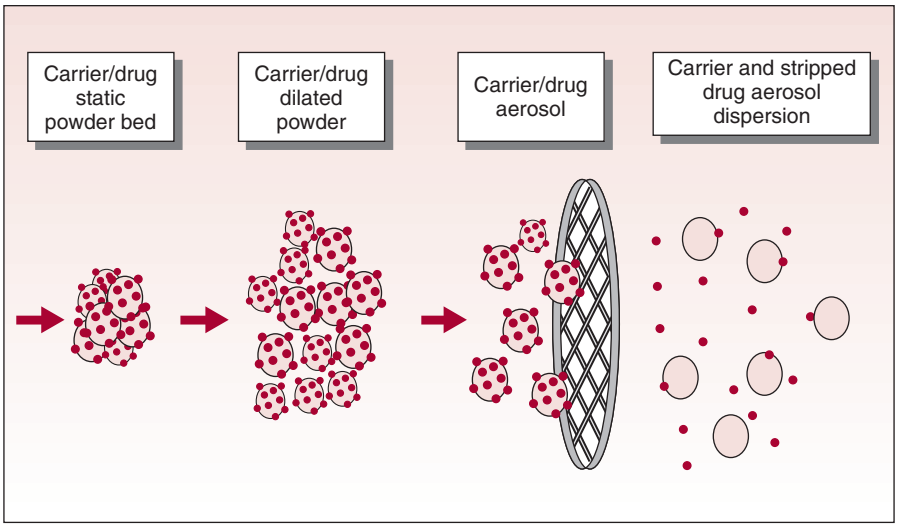

FIGURE 39-12 Aerosolization of dry powder. (Modified from Dhand R, Fink J: Dry powder inhalers. Respir Care 44:940, 1999.)

determine the delivery efficiencies of spacer devices before using the device in a particular population.

Accessory devices are used with either the manufacturer-designed boot that comes with the pMDI or with a "universal adapter" that triggers the pMDI canister. Different formulations of pMDI drugs operate at different pressures and have a different-sized orifice in the boot that is specifically designed by the manufacturer for use exclusively with that pMDI. The output characteristics of a pMDI change when an adapter with a different-sized orifice is used. With HFA pMDIs, the diameter of the actuator orifice is smaller, and the spray is predictably finer. When the HFA pMDI is used in an actuator designed for use with CFC pMDIs, output is reduced. When these HFA formulations are used with any particular spacer, it is important to know how comparable the available dose and particle size distribution are to the dose and particle size from an existing CFC pMDI.[23]

Cost

Many hospitals are moving away from the use of HFA pMDIs because of the high cost of these devices. Regardless of drug delivered, these devices cost between $200 to $300 dollars compared to pennies a dose for the same drug in a preparation to be used in a nebulizer. The use of these less expensive preparations with a vibrating mesh nebulizer (see later discussion) has now become the norm in many hospitals because of cost.

Dry Powder Inhalers

A DPI is typically a breath-actuated dosing system. With a DPI, the patient creates the aerosol by drawing air though a dose of finely milled drug powder with sufficient force to disperse and suspend the powder in the air. DPIs are inexpensive, do not need propellants, and do not require the hand-breath coordination needed for pMDIs. However, dispersion of the powder into respirable particles depends on the creation of turbulent flow in the inhaler. Turbulent flow is a function of the ability of the patient to inhale the powder with a sufficiently high inspiratory flow rate (Figure 39-12). In terms of both lung deposition and drug response, DPIs are as effective as pMDIs.[33]

Equipment Design and Function

Most passive dry powder–dispensing systems require the use of a carrier substance (lactose or glucose) mixed into the drug to enable the drug powder to deaggregate more readily and flow out of the device. Reactions to lactose or glucose seem to be fewer than reactions to the surfactants and propellants used in pMDIs, even though the amount of these substances is substantially greater than the amount of the drug and can represent 98% or more of the weight per inhaled dose in some formulations.

As shown in Figure 39-13, *A*, *B*, and *C*, there are numerous DPIs on the market, which can be divided into three categories based on the design of their dose containers: (1) unit-dose DPI, (2) multiple unit-dose DPI, and (3) multiple dose drug reservoir DPI.

Unit-dose DPIs, such as the Aerolizer (Schering-Plough, Kenilworth, NJ) and the HandiHaler (Boehringer Ingleheim, Ingelheim am Rhein, Germany), dispense individual doses of drug from punctured gelatin capsules. Multiple unit-dose DPIs (Diskhaler; GlaxoSmithKline, Philadelphia) contain a case of four or eight individual blister packets of medication on a disk inserted into the inhaler. Multiple dose DPIs include the Twisthaler (Schering-Plough), Flexhaler (AstraZeneka, London), and the Diskus (GlaxoSmithKline). The Twisthaler and Flexhaler have a multidose reservoir powder system preloaded with a quantity of pure drug sufficient for dispensing 120 doses of medication, and the Diskus incorporates a tape system that contains up to 60 sealed single doses (Figure 39-14).

The particle size of the dry powder particles of drug ranges from 1 to 3 µm. However, the size of the lactose or glucose particles can range from approximately 20 to 65 µm, so most of the carrier (≤80%) is deposited in the oropharynx.

FIGURE 39-13 Some currently available DPIs: **A** and **B,** Multiple-dose dpi: diskus inhaler **C,** Unit-dose dpi: aerolizer. (**A,** GlaxoSmithKline, used with permission. **B** and **C,** Merck & Co. Inc. Whitehouse Station, NJ.)

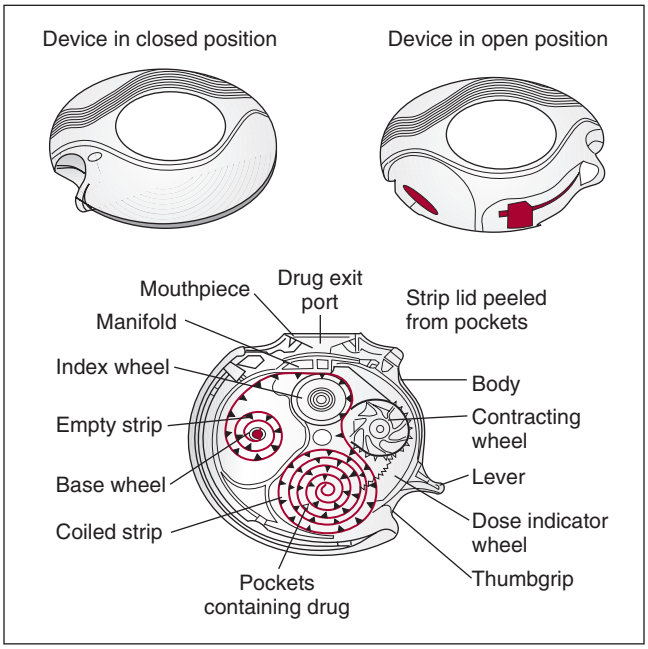

FIGURE 39-14 Diskus DPI (Glaxo Wellcome, Research Triangle Park, NC). The doses are contained in 60 sealed pockets along an aluminum-foil strip that is advanced by the lever. As the drug pocket reaches the mouthpiece, the cover is peeled away, making the drug available for inhalation. A dose counter indicates the number of doses remaining in the device. (Modified from Dhand R, Fink J: Dry powder inhalers. Respir Care 44:940, 1999.)

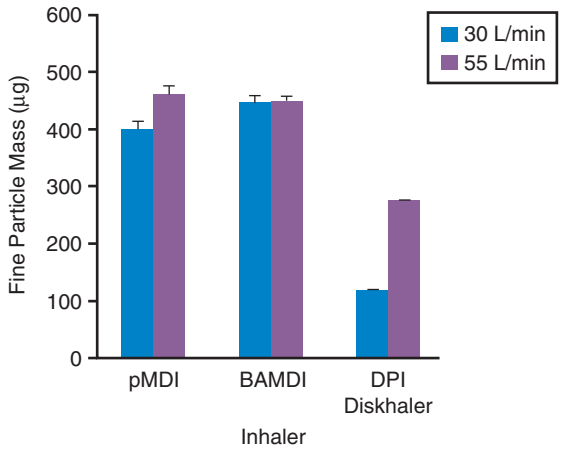

FIGURE 39-15 Fine particle mass delivered from a 1000-mg dose (± standard deviation) as a function of flow. *BAMDI,* Breath-actuated pMDI (Autohaler); *DPI,* dry powder inhaler (Diskhaler); *pMDI,* pressurized metered dose inhaler. (Modified from Smith KJ, Chan HK, Brown KF: Influence of flow rate on aerosol particle size distributions from pressurized and breath-actuated inhalers. J Aerosol Med 11:231, 1998.)

Factors Affecting Dry Powder Inhaler Performance and Drug Delivery

Intrinsic Resistance and Inspiratory Flow Rate. Optimal performance for each DPI design occurs at a specific inspiratory flow rate. The fine-particle fraction of respirable drug from existing DPIs ranges from 10% to 60% of the nominal dose. The amount varies with inspiratory flow and device design. The higher the resistance or the greater the flow requirement of a DPI device, the more difficult it is for a compromised or young patient to generate inspiratory flow sufficient to obtain the maximum dose of drug from the device.

Exposure to Humidity and Moisture. The emitted dose of DPI decreases in a humid environment, likely because of powder clumping. The longer the exposure and the greater the level of absolute humidity, the lower the dose emitted. New DPIs with multiple unit-doses minimize the effects of moisture on the powder as long as individual doses are inhaled as soon as the seal is broken.

Patient's Inspiratory Flow Ability. High peak inspiratory flow rates (>60 L/min) are required to dispense the drug powder from most current DPI designs and result in a pharyngeal dose comparable to the dose received from a typical pMDI without an add-on device. If a patient does not inhale at the optimal inspiratory flow rate for a particular device, delivery to the lung decreases as the dose of drug dispensed decreases and the particle size of the powder aerosol increases (Figure 39-15).[33]

Passive, or patient-driven, DPIs rely on the patient's inspiratory effort to dispense the dose. The result is differences in lung

delivery and clinical response. Active or powered DPI devices, which deaggregate the powder before inhalation, are independent of patient effort. Active DPIs use an energy source to deaggregate the powder and suspend the powder into an aerosol, allowing the dose to be suspended independent of patient inspiratory flow rates.

Technique. Proper technique is essential to derive the maximum benefit from a DPI. Box 39-4 outlines the basic steps for ensuring optimal drug delivery. The most critical factor in using a passive DPI is the need for high inspiratory flow. Patients must generate an inspiratory flow rate of at least 40 to 60 L/min to produce a respirable powder aerosol. Because infants, small children (<5 years old) (Figure 39-16), and patients who are unable to follow instructions cannot develop inspiratory flows this high, these patients cannot use DPIs. Because patients with severe airway obstruction may be unable to achieve the required flow, they should not use DPIs during acute bronchospasm.

Exhalation into a DPI before inspiration can result in loss of drug delivery to the lung. Some DPIs also require assembly, which can be cumbersome or difficult for some patients, especially in an emergency. It is important that patients receive demonstrations with their inhalers and have the opportunity to assemble and use the DPI (return demonstration) before self-administration. Although the DPI may require cleaning in accordance with the product label, the device should never be submerged in water. Moisture in the device dramatically reduces available dose. Table 39-1 provides methods to determine the dose of the different types of DPI.

Box 39-4 Optimal Technique for Use of a Dry Powder Inhaler

1. Assemble the apparatus.
2. Load dose, keeping device upright.
3. Exhale slowly to functional residual capacity.
4. Seal lips around the mouthpiece.
5. Inhale deeply and forcefully (>60 L/min). A breath hold should be encouraged but is not essential.
6. Repeat the process until dose is completed.
7. Monitor adverse reactions.
8. Assess beneficial effects.

Modified from Pedersen S: How to use a Rotahaler. Arch Dis Child 61:11, 1986; and Hansen OR, Pedersen S: Optimal inhalation technique with terbutaline. Turbuhaler Eur Respir J 2:637, 1989.

New Dry Powder Inhaler Technologies

Easyhaler®. The Easyhaler® (Orion Corporation, Espoo, Finland) is approved for marketing in Europe for delivery of beclomethasone, albuterol, formoterol, and budesonide. The device is similar to the pMDI in terms of its shape and operation. However, it is a DPI and has a dose counter which gives a red signal when 20 doses are left in the device.

Ellipta®. The Ellipta® (GlaxoSmithKline, Research Triangle Park, NC) is a disposable multidose DPI in which the drug is stored in double-foil blister strips. The device has a 3-step technique (open-inhale-close) and provides auditory feedback with the opening of the inhaler that results in loading the dose and an advancement in the dose counter. When a patient does not inhale the dose from the Ellipta®, the drug is dumped internally to prevent overdosing. The Ellipta® has three categories that provide different drugs or drug combinations: (1) Incruse™

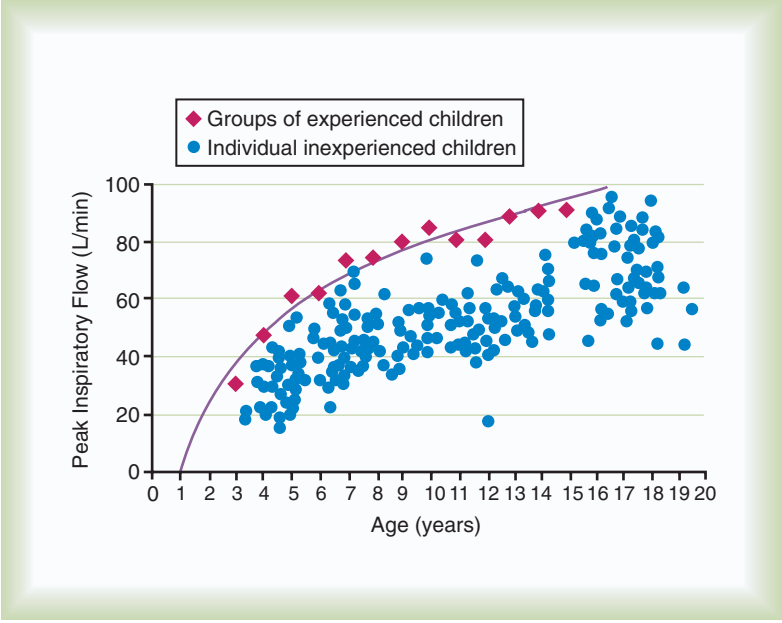

FIGURE 39-16 Peak inspiratory flows in individual inexperienced children (Pedersen et al, 1990) and groups of experienced children (Agertoft et al, 1995). (Modified from Pedersen S: Delivery options for inhaled therapy in children over the age of 6 years. J Aerosol Med 10[Suppl 1]:S41, 1997.)

TABLE 39-1

Determining Doses Left in the Dry Powder Inhaler

		Drug Container	Doses	Type Indicator	Meaning of Dose Indicator
Unit-Dose DPI	Aerolizer or HandiHaler	Single capsule	1	None	Check capsule to ensure full dose was inhaled. Repeat to empty capsule
Multiple Unit-Dose DPI	Diskhaler	Dose blisters	4 or 8	None	Inspect visually to confirm use of all blisters
Multiple Dose DPI	Diskus	Blister strip	60	Red numbers	Red numbers indicate that ≤5 doses are left in DPI
	Flexhaler	Reservoir	60 or 120	"0"	Marked in intervals of 10 doses; "0" indicates empty
	Twisthaler	Reservoir	30	"01"	"01" indicates last dose

Ellipta® delivers umeclidinium, a long-acting muscarinic antagonist that is used in the treatment of COPD, (2) Breo™ Ellipta® has a combination of fluticasone furoate and vilanterol (long-acting β2-agonist), and (3) Anoro™ Ellipta® includes a combination of umeclidinium and vilanterol.

Podhaler™. As a single-dose reusable DPI, the Podhaler™ (Novartis Pharmaceutical Corporation, San Carlos, CA) delivers TOBI for the treatment of chronic infection in patients with cystic fibrosis. The device produces light porous particles with improved flow and dispersion characteristics by using the PulmoSphereTM technology that has less interparticle cohesive forces. When using the Podhaler, a patient opens the mouthpiece, inserts the capsule in the device, and then inhales. The manufacturer suggests disposing of the device after 7 days of use.

Taifun™. The TaifunTM is a reservoir based multidose DPI in which drug within the reservoir is protected from moisture. It is a user friendly device with a dose counter that is used to deliver salbutamol, fentanyl, formoterol, and budesonide in Europe. Although the TaifunTM has reproducible and uniform metered doses, more research is needed about patient acceptance, preference, safety, and clinical efficacy of the device.

Tudorza™ Pressair™. The Tudorza™ Pressair™ (Forest Laboratories, St Louis, MO) is a multidose DPI that delivers aclidinium bromide, a long-acting anticholinergic. The device has a dose counter that decreases by 10 doses and shows a red mark with a "0" sign when it is empty. It also has a lockout system at the end of the dose. The Tudorza™ Pressair™ provides both visual feedback and auditory feedback during therapy. The visual feedback displays red color in the control window with incorrect technique and shows green color when the patient inhales the dose completely with the correct use of the device.

Spiromax®. As a multidose passive DPI, the Spiromax® (Teva Pharmaceuticals) is used to deliver albuterol, fluticasone/salmeterol, and budesonide/formoterol in the treatment of pulmonary diseases in Europe. When the patient opens the cap on the mouthpiece, the dose is loaded to the DPI and then is ready for the patient to inhale the medication.

Staccato®. The Staccato® (Alexza Pharmaceuticals) uses a thermal aerosol technology that has three components including a heating substrate, a thin film of pure drug, and a channel where aerosol forms. It is a small, portable, breath-actuated device that does not require any type of special breathing technique. Therefore, unlike other DPIs, the Staccato is insensitive to patient inhalation rates. The device generates aerosols by heating a thin film of drug to form pure drug vapor. When the patient inhales, the vapor cools and condenses into 1- to 3-μm-diameter particles. Thus, pure drug can be delivered to the alveoli without extensive thermal degradation and with the optimal range of particle diameter, promoting very fast systemic drug absorption. The Staccato has been approved in the United States for delivery of loxapine.

Nebulizers

Nebulizers generate aerosols from solutions and suspensions. The three categories of nebulizers include (1) pneumatic jet nebulizers, (2) USNs, and (3) vibrating mesh (VM) nebulizers. Nebulizers are also described in terms of their reservoir size. Small volume nebulizers (SVNs) most commonly used for medical aerosol therapy hold 5 to 20 ml of medication. Large volume nebulizers, also known as *jet nebulizers,* hold up to 200 ml and may be used for either bland aerosol therapy (see Chapter 38) or continuous drug administration.

Pneumatic (Jet) Nebulizers

Gas-powered jet nebulizers (Figure 39-17, *A*) have been in clinical use for longer than 100 years. Most modern jet nebulizers are powered by high-pressure air or oxygen (O_2) provided by a portable compressor, compressed gas cylinder, or 50-psi wall outlet.

Factors Affecting Nebulizer Performance. Nebulizer design, gas pressure, gas density, and medication characteristics affect SVN performance (Box 39-5).

Nebulizer Design. As shown in Figure 39-17, *B,* a typical SVN is powered by a high-pressure stream of gas directed through a restricted orifice (the jet). The gas stream leaving the jet passes by the opening of a capillary tube immersed in solution. Because it produces low lateral pressure at the outlet, the high jet velocity draws the liquid up the capillary tube and into the gas stream, where it is sheared into filaments of liquid that break up into droplets. This primary spray produces a heterodisperse aerosol with droplets ranging from 0.1 to 500 μm.[34]

This spray is directed against one or more baffles. A **baffle** is a surface on which large particles impact and fall out of suspension, whereas smaller particles remain in suspension, reducing

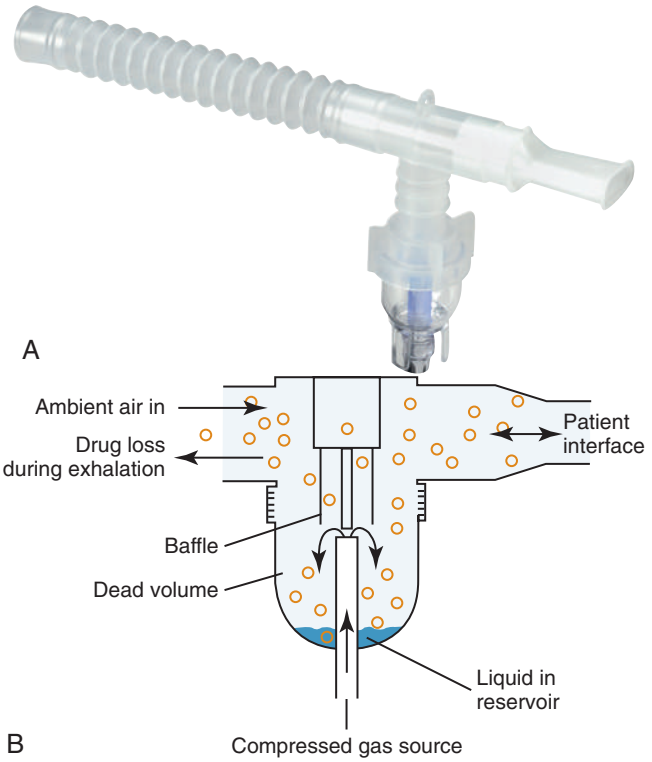

FIGURE 39-17 **A,** Small volume jet nebulizer with tube reservoir for liquid drug delivery. **B,** Schematic of a small volume jet nebulizer. (**A,** DeVilbiss Healthcare, Somerset PA. **B,** From Gardenhire, D: Rau's Respiratory Care Pharmacology, ed 8, St. Louis, 2012, Mosby.)

the size of particles remaining in the aerosol. In many designs, droplets that impact baffles in the SVN return to the medication reservoir for nebulization again.

Baffles are key elements in nebulizers; well-designed baffling systems decrease both the MMAD (size) and the GSD (range of sizes) of the generated aerosol. Atomizers operate with the same basic principles as nebulizers without baffling and produce aerosols with larger MMAD and GSD. **Residual drug volume**, or dead volume, is the medication that remains in the SVN after the device stops generating aerosol and "runs dry."[35] The residual volume of a 3-ml dose can range from 0.5 to more than 2.2 ml, which can be more than two-thirds of the total dose. The greater the residual drug volume, the more drug that is unavailable as aerosol, and the less efficient the delivery system. Residual volume also depends on the position of the SVN. Some SVNs stop producing aerosol when tilted 30 degrees from vertical. Increasing the fill volume allows a greater proportion of active medication to be nebulized. In a nebulizer with a residual volume of 1.5 ml, a fill of 3 ml would leave only 50% of the nebulizer volume (nominal dose) available for nebulization. In contrast, a fill of 5 ml would make 3.5 ml, or more than 70% of the medication, available to be inhaled. The unit-dose volumes of drugs were based on clinical response of patients using nebulizers with substantial residual drug volumes. Although increasing dose volume may increase available dose, it should be considered off-label administration, and there is no significant difference in clinical response with varying diluent volumes and flow rates.

Flow. Droplet size and nebulization time are inversely proportional to gas flow through the jet. The higher the flow of gas to the nebulizer, the smaller the particle size generated, and the shorter is the time required for nebulization of the full dose. Nebulizers that produce smaller particle sizes by use of baffles, such as one-way valves, may reduce total drug output per minute compared with the same nebulizer without baffling and require more time or nominal dose to deliver a standard dose of medication to the lungs.

Gas Source (Hospital Versus Home). Gas pressure and flow through the nebulizer affect particle size distribution and output. Within operating limits, the higher the pressure or flow, the smaller the particle size, the greater the output, and the shorter the treatment time. A nebulizer that produces an MMAD of 2.5 µm when driven by a gas source of 50 psi at 6 to 10 L/min may produce an MMAD of more than 5 µm when operated on a home compressor (or ventilator) developing 10 psi. Too low a gas pressure or flow can result in negligible nebulizer output. Consequently, nebulizers used for home care should be matched to the compressor according to data supplied by the manufacturer. Thus, the combination of specific equipment improves efficient nebulization of the desired medications prescribed for the patient.

Other concerns in the use of disposable nebulizers with compressors at home involve possible degradation of performance of the plastic device over multiple uses. One study showed that repeated use of nebulizers did not alter MMAD or output as long as the nebulizer was cleaned properly. Failure to clean the nebulizer properly caused degradation of performance because of clogging of the jet orifice, reducing the output flow, and buildup of electrostatic charge in the device.

Density. Gas density affects both aerosol generation and delivery to the lungs. The lower the density of the carrier gas,

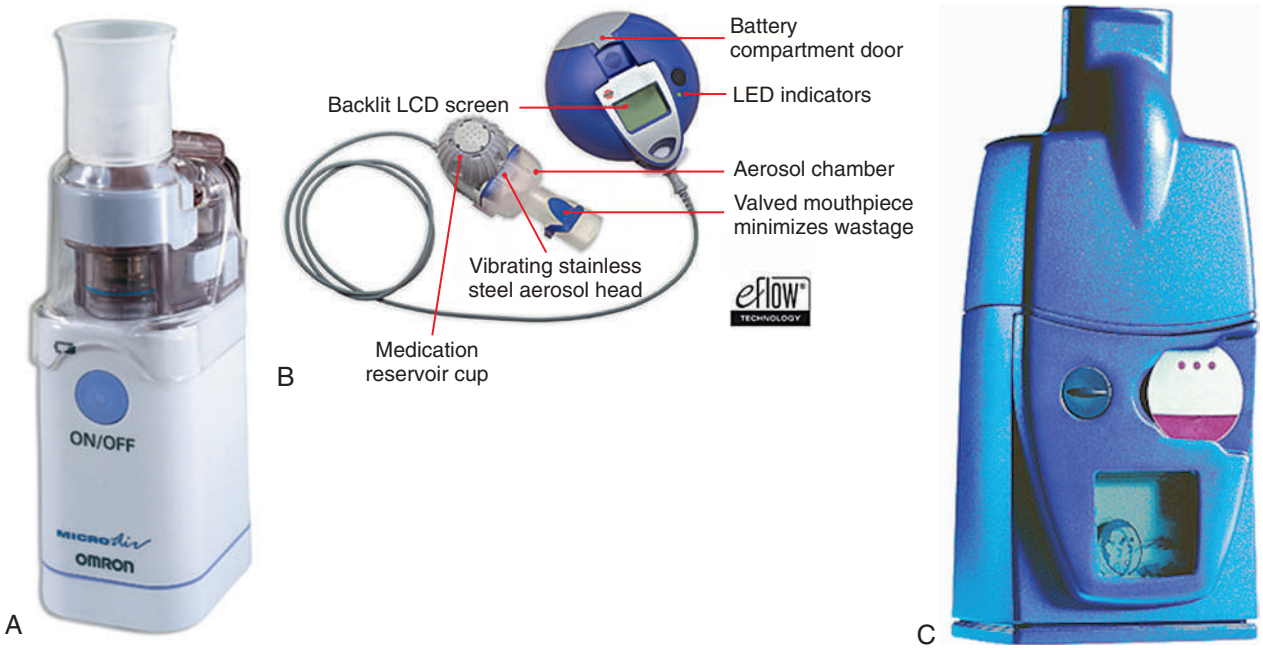

FIGURE 39-18 Variety of available aerosol devices. **A** and **C,** Passive mesh. **B,** Active vibrating mesh. (**A** and **C,** Courtesy Omron Healthcare, Inc. Bannockburn, IL. **B,** Courtesy PARI Respiratory Equipment, Inc., Midloathian, VA.)

the less aerosol impaction as gas passes through the airways, and the greater the deposition of aerosol in the lungs.[36] However, when heliox is used to drive a jet nebulizer at standard flow rates, aerosol output is substantially less than with air or O_2, and aerosol particles are considerably smaller. When driving a nebulizer with heliox, twofold to threefold greater flow is required to produce a comparable aerosol output. Heliox concentrations of 40% or greater have been shown to improve aerosol deposition.[37]

Humidity and Temperature. Humidity and temperature can affect particle size and the concentration of drug remaining in the nebulizer. Evaporation of water and adiabatic expansion of gas can reduce the temperature of the aerosol to 10° C less than ambient temperature. This cooling may increase solution viscosity and reduce the nebulizer output, while decreasing particle MMAD.[38] Aerosol particles entrained into a warm and fully saturated gas stream increase in size. These particles also can coalesce (stick together), increasing the MMAD further and, in the case of a DPI, can severely compromise the output of respirable particles. How much these particles enlarge depends primarily on the tonicity of the solution. Aerosols generated from isotonic solutions probably maintain their size as they enter the respiratory tract. Hypertonic solutions tend to enlarge, whereas evaporation can cause hypotonic droplets to evaporate and shrink.

Characteristics of Drug Formulation. The viscosity and density of a drug formulation affect both output and particle size. Some drugs, such as antibiotics, are so viscous that they cannot be used effectively for nebulization in some standard SVNs. Also, in some suspensions, some aerosolized particles contain no active drug, whereas other particles, generally larger, carry the active medication.

Small Volume Nebulizers

Four categories of jet SVNs include (1) continuous nebulizer with simple reservoir, (2) continuous nebulizer with collection reservoir bag, (3) breath-enhanced nebulizer, and (4) breath-actuated nebulizer (Figure 39-18, *A*, *B*, and *C*). The most commonly used SVN is the constant output design. Aerosol is generated continuously, with 30% to 60% of the nominal dose being trapped as residual volume in the nebulizer, and more than 60% of the emitted dose is wasted to the atmosphere. Continuous nebulization wastes medication because the aerosol is produced throughout the respiratory cycle and is largely lost to the atmosphere, as shown in Figure 39-19. Patients with an I : E ratio of 40 : 60 (or 1 : 1.5) lose 60% of the aerosol generated to the atmosphere. If 50% of the total dose is emitted from the nebulizer, and 50% of that aerosol is in the respiratory range and 40% of that is inhaled by the patient, less than 10% deposition is commonly measured in adults receiving continuous nebulizer therapy. In neonates and infants, given the small minute volumes and small airways with increased impaction and reduced sedimentation, deposition can be only 0.5%.

Aerosolized medication can also be conserved with reservoirs.[39] A reservoir on the expiratory limb of the nebulizer conserves drug aerosol.

Small Volume Nebulizer With a Reservoir. Many types of disposable SVNs are packaged with a 6-inch (15-cm) piece of aerosol tubing to be used as a reservoir (Figure 39-17, *A*). This may increase inhaled dose by 5% to 10% or increase the inhaled dose from 10% to approximately 11% with the reservoir tube.

Continuous Small Volume Nebulizer With Collection Bag. Bag reservoirs hold the aerosol generated during exhalation and allow the small particles to remain in suspension for inhalation with the next breath, while larger particles rain out.

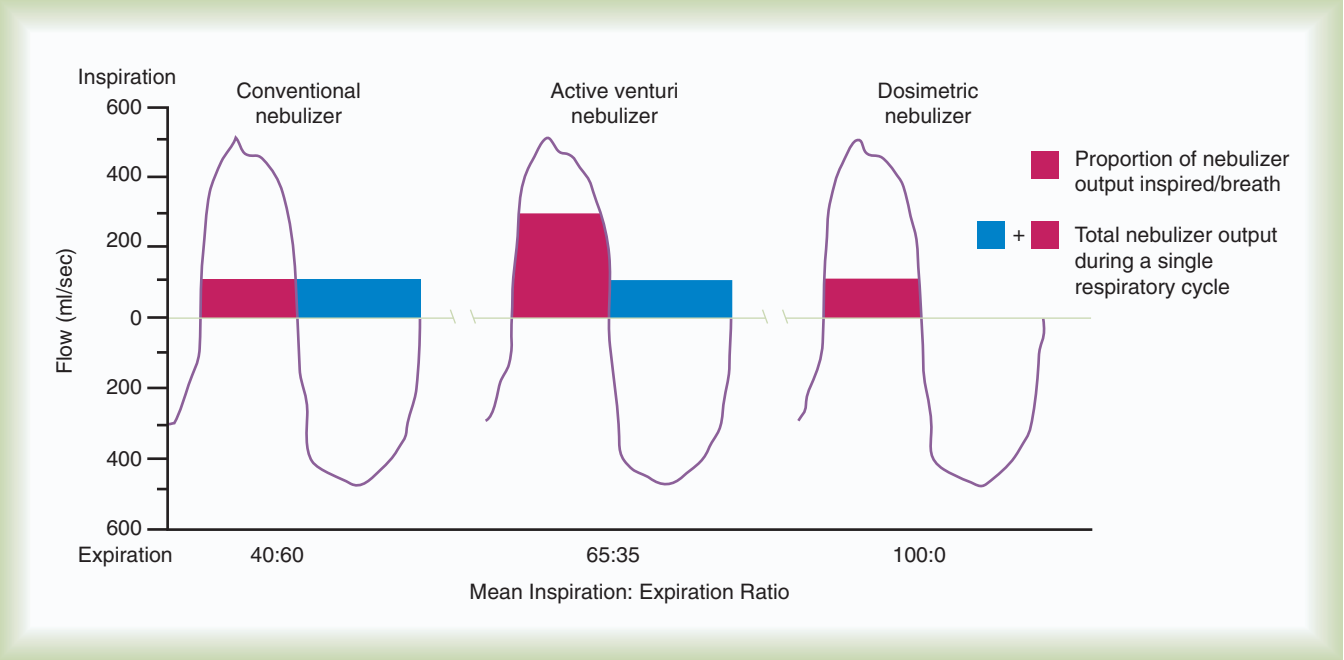

FIGURE 39-19 Proportions of nebulizer output inhaled with continuous standard jet nebulizer, vented nebulizer, and dosimetric (breath-actuated) nebulizer. (Modified from Nikander K: Drug delivery systems. Aerosol Med 7[Suppl 1]:S19, 1994.)

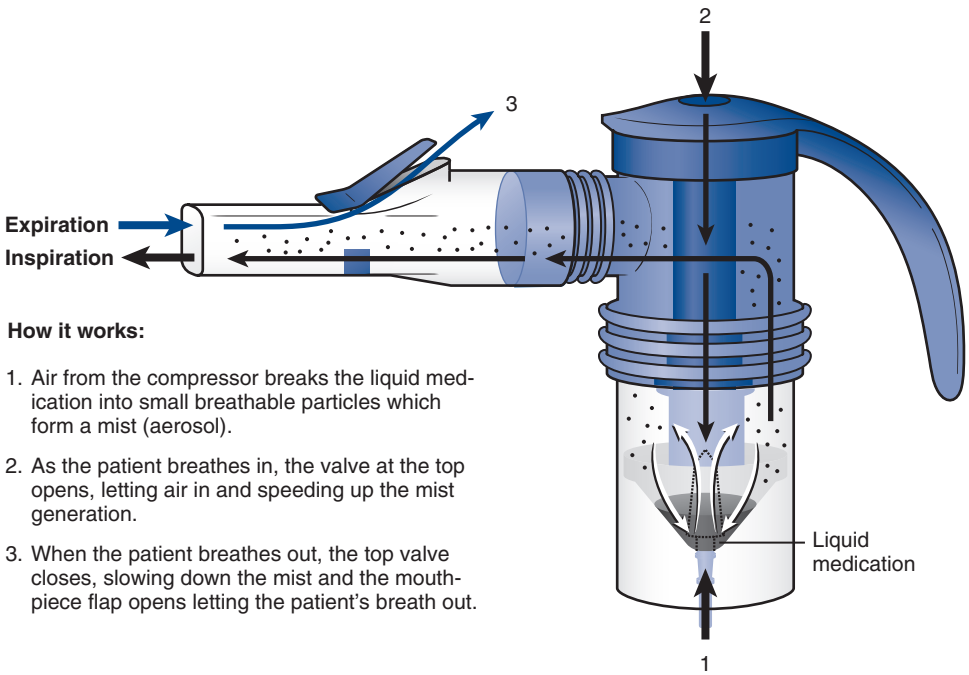

FIGURE 39-20 Operating principles of the Sprint (Pari, Midlothian, VA) breath-enhanced nebulizer. (From Cairo JM, Pilbeam SP: Mosby's respiratory care equipment, ed 8, St. Louis, 2009, Mosby.)

These additions have been attributed with a 30% to 50% increase in inhaled dose.[39] A collection bag is attached on the expiratory side of the nebulizer "T," which collects aerosol leaving the SVN when the patient is not actively inhaling. Some of the aerosol in the bag is inhaled with the next inspiration, increasing total dose efficiency.

Breath-Enhanced Nebulizers. **Breath-enhanced nebulizers** generate aerosol continuously, using a system of vents and one-way valves to minimize aerosol waste.[40] In the Pari LC Sprint (Pari, Midlothian, VA) breath-enhanced nebulizer (Figure 39-20), an inspiratory vent allows the patient to draw in air through the nebulization chamber generating and

containing aerosolized drug. On exhalation, the inlet vent closes, and aerosol exits by a one-way valve near the mouthpiece; this process can increase inhaled mass by 50% over standard continuous nebulizers and reduces aerosol waste to the atmosphere.

MINI CLINI

Home Nebulizer Therapy

PROBLEM: Many patients are sent home with a prescription for home nebulizer therapy prescribed with the intention of giving the patient the same quality of aerosol therapy he or she received in the hospital. However, the patient often is given the same type of nebulizer used in the hospital because it is inexpensive. These nebulizers provide an aerosol that is too large for optimal deposition in the lungs. What should be done instead?

DISCUSSION: Home nebulizers designed for use with compressors should be matched to ensure an MMAD of 1 to 5 µm with the medication being administered. Nebulizer manufacturers such as Pari and Medic-Aid offer matched nebulizer-compressor systems for home use. Although these devices cost a little more, they are more likely to meet therapeutic objectives.

Breath-Actuated Nebulizers. Breath-actuated nebulizers synchronize aerosol generation with inspiration, reducing waste of aerosol during exhalation and increasing inhaled dose up to threefold more than continuous and breath-enhanced nebulizers. Dosimeters, used in pulmonary function laboratories, sense inspiration and pulse airflow to the jet orifice and transform a conventional nebulizer into a breath-actuated system. Manual systems allow the user to cover a thumb port directing compressed gas to the jet nebulizer.

AeroEclipse (Trudell Medical International, London, Ontario, Canada) is a breath-actuated SVN. A unique, spring-loaded, one-way valve design draws the jet to the capillary tube during inspiration and causes nebulization to cease when the patient's inspiratory flow decreases below the threshold or the patient exhales into the device (Figure 39-21). Expiratory pressure on the valve at the initiation of exhalation moves the nebulizer baffle away from its position directly above the jet orifice, reduces the pressure, and stops aerosolization. Because aerosol is generated only during inhalation, exhaled aerosol and contamination of the environment during the expiratory phase of the breathing cycle are largely reduced.

It can be difficult to determine when a nebulizer treatment is complete. Aerosol delivery from a jet nebulizer ceased after the onset of inconsistent nebulization (sputtering) (Figure 39-22).[41] Aerosol output declined by one-half within 20 seconds of the onset of sputtering. The concentration of albuterol in the nebulizer cup increased significantly when the aerosol output declined, and further weight loss in the nebulizer was caused primarily by evaporation. Most consider aerosolization past the point of initial nebulizer sputter ineffective.

Table 39-2 summarizes some of these key factors for many commercially available SVNs.[42] Numerous SVNs are on the market, and they vary widely in design and performance. SVNs of the same design and lot number can exhibit variable performance, even to the point that some nebulizers of the same model number do not work at all.[43] Managers and clinicians always must evaluate SVNs carefully before purchasing or using them. Manufacturers should provide data on the performance of their nebulizers under common use conditions.

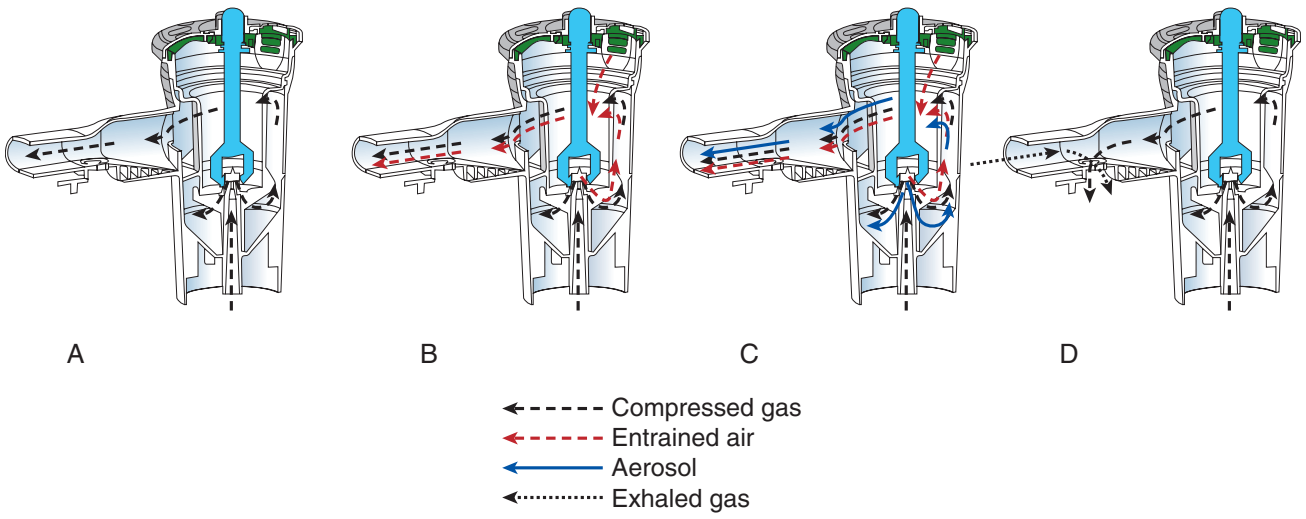

FIGURE 39-21 Breath-actuated pneumatic nebulizer (AeroEclipse BANII) flow path diagram. **A,** Before inhalation, actuator is up, and compressed gas freely circulates with no aerosol produced. **B,** Patient inhales, and actuator starts to move down. **C,** Negative pressure pulls the diaphragm down (with actuator moved down sealing around the nozzle cover), producing aerosol. **D,** Patient exhales through valve in mouthpiece; as pressure increases, the diaphragm and actuator move up, stopping aerosol production. (Courtesy Trudell Medical International, London, Ontario, Canada.)

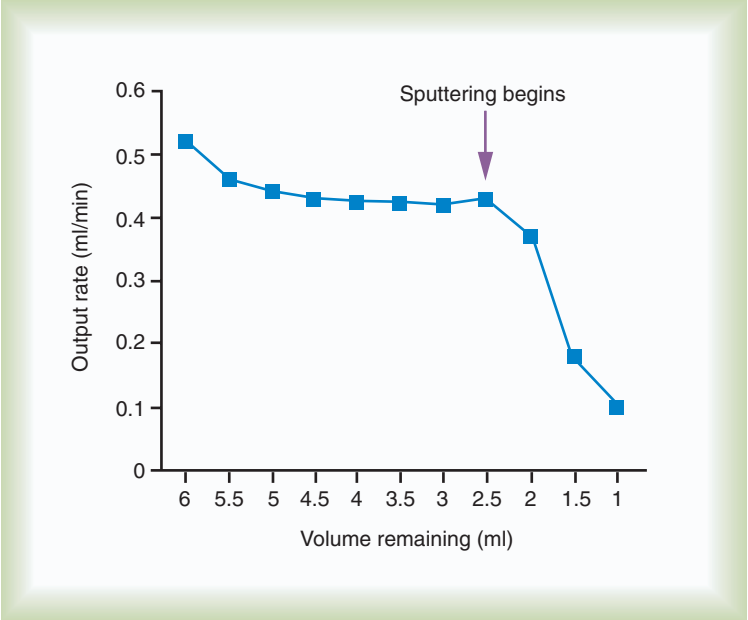

FIGURE 39-22 Output rate for jet nebulizers is substantially reduced as the nebulizer begins to sputter. The decrease in output rate correlates with reduced drug output. This finding supports a recommendation to end treatment when sputtering begins. (Modified from Malone RA, Hollie MC, Glynn-Barnhart A, et al: Optimal duration of nebulized albuterol therapy. Chest 104:1114, 1993.)

Suspensions	Low efficiency	Poor efficiency	Variable efficiency
Denaturation	Possible‡	Probable‡	Possible‡
Cleaning	Required, after single use	Required, after multiple use	Required after single use
Cost	Very low	High	High

Modified from Dolovich MB, Dhand R: Aerosol drug delivery: developments in device design and clinical use. Lancet 377:1032, 2011.
*For jet nebulizers, the temperature of the reservoir fluid decreases about 15° C during nebulization because of evaporation.
†For ultrasonic nebulizers, vibration of the reservoir fluid causes a temperature increase during aerosol generation, which can be 10° C to 15° C.
‡Denaturation of DNA occurs with all the nebulizers.

Technique. Box 39-6 outlines the optimal technique for using an SVN for aerosol drug delivery. Use of an SVN is less technique-dependent and device-dependent than use of a pMDI or DPI delivery system. Slow inspiratory flow optimizes SVN aerosol deposition. However, deep breathing and breath holding during SVN therapy do little to enhance deposition over normal tidal breathing.[44] Because the nose is an efficient filter of particles larger than 5 µm, many clinicians prefer not to use a mask for SVN therapy. As long as the patient is mouth breathing, there is little difference in clinical response between therapy given by mouthpiece and therapy given by mask. The selection of delivery method (mask or mouthpiece) should be based on patient ability, preference, and comfort.

Infection Control Issues. The CDC recommends that nebulizers be cleaned and disinfected, rinsed with sterile water, or air dried between uses. Jet SVNs have reservoirs that are open

to and positioned below the mouthpiece or mask. This allows secretions from the patient to enter the medication cup, contaminating medication.

Multidose drug containers have been associated with contamination. After 7 days of nebulizer use five of six multidose containers of medication solutions were found to be contaminated.[45] Refrigerating solutions and discarding syringes every 24 hours eliminated bacterial contamination. Use of single dose ampoules have not been associated with contamination of medications. In addition, some recommend one nebulizer for one treatment. The Cystic Fibrosis Foundation recommends that standard small volume nebulizers should be discarded after each treatment to prevent infection in cyctic fibrosis patients.

Box 39-6 Optimal Technique for Using a Small Volume Nebulizer

1. Assess the patient for need (clinical signs and symptoms, breath sounds, peak flow, $\%FEV_1$).
2. Select mask or mouthpiece delivery (nose clips may be needed with mouthpiece).
3. Use conserving system (thumb port, breath actuator or reservoir) if indicated.
4. Place drug in the nebulizer. If using a multidose vial, add saline to approved dose volume (per drug label).
5. Set gas flow to nebulizer at 6 to 10 L/min (per manufacturer label).
6. Coach patient to breathe slowly through the mouth at normal V_T.
7. Continue treatment until nebulizer begins to sputter.
8. Rinse the nebulizer with sterile water and air dry, or discard, between treatments.
9. Monitor patient for adverse response.
10. Assess outcome (change in peak flow, $\%FEV_1$).

Large Volume Jet Nebulizers

Large volume jet nebulizers are also used to deliver aerosolized drugs to the lung and are particularly useful when traditional dosing strategies are ineffective in the management of severe bronchospasm. When a patient with airway obstruction does not respond to a standard dosage of bronchodilator, it is common to repeat the treatment every 15 minutes. An alternative approach is to provide continuous nebulization with a specialized large volume nebulizer.

The high-output extended aerosol respiratory therapy nebulizers HEART (Cardinal Health, Dublin, OH) and HOPE (B & B Medical Technologies, Carlsbad, CA) are examples of devices designed for this purpose. These nebulizers have a reservoir greater than 200 ml that produces an aerosol with an MMAD of 2.2 to 3.5 µm. Actual output and particle size vary with the pressure and flow at which the nebulizer operates. A concern with continuous bronchodilator therapy (CBT) is increased drug concentration. Patients receiving CBT need close monitoring for signs of drug toxicity (e.g., tachycardia and tremor). An additional strategy is to use an intravenous infusion pump to drip premixed bronchodilator solution into a standard SVN. Although this is an equipment-intensive approach, this technique can provide dosing equivalent to therapy performed every 15 minutes.[46]

Another special-purpose large volume nebulizer is a *small particle aerosol generator (SPAG)* (Figure 39-23). The SPAG was developed in the 1940s to study pathogen aerosols, and subsequently manufactured by ICN Pharmaceuticals specifically for administration of ribavirin (Virazole) to infants with respiratory syncytial virus infection. The device is unique in clinical respiratory care practice. It incorporates a drying chamber with its own flow control to produce a stable aerosol. The SPAG reduces medical gas source from the normal 50 *pounds per square inch gauge (psig)* line pressure to 26 psig with an

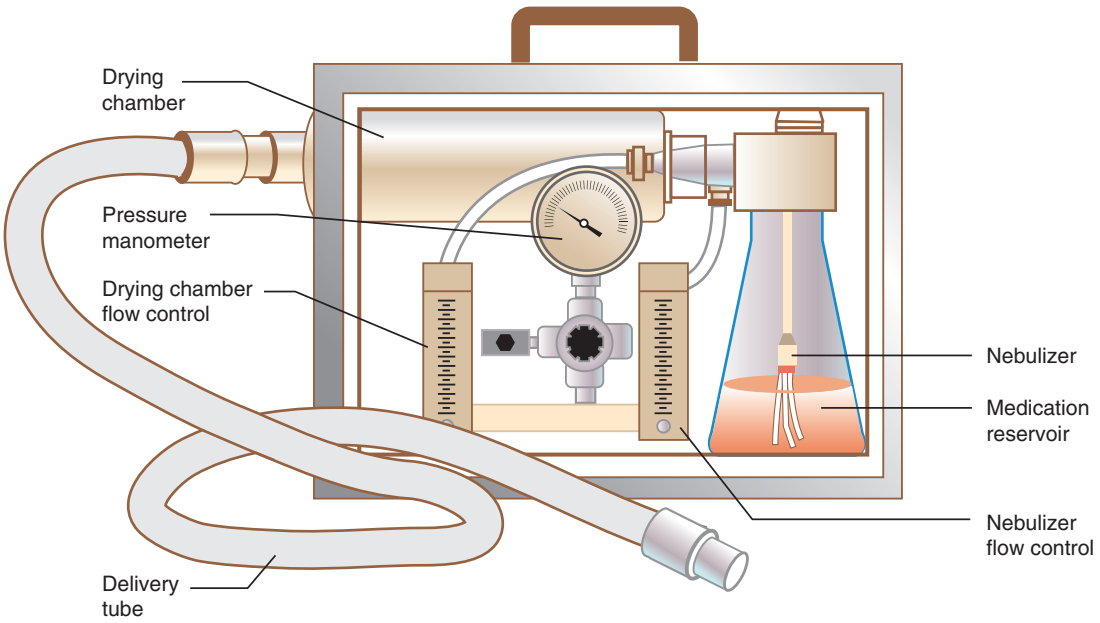

FIGURE 39-23 Small particle aerosol generator (SPAG).

adjustable regulator. The regulator is connected to two flowmeters that separately control flow to the nebulizer and flow through the drying chamber. The nebulizer is located within the glass medication reservoir, the fluid surface and wall of which serve as primary baffles. As it leaves the medication reservoir, the aerosol enters a long, cylindrical drying chamber. Here the second (separate) flow of dry gas is added, reducing particle size by evaporation, creating a monodisperse aerosol with an MMAD of 1.2 to 1.4 μm. Nebulizer flow should be maintained at approximately 7 L/min with total flow from both flowmeters not less than 15 L/min. The latest model operates consistently even with back pressure and can be used with masks, hoods, tents, or ventilator circuits.

Two specific problems are associated with SPAG use to deliver ribavirin. The first is caregiver exposure to the drug aerosol. Approaches to limit caregiver exposure are discussed later (see the section on Controlling Environmental Contamination). The other problem occurs only when the SPAG is used to deliver ribavirin through a mechanical ventilator circuit. Drug precipitation can jam breathing valves or occlude the ventilator circuit. This problem can be overcome by (1) placing a one-way valve between the SPAG and the circuit and (2) filtering out the excess aerosol particles before they reach the exhalation valve, and changing filters frequently to avoid increasing expiratory resistance.[44]

Hand-Bulb Atomizers and Spray Pumps

Hand-bulb atomizers and nasal spray pumps are used to administer sympathomimetic, anticholinergic, antiinflammatory, and anesthetic aerosols to the upper airway, including nasal passages, pharynx, and larynx (see also Chapter 35). These agents are used to manage upper airway inflammation and rhinitis, to provide local anesthesia, and to achieve systemic effects.

Because the spray pump generates relatively low pressure and does not have baffles, it produces an aerosol with large particle size (high MMAD and GSD), ideal for upper airway deposition. (Nasopharyngeal deposition is greatest for particles 5 to 40 μm.) Deposition with the hand-bulb atomizer applied to the nose occurs mostly in the anterior nasal passages with clearance to the nasopharynx. The 100-mcl puffs appear to deposit more medication than 50-mcl puffs, and deposition to a greater surface area occurs with a 35-degree spray angle than with a 60-degree angle.

Ultrasonic Nebulizers

The USN uses a piezoelectric crystal to generate an aerosol. The crystal transducer converts an electrical signal into high-frequency (1.2- to 2.4-MHz) acoustic vibrations. These vibrations are focused in the liquid above the transducer, where they disrupt the surface and create oscillation waves (Figure 39-24). If the frequency of the signal is high enough and its amplitude strong enough, the oscillation waves form a standing wave that generates a geyser of droplets that break free as fine aerosol particles.

USNs are capable of higher aerosol outputs (0.2 to >1.0 ml/min) and higher aerosol densities than conventional jet nebulizers. Output is determined by the amplitude setting (sometimes user-selected). The greater the signal amplitude, the greater the nebulizer output. Particle size is inversely proportional to the frequency of vibrations. Frequency is device-specific and is not user-adjustable. For example, the DeVilbiss (Somerset, PA) Portasonic nebulizer operating at a frequency of 2.25 MHz produces particles with an MMAD of 2.5 μm, whereas the DeVilbiss Pulmosonic nebulizer operating at 1.25 MHz produces particles in the 4- to 6-μm range. Particle size and aerosol density also depend on the source and flow of gas conducting the aerosol to the patient.

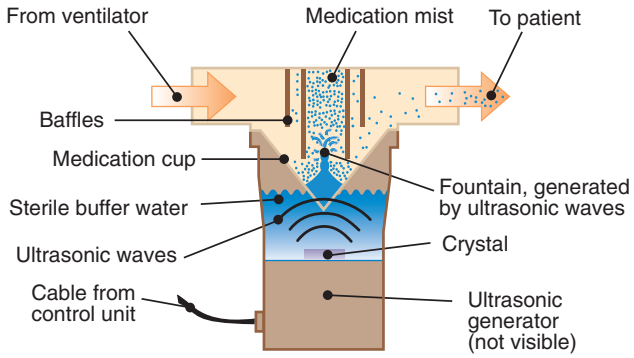

FIGURE 39-24 Small volume USN designed for use with mechanical ventilation. A vibrating piezoceramic crystal generates ultrasonic waves that pass through couplant (sterile buffer water) and the medication cup to generate a fountain (or standing wave) of medication that produces aerosol particles. (Courtesy Siemens, Tarrytown, New York.)

Large Volume Ultrasonic Nebulizers. Large volume USNs (used mainly for bland aerosol therapy or sputum induction) incorporate air blowers to carry the mist to the patient (Chapter 38). Low flow through the USN is associated with higher mist density. In contrast to jet nebulizers, the temperature of the solution placed in a USN increases during use. As the temperature increases, the drug concentration increases, and proteins can be denatured.

Small Volume Ultrasonic Nebulizers. Many small volume USNs have been marketed for aerosol drug delivery (see Figure 39-24). In contrast to the larger units, some of these systems do not use a couplant compartment; the medication is placed directly into the manifold on top of the transducer. The transducer is connected by a cable to a power source, often battery-powered to increase portability. These devices have no blower; the patient's inspiratory flow draws the aerosol from the nebulizer into the lung.

Small volume USNs administer a wide variety of formulations ranging from bronchodilators to antiinflammatory agents and antibiotics.[47] Suspensions such as budesonide may not nebulize well with USNs, because large suspension aerosol particles that are larger than the aerosol particles remain in the medication cup. Use of a small volume USN may increase available respirable mass for designs with less residual drug volume than SVNs; this may reduce the need for a large quantity of diluent to ensure delivery of the drugs. The contained portable power source adds a great deal of convenience in mobility.

However, sometimes the theoretical advantages of the ultrasonic devices are outweighed by relatively high purchase costs and poor reliability.

Small volume USNs have been used to administer undiluted bronchodilators to patients with severe bronchospasm.[47] Because the nebulizers have minimal residual drug volume, the treatment time is reduced with smaller volumes; however, it may be increased with standard dosing volumes. Some ventilator manufacturers (e.g., Maquet, Rastatt, Germany) have promoted the use of USNs for administration of aerosols during mechanical ventilation. In contrast to SVNs, USNs do not add extra gas flow to the ventilator circuit during use. This feature reduces the need to change and reset ventilator and alarm settings during aerosol administration.[48]

Vibrating Mesh Nebulizers

Two types of VM nebulizers, active and passive, are available commercially.[49] Active VM nebulizers use a dome-shaped aperture plate, containing more than 1000 funnel-shaped apertures. The dome is attached to a plate that is also connected to a piezoceramic element surrounding the aperture plate. Electrical energy applied to the piezoceramic element vibrates the aperture plate at a frequency of approximately 130 kHz (or one-tenth that of a USN), moving the aperture plate up and down by approximately 1 µm, creating an electronic micropump. The plate actively pumps the liquid through the apertures, where it is broken into fine droplets. The exit velocity of the aerosol is low (<4 m/sec), and the particle size can range from 3 to 4 µm (MMAD), varying with the exit diameter of the apertures (Figure 39-25, *A* and *B*). Examples of an active VM nebulizer include the Aeroneb Go, Pro, and Solo nebulizers (Aerogen, Inc, Galway, Ireland) and the eFlow nebulizers (Pari, Midlothian, VA). An active VM nebulizer can nebulize single drops of 15 mcl of formulations containing small and large molecules, suspensions, microsuspensions, and liposomes.

Passive VM nebulizers use a mesh separated from an ultrasonic horn by the liquid solution for nebulization. A piezoelectric transducer vibrates the ultrasonic horn, which pushes fluid through the mesh. Passive VM nebulizers include the NEU-22 (Omron, Kyoto, Japan) and the I-Neb (Philips Respironics, Murraysville, PA).

The residual drug volumes with either type of VM nebulizer range from 0.1 to 0.4 ml, in contrast to other types of liquid aerosol generators with residual drug volumes of 0.8 to 1.5 ml. Because a greater percentage of standard unit doses is emitted as aerosol, care should be exercised when transitioning to these devices to ensure that the higher dose does not create adverse effects.

New-Generation Nebulizers

Low-velocity (soft mist) aerosol, smaller particle size distribution, and systems that minimize residual volume of medication left in the nebulizer substantially improve aerosol device efficiency. Along with improved performance, some "smart" nebulizers have the capability to monitor patient compliance and aid in managing the patient's treatment schedule.

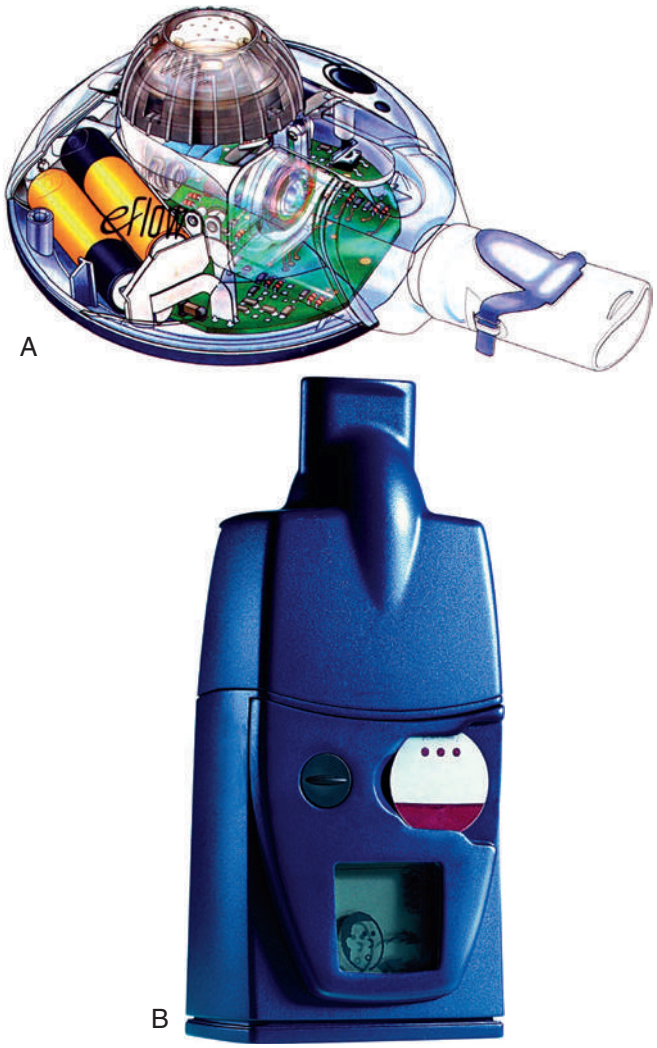

FIGURE 39-25 VM nebulizers use two basic configurations. Active VM nebulizer **(A)** has an aperture plate with funnel-shaped holes vibrated by a piezoelectric transducer surrounding the aperture plate found in the Aeroneb Solo (Aerogen, Galway, Ireland) and eFlow (Pari, Midlothian, VA; **A**). Passive VM nebulizer **(B)** uses an ultrasonic horn to push fluid through a stationary mesh found in the NEU-22 (Omron; **B**) and iNeb (Phillips/Respironics, Murrysville, PA).

With pulmonary deposition increased from the old standard of approximately 10% to more than 60% of the nominal dose, these recent device improvements may be accompanied by greater systemic side effects, unless the delivered dose is reduced. The key is to be able to target an effective delivered dose to the lungs.

New Nebulizer Designs for Liquids. New nebulizer designs are available for delivery of liquids.[50,51]

AERx. The AERx (Aradigm Corp, Hayward, CA) uses a drug solution in a unit-dose, sterile, preservative-free blister pack containing 25 to 50 mcl of fluid. The drug is extruded under pressure through a nozzle containing many small, precision-drilled holes that produce a fine, respirable spray on inhalation. The aerosolization nozzle is part of the disposable

blister and is not reused. The dose from a single blister is metered in approximately 1.5 seconds. The emitted dose is more than 70% of the dose contained in the blister with an inspiratory flow rate range of 30 to 85 L/min. The AERx is being tested for use with numerous drugs in liquid form for both topical and systemic therapy. It has built-in electronic monitoring capabilities for measuring *inspiratory flow rate* during dosing and for triggering and dispensing the dose at the appropriate inspiratory flow rate for optimal delivery. The dose administered is logged to provide a record of treatments and an indication of patient compliance with therapy.

Fox. The Fox inhalation system (Vectura Group, Wilshire, UK) is an active vibrating mesh nebulizer with a flow- and volume-controlled inhalation system that increases intrapulmonary deposition. The device targets aerosol deposition in the peripheral and central airways by controlling the time of aerosol release during therapy. While releasing the aerosol at the beginning of inspiration leads to peripheral deposition, the release of aerosols in the middle of inhalation results in aerosol deposition in central airways. The Fox inhalation system is approved for delivery of different medications in Europe but not available in the United States.

Tyvaso®. The Tyvaso® Optineb is a pulsed ultrasonic nebulizer that is used for delivery of treprostinil. Device preparation requires assembly of different parts of the device including dome, inhalation piece, filters, and mouthpiece. A couplant chamber is filled with water between the piezo and the medication cup. A daily dose is placed in the medication cup and patients are instructed to take a set number of breaths per treatment, at set intervals during the day, with the device cleaned at the end of the day. The Optineb provides auditory and visual feedback on the patient's inhalation technique. Also, if a patient stops inhalations during therapy, the device shows the remaining breaths in the numerical display that are needed to complete the treatment.

Respimat. The Respimat soft mist inhaler (Boehringer, Ingelheim am Rhein, Germany) is a small hand-held inhaler that uses mechanical energy to create an aerosol from liquid solutions to produce a low-velocity spray (10 mm/sec) that delivers a unit dose of drug in a single actuation. To operate the device, patients twist the body of the device to load an internal spring, place the mouthpiece of the Respimat between the lips, and press a button to release the drug through a uniblock to create the aerosol, which is released over 1.1 to 1.4 seconds, depending on the formulation configuration. The Respimat requires hand-breath coordination on the part of the patient, as does a pMDI, but because of the longer aerosolization time, it seems more likely that the patient will get a greater percent of emitted dose despite coordination issues. Because of the small particle size and low-velocity spray, pulmonary deposition of 40% is independent of inspiratory flows with oral deposition (40%) half the oral deposition with most pMDIs and DPIs (80%). The Respimat is currently available with several drugs in Europe and with tiotropium in the United States.[52]

Smart Nebulizers. The I-Neb (Phillips Respironics, Murrysville, PA) is a breath-actuated passive VM nebulizer with *adaptive aerosol delivery* that monitors pressure changes and inspiratory time for the patient's first three consecutive breaths (Figure 39-26).[53] Drug is then aerosolized over 50% of the inspiratory maneuver during the fourth and all subsequent breaths. *Targeted inhalation mode* guides the patient to take serially longer inspirations to achieve optimal inhalation duration, reducing the time for administration. When the prescribed emitted dose has been aerosolized, the system provides an audible signal indicating the treatment should be stopped and the remaining medication discarded. Built-in electronics monitor patient treatment schedules and delivered doses with the goal to improve compliance with therapy. The I-Neb has been released for delivery of prostacyclin.

The Akita (Activaero, Gemuenden/Wohra, Germany) allows controlled inhalation of aerosol produced by either a jet or VM nebulizer. The Akita controls inspiratory flow to keep it slow (12 to 15 L/min), reducing impaction loss of aerosols in the upper airways. Patient pulmonary function is stored on a smart card programmed to tell the device when to generate aerosol during inspiration. Aerosol generated early targets distal airways, whereas aerosol generated later in the breath targets larger, more central airways.[54] Smart nebulizers can track the actual time, duration, and dose administered for each treatment and provide logs of use that can be downloaded for the medical or research record.

Advantages and Disadvantages of Aerosol Systems

Knowledge of the advantages and disadvantages of various aerosol drug delivery systems is crucial for proper selection and application. Table 39-3 compares pMDI, DPI, SVN, and USN delivery systems.

Special Medication Delivery Issues for Infants and Children

Children and infants have a smaller airway diameter than adults. In addition, their breathing rate is faster, and nose breathing filters out large particles and deposits more medication in the upper airway. Also, mouthpiece administration often cannot be used before 3 years of age. Patient cooperation and ability vary with age and developmental ability. Finally, infants and small children have lower minute volumes than adults and so inhale a smaller proportion of the output of continuous nebulizers than adults.[6]

Normal tidal breathing is the most effective method for administering aerosols to an infant. Mouth breathing enhances medication delivery to the airways of adults, but there is little evidence to show that this is true for infants, who are preferential nose breathers up to 1 year of age. Crying greatly reduces lower airway deposition of aerosol medication; therefore, aerosols should not be administered to a crying child (Figure 39-27).

For infants and children who can tolerate a mask, a medication nebulizer can be fitted to an appropriately sized aerosol mask. There is no difference in clinical response between mouthpiece and close-fitting mask treatment, so patient tolerance, compliance, and preference should guide selection of the

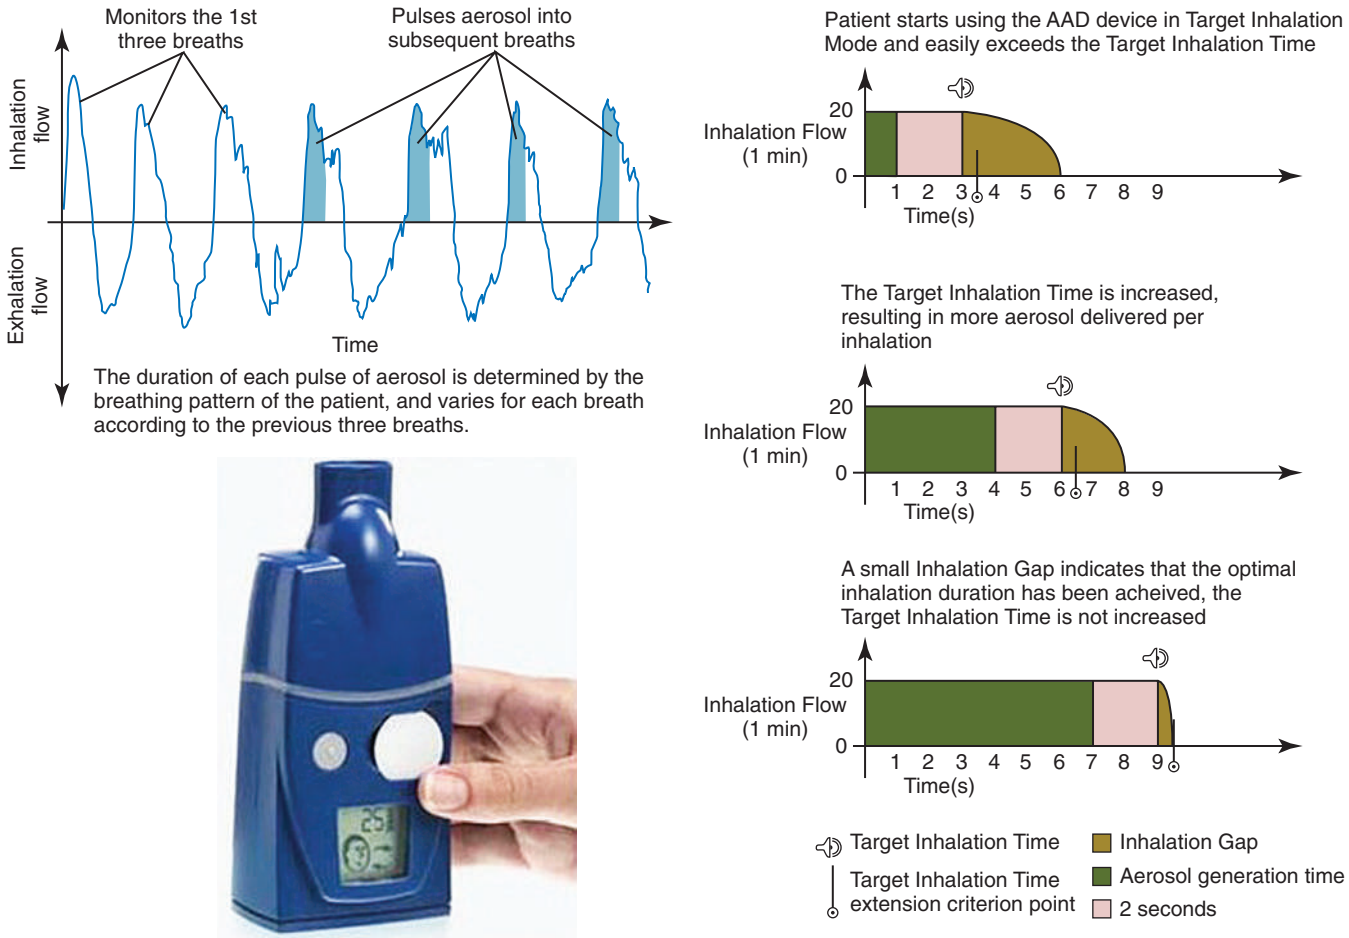

FIGURE 39-26 The iNeb *(bottom left)* is a smart nebulizer with adaptive aerosol delivery (AAD) and targeted inhalation mode (TIM). AAD delivers a precise preset dose with variation between patients. A microprocessor tracks the patient's breathing pattern on a running average of the previous three breaths, generating aerosol for 50% of the predicted inspiration *(upper left)*. TIM progressively guides the patient to take longer inspirations, increasing to achieve optimal inhalation duration *(right)*.

device. There is evidence that the aerosol available to the patient is substantially less when a loosely fitting mask (>1-cm leak) is used rather than a snug mask or mouthpiece with either a nebulizer or a pMDI with a holding chamber.[54,55] If a patient cannot tolerate mask treatment (e.g., will not wear a close-fitting mask without agitation), a commonly used strategy is the "blow-by" technique, in which the practitioner directs the aerosol from the nebulizer toward the patient's nose and mouth from a distance of several inches from the face. Studies suggest a greatly reduced inhaled dose with blow-by. Rather than "blow-by," it may be more efficient to take the time to condition the infant or child to tolerate the mask without crying or to deliver medication with a close-fitting mask when the patient is asleep.[56]

A pediatric mask with an integrated pacifier uses the infant's pull on the pacifier to hold the mask in place with improved face-mask seal which may reduce agitation and crying associated with standard masks (Soothermask InspiRx Inc, Somerset, NJ). Given the cognitive and functional limitations of very young patients, not all delivery devices are suitable for these patients. To help guide clinicians, the accompanying Rule of Thumb outlines age-specific guidelines for using aerosol devices in pediatric and neonatal patients.

RULE OF THUMB

Guidelines for Use of Aerosol Devices in the Care of Infants and Children

Device	Age Group
SVN	Neonate to all ages
Valved chamber with mask	Neonate/infant/toddler
Valved chamber with mouthpiece	>3 years
pMDI alone	>4 years
Breath-actuated Neb	>4 years
DPI	≥4 years

Spontaneous breathing in all patient populations results in greater deposition of aerosol from an SVN than occurs with positive pressure breaths (e.g., intermittent positive pressure ventilation [IPPB]). IPPB reduces aerosol deposition more than 30% compared with spontaneously inhaled aerosols.[57]

TABLE 39-3

Advantages and Disadvantages of Aerosol Drug Delivery Systems

Advantages	Disadvantages
pMDI	
Convenient	Patient coordination required
Inexpensive	Patient activation required
Portable	High percentage of pharyngeal deposition
No drug preparation required	Risk of abuse
Difficult to contaminate	Difficult to deliver high doses
	Not all medications are available
	Most units still use ozone-depleting CFCs
	Expensive
pMDI With Accessory Device	
Less patient coordination required	More complex for some patients
	More expensive than MDI alone
Less pharyngeal deposition	Less portable than MDI alone
No drug preparation required	Not all medications available
DPI	
Less patient coordination required	Requires high inspiratory flow
	Most units are single dose
Breath-activated	Risk of pharyngeal deposition
Breath hold not required	Not all medications are available
Can provide accurate dose counts	Difficult to deliver high doses
	Expensive
No CFCs	
SVN	
Inexpensive	Wasteful
Less patient coordination required	Drug preparation required
	Contamination possible if device not cleaned carefully
High doses possible (even continuous)	Not all medications available
No CFC release	Pressurized gas source required
	Long treatment times
USN	
Moderate residual volume	Expensive
Quiet	Prone to electrical or mechanical breakdown
Smaller residual drug volume than SVN	Not all medications available
Aerosol accumulates during exhalation	Drug preparation required
VM Nebulizer	
Low residual volume	Expensive
Quiet	Not all medications available
Does not require gas or propellant	Drug preparation required
Flow-independent delivery	
Shorter treatment times	

Modified from Hess D: Aerosol delivery. Respir Care Clin N Am 1:235, 1995.

Selecting an Aerosol Drug Delivery System

pMDIs, DPIs, and nebulizers all work with comparable clinical results, as long as they are prescribed for the appropriate patients and are used properly.[58-60] Consequently, clinicians need to know the strengths and limitations of each type of device, match the device to each patient, and ensure that the patient or caregiver is trained to use the device properly.[51] Figure 39-28 is an algorithm that provides guidance regarding device selection.

Box 39-7 Factors Associated With Reduced Aerosol Drug Deposition in the Lung

- Mechanical ventilation
- Artificial airways
- Reduced airway caliber (e.g., infants and children)
- Severe airway obstruction
- High gas flows
- Low minute volumes
- Poor patient compliance or technique
- Limitation of specific delivery device

Regardless of the device used, the clinician must be aware of the limitations of aerosol drug therapy. First, depending on the device and patient, 10% or less of drug emitted from an aerosol device may be deposited in the lungs (Figure 39-29). As indicated in Box 39-7, additional reductions in lung deposition can occur in many clinical situations that sometimes necessitate the use of higher dosages. Clinical efficacy varies according to both patient technique and device design. For these reasons, the best approach to aerosol drug therapy is to use an assessment-based protocol that emphasizes individually tailored therapy modified according to patient response.

ASSESSMENT-BASED BRONCHODILATOR THERAPY PROTOCOLS

Although the choice of delivery system affects how well an aerosolized drug works, it is ultimately the patient's response that determines the therapeutic outcome. Because patients vary markedly in response to the dose and route of drug administration, it makes sense to tailor aerosol drug therapy to each patient. This approach is best determined with an assessment-based protocol.

Sample Protocol

Figure 39-30 is an algorithm of a bronchodilator therapy protocol for acutely ill adults or children admitted to an emergency department.[61] The protocol relies heavily on bedside assessment of the severity of airway obstruction based on the patient's response to varying drug dosages.

According to the algorithm, a patient with acute airway obstruction (wheezing, cough, dyspnea, and peak expiratory flow rate [PEFR] <60% of predicted value) would receive up to three SVN treatments with a standard dose of albuterol, repeated at 20-minute intervals, or 4 puffs of pMDI albuterol with a holding chamber (up to 12 puffs). Each treatment is followed by a dose-response assessment to determine the "best" dose. Once determined, this best dose, with the pMDI or SVN, is repeated 1 hour later, then every 4 hours as needed, supplemented with patient education. If use of the SVN or pMDI with

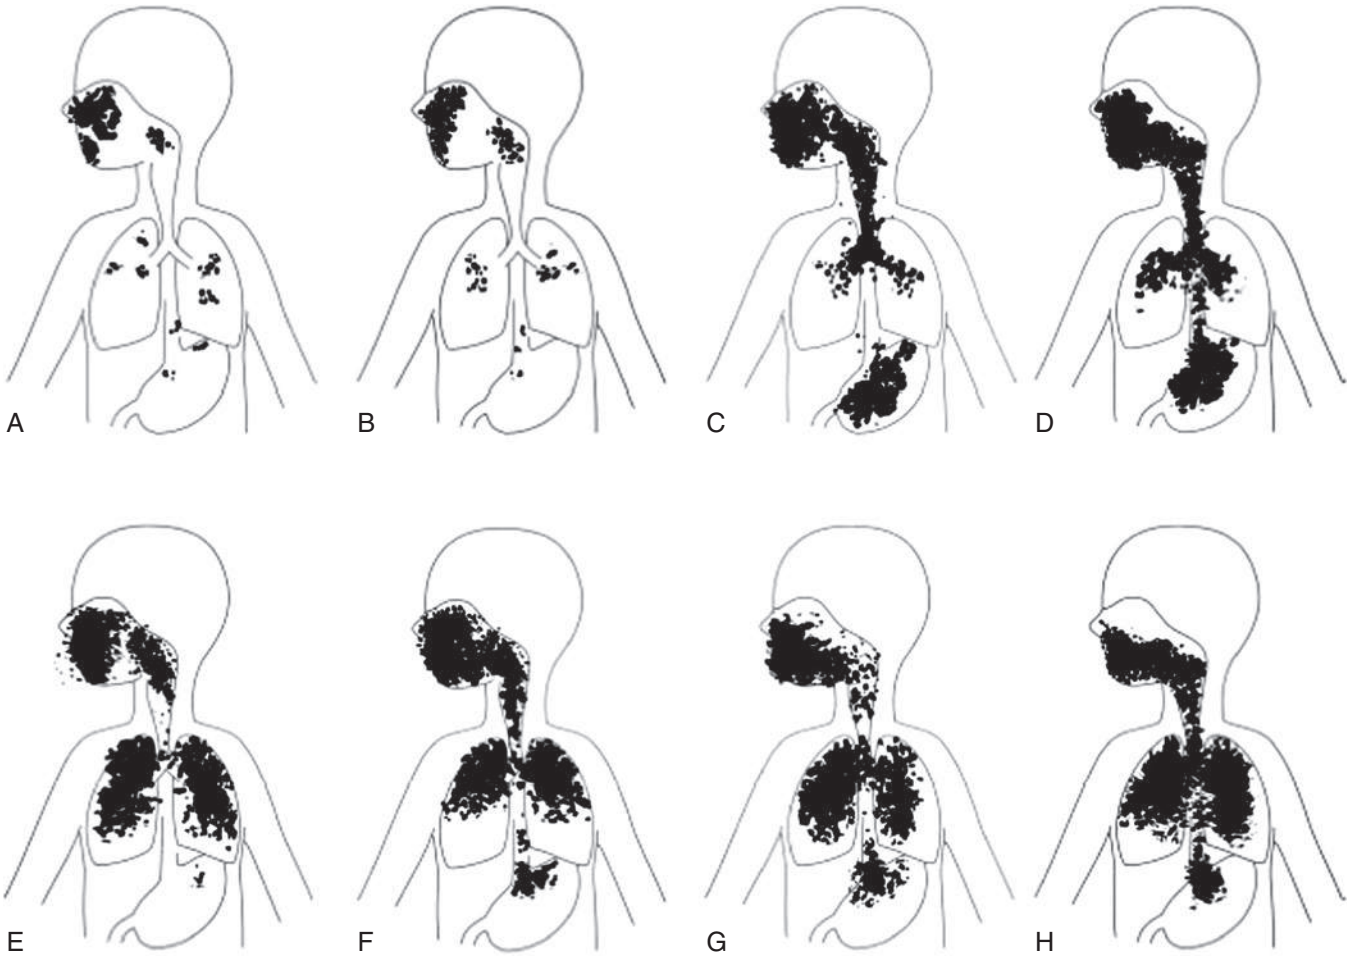

FIGURE 39-27 Drug deposition of radiolabeled albuterol in a young child **(A)** inhaling with a pMDI/space through a non-tightly fitted facemask; **(B)** inhaling with a nebulizer through a non-tightly fitted facemask; **(C)** inhaling with a pMDI/spacer through a tightly fitted facemask, screaming during inhalation; **(E, F)** inhaling with a pMDI/spacer through a tightly fitted facemask, quietly inhaling; and **(G, H)** inhaling from a nebulizer through a tightly fitted facemask, quietly inhaling. (Redrawn from Erzinger, S, Schueepp, KG, Brooks-Wildhaber, J, et al: Facemasks and aerosol delivery in vivo. J Aerosol Med 2007;20(Suppl 1.):S78–S84.)

holding chamber fails to relieve the symptoms, CBT with 15 mg/hr albuterol is generally started.

Assessing Patient Response

Careful, ongoing patient assessment is key to an effective bronchodilator therapy protocol.

Use and Limitations of Peak Flow Monitoring

Because the peak flow measurement is effort-dependent and volume-dependent, evaluation of patient performance is subjective, and there are no good acceptability criteria. In addition, agreement between conventional spirometry values, such as forced vital capacity (FVC) and FEV_1, and bedside PEFR values are poor for individual patients. Although peak flow measurement can be used at the bedside to assess treatment effectiveness and to monitor trends, conventional spirometry remains the standard for determining bronchodilator response.

Some peak flowmeters are more accurate and reliable than others. Even different units of the same model may give variable results. For this reason, when monitoring trends, the same unit should be used for a given patient and the patient's range be reestablished if a different flowmeter is used.

Other Components of Patient Assessment

Tests of expiratory airflow for assessing patient response to therapy are commonly used, but not all patients can perform these maneuvers. Other components of patient assessment useful in evaluating bronchodilator therapy include patient interviewing and observation, measurement of vital signs, auscultation, blood gas analysis, and oximetry.

When possible, the patient should be interviewed to determine the pertinent respiratory history and current level of dyspnea. A validated dyspnea rating scale may be useful for this purpose. Initial determination of patient age and level of consciousness is helpful in selecting both delivery device and starting drug dosage. Observing the patient for signs of increased work of breathing (e.g., tachypnea, accessory muscle use) provides a baseline for assessing status as therapy progresses. Restlessness, diaphoresis, and tachycardia also may indicate severity

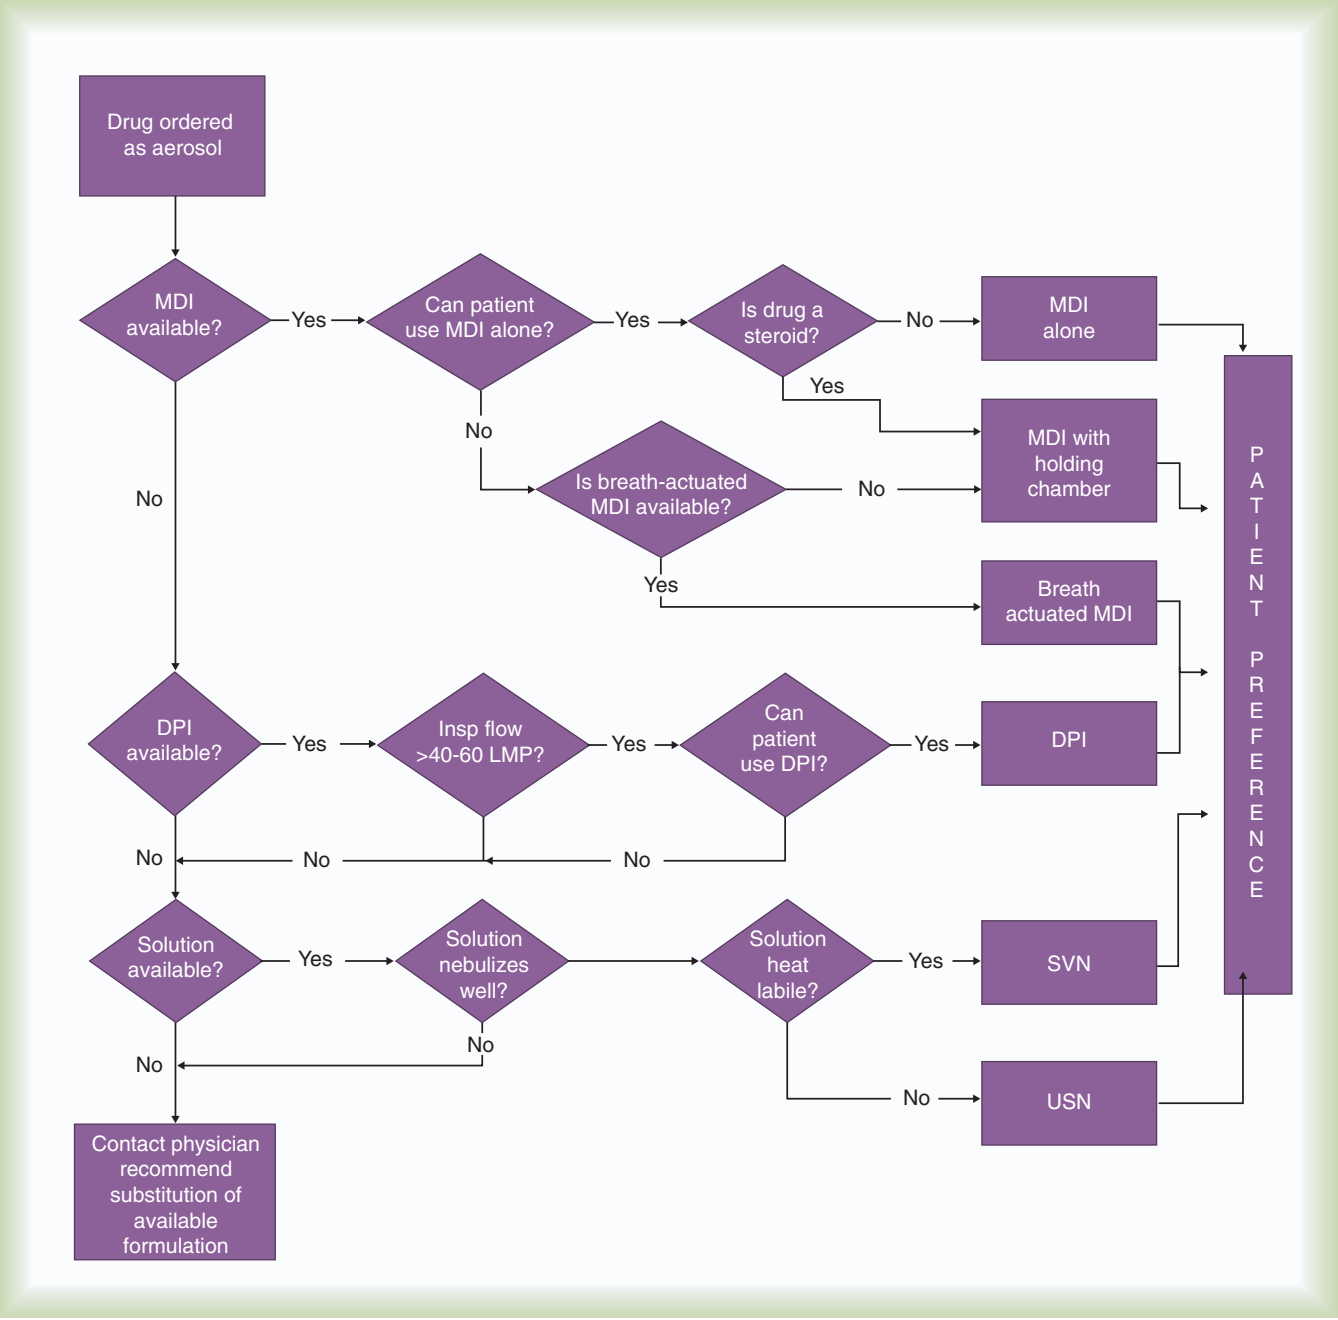

FIGURE 39-28 Selecting an aerosol drug delivery system. When the need is established for aerosol drug delivery, the formulations available for the prescribed medication should be determined. If a pMDI is available, it is the first choice for cost and convenience. The patient's ability to coordinate actuation with inspiration and the need to reduce oropharyngeal deposition (e.g., steroids) determine need for a holding chamber or a breath-actuated unit. Nebulizers are the first choice when the formulation is available only as a solution. When the ordered medication is unavailable for inhalation use, the RT should recommend a substitution to the ordering physician.

of airway obstruction but must not be confused with bronchodilator overdose.

Increased cough has been associated with the onset of asthma. The frequency, severity, and effectiveness of cough should be assessed before and after therapy.

In terms of breath sounds, a decrease in wheezing accompanied by an overall decrease in the intensity of breath sounds indicates worsening airway obstruction or patient fatigue. Improvement is indicated when wheezing decreases and the overall intensity of breath sounds increases.

All patients with acute airway obstruction should be monitored for oxygenation status with pulse oximetry. This value can be used in conjunction with observational assessment to titrate the level of inspired O_2 given to the patient (see Chapter 38).

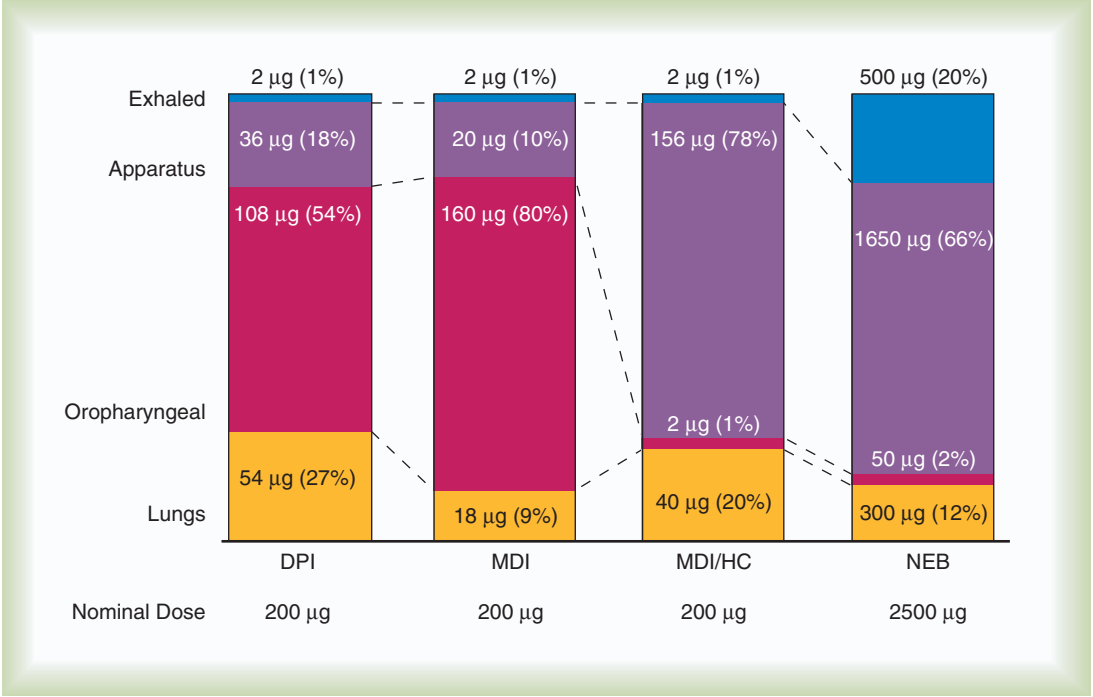

FIGURE 39-29 Distribution of albuterol via nebulizer, pMDI, pMDI with a holding chamber, and DPI. (Modified from Fink J: Metered-dose inhalers, dry powder inhalers and transitions. Respir Care 45:623, 2000.)

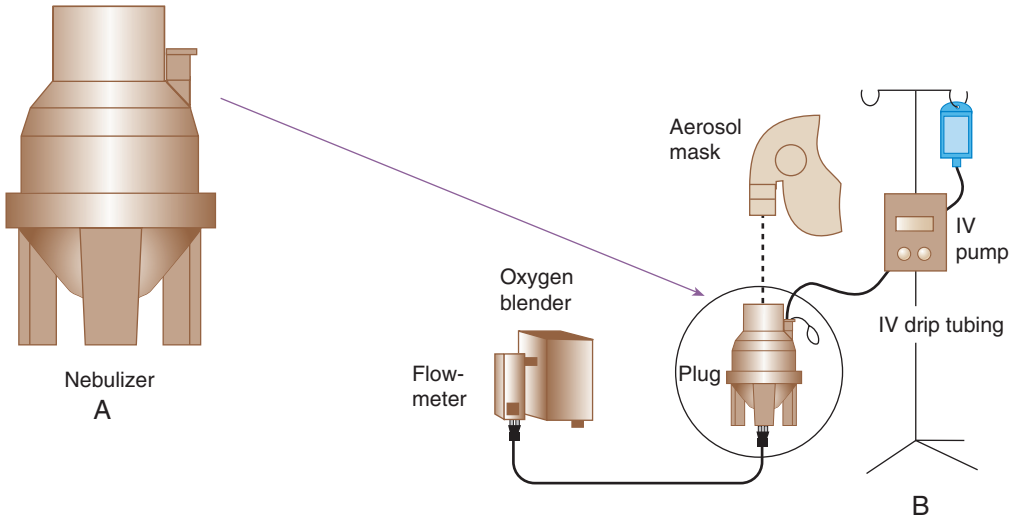

FIGURE 39-30 Algorithm underlying a bronchodilator therapy protocol for acutely ill adults or children admitted to an emergency department. *PEFR,* Peak expiratory flow rate; *VS,* vital signs.

Arterial blood gases are not essential for determining patient response to bronchodilator therapy but may be needed for patients in severe distress to assess for hypercapnic respiratory failure.

Dose-Response Assessment

Poor patient response to bronchodilator therapy often occurs because an inadequate amount of drug reaches the airway. To determine the "best" dose for patients with moderate obstruction, the respiratory therapist should conduct a dose-response titration.

A simple albuterol dose-response titration involves giving an initial 4 puffs (90 mcg/puff) at 1-minute intervals through a pMDI with a holding chamber. After 5 minutes, if airway obstruction is not relieved, the RT gives 1 puff per minute until symptoms are relieved, heart rate increases by more than

Box 39-8 Frequency of Assessment of Bronchodilator Therapy

FOR PATIENT WITH AN ACUTE DISORDER WHO IS IN UNSTABLE CONDITION

- Whenever possible, perform a full assessment and obtain a pretreatment baseline.
- Assess and document all appropriate variables before and after each treatment (breath sounds, vital signs, side effects during therapy, and PEFR or FEV_1).
- The frequency with which physical examination and PEFR or FEV_1 are repeated should be based on the acuteness of the disorder and the severity of the patient's condition.
- SpO_2 should be monitored continuously, if possible.
- Assessment should continue as dosages are changed to optimize patient response (e.g., if an asthmatic patient achieves 70% to 90% of predicted or "personal best" or becomes symptom-free).

FOR STABLE PATIENT

- In the hospital, PEFR should be measured initially before and after each bronchodilator administration. Thereafter, twice-daily determinations may be adequate.
- In the home, PEFR ideally should be measured three or four times a day: on rising, at noon, between 4 PM and 7 PM, and at bedtime.
- For a stable COPD patient at home, measuring PEFR twice a day may be adequate.
- Patients with asthma should adjust the frequency of PEFR measurement according to the severity of symptoms.
- PEFR levels before and after bronchodilator use, medication dose, date and time, and dyspnea score should be documented.
- The patient should be reevaluated periodically for response to therapy.

20 beats/min, tremors increase, or 12 puffs are delivered. The best dose is the dose that provides maximum relief of symptoms and the highest PEFR without side effects.

Frequency of Patient Assessment

How frequently patients should undergo assessment for bronchodilator therapy depends primarily on the acuity of the condition. An unstable patient in acute distress should undergo closer and more frequent scrutiny than a patient in stable condition. Box 39-8 provides guidance regarding the frequency of assessment according to acuity.

Patient Education

The desired outcome of all bronchodilator protocols is restoration of normal airflow and cessation of therapy. For patients who need ongoing maintenance therapy after the acute phase of illness, the goal should be effective self-administration. An effective program of aerosol drug self-administration depends on thorough patient education.

The patient's ability to understand the therapy and its goals significantly affects the therapeutic efficacy of any treatment. Whenever possible, patients should be taught to understand the basic administration techniques, to keep track of dosing requirements, to recognize undesirable side effects, and to understand the options and actions required to reduce or eliminate these effects. In addition, patients should be able to demonstrate good technique regarding the use of each aerosol device that they are expected to use in self-care. Practitioner demonstration followed by repeated patient return demonstration is a must and should be done frequently, with each office or clinic visit.

SPECIAL CONSIDERATIONS

Aerosol Therapy for Treatment of Pulmonary Arterial Hypertension

Epoprostenol (Veletri®, Actelion Pharmaceuticals US, Inc, South San Francisco, CA), epoprostenol sodium (Flolan®, GlaxoSmithKline, Research Triangle Park, NC), iloprost (Ventavis®, Actelion Pharmaceuticals US Inc, South San Francisco, CA), and treprostinil (Tyvaso) are inhaled prostacyclins used for treatment of pulmonary arterial hypertension. Whereas epoprostenol administration is associated with positive effects on symptoms, hemodynamics, exercise capacity, disease progression and survival,[62-64] it has not been approved for inhalation, and due to its short half-life of 30 to 90 seconds, requires continuous nebulization. In contrast, iloprost and treprostinil are approved for inhalation with a half-life of 60 to 90 minutes, allowing more convenient dosing to ambulatory patients.

Acute Care and Off-Label Use

Every drug approved for inhalation to date has been designed for and tested in populations of ambulatory patients with moderate disease. As patients with lung disease become acutely and critically ill, the approved label doses, frequency of administration, and devices may not be practical or effective, especially for treatment of patients requiring ventilatory support. In such cases, clinicians may explore and consider nonstandard methods (doses, frequency, and devices) for administration of approved inhaled drugs to patients in the acute care environment, known as *off-label use*. Another type of off-label use involves drugs that have not been approved for inhalation, ranging from heparin to certain antibiotics. Although physicians may order such drugs via inhalation, the risk to the patient and institution is greater when the administration of such drugs via inhalation has not been thoroughly studied. All forms of off-label use should be avoided when approved and viable alternatives exist. Likewise, off-label administration should always be backed by appropriate departmental or institutional policies and procedures.

Continuous Nebulization for Refractory Bronchospasm

Patients in the emergency department with severe exacerbation of asthma or acute bronchospasm often have been taking standard doses of their bronchodilators for 24 to 36 hours before admission without response. Giving nebulizer treatments with standard bronchodilator doses and repeating the treatments until the symptoms are relieved can require hours of staff time. Administering higher doses of albuterol in short time frames

can be accomplished by nebulization of undiluted albuterol (8 to 20 breaths) or by protocol titration with a pMDI and holding chamber (up to 12 puffs). If these strategies fail to provide relief, CBT with albuterol nebulization doses ranging from 5 to 20 mg/hr have proved safe and effective for adult and pediatric patients (Figure 39-31).

Figure 39-32 is a treatment algorithm for high-dose therapy and CBT for pediatric patients with status asthmaticus who are unable to perform peak flow maneuvers.[65] Candidates for this protocol are children who, despite frequent beta agonist treatments, remain in extremis with bronchospasm, dyspnea, cough, chest tightness, and diminished breath sounds.

According to this protocol, children older than 6 years with tachypnea, hypoxemia, increased work of breathing, and restlessness who do not respond to standard therapy are given CBT

FIGURE 39-31 Continuous line from a syringe pump attached to a nebulizer.

with a large volume nebulizer or SVN at a dose rate of 15 mg/hr (see the accompanying Mini Clini "CBT Dosage Computations" for dosage computations). A standardized asthma score is used to evaluate children younger than 6 years for the severity of the condition (Table 39-4). Patients with an asthma score of 4 or higher are given CBT.

After CBT is started, the patient is carefully assessed every 30 minutes for the first 2 hours and thereafter every hour. A positive response is indicated by an increase in PEFR of at least 10% after the first hour of therapy. The goal is at least 50% of the predicted value. For small children, improved oxygenation (oxygen saturation by pulse oximeter [SpO_2] >92% on room air) with evidence of decreased work of breathing indicates a favorable response. Once the patient "opens up," intermittent SVN administration is resumed, or a pMDI dose-response assessment is conducted.

The patient has responded poorly to CBT if any of the indicators listed in Table 39-4 worsens. The patient must be observed for adverse drug responses, including worsening tachycardia, palpitations, and vomiting. In these situations, the attending physician must be contacted immediately.

As an alternative to large volume drug nebulizers, some protocols are based on high-dose pMDI therapy (12 to 24 puffs per hour).[66] To provide an extra margin of safety, some clinicians recommend that patients receiving CBT undergo continuous electrocardiogram monitoring and measurement of serum potassium level every 4 hours.

Aerosol Administration to Mechanically Ventilated Patients

Since the advent of modern mechanical ventilation, clinicians have administered aerosols to patients with the sickest of lungs. Four primary forms of aerosol generator are used to deliver aerosols during mechanical ventilation: SVN, USN, VM nebulizer, and pMDI with third-party adapter. Table 39-5 summarizes the factors affecting aerosol drug delivery to mechanically ventilated patients. Techniques to optimize delivery to patients receiving ventilatory support are described.[67]

TABLE 39-5

Factors Affecting Aerosol Drug Delivery During Mechanical Ventilation

Category	Factor
Ventilator-related	Mode of ventilation
	V_T
	Respiratory rate
	Duty cycle
	Inspiratory waveform
	Breath-triggering mechanism
Circuit-related	Size of endotracheal tube
	Type of humidifier
	Relative humidity

MINI CLINI

Continuous Bronchodilator Therapy Dosage Computations

PROBLEM: Dosages for CBT are ordered in milligrams per hour, and delivery depends on both drug concentration and nebulizer output. Compute the volume of 1 : 200 (0.5%) albuterol and the volume of diluent (normal saline solution) needed to provide 4 hours of CBT with 15 mg/hr of albuterol in a nebulizer with an output of 25 ml/hr.

DISCUSSION: *Step 1:* Compute the volume of albuterol given per hour (mg/hr × ml/mg).

$$15.0\ \text{mg/hr} \times 0.2\ \text{ml/mg} = 3.0\ \text{ml/hr albuterol}$$

Step 2: Compute the volume of albuterol for the treatment period (hours × ml/hr).

$$4\ \text{hours} \times 3.0\ \text{ml/hr} = 12\ \text{ml/4 hr albuterol}$$

Step 3: Compute the volume of nebulization solution (ml/hr nebulizer output × hours).

$$25\ \text{ml/hr} \times 4\ \text{hours} = 100\ \text{ml}$$

Step 4: Compute the volume of diluent required.

$$100\ \text{ml} - 12\ \text{ml} = 88\ \text{ml normal saline solution}$$

To prepare this dosage, mix 12 ml of 0.5% albuterol with 88 ml of normal saline solution, for a total nebulizer solution volume of 100 ml. In this example, residual volume of the nebulizer decreases total treatment time and dose.

Regarding doses, the amount of drug required to achieve the same therapeutic end point is substantially similar for medications delivered by pMDI to intubated patients (8%) and patients who are not intubated (8% to 10%). In stable patients with COPD receiving ventilatory support, 4 puffs of albuterol via pMDI with chamber and 2.5 mg via SVN were shown to produce maximum bronchodilation with effects lasting for 4 hours. However, some differences in response were noted that may have been due to the level of airway obstruction and the techniques used for assessing response.

Techniques for assessing the response to a bronchodilator in intubated patients undergoing mechanical ventilation differ from techniques used in the care of spontaneously breathing patients because expiration is passive during mechanical ventilation, and forced expiratory values (PEFR, FVC, FEV_1) cannot normally be obtained. Additional techniques can be used for mechanically ventilated patients because (1) a change in the differences between peak and plateau pressures (volume ventilation with constant flow, the most reliable indicator of a change in airway resistance during continuous mechanical ventilation) can be measured, (2) automatic positive end expiratory pressure levels may decrease in response to bronchodilators (see Chapter 44), and (3) breath-to-breath variations make measurements more reliable when the patient is not actively breathing with the ventilator.[68]

Techniques for aerosol administration vary by type of aerosol generator and device used. The optimal technique for drug delivery to mechanically ventilated patients with each type of aerosol generator is described in Box 39-9.

Use of a Small Volume Nebulizer During Mechanical Ventilation

The aerosol administered by SVN to intubated patients receiving mechanical ventilation tends to be deposited mainly in the tubing of the ventilator circuit and expiratory filter. Under normal conditions with heated humidification and standard jet nebulizers, pulmonary deposition ranges from 1.5% to 3.0%.[68,69] When nebulizer output, humidity level, V_T, flow, and I : E ratio are optimized, deposition can increase to 15%.

There are several disadvantages with SVN use during mechanical ventilation. Although in vitro models showed 40% higher aerosol delivery with an unheated, unhumidified circuit compared with heated humidity, these effects have not been shown in patients, whereas the risks associated with administering cold and dry gas through an endotracheal tube include drying of secretions, bronchospasm, and airway obstruction. A heat and moisture exchanger should be considered a barrier to aerosol administration and should always be removed if placed between the nebulizer and the patient airway. When available with the specific ventilator being used, breath actuation can increase aerosol delivery by 30%, but it may extend administration time by more than threefold. Introducing additional flow into the ventilator circuit may change parameters of flow and delivered volumes and require changes to alarm settings during and after nebulization. The smaller the patient, the greater the impact of added flow into the ventilator circuit, where 6 L/min of additional gas flow can more than double V_T and inspiratory pressure, placing the patient at risk. Risk is high for not changing ventilator parameters and not returning parameters to pretreatment levels after administration. There is also a tendency for condensate and secretions to drain into the nebulizer reservoir, contaminating medication being delivered to the lungs.

Box 39-9 Optimal Technique for Aerosolized Drug Delivery to Mechanically Ventilated Patients

1. Review order, identify the patient, gather equipment, and assess the need for bronchodilators.
2. Clear the airways as needed, by suctioning the patient as needed.
3. If using a circuit with heat and moisture exchanger (HME), remove HME from between the aerosol generator and the patient.
4. If using heated humidifier, do not turn off or disconnect before or during treatment.
5. Assemble equipment (tubing, nebulizer, circuit adapter).
6. Fill the nebulizer with recommended volume and medication per physician order and label.
7. Place adapter in the inspiratory limb, 6 inches from the "wye," and connect aerosol generator.
8. Turn off or minimize bias flow during treatment.
9. Connect the nebulizer to a gas or power source, as appropriate.

10a. For jet nebulizer (including SVN): Use gas source on ventilator to synchronize nebulization with inspiration, if available; otherwise, set gas flow 6 to 10 L/min as recommended on nebulizer label, and adjust ventilator volume or pressure limit and alarms to compensate for added flow and volume.

10b. For USN and VM nebulizer: Attach power source and cable from controller.

10c. For pMDI: Shake canister and connect to spacer or adapter; actuate at beginning of inspiration.

11. Observe aerosol cloud for adequate aerosol generation during nebulization.
12. After appropriate dose is administered, remove aerosol generator from the ventilator circuit.
13. Reconnect HME, as appropriate.
14. Return ventilator settings and alarms to previous values.
15. Ensure there is no leak in the ventilator circuit.
16. Rinse the nebulizer with sterile or distilled water, shake off excess water, and allow to air dry.
17. Store aerosol device in a clean, dry place.
18. Monitor heart rate, SpO_2, blood pressure, and patient-ventilator synchronization.
19. Monitor the patient for adverse response.
20. Assess the airway, and suction as needed; document findings.

Use of a Vibrating Mesh Nebulizer During Mechanical Ventilation

Aerosol administration by a VM nebulizer has been estimated to deliver greater than 10% deposition in adults and infants without the addition of gas into the ventilator circuit. The low residual drug volume and small particle size are associated with higher efficiency. Similar to the USN, the VM nebulizer does not add gas flow into the ventilator circuit, so ventilator

MINI CLINI

Never Emptying Nebulizer

PROBLEM: Jet nebulizers and USNs are commonly used to administer aerosol to patients during mechanical ventilation. Commonly, a nebulizer is filled with a standard unit dose of 3 ml of medication at the beginning of the aerosol treatment, and the RT finds as much or more fluid in the medication reservoir 20 to 30 minutes later. The additional fluid is usually condensate (often contaminated from patient secretions), which drains from the inspiratory limb into the gravity-dependent reservoir of the nebulizer. Even heated wire circuits may have condensate. Although pathogens in a dry circuit have minimal chance of contaminating the patient's airway, aerosolizing the pathogens provides a vehicle for infectious material to enter the airway and the lung parenchyma.

SOLUTION: The nebulizer should be positioned so that the upper end of the reservoir is superior to (higher than) the ventilator tubing attached to both ends of the nebulizer. This position allows the condensate and secretions to drain away from the nebulizer. Alternatively, nebulizers with physical barriers between the ventilator circuit tubing and the medication reservoir can be used. These options include use of a pMDI with spacer or a VM nebulizer.

parameters and alarms do not need to be adjusted before, during, or after nebulization. In contrast to jet SVNs and USNs, the medication reservoir of the VM nebulizer is above the circuit and separated from the ventilator tubing by the mesh, reducing the risk of retrograde contamination of medication in the reservoir from the ventilator circuit. Because of the nature of the mesh, the reservoir can be opened and medication can be added to the nebulizer without creating a perceptible leak during ventilation.

Use of a Pressurized Metered Dose Inhaler During Mechanical Ventilation

Results of in vitro studies show that effective aerosol delivery by pMDIs during mechanical ventilation can range from 2% to 30%. Direct pMDI actuation by simple elbow adapters typically results in the least pulmonary deposition, with most of the aerosol impacting in either the ventilator circuit or the tracheal airway. Higher aerosol delivery percentages occur only when an actuator or spacer is placed in-line in the ventilator circuit. These spacers allow an aerosol "plume" to develop before the bulk of the particles impact on the surface of the circuit or endotracheal tube. The result is a more stable aerosol mass that can penetrate beyond the artificial airway and be deposited mainly in the lung. This situation leads to a better clinical response at lower doses.[49]

Aerosol Generator Placement

Placement of aerosol generators in the ventilator circuit can have a substantial impact on the available lung dose of drug. During adult ventilation without bias flow, placement of aerosol generators 18 to 24 inches from the patient in the inspiratory limb increases inhaled dose for jet nebulizers, where continuous gas flow acts to charge the inspiratory limb of the ventilator circuit with aerosol. In contrast, pMDI, USN, and VM nebulizer devices are more efficient when placed close to the patient at the circuit wye.[70,71] With continuous or bias flow through the adult and pediatric ventilator circuit, the delivery is reduced as flow increases, whereas placement of a VM or USN nebulizer near the ventilator increases delivery (Figure 39-33).[71,72]

Placement During Noninvasive Ventilation

Noninvasive ventilation may be administered with standard and bilevel ventilators. Bilevel ventilators often use a flow turbine, with a fixed leak in the circuit that permits excess flow to vent to atmosphere. Placement of the aerosol generator between the leak and the patient's airway seems to provide the highest aerosol delivery efficiency.[73,74] A VM nebulizer delivers a greater inhaled dose than an SVN during noninvasive ventilation, presumably because of the lower residual drug volume and lower total flow in the circuit.[75]

Placement During High-Flow Nasal Cannula

Delivery of aerosol via a high-flow nasal cannula (HFNC) with infant, pediatric, and adult cannulas, is markedly limited.[76] Figure 39-34 shows the setup with HFNC, including the location of the VM nebulizer. However, placement of the VM nebulizer prior to the humidifier increases aerosol deposition with HFNC.[77] In addition to the location of the nebulizer with HFNC, the inhaled dose seems to vary based on cannula size, respiratory pattern, and O_2 flow. Heliox (80 : 20) appears to improve aerosol delivery at higher flow rates with these setups.[77] The administration of aerosolized medications via HFNC is less efficient than removing the cannula during administration.[78] When delivering aerosolized medications by mask, the benefit of increased aerosol delivery must be weighed against the risk of desaturation when nasal prongs are removed.

Placement During Intrapulmonary Percussive Ventilation

Intrapulmonary percussive ventilation provides high-frequency oscillation of the airway while administering aerosol particles. During intrapulmonary percussive ventilation, the aerosol generator should be placed in the circuit as close to the patient's airway as practical. A comparison study found the MMAD was smaller with intrapulmonary percussive ventilation than with the jet (0.2 μm vs. 1.89 μm), and the fine-particle fraction was lower (16.2% vs. 67.5%). However, lung dose was similar (2.49% with intrapulmonary percussive ventilation vs. 4.2% with the jet nebulizer). It was concluded that intrapulmonary percussive ventilation was too variable and too unpredictable to recommend for drug delivery to the lung.[79]

Placement During High-Frequency Oscillatory Ventilation

When used in conjunction with high-frequency oscillatory ventilation, administration of albuterol sulfate via a VM nebulizer

FIGURE 39-34 Placement of SVN and VM nebulizer aerosol generators in two positions in the ventilator circuit with 2 L/min and 5 L/min of bias flow results in different deposition efficiency.

placed between the ventilator circuit and the patient airway has been reported to deliver greater than 10% of dose to both infants and adults.[80,81] A pMDI with adapter placed immediately proximal to the endotracheal tube achieved similar results in adult patients ventilated via high-frequency oscillatory ventilation.[82]

CONTROLLING ENVIRONMENTAL CONTAMINATION

Drugs for nebulization that escape from the nebulizer into the atmosphere or are exhaled by the patient can be inhaled by anyone in the vicinity of the treatment. The risk imposed by this environmental exposure is clear and is associated with a range of drugs and patients with infectious disease. Pentamidine and ribavirin were associated with health risks to health care providers even when used in conjunction with filters on exhalation ports of nebulizers, containment and scavenger systems, and *high-efficiency particulate air (HEPA)* filter hoods and ventilation systems (Figure 39-35).

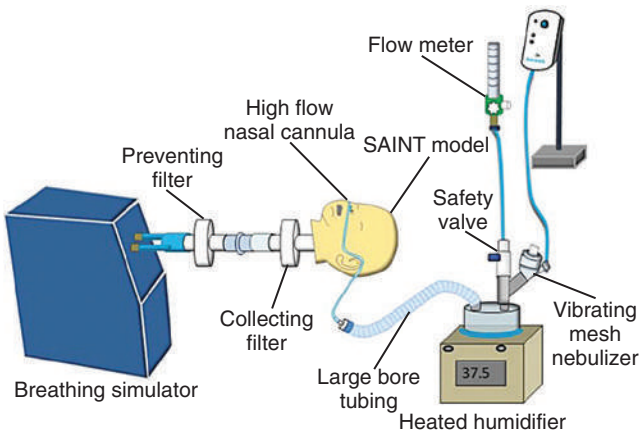

FIGURE 39-35 In vitro model. (From Bhashyam AR, Wolf MT, Marcinkowski AL, et al: Aerosol delivery through nasal cannulas: an in vitro study. J Aerosol Med Pulm Drug Deliv 21:181, 2008.)

Continuous pneumatic nebulizers produce the greatest amount of secondhand aerosol, with most (60%) of the aerosol produced passing directly into the environment. The Respirgard II (Vital Signs, Totowa, NJ) nebulizer was developed for administration of pentamidine, adding one-way valves and an expiratory filter to contain aerosol that is exhaled and not inhaled. Breath-actuated nebulizers, DPIs, and pMDIs tend to generate less secondhand aerosol.

A survey found that RTs were more than twice as likely as physical therapists to develop asthma-like symptoms during the course of their careers. The authors associated this with administration of ribavirin and exposure to gluteraldehyde.[16] There have been anecdotal reports of respiratory care clinicians who have developed a sensitivity to secondhand aerosol from bronchodilators. Further research is required to understand more thoroughly the hazards of secondhand exposure to aerosols in the clinical setting. Most nebulizer therapy currently delivered does not include filtering systems.

Patients with infectious and resistant organisms, such as tuberculosis, severe acute respiratory syndrome, and H1N1 virus, require respiratory isolation, and caregivers require protection. RTs have a duty to take appropriate steps to protect themselves and their patients. In these cases, the aerosols generated by the patient from coughing, speaking, or laughing can transmit disease. These aerosols can travel substantial distances between rooms and even floors in institutions. Although exposure to secondhand aerosol generated by a nebulizer is undesirable, it poses less risk than the infected aerosols produced by mucosa of patients.[83] In essence, it is unlikely that any medical aerosol that is inhaled by the patient would be contaminated. Nonetheless, during the severe acute respiratory syndrome outbreak, some centers outlawed use of medical aerosols to reduce exposure. Efforts should be taken to reduce transmission of both nebulizer aerosols and patient-generated aerosols to the environment.

Various techniques are available for protecting patients and caregivers from environmental exposure during aerosol drug therapy. The greatest occupational risk for RTs has been associated with the administration of ribavirin and pentamidine. Conjunctivitis, headaches, bronchospasm, shortness of breath, and rashes have been reported among individuals administering these drugs.[84] Patients given aerosolized ribavirin or pentamidine must be treated in a private negative room, booth, or tent or at a special station designed to minimize environmental contamination with the caregiver wearing an N95 mask during all periods in the room during administration and at for least 10 minutes after completion of administration of the aerosol.

Negative Pressure Rooms

When ribavirin or pentamidine is given, the treatment is provided in a private room. The room should be equipped for negative pressure ventilation with adequate air exchanges (at least six per hour) to clear the room of residual aerosols before the next treatment. HEPA filters should be used to filter room or tent exhaust, or the aerosol should be scavenged to the outside.

FIGURE 39-36 Emerson treatment booth provides containment of aerosol during therapy.

Booths and Stations

Booths or stations should be used for sputum induction and aerosolized medication treatments given in any area where more than one patient is treated. The area should be designed to provide adequate airflow to draw aerosol and droplet nuclei from the patient into an appropriate filtration system or an exhaust system directly to the outside. Booths and stations should be adequately cleaned between patients.

A variety of booths and specially designed stations are available for delivery of pentamidine or ribavirin. The Emerson containment booth (Figure 39-36) is an example of a system that completely isolates the patient during aerosol administration. The AeroStar Aerosol Protection Cart (Respiratory Safety Systems, San Diego, CA) is a portable patient isolation station for administration of hazardous aerosolized medication. It has been used during sputum induction and for pentamidine treatment. The patient compartment is collapsible with a swing-out counter and three polycarbonate walls. Captured aerosols are removed with a HEPA filter. A prefilter is used to retain larger dust particles and to prevent early loading of the more expensive HEPA filter.

Filters and nebulizers used in treatments with pentamidine and ribavirin should be treated as hazardous wastes and disposed of accordingly. Goggles, gloves, and gowns should be used as splatter shields and to reduce exposure to medication residues and body substances. Staff members should be screened for adverse effects of exposure to the aerosol medication. The risks and safety procedures should be reviewed regularly.

In addition to the risks associated with administration of aerosol medication, risk of tuberculosis transmission has become a great concern because of an increase in case numbers and the development of multidrug-resistant strains of the organism. Tuberculosis is transmitted in the form of droplet nuclei (0.3 to 0.6 μm) that carry tuberculosis bacilli. Patients

with known or suspected tuberculosis need private rooms with negative pressure ventilation that exhausts to the outside. If environmental isolation is impossible or the health care worker must enter the patient's room, personal protective equipment should be used.

Personal Protective Equipment

Personal protective equipment is recommended when caring for any patient with a disease that can be spread by the airborne route.[85] The greatest risk is communication of tuberculosis or chickenpox. Although environmental controls should be instituted in the care of these patients, standard and airborne precautions should also be implemented. Various masks and respirators have been recommended for use when caring for a patient with tuberculosis or other respiration-transmitted diseases. Traditional surgical masks, particulate respirators, disposable and reusable HEPA filters, and powered air-purifying respirators (PAPR) have been used. No data are available for determining the most effective and most clinically useful device to protect health care workers and others, although the U.S. Occupational Safety and Health Administration requires specific levels of protection (HEPA filters and powered air-purifying respirators). Guidelines from the World Health Organization recommend surgical masks for all patient care with the exception of N95 masks for aerosol-generating procedures such as sputum induction. Evidence from laboratory studies of potential airborne spread of influenza from contagious patients indicates that guidelines related to the current 1-m respiratory zone may need to be extended to a larger respiratory zone and include eye protection.[86]

SUMMARY CHECKLIST

- An aerosol is a suspension of solid or liquid particles in gas. In the clinical setting, therapeutic aerosols are made with atomizers or nebulizers.
- The general aim of aerosol drug therapy is delivery of a therapeutic dose of the selected agent to the desired site of action.
- Where aerosol particles are deposited in the respiratory tract depends on their size, shape, and motion and on the physical characteristics of the airways. Key mechanisms causing aerosol deposition include inertial impaction, sedimentation, and brownian diffusion.
- For targeting aerosols for delivery to the upper airway (nose, larynx, trachea), particles in the 5- to 20-µm MMAD range are used; for the lower airways, 2- to 5-µm particles are used; and for the lung parenchyma (alveolar region), 1- to 3-µm particles are used.
- The primary hazard of aerosol drug therapy is an adverse reaction to the medication being administered. Other hazards include infection, airway reactivity, systemic effects of bland aerosols, and drug reconcentration.
- Drug aerosol delivery systems include pMDIs, DPIs, SVNs, large volume jet nebulizers, hand-bulb atomizers (nasal spray pumps), USNs, and VM nebulizers.
- MDIs are the preferred method for maintenance delivery of bronchodilators and steroids to spontaneously breathing patients. The effectiveness of this therapy is highly technique-dependent.
- Accessory devices, spacers, and holding chambers are used with pMDIs to reduce oropharyngeal deposition of a drug and to overcome problems with poor hand-breath coordination.
- Effective use of DPIs does not require hand-breath coordination, but it does require high inspiratory flows. Some patients in stable condition prefer DPI delivery systems.
- Compared with pMDI and DPI delivery systems, use of an SVN is less technique-dependent and is more commonly used in acute care.
- Large volume drug nebulizers can be used to provide continuous aerosol delivery when traditional dosing strategies are ineffective in controlling severe bronchospasm.
- Small volume USNs can be used to administer bronchodilators, antiinflammatory agents, and antibiotics.
- Because patients vary greatly in their response to a particular drug dose and route of administration, aerosol drug therapy should be tailored to each patient with an assessment-based protocol.
- Careful, ongoing patient assessment is the key to an effective bronchodilator therapy protocol. Components of the assessment include a patient interview, observation, expiratory airflow tests, vital sign measurements, auscultation, blood gas analysis, and oximetry.
- Protocols for CBT have proved safe and effective in the management of refractory bronchospasm in both adults and children.
- Many factors affect the efficiency of aerosol drug delivery during mechanical ventilation. Proper selection of aerosol generator type, position in the circuit, dose, and accessory equipment is needed to optimize deposition and achieve the desired clinical outcome.
- Various techniques are available to protect patients and caregivers from environmental exposure during aerosol drug therapy.

CHAPTER 40

Storage and Delivery of Medical Gases

DAVID L. VINES

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe how medical gases and gas mixtures are produced.
- Discuss the clinical applications for medical gases and gas mixtures.
- Distinguish between gaseous and liquid storage methods.
- Calculate the duration of remaining contents of a compressed oxygen cylinder.
- Calculate the duration of remaining contents of a liquid oxygen cylinder.
- Describe how to store, transport, and use compressed gas cylinders properly.
- Distinguish between gas supply systems.
- Describe what to do if a bulk oxygen supply system fails.
- Differentiate among safety systems that apply to various equipment connections.
- Select the appropriate devices to regulate gas pressure or control flow in various clinical settings.
- Describe how to assemble, check for proper function, and identify malfunctions in gas delivery equipment.
- Identify and correct common malfunctions of gas delivery equipment.

CHAPTER OUTLINE

KEY TERMS

American standard safety system
Bourdon gauge
cryogenic
diameter-index safety system
downstream
filling density
flammable
flowmeter
fractional distillation
heliox
manifold
nonflammable
oxidizing
pin-index safety system
psig
reducing valve
regulator
Thorpe tube
upstream
zone valves

The hospital "oxygen service" is the origin from which the current technology-laden field of respiratory care evolved. Although respiratory therapists (RTs) have assumed many more challenging duties, ensuring the safe and uninterrupted supply of medical gases remains a key responsibility.

There are many commercially produced gases, but only a few are used medically (Table 40-1). Medical gases are classified as laboratory gases, therapeutic gases, or anesthetic gases. *Laboratory gases* are used for equipment calibration and diagnostic testing. *Therapeutic gases* are used to relieve symptoms and improve oxygenation of patients with hypoxemia. *Anesthetic*

TABLE 40-1

Physical Characteristics of Medical Gases

Gas	Chemical Symbol	Color	Taste	Odor	Can Support Life	Flammability
Laboratory Gases						
Nitrogen	N	Colorless	Tasteless	Odorless	No	Nonflammable
Helium	He	Colorless	Tasteless	Odorless	No	Nonflammable
Carbon dioxide	CO_2	Colorless	Slightly acidic	Odorless	No	Nonflammable
Therapeutic Gases						
Air	AIR	Colorless	Tasteless	Odorless	Yes	Supports combustion
Oxygen	O_2	Colorless	Tasteless	Odorless	Yes	Supports combustion
Helium/oxygen (heliox)	He/O_2	Colorless	Tasteless	Odorless	Yes	Supports combustion
Carbon dioxide/oxygen	CO_2/O_2	Colorless	Slightly acidic	Odorless	No	Supports combustion
Nitric oxide	NO	Colorless	Tasteless	Metallic	No	Supports combustion
Anesthetic Gas						
Nitrous oxide	N_2O	Colorless	Slightly sweet	Slightly sweet	No	Supports combustion

gases are combined with oxygen (O_2) to provide anesthesia during surgery. It is important for RTs to be familiar with all aspects of gases used in the clinical setting, especially the chemical symbols, physical characteristics, ability to support life, and fire risk. In regard to fire risk, medical compressed gases are classified as either **nonflammable** (do not burn), nonflammable but supportive of combustion (also termed **oxidizing**), or **flammable** (burns readily, potentially explosive).[1] Of the gases listed in Table 40-1, the focus of this chapter is on the therapeutic gases.

CHARACTERISTICS OF MEDICAL GASES

Oxygen

Characteristics

O_2 is a colorless, odorless, transparent, and tasteless gas.[1] It exists naturally as free molecular O_2 and as a component of a host of chemical compounds. At *standard temperature, pressure, and dry (STPD),* O_2 has a density of 1.429 g/L, being slightly heavier than air (1.29 g/L). O_2 is not very soluble in water. At room temperature and 1 atm pressure, only 3.3 ml of O_2 dissolves in 100 ml of water.

O_2 is nonflammable, but it greatly accelerates combustion. Burning speed increases with either (1) an increase in O_2 percentage at a fixed total pressure or (2) an increase in total pressure of O_2 at a constant gas concentration. Both O_2 concentration and partial pressure influence the rate of burning.[1,2]

Production

O_2 is produced through one of several methods. Chemical methods for producing small quantities of O_2 include *electrolysis of water* and *decomposition of sodium chlorate* ($NaClO_3$). Most large quantities of medical O_2 are produced by fractional distillation of atmospheric air.[1] Small quantities of concentrated O_2 are produced by physical separation of O_2 from air.

Fractional Distillation. **Fractional distillation** is the most common and least expensive method for producing O_2. The process involves several related steps. First, atmospheric air is filtered to remove pollutants, water, and carbon dioxide (CO_2). The purified air is liquefied by compression and cooled by rapid expansion *(Joule-Thompson effect)*.

The resulting mixture of liquid O_2 and nitrogen (N, N_2) is heated slowly in a distillation tower. N_2, with its boiling point of 195.8° C (320.5° F), escapes first, followed by the trace gases of argon, krypton, and xenon. The remaining liquid O_2 is transferred to specially insulated **cryogenic** (low-temperature) storage cylinders. An alternative procedure is to convert O_2 directly to gas for storage in high-pressure metal cylinders. These methods produce O_2 that is approximately 99.5% pure. The remaining 0.5% is mostly N_2 and trace argon. U.S. Food and Drug Administration (FDA) standards require an O_2 purity of at least 99.0%.[3]

Physical Separation. Two methods are used to separate O_2 from air.[4] The first method entails use of molecular "sieves" composed of inorganic sodium aluminum silicate pellets. These pellets absorb N_2, "trace" gases, and water vapor from the air, providing a concentrated mixture of more than 90% O_2 for patient use. The second method entails use of a vacuum to pull ambient air through a semipermeable plastic membrane. The membrane allows O_2 and water vapor to pass through at a faster rate than N_2 from ambient air. This system can produce an O_2 mixture of approximately 40%. These devices, called *oxygen concentrators,* are used primarily for supplying low-flow O_2 in the home care setting. For this reason, details about the principles of operation and appropriate use are discussed in Chapter 56.

Air

Atmospheric air is a colorless, odorless, naturally occurring gas mixture that consists of 20.95% O_2, 78.1% N_2, and approximately 1% "trace" gases, mainly argon. At STPD, the density of air is 1.29 g/L, which is used as the standard for measuring specific gravity of other gases. O_2 and N_2 can be mixed to produce a gas with an O_2 concentration equivalent to that of air. Medical-grade air usually is produced by filtering and compressing atmospheric air.[1,5]

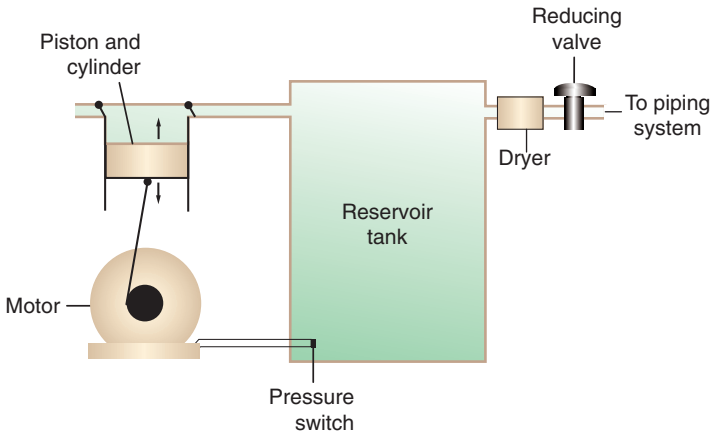

FIGURE 40-1 Large medical air compressor. The compressor sends gas to the reservoir at higher than line pressure. When the preset pressure level is reached, the pressure switch shuts off the compressor. Gas leaves the reservoir and passes through the dryer to remove moisture, and the reducing valve reduces gas to the desired line pressure. When reservoir pressure has decreased to near line pressure, the pressure switch turns the compressor back on.
