Dedication

To my wife, Brie, and my children, Palmer and Emery. You add fulfillment to my life daily.

To my father, who taught me the importance of the phrase that preceded all of his books, "To all the people who preserved this body of knowledge, added to it and passed it on for another generation." To my mother for her continued love and support.

To my colleagues at Southeast Pain & Spine Care. The level at which you take care of our patients on a daily basis exemplifies the best in medicine.

To Dr. Brandon Valentine for his review of the upper extremity chapter.

To the NYU Department of Neurology, which provides superb training and a wonderful environment to grow.

To the Chicago Medical School.

J. D. Hoppenfeld

To my family.

Stanley Hoppenfeld

Preface

While the years have passed since the first edition of this book, basic anatomy has not. This book reflects improvements in medical illustration as well as teaching techniques. The updated version makes learning anatomy more simple and clear. Advances in how we diagnose and treat patients with spinal injuries are reflected in the updated text as well.

J. D. Hoppenfeld

Preface to the Previous Edition

Years ago, I felt the need for a manual that would reduce the diagnosis of neurologic levels to its common denominators and combine them with the basic principles of neurology to assist in the appraisal of spinal cord and nerve root problems. As the book began to take shape in my mind, it became apparent that the most important aspects of transmitting this information would lie in its organization and the clarity of illustrations. The final structure would have to be simple and clear, containing the material essential to teach the crucial concepts of examination and diagnosis.

This book has been written for those who wish to understand more clearly the *clinical* concepts behind neurologic levels. It has been designed to be read sequentially, from cover to cover. Each chapter presents basic neurologic information first, and then gives it clinical significance by applying it to the diagnosis of the more common neurologic pathologies. The pattern of teaching thus moves from concept to practice and from the general rule to its specific application.

However, clinical experience remains the key to real understanding. A book can do no more than present, clearly and concisely, suggested methods of evaluation. In the interest of such clarity, some of the information presented here has been simplified. The clinical findings for each neurologic level have, for example, been stylized to make basic concepts and facts easier to understand; it must be clinical experience that uncovers the variations and exceptions that arise in individual patients. As Goethe said, "What one knows, one sees."

This book is an expression of my teaching experience at the Albert Einstein College of Medicine, where I have watched orthopaedic, neurosurgical, neurologic, physical medicine, and family practice residents, as well as physical therapists, seek this knowledge. I hope this information, and the special way in which it is organized, provide the understanding necessary to assess the involvement of neurologic levels.

Part 2 Spinal Cord Lesions by Neurologic Level

Introduction

The spinal cord is divided into segments. Nerve roots exit the spinal cord at each segmental level and are numbered in relation to the level from which they exit. There are 8 cervical, 12 thoracic, 5 lumbar, and 5 sacral nerves. The C5-T1 segments innervate the upper extremity, and the T12-S4 segments the lower extremity; these two sections of the cord have the greatest clinical significance.

Pathology affecting the spinal cord and nerve roots commonly produces symptoms and signs in the extremities according to the specific neurologic levels involved. These levels can usually be diagnosed clinically, because each level of injury has its own characteristic pattern of denervation.

The common denominator in injuries to either the cord or the nerve root lies in the segmental pattern of alteration of motor power, sensation, and reflex in the extremities. Evaluation of the integrity of the neurologic levels depends on a knowledge of the *dermatomes, myotomes,* and *reflexes.* Different dermatomes (areas of sensation on the skin supplied by a single spinal segment) and myotomes (groups of muscles innervated by a single spinal segment) are affected depending upon the level involved and upon whether the pathology involves the cord or the nerve roots emanating from it. It is through a clinical evaluation of motor power, sensation, and reflex that the correct neurologic level of involvement can be established.

Motor Power

The impulses that supply motor power are transported in the spinal cord via the long tracts and, in particular, via the corticospinal tracts. Interruption of the nerve root causes denervation and paralysis of its myotome; interruption of the tract causes spastic paralysis (Fig. I-1). Pressure on the nerve root may produce a decrease in muscle strength that can be evaluated best through the standards set by the National Foundation of Infantile Paralysis, Inc., Committee on After-Effects, and adopted by the American and British Academies of Orthopaedic

Surgeons (Table I-1).

In learning to grade a muscle, it is best to remember that a grade 3 muscle can move the joint through a range of motion against gravity. Above grade 3 (grades 4 and 5), resistance is added to the muscle test; below grade 3 (grades 2, 1, and 0), gravity is eliminated as a factor.

Muscle testing should be repeated on a regular basis to determine whether the level of the lesion has changed and created either further muscular paralysis or improvement. Repetitive muscle testing against resistance helps determine whether the muscle fatigues easily, implying weakness and neurologic involvement.
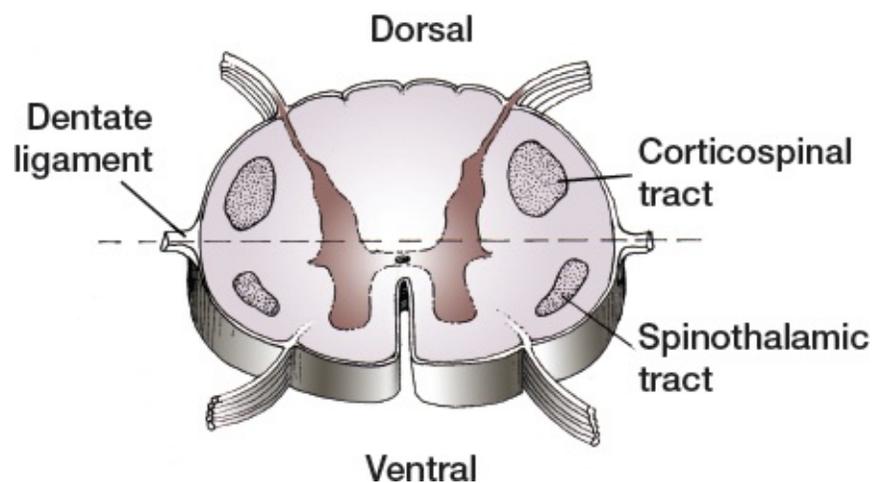

FIGURE I-1 The corticospinal and spinothalamic tracts.

TABLE I-1 MUSCLE GRADING CHART

MUSCLE GRADATIONS	DESCRIPTION
5–Normal	Complete range of motion against gravity with full resistance
4–Good	Complete range of motion against gravity with some resistance
3–Fair	Complete range of motion against gravity
2–Poor	Complete range of motion with gravity eliminated
1–Trace	Evidence of slight contractility. No joint motion
0–Zero	No evidence of contractility

Sensation

Sensation of pain and temperature is carried in the spinal cord via the lateral spinothalamic tract, whereas touch is carried in the ventral spinothalamic tract (Fig. I-1). Pathology to the cord or nerve root results in the loss of light touch, followed by loss of sensation of pain. During a recovery from nerve root injury, sensation of pain returns before light touch. The two sensations are tested separately, light touch with a cotton swab and pain with pinpricks.

When testing for pain, use a pin in a gentle sticking motion. The pinpricks should follow in succession, but not too rapidly. A pinwheel is an excellent alternative method of evaluating alterations in sensation, because two neurologic pinwheels can be used simultaneously, one on each side, to permit bilateral comparison. Safety pins may also be used. The use of needles is not recommended because they have cutting surfaces and may injure the patient. Once an area of altered sensation is found, it can be located more precisely by repeated testing from the area of diminished sensation to the area of normal sensation. Sensation tests depend largely on subjective responses; full cooperation of the patient is necessary.

After sensation is evaluated, the results should be recorded on a dermatome diagram as normal, hyperesthetic (increased), hypesthetic (decreased), dysesthetic (altered), or anesthetic (absent).

Reflex

The stretch reflex arc is composed of an organ capable of responding to stretch (muscle spindle), a peripheral nerve (axon), the spinal cord synapse, and muscle fibers (Fig. I-2). Impulses descend from the brain along long (upper motor neuron) tracts to modulate the reflex. As a general rule, an interruption in the basic reflex arc results in the loss of reflex, whereas pressures on the nerve root itself may decrease its intensity (hyporeflexia). Interruption of the upper motor neuron's regulatory control over the reflex will ultimately cause it to become hyperactive (hyperreflexia).

Reflexes should be reported as normal, increased, or decreased, an evaluation which requires that one side be compared with the other. Bilateral comparison provides a direct, immediately accessible way to detect any alteration in reflexes and is essential for an accurate diagnosis of pathology because the degree of reflex activity varies from person to person.

The concept of determining neurologic levels applies to the evaluation of

spinal injuries, developmental anomalies, herniated discs, osteoarthritis, and pathologic processes of the cord itself. All these pathologic processes result in specific segmental distribution of neurologic signs in the extremities because of their direct effect on the spinal cord and nerve roots.
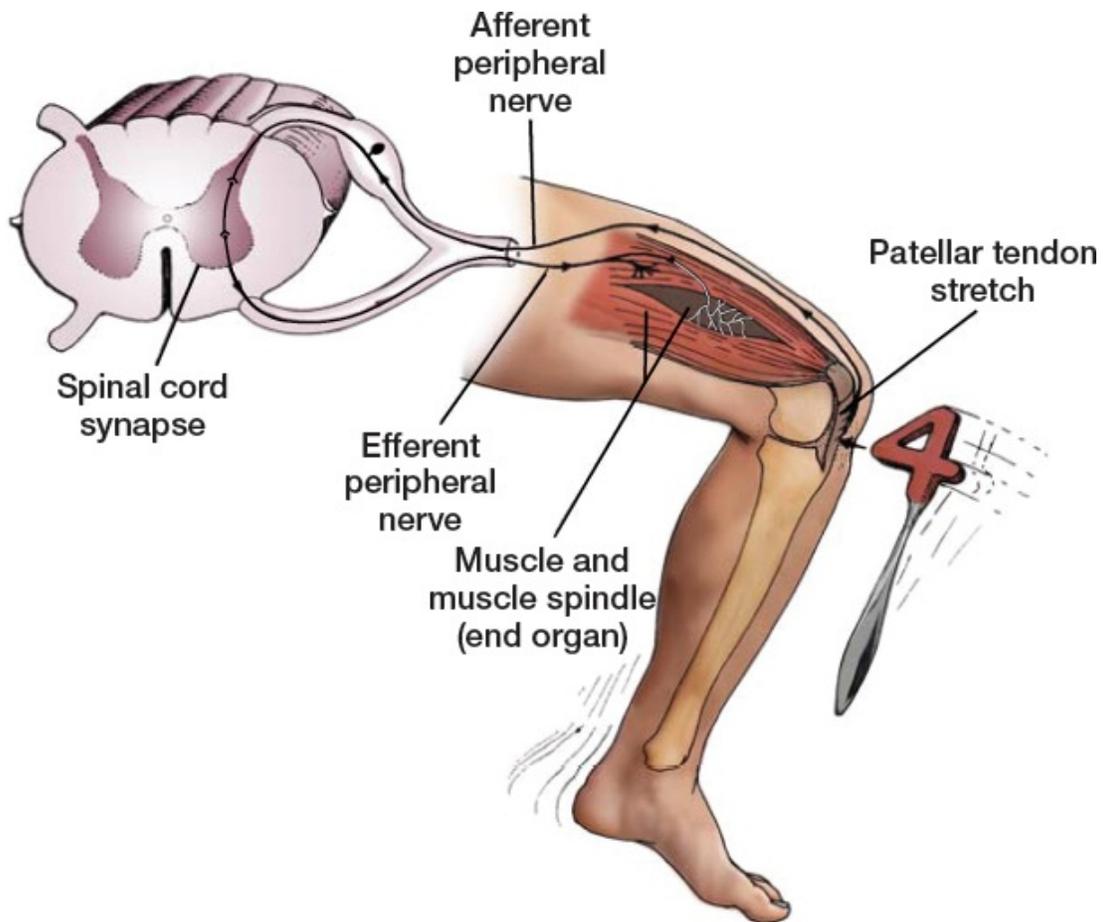

FIGURE I-2 The stretch reflex arc.

Note that the difference in findings between cord or nerve root pathology and peripheral nerve injuries is reflected in differences in the distribution of the neurologic findings of motor power, sensation, and reflex. Although each dermatome and myotome is innervated at a cord level and by a peripheral nerve, each has its own distinct pattern of innervation.

Nerve Root Lesions by Neurologic Level

1

Evaluation of Nerve Root Lesions Involving the Upper Extremity

Examination by neurologic level is based on the fact that the effects of pathology in the cervical spine are frequently manifested in the upper extremity (Fig. 1-1). Problems that affect the spinal cord itself or nerve roots emanating from the cord may surface in the extremity as muscle weakness or abnormality, reflex abnormality, and sensory diminution; the distribution of neurologic findings depends on the level involved. Thus, a thorough neurologic testing of the extremity helps determine any involvement of neurologic levels; it may also assist in the evaluation of an assortment of problems originating in the cervical cord or its nerve roots.

The following diagnostic tests demonstrate the relationship between neurologic problems in the upper extremity and pathology involving the cervical nerve roots. For each neurologic level of the cervical spine, motor power, reflexes, and areas of sensation in the upper extremity should be tested, so that the level involved can be identified. We have begun individual nerve root testing with C5, the first contribution to the clinically important brachial plexus. Although C1-C4 are not included in our tests because of the difficulty of testing them, it is crucial to remember that the C4 segment is the major innervation to the diaphragm (via the phrenic nerve).
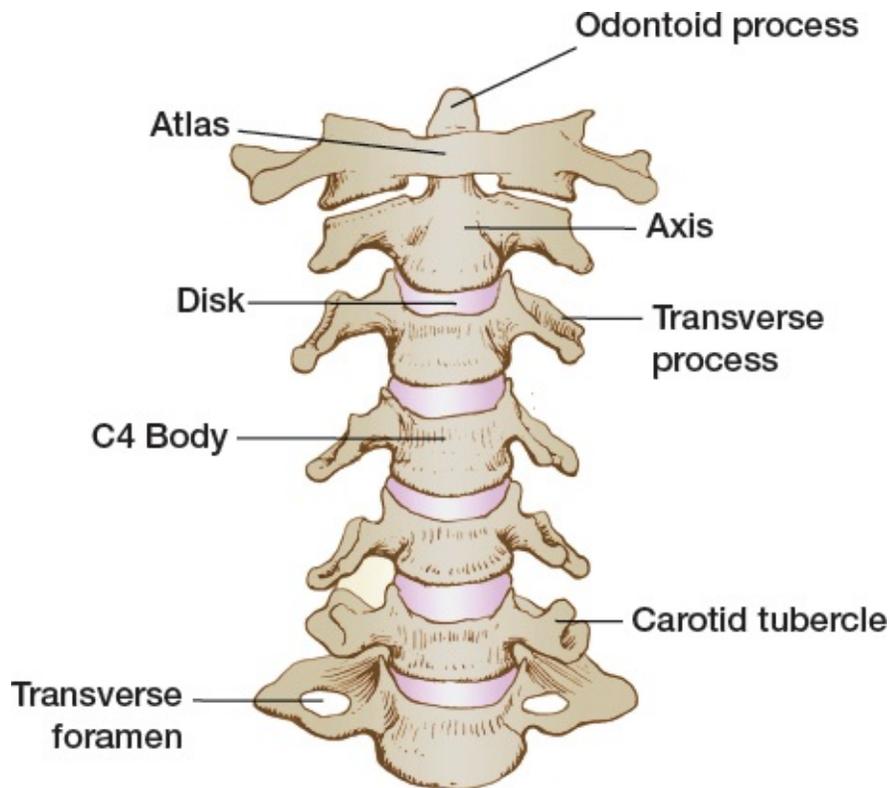

FIGURE 1-1 The cervical spine.

Testing of Individual Nerve Roots: C5-T1

Neurologic Level C5

Muscle Testing

The deltoid and biceps are the two most easily tested muscles with C5 innervation. The deltoid is almost a pure C5 muscle; the biceps is innervated by both C5 and C6, and evaluation of its C5 innervation may be slightly blurred by this overlap (Fig. 1-2).
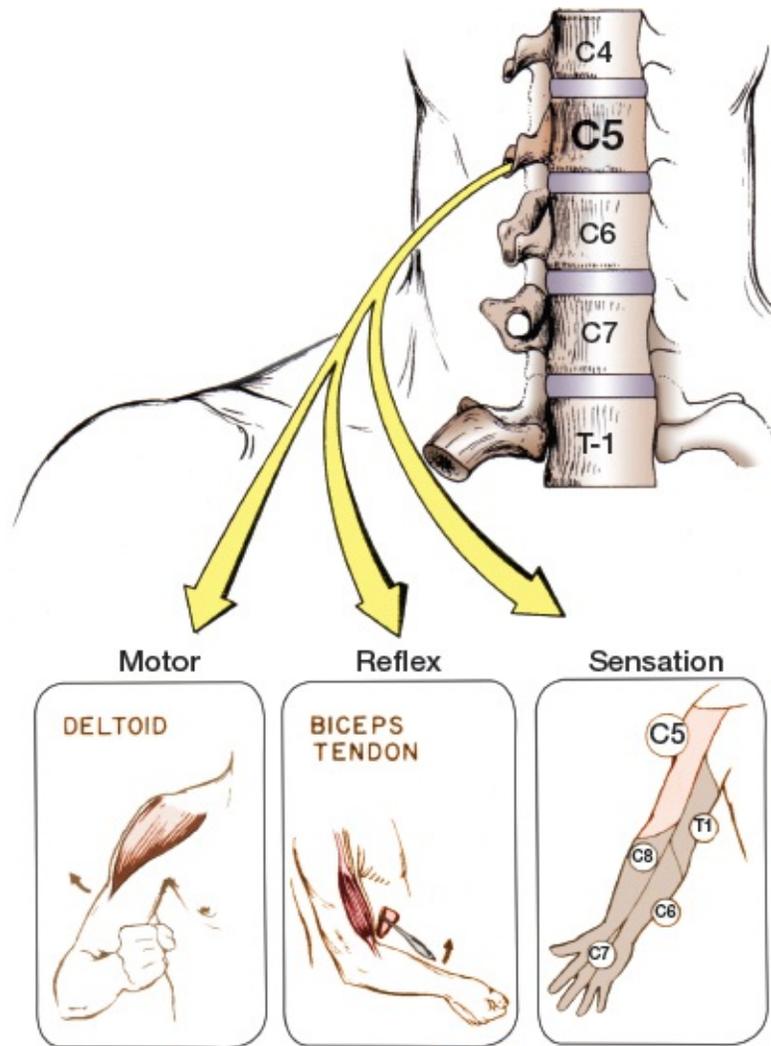

FIGURE 1-2 Neurologic level C5.

Deltoid: C5 (Axillary Nerve): The deltoid is actually a three-part muscle. The anterior deltoid flexes, the middle deltoid abducts, and the posterior deltoid extends the shoulder; of the three motions, the deltoid acts most powerfully in abduction (Fig. 1-2). Because the deltoid does not work alone in any motion, it may be difficult to isolate it for evaluation. Therefore, note its relative strength in abduction, its strongest plane of motion (Fig. 1-3).

Primary shoulder abductors (Fig. 1-4):

1. Supraspinatus
   C5, C6 (suprascapular nerve)
2. Deltoid (middle portion)
   C5, C6 (axillary nerve)

Secondary shoulder abductors:

1. Deltoid (anterior and posterior portions)
2. Serratus anterior (by direct stabilizing action on the scapula, because abduction of the shoulder requires a stable scapula).

Stand behind the patient and stabilize the acromion. Slide your stabilizing hand slightly laterally so that, while you stabilize the shoulder girdle, you can also palpate the middle portion of the deltoid.

Instruct the patient to abduct their arm with the elbow flexed to 90°. As the patient moves into abduction, gradually increase your resistance to their motion until you have determined the maximum resistance the patient can overcome (Fig. 1-5). Record your findings in accordance with the muscle grading chart (see page 2).

Biceps: C5-C6 (Musculocutaneous Nerve): The biceps is a flexor of the shoulder and elbow and a supinator of the forearm (Fig. 1-6); to understand its full function, envision a man driving a corkscrew into a bottle of wine (supination), pulling out the cork (elbow flexion), and drinking the wine (shoulder flexion) (Fig. 1-7).

Function of the Three Parts of the Deltoid Muscle

Anterior deltoid   Lateral deltoid   Posterior deltoid
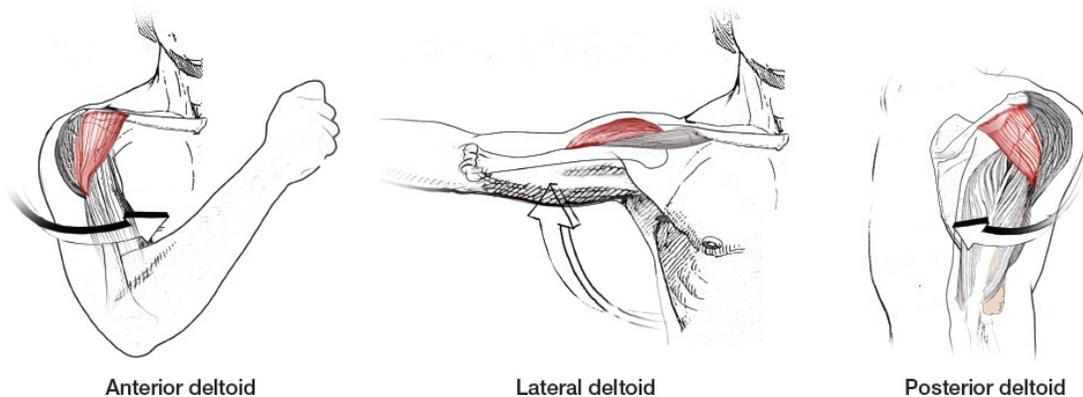

FIGURE 1-3 Each head of the deltoid and its function.
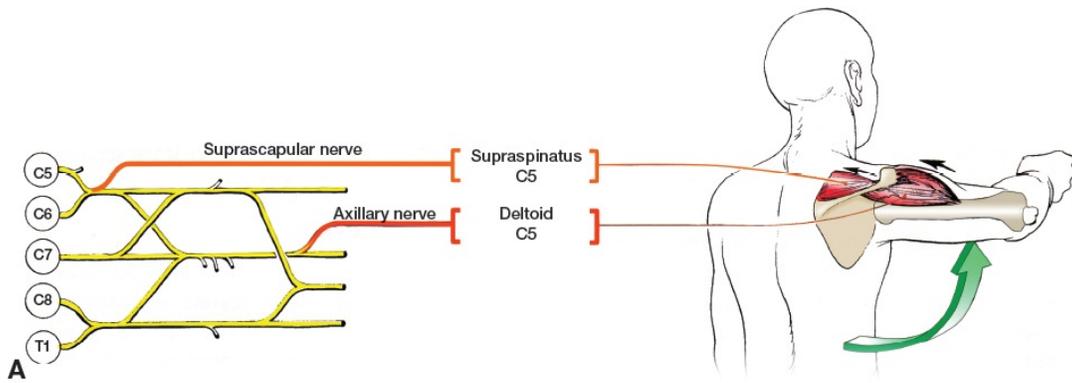

FIGURE 1-4A Shoulder abduction.
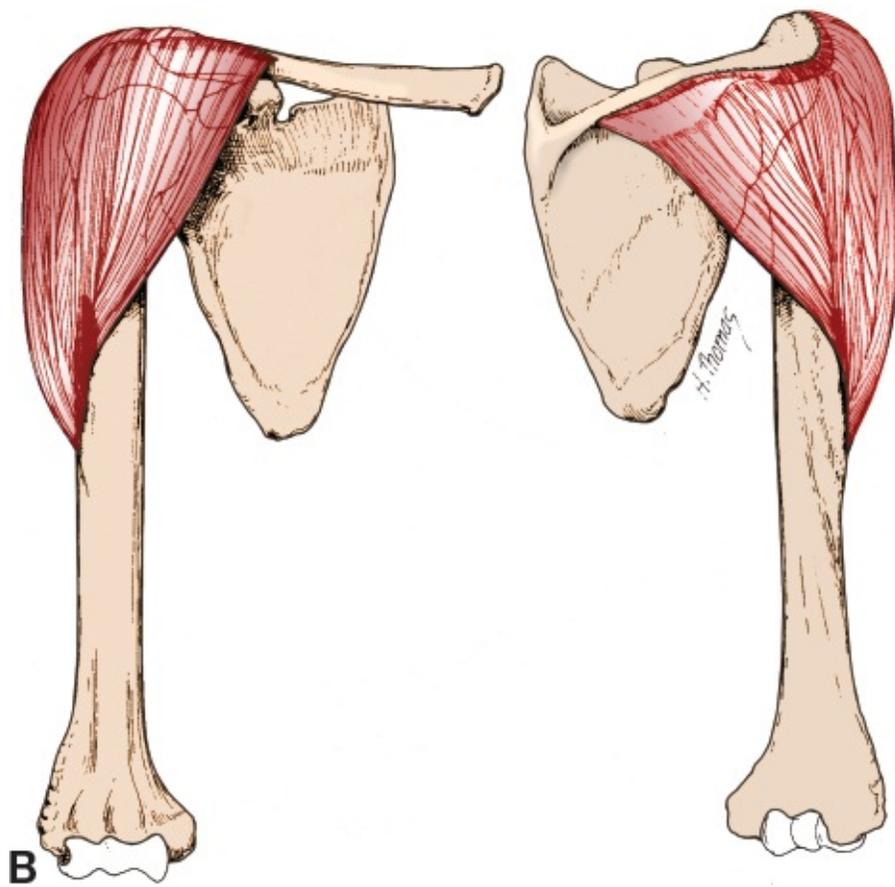

FIGURE 1-4B *Deltoid.*
Origin: Lateral third of clavicle, upper surface of acromion, spine of scapula.
Insertion: Deltoid tuberosity of humerus.
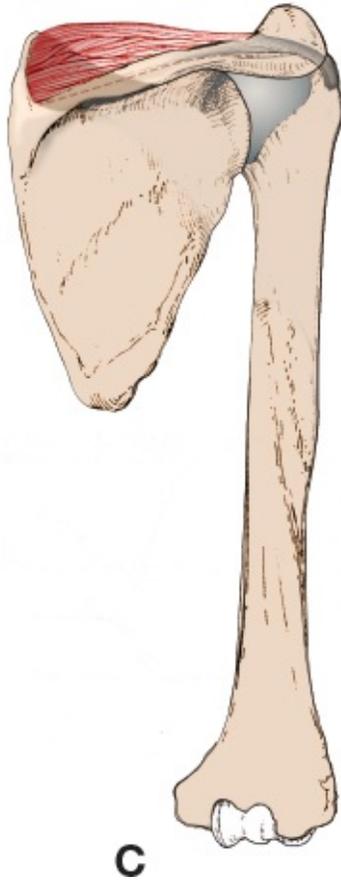

FIGURE 1-4C *Supraspinatus.*.
Origin: Supraspinous fossa of scapula.
Insertion: Superior facet of greater tuberosity of humerus,
capsule of shoulder joint.

To determine the neurologic integrity of C5, we shall test the biceps only for elbow flexion. Because the brachialis muscle, the other main flexor of the elbow, is also innervated by C5, testing flexion of the elbow should give a reasonable indication of C5 integrity.

To test flexion of the elbow, stand in front of the patient, slightly toward the side of the elbow being tested. Stabilize his upper extremity just proximal to the elbow joint by cupping your hand around the posterior portion of the elbow. The forearm must remain in supination to prevent muscle substitution, which may assist elbow flexion.

Instruct the patient to flex his arm slowly. Apply resistance as the patient approaches 45° of flexion; determine the maximum resistance that the patient can overcome (Fig. 1-8).

Reflex Testing

Biceps Reflex: The biceps reflex is predominantly an indicator of C5 neurologic integrity; it also has a smaller C6 component. Note that, because the biceps has two major levels of innervation, the strength of the reflex needs to be only slightly weaker than the strength of the opposite side to indicate pathology. It is essential to compare opposite sides of the body.
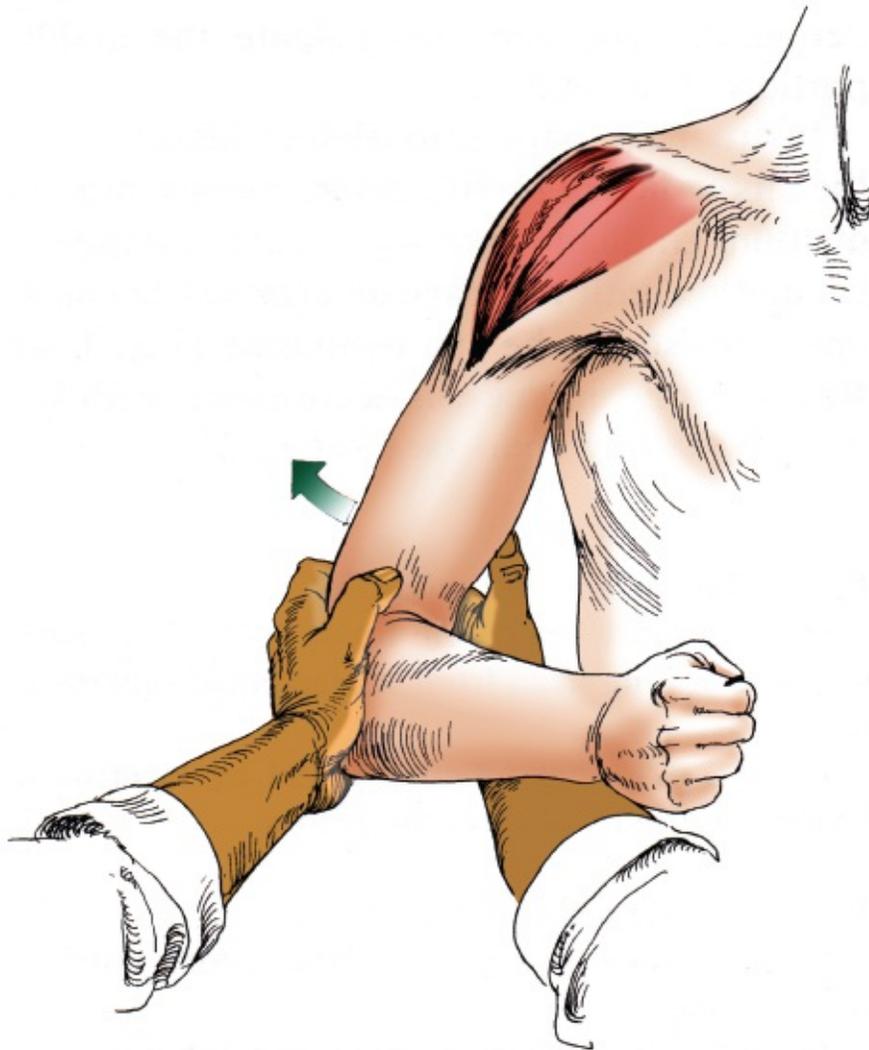

FIGURE 1-5 Muscle test for shoulder abduction.

To test the reflex of the biceps muscle, place the patient's arm so that it rests comfortably across your forearm. Your hand should be under the medial side of the elbow, acting as support for the arm. Place your thumb on the biceps tendon in the cubital fossa of the elbow (Fig. 1-9). To find the exact location of the biceps tendon, have the patient flex his elbow slightly. The biceps tendon

will stand out under your thumb.

Instruct the patient to relax the extremity completely and to allow it to rest on your forearm, with the elbow flexed to approximately 90°. With the narrow end of a reflex hammer, tap the nail of your thumb. The biceps should jerk slightly, a movement that you should be able to either see or feel. To remember the C5 reflex level more easily, note that when the biceps tendon is tapped, *five* fingers come up in a universal gesture of disdain (Fig. 1-9).
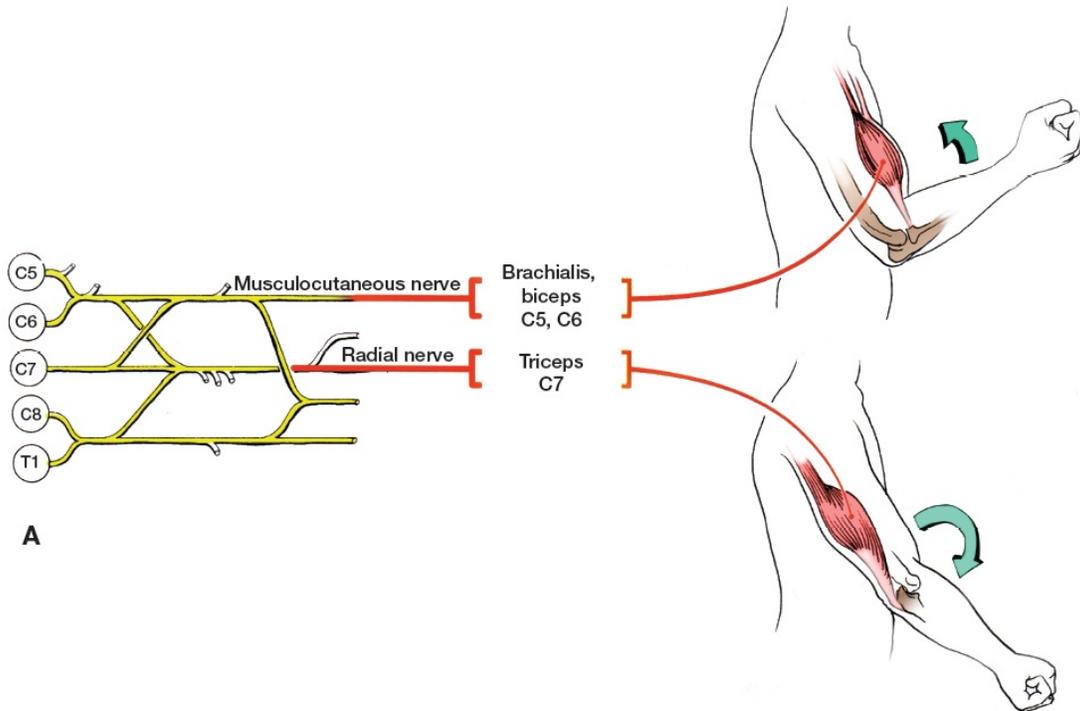

FIGURE 1-6A Elbow extension and flexion.

FIGURE 1-6C *Brachialis* (right).
Origin: Lower two-thirds of the anterior surface of the humerus.
Insertion: Coronoid process and tuberosity of the ulna.

Sensation Testing

Lateral Arm (Axillary Nerve): The C5 neurologic level supplies sensation to the

lateral arm, from the summit of the shoulder to the elbow. The purest patch of axillary nerve sensation lies over the lateral portion of the deltoid muscle. This localized sensory area within the C5 dermatome is useful for indicating specific trauma to the axillary nerve as well as general trauma to the C5 nerve root (Fig. 1-10).
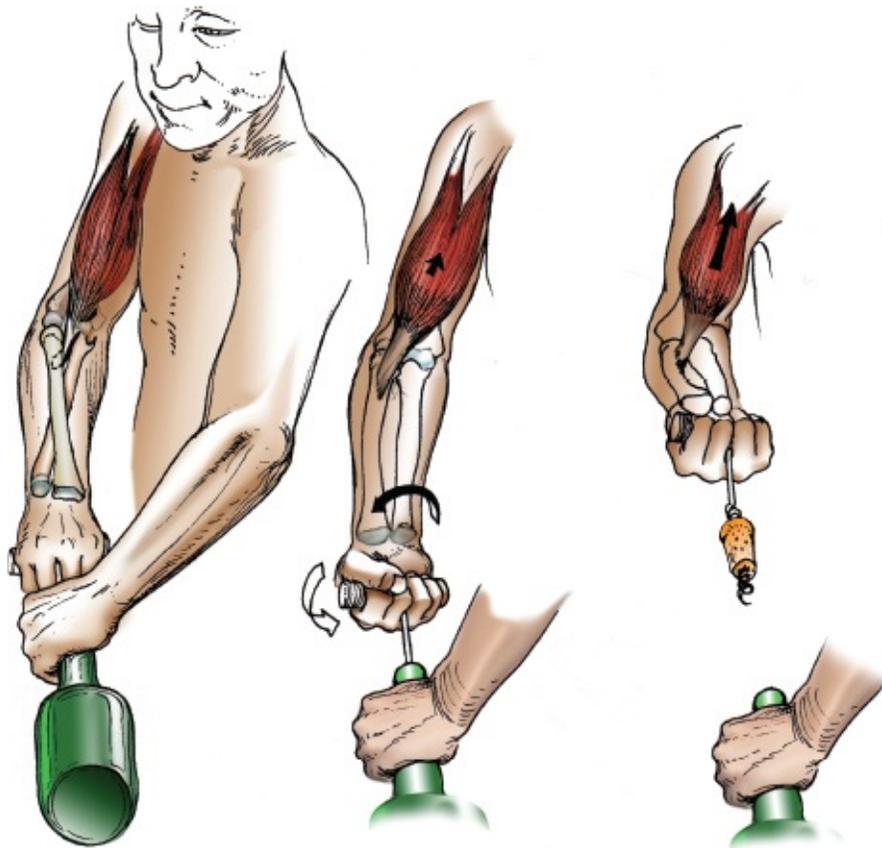

FIGURE 1-7 Various functions of the biceps. (Hoppenfeld, S.: *Physical Examination of the Spine and Extremities*. Norwalk, CT: Appleton-Century-Crofts, 1976.)
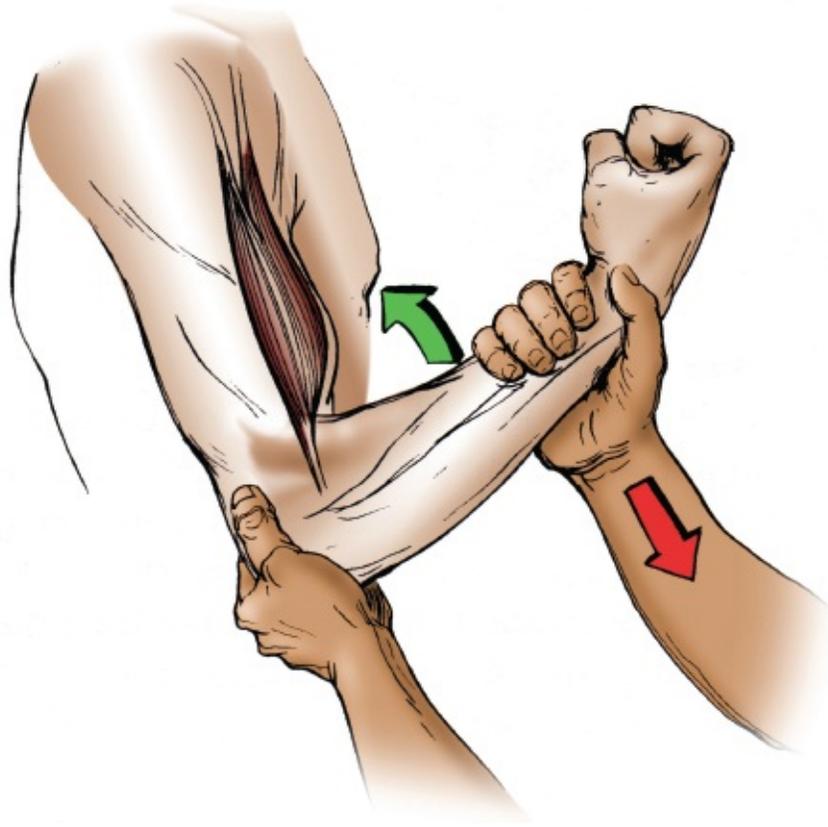

FIGURE 1-8 Muscle test for the biceps.

Neurologic Level C6

Muscle Testing

Neither the wrist extensor group nor the biceps muscle has pure C6 innervation. The wrist extensor group is innervated partially by C6 and partially by C7; the biceps has both C5 and C6 innervation (Fig. 1-11).

A

C5
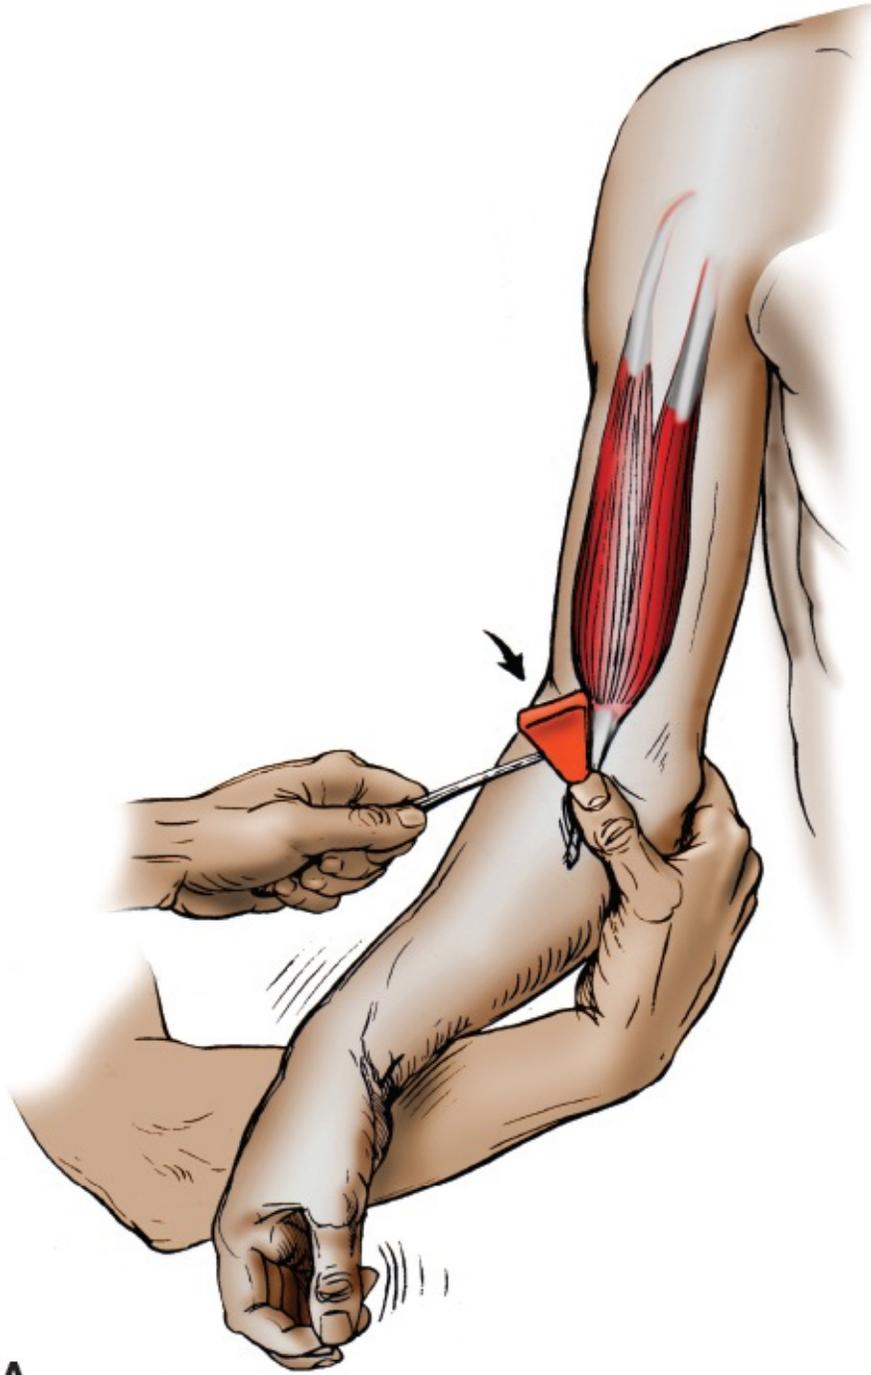

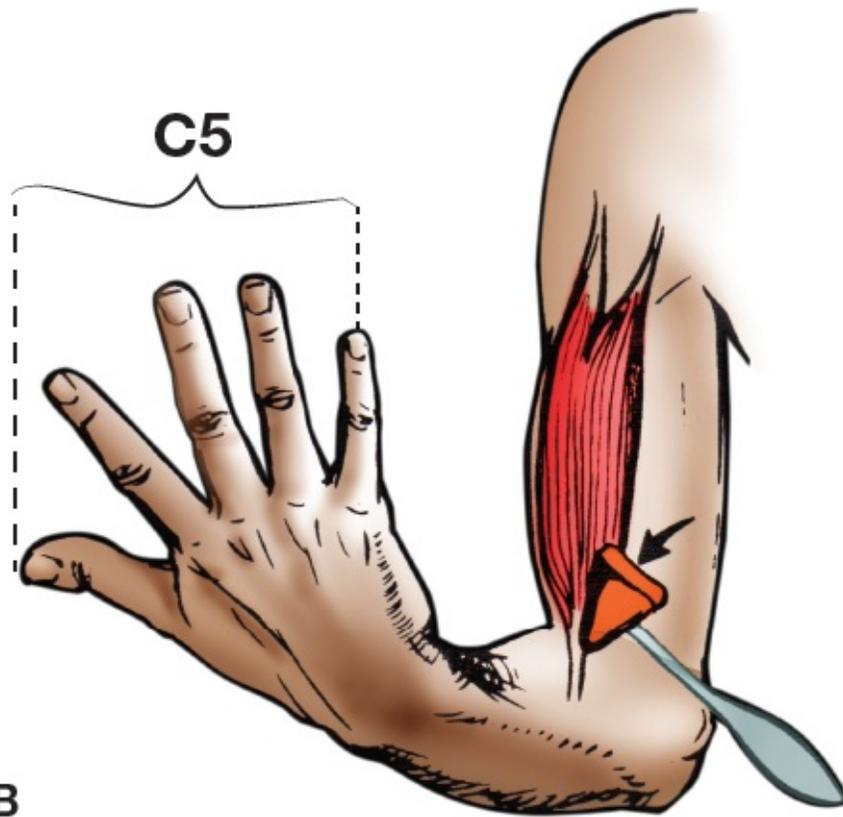

B

FIGURE 1-9A Biceps reflex test.
FIGURE 1-9B An easy way to remember that the biceps reflex is innervated by C5 is to associate *five* fingers with neurologic level C5.
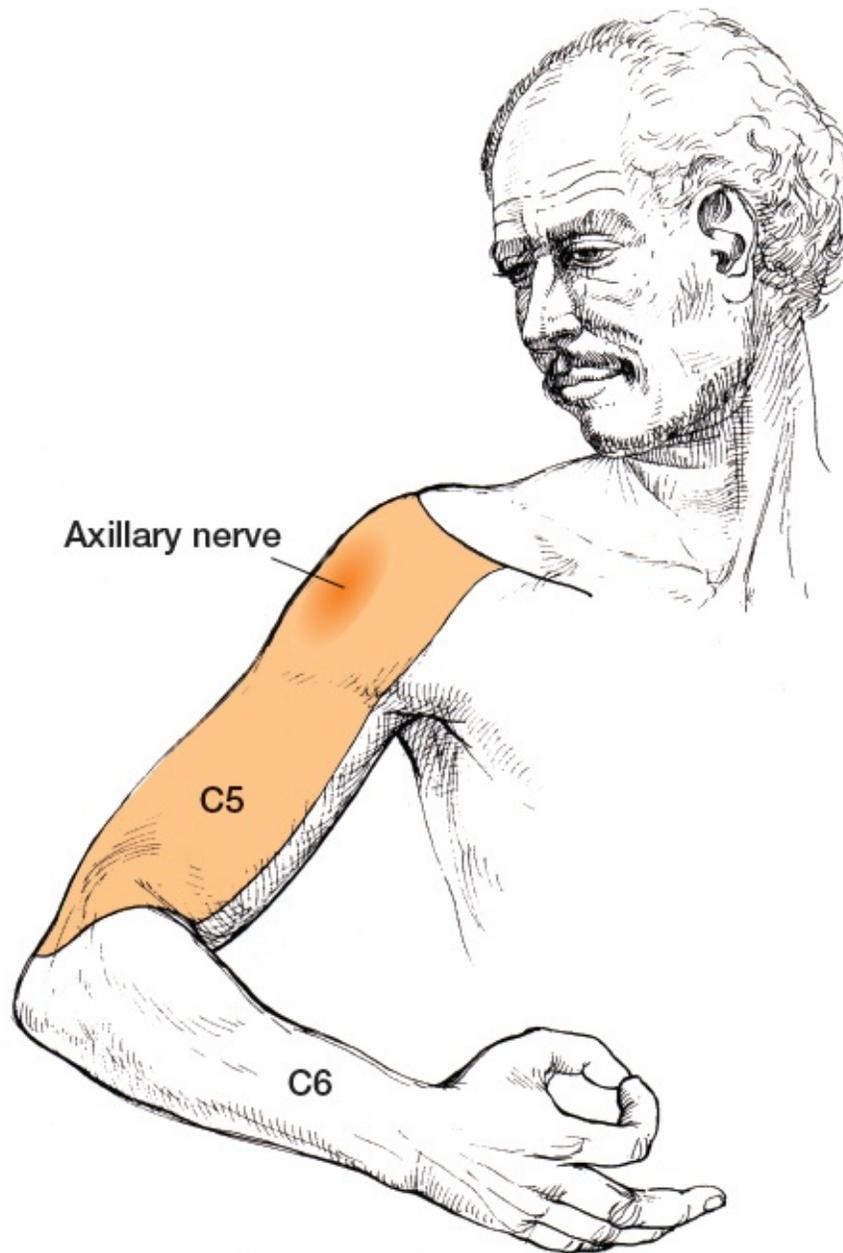

FIGURE 1-10 The sensory distribution of the C5 neurologic level.
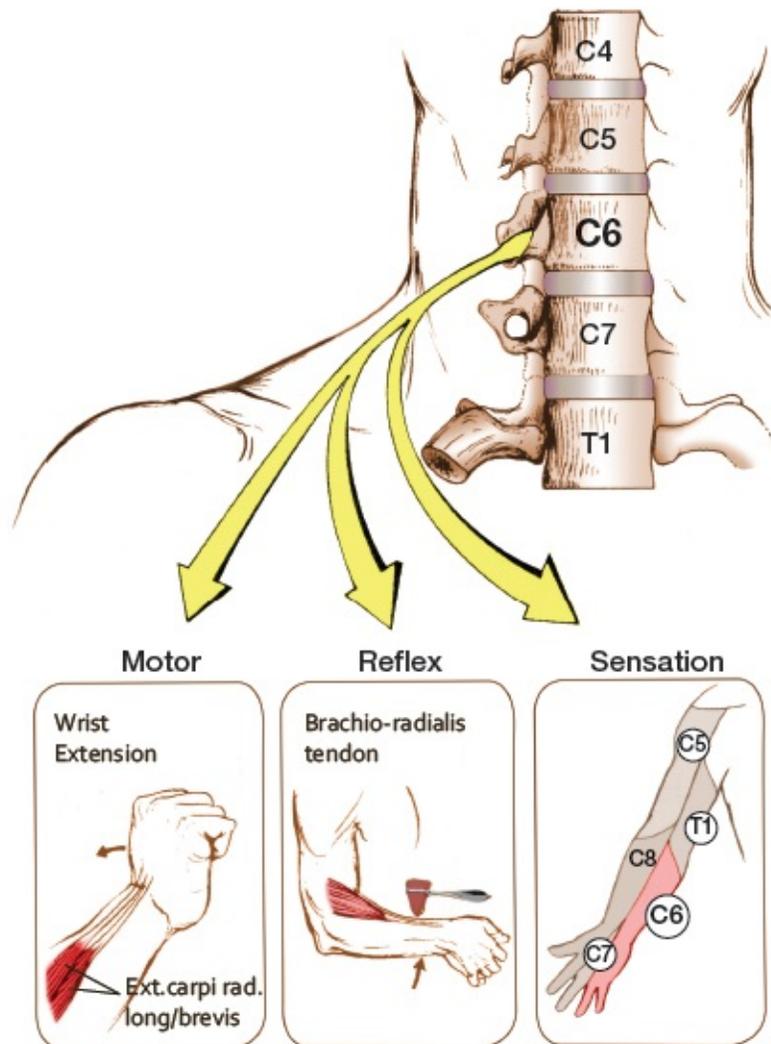

FIGURE 1-11 Neurologic level C6.

Wrist Extensor Group: C6 (Radial Nerve)

Radial extensors (Fig. 1-12):
1. Extensor carpi radialis longus and brevis,
   Radial nerve, C6
Ulnar extensor:
1. Extensor carpi ulnaris
2. C7

    To test wrist extension, stabilize the forearm with your palm on the dorsum of the wrist and your fingers wrapped around it. Then instruct the patient to extend his wrist. When the wrist is in full extension, place the palm of your resisting hand over the dorsum of the hand and try to force the wrist out of the

extended position (Fig. 1-13). Normally, you will be unable to move it. Test the opposite side as a means for comparison. Note that the radial wrist extensors, which supply most of the power for extension, are innervated by C6, whereas the extensor carpi ulnaris is innervated primarily by C7. If C6 innervation is absent and C7 is present, the wrist will deviate to the ulnar side during extension. On the other hand, in a spinal cord injury where C6 is completely spared and C7 is absent, radial deviation will occur (Fig. 1-14).

Biceps: C6 (Musculocutaneous Nerve): The biceps muscle, in addition to its C5 innervation, is partially innervated by C6. Test the biceps by muscle testing flexion of the elbow. (For details, see page 11.)
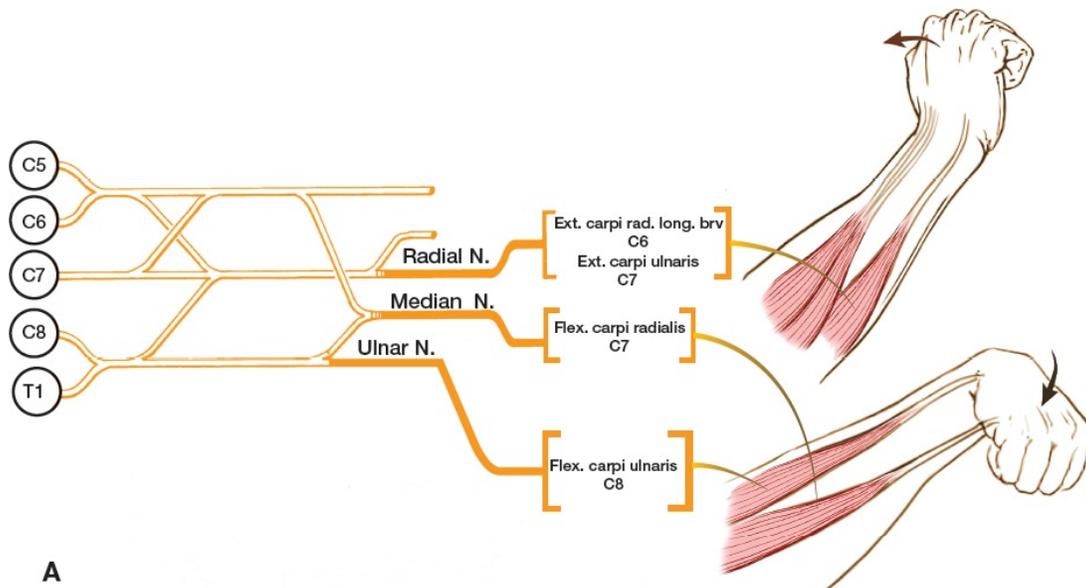

FIGURE 1-12A Wrist extension and flexion.

FIGURE 1-12C *Extensor carpi radialis longus* (right).
Origin: Lower third of lateral supracondylar ridge of humerus, lateral intermuscular septum.
Insertion: Dorsal surface of the base of the 2d metacarpal bone.
FIGURE 1-12C *Extensor carpi radialis brevis* (right).
Origin: From common extensor tendon from lateral epicondyle of humerus, radial collateral ligament of elbow joint, and

intermuscular septa.
Insertion: Dorsal surface of base of 3d metacarpal bone.

Reflex Testing

Brachioradialis Reflex: The brachioradialis is innervated by the radial nerve via the C6 neurologic level. To test the reflex, support the patient's arm as you did in testing the biceps reflex. Tap the tendon of the brachioradialis at the distal end of the radius, using the flat edge of your reflex hammer; the tap should elicit a small radial jerk (Fig. 1-15). Test the opposite side and compare results. The brachioradialis is the preferred reflex for indicating C6 neurologic level integrity.

Biceps Reflex: The biceps reflex may be used as an indicator of C6 neurologic integrity as well as C5. However, because of this dual innervation, the strength of its reflex need only weaken slightly in comparison to the opposite side to indicate neurologic problems. The biceps reflex is predominantly a C5 reflex.
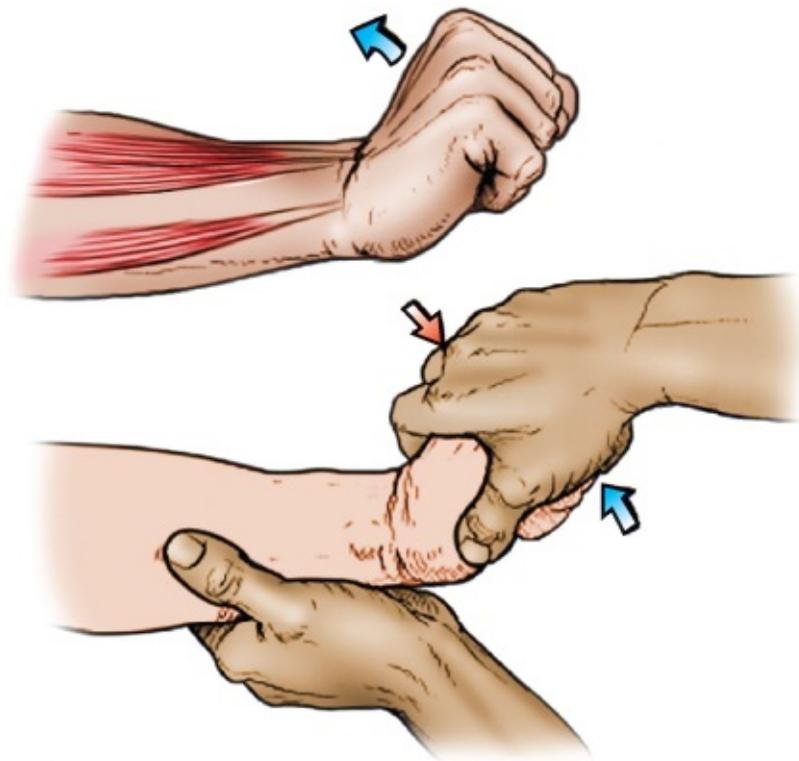

FIGURE 1-13 Muscle test for wrist extension.

To test the biceps reflex, tap its tendon as it crosses the elbow. (For details,

see page 11.)

Sensation Testing

Lateral Forearm (Musculocutaneous Nerve): C6 supplies sensation to the lateral forearm, the thumb, the index finger, and one-half of the middle finger. To remember the C6 sensory distribution more easily, form the number 6 with your thumb, index, and middle fingers by pinching your thumb and index finger together while extending your middle finger (Fig. 1-16).

Neurologic Level C7

Muscle Testing

Although the triceps, wrist flexors, and finger extensors are partially innervated by C8, they are predominantly C7 muscles. All of these motions come together in the throwing motion of a baseball (Fig. 1-17).

Triceps: C7 (Radial Nerve): The triceps is the primary elbow extensor (Fig. 1-18). To test it, stabilize the patient's arm just proximal to the elbow and instruct the patient to extend his arm from a flexed position. Before the patient reaches 90°, begin to resist the patient motion until you have discovered the maximum resistance the patient can overcome (Fig. 1-19). Your resistance should be constant and firm, because a jerky, pushing type of resistance cannot permit an accurate evaluation. Note that gravity is normally a valuable aid in elbow extension; if extension seems very weak, you must account for it, as well as for the weight of the arm. If extension seems weaker than grade 3, test the triceps in a gravity-free plane. Triceps strength is important because it permits the patient to support weight bearing on a cane or a standard crutch (Fig. 1-20).
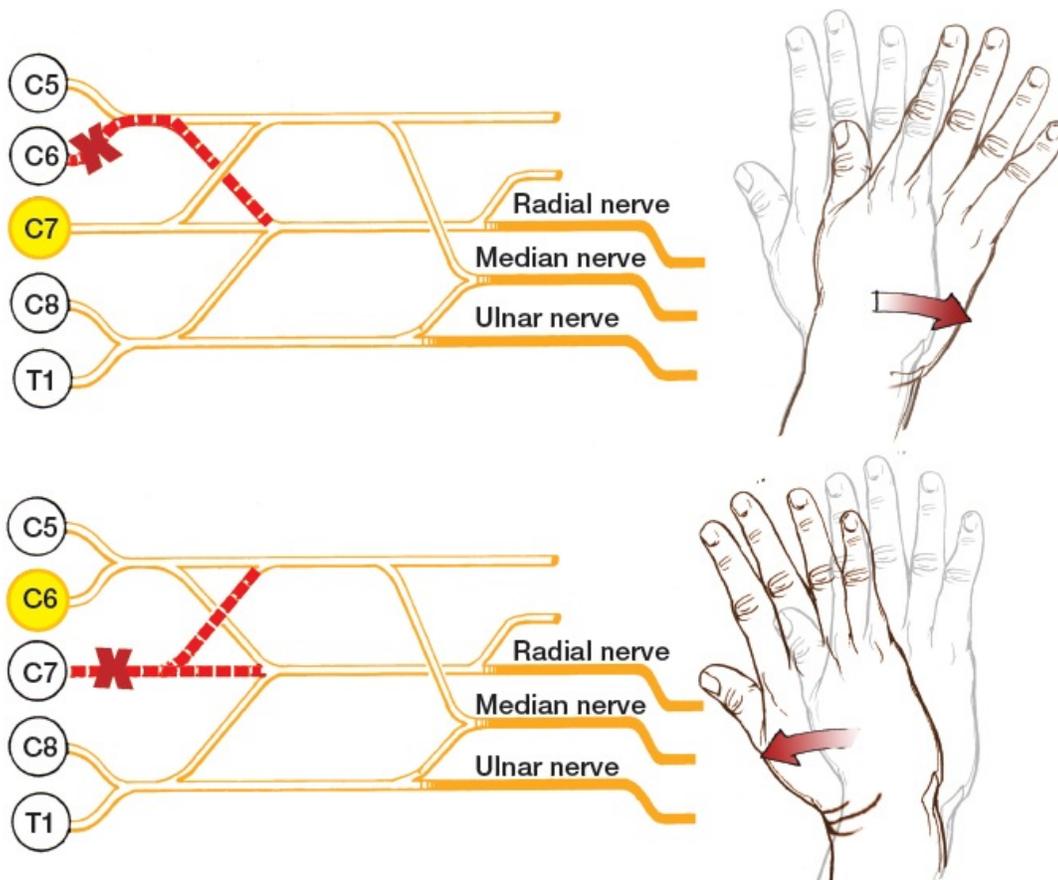

FIGURE 1-14 Wrist deviation with C6 and C7 injuries.

Wrist Flexor Group: C7 (Median and Ulnar Nerves)
1. Flexor carpi radialis (Fig. 1-12)
   Median nerve, C7
2. Flexor carpi ulnaris
   Ulnar nerve, C8

   The flexor carpi radialis (C7) is the more important of these two muscles and provides most of the power for wrist flexion. The flexor carpi ulnaris, which is primarily innervated by C8, provides less power but acts as an axis for flexion. To understand this, note the ulnar direction that normal flexion takes.
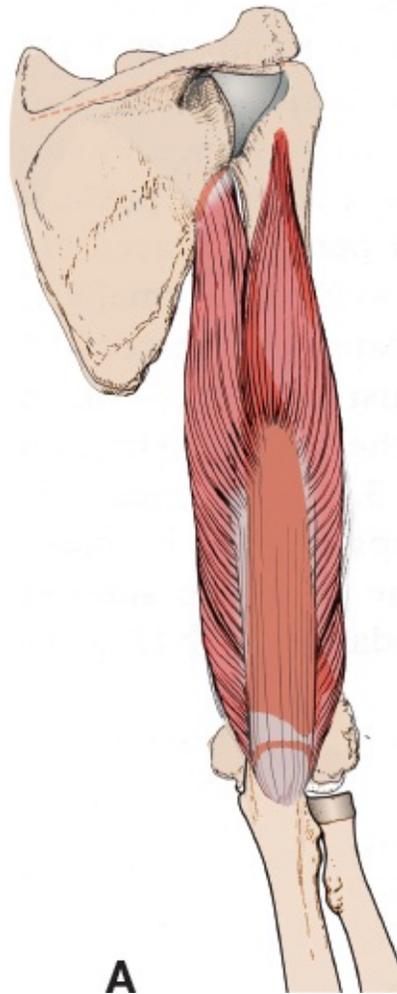

FIGURE 1-19A *Triceps brachii.*
Origin: Long head from infraglenoid tuberosity of scapula, lateral head from posterior and lateral surfaces of humerus, medial head from lower posterior surface of humerus.
Insertion: Upper posterior surface of olecranon and deep fascia of forearm.
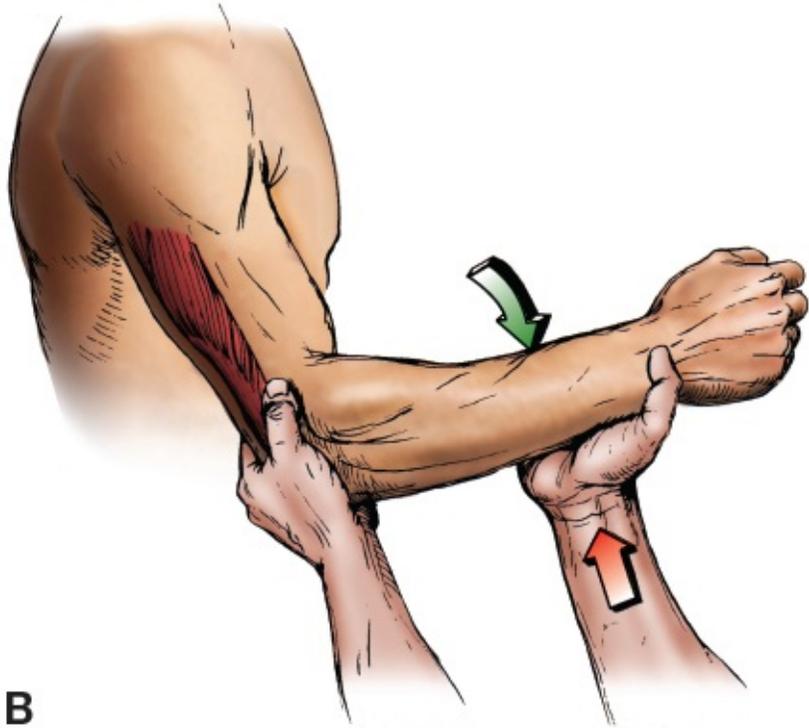

B

FIGURE 1-19B Muscle test of the triceps muscle.

FIGURE 1-20 Walking with a standard crutch requires an active triceps muscle.

To prepare for the wrist flexion test, instruct the patient to make a fist. The finger flexors can, in some instances, act as wrist flexors; finger flexion removes them as factors during the test, because the muscles have contracted before the test begins. Stabilize the wrist, then instruct the patient to flex a closed fist. When the wrist is in flexion, hold the patient's closed fist and try to pull the wrist out of its flexed position (Fig. 1-21).

Finger Extensors: C7 (Radial Nerve)
1. Extensor digitorum communis (Fig. 1-22)
2. Extensor indicis proprius
3. Extensor digiti minimi

To test extension of the fingers, stabilize the wrist in the neutral position. Instruct the patient to extend their metacarpophalangeal joints and flex the interphalangeal joints at the same time. Flexion of the interphalangeal joints prevents the substitution of the intrinsic muscles of the hand for the long finger extensors. Place your hand on the dorsum of the extended proximal phalanges and try to force them into flexion (Fig. 1-23).

Reflex Testing

Triceps Reflex: The triceps reflex is innervated by the C7 component of the radial nerve.

To test the reflex of the triceps muscle, rest the patient's arm on your forearm; the position is exactly the same as it was in the test for the biceps reflex. Instruct the patient to relax his arm completely. When you know that the arm is relaxed (you can feel the lack of tension in the triceps muscle), tap the triceps tendon as it crosses the olecranon fossa (Fig. 1-24). The triceps tendon should jerk slightly, a movement that you can either feel along your supporting forearm or see.
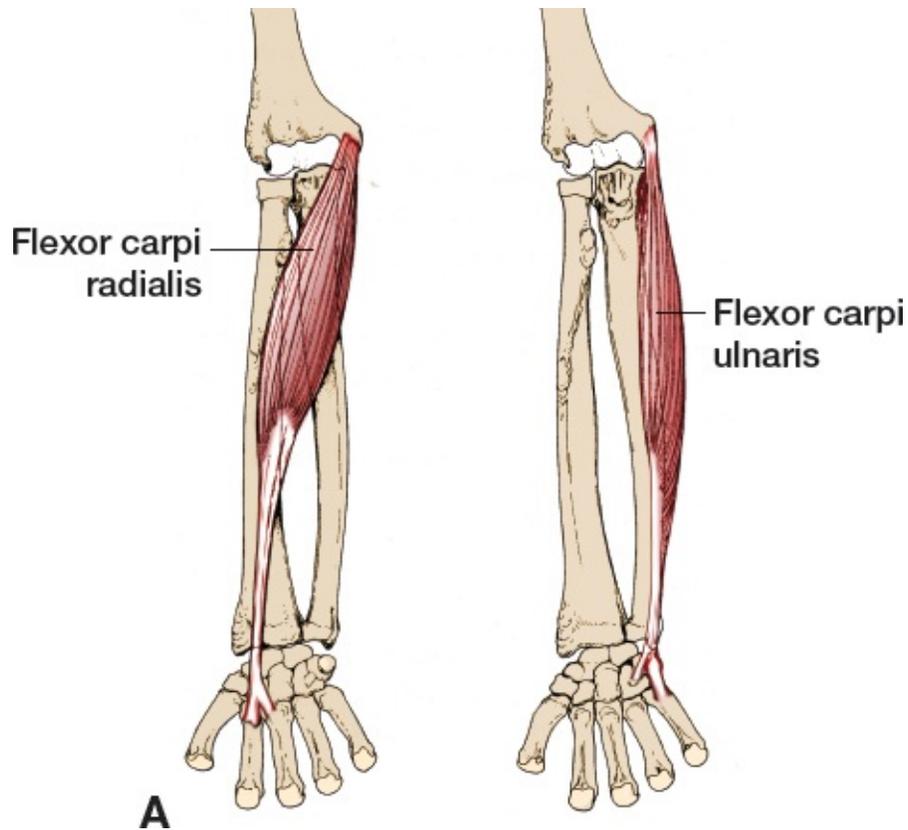

FIGURE 1-21A *Flexor carpi radialis* (left).

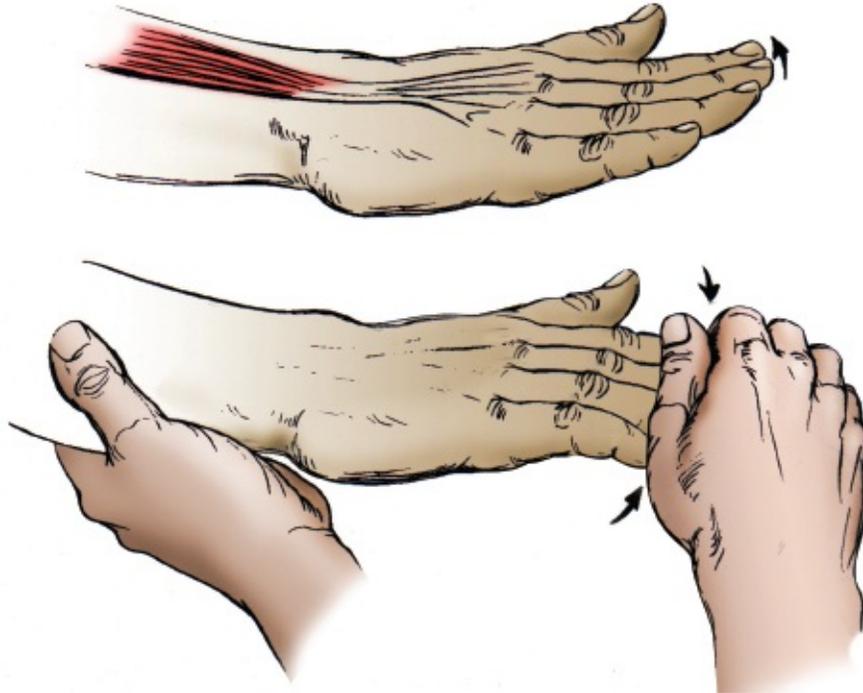

FIGURE 1-23 Muscle test for finger extension.

Olecranon fossa

Olecranon bursa
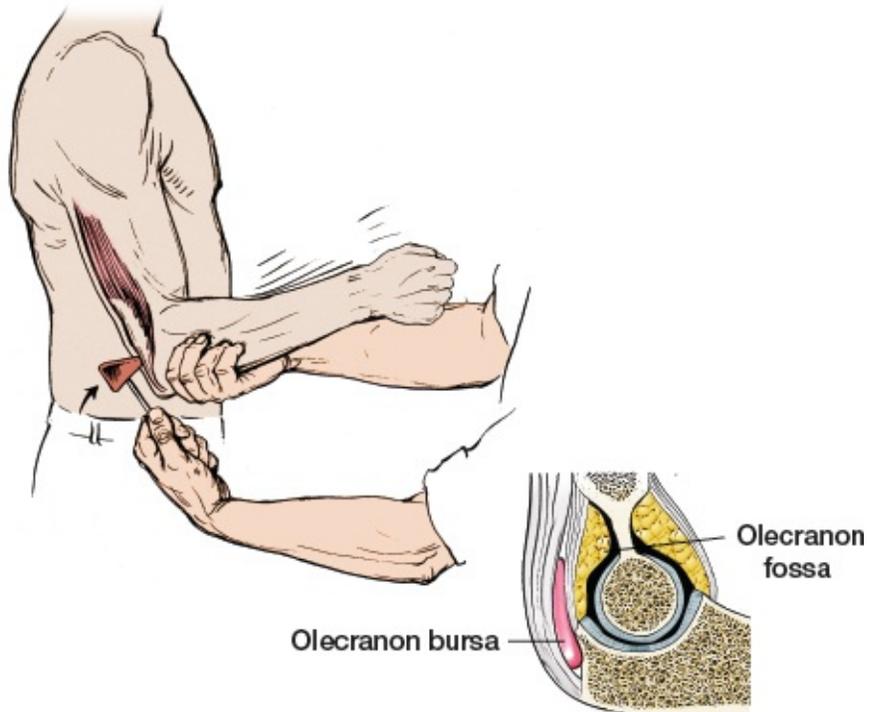

FIGURE 1-24 Triceps reflex test.

Sensation Testing

Middle Finger: C7 supplies sensation to the middle finger. Because middle finger sensation is also occasionally supplied by C6 and C8, there is no conclusive way to test C7 sensation.

Neurologic Level C8

Muscle Test

Finger Flexors
1. Flexor digitorum superficialis (Fig. 1-22)
   Median nerve, C8
2. Flexor digitorum profundus
   Median and ulnar nerves, C8
3. Lumbricals
   Median and ulnar nerves, C8 (T1)

The flexor digitorum profundus, which flexes the distal interphalangeal joint, and the lumbricals, which flex the metacarpophalangeal joint, usually receive innervation from the ulnar nerve on the ulnar side of the hand and from the median nerve on the radial side. If there is an injury to the C8 nerve root, the entire flexor digitorum profundus becomes weak, with secondary weakness in all finger flexors. If, however, there is a peripheral injury to the ulnar nerve, weakness will exist only in the ring and little fingers. The flexor digitorum superficialis, which flexes the proximal interphalangeal joint, has only median nerve innervation and is affected by root injury to C8 and peripheral injuries to the median nerve (Fig. 1-25).

To test flexion of the fingers, instruct the patient to flex his fingers at all three sets of joints: the metacarpophalangeal joints, the proximal interphalangeal joints, and the distal interphalangeal joints. Then curl or lock your four fingers into the patients (Fig. 1-26). Try to pull the fingers out of flexion. As you evaluate the results of your test, note which joints fail to hold flexion against your pull. Normally, all joints should remain flexed. To remember the C8 motor level more easily, note that the muscle test has four of your fingers intertwined with four of the patient's; the sum equals eight (Fig. 1-27).

Sensation Testing

Medial Forearm (Medial Antebrachial-Cutaneous Nerve): C8 supplies sensation to the ring and little fingers of the hand and the distal half of the forearm. The

ulnar side of the little finger is the purest area for sensation of the ulnar nerve (which is predominantly C8) and is the most efficient location for testing. Test the opposite side as a means for comparison and grade your patient's sensation as absent (anesthesia), diminished (hypoesthesia), normal, or increased (hyperesthesia) (Fig. 1-28).
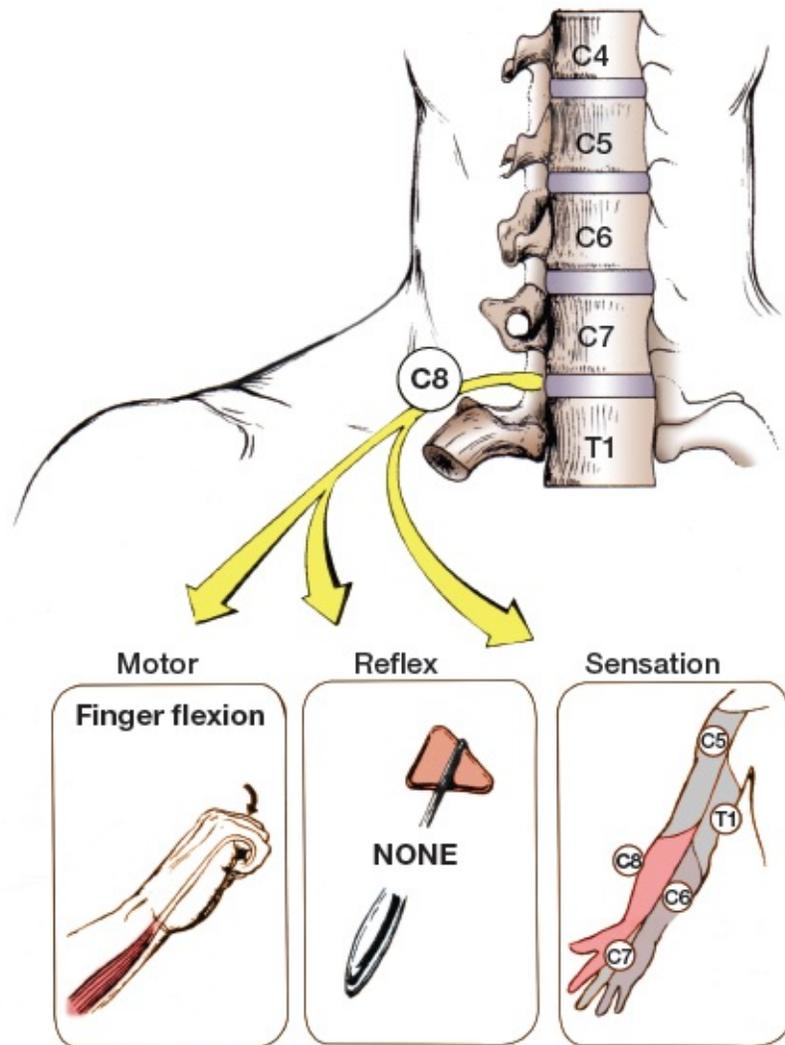

FIGURE 1-25 Neurologic level C8.
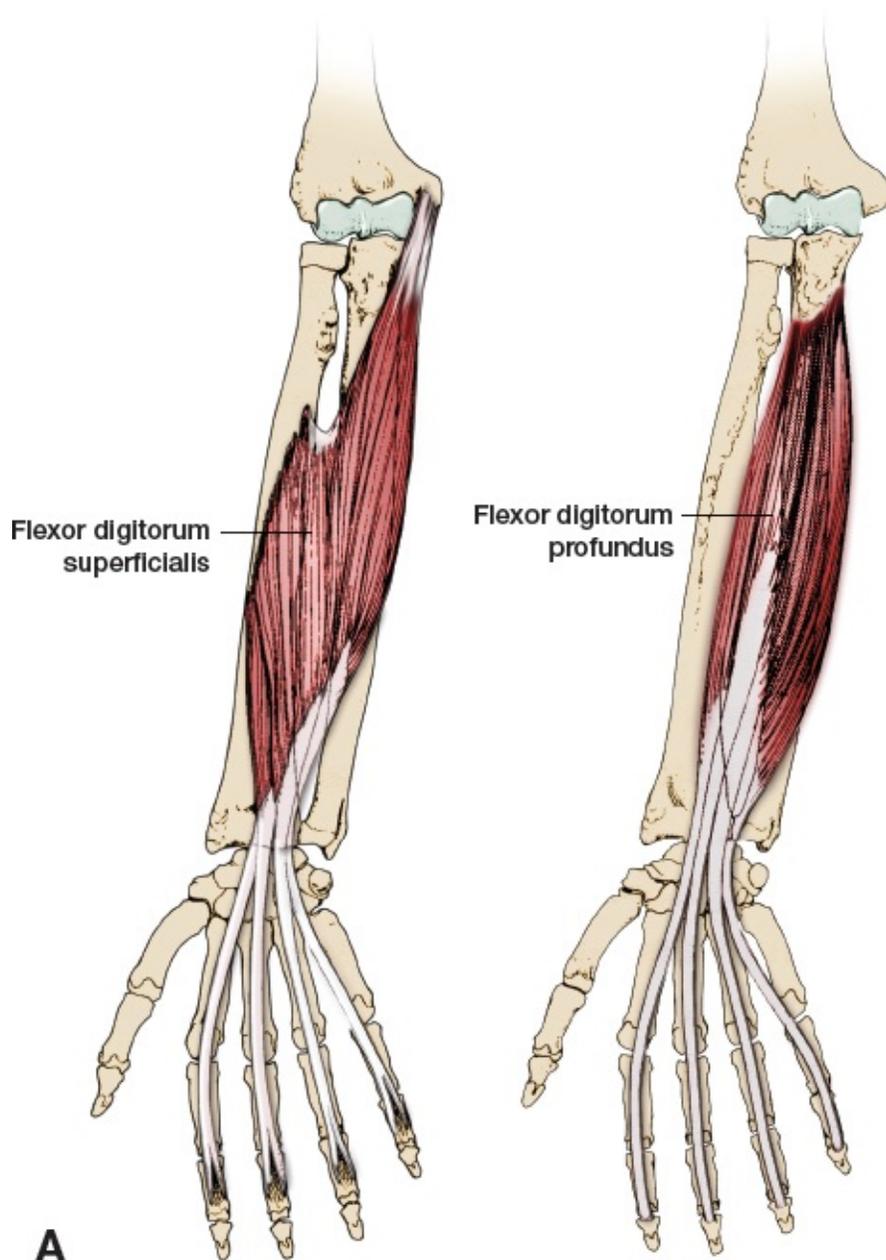

FIGURE 1-26A *Flexor digitorum superficialis* (left). *Origin: Humeral head* from common flexor tendon from medial epicondyle of humerus, *ulnar head* from coronoid process of ulna, *radial head* from oblique line of radius.
Insertion: Margins of palmar surface of middle phalanx of medial four digits.
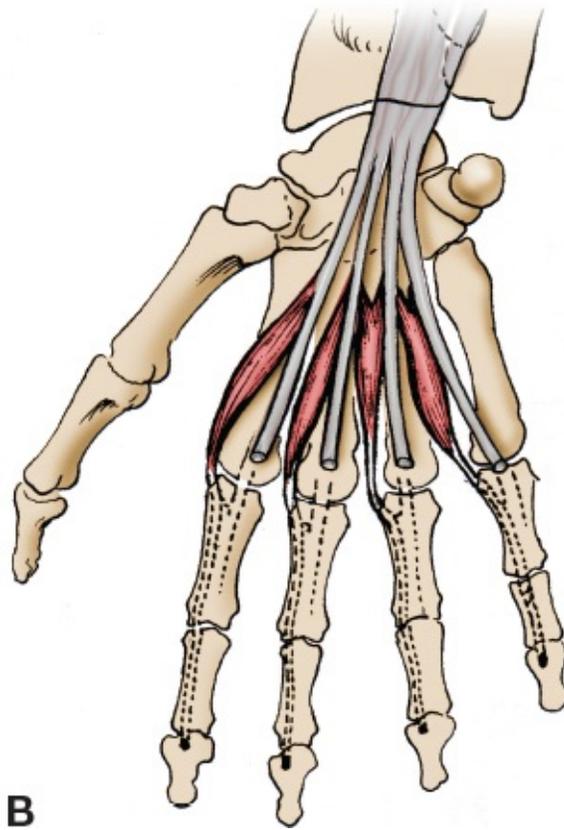

FIGURE 1-26B *Lumbricals.*

Origin: There are four lumbricals, all arising from tendons of flexor digitorum profundus: 1st from radial side of tendon for index finger, 2d from radial side of tendon for middle finger, 3d from adjacent sides of tendons for middle and ring fingers, 4th from adjacent sides of tendons for ring and little fingers.
Insertion: With tendons of extensor digitorum and interossei into bases of terminal phalanges of medial four digits.
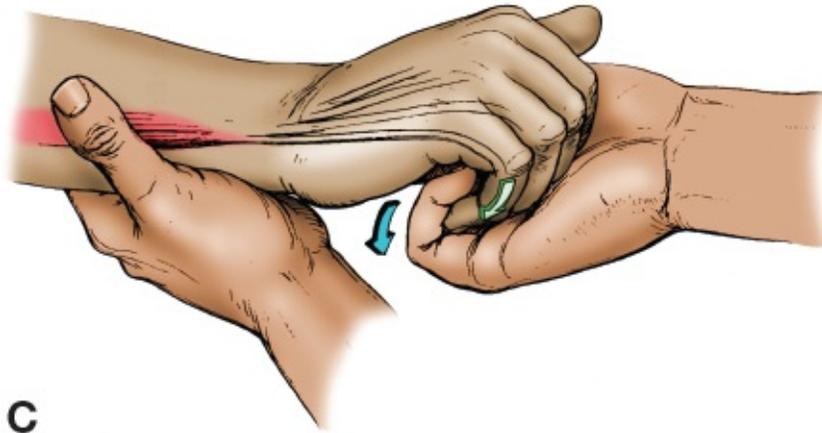

FIGURE 1-26C Muscle testing of the finger flexors.

Neurologic Level T1

Test T1 for its motor and sensory components, because T1, like C8, has no identifiable reflex associated with it (Fig. 1-29).

Muscle Testing

Finger Abduction

1. Dorsal interossei (DAB)—(The initials indicate that the Dorsal interossei ABduct.) Ulnar nerve, T1 (Fig. 1-30)
2. Abductor digiti quinti (5 finger)
   Ulnar nerve, T1

cutaneous nerve
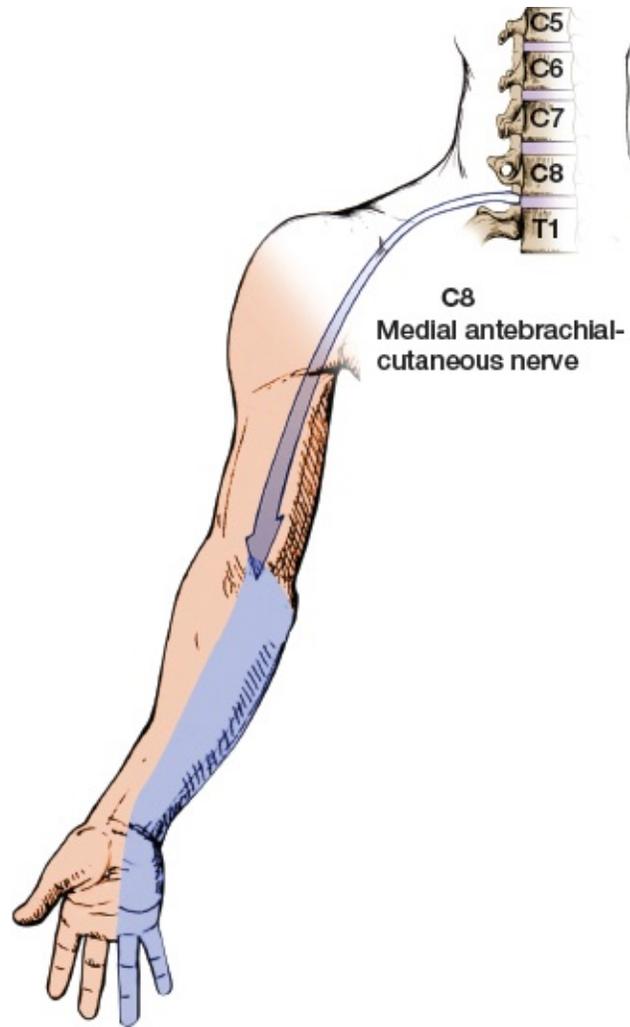

FIGURE 1-28 C8 sensory distribution.
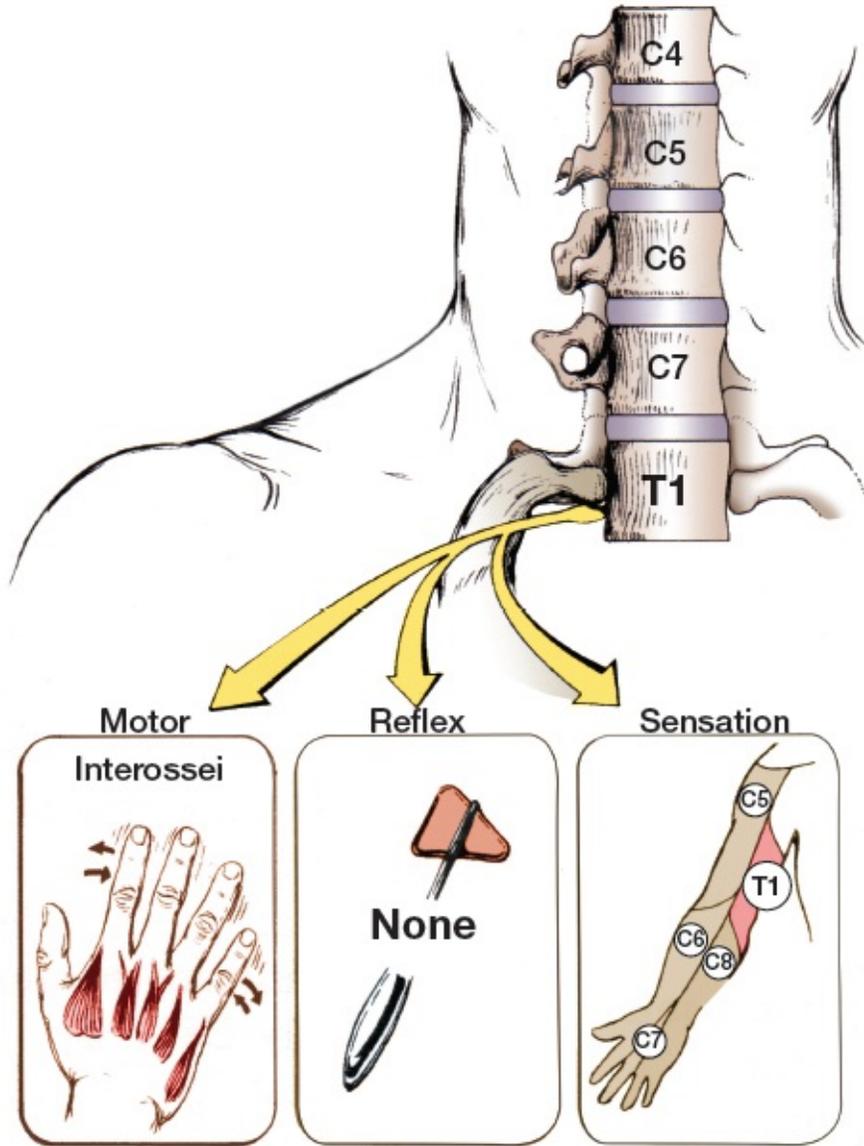

FIGURE 1-29 Neurologic level T1.
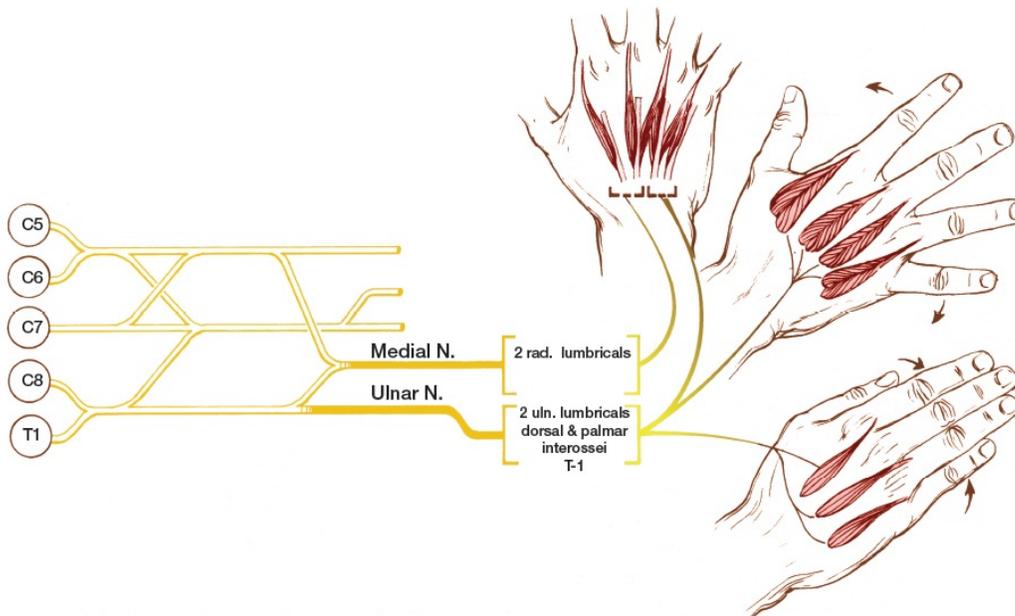

FIGURE 1-30 *Interossei dorsales*.
Origin: There are four dorsal interossei, each arising by two heads from adjacent sides of metacarpal bones.

Note that all small muscles of the hand are innervated by T1. To test finger abduction, instruct the patient to abduct their extended fingers away from the axial midline of the hand. Then pinch each pair of fingers to try to force them together: pinch the index to the middle, ring, and little fingers; the middle to the ring and little fingers; and the ring to the little fingers (Fig. 1-31). Observe any obvious weaknesses between pairs, and test the other hand as a means of comparison.

Note that pushing the little finger to the ring finger tests the abductor digiti quinti.

Finger Adduction
Primary adductor (Fig. 1-30)
1. Palmar Interossei (PAD)—(The initials indicate that the Palmar interossei ADduct.)
   Ulnar nerve, C8, T1

To test finger adduction, have the patient try to keep his extended fingers together while you attempt to pull them apart. Test in pairs as follows: the index and middle fingers, the middle and ring fingers, and the ring and little fingers.

FIGURE 1-31 Muscle test for finger abduction.

Finger adduction can also be checked if you place a piece of paper between two of the patient's extended fingers and pull it out from between. The strength of his grasp should be compared with that of the opposite hand (Fig. 1-32). To remember the T1 neurologic level more easily, pull a *one*-dollar bill from between the extended fingers and associate the *one* dollar with neurologic level *T1*.

Sensation Testing

Medial Arm (Medial Brachial Cutaneous Nerve): T1 supplies sensation to the upper half of the medial forearm and the medial portion of the arm (Fig. 1-33).

Summary

The following scheme is recommended for testing neurologic levels in the upper extremity. In the neurologic examination of the upper extremity, it is practical to evaluate all motor power first, then all reflexes and finally sensation. This method permits economy of effort and creates a minimum of disturbance for the patient.

   Motor power can be tested almost completely in the wrist and hand with minimal motion and effort for the examiner and patient. Wrist extension (C6), wrist flexion and finger extension (C7), finger flexion (C8), and finger abduction and adduction (T1) can all be performed in one smooth motion. Only C5 must be tested elsewhere, with the deltoid and biceps muscles (Fig. 1-34).
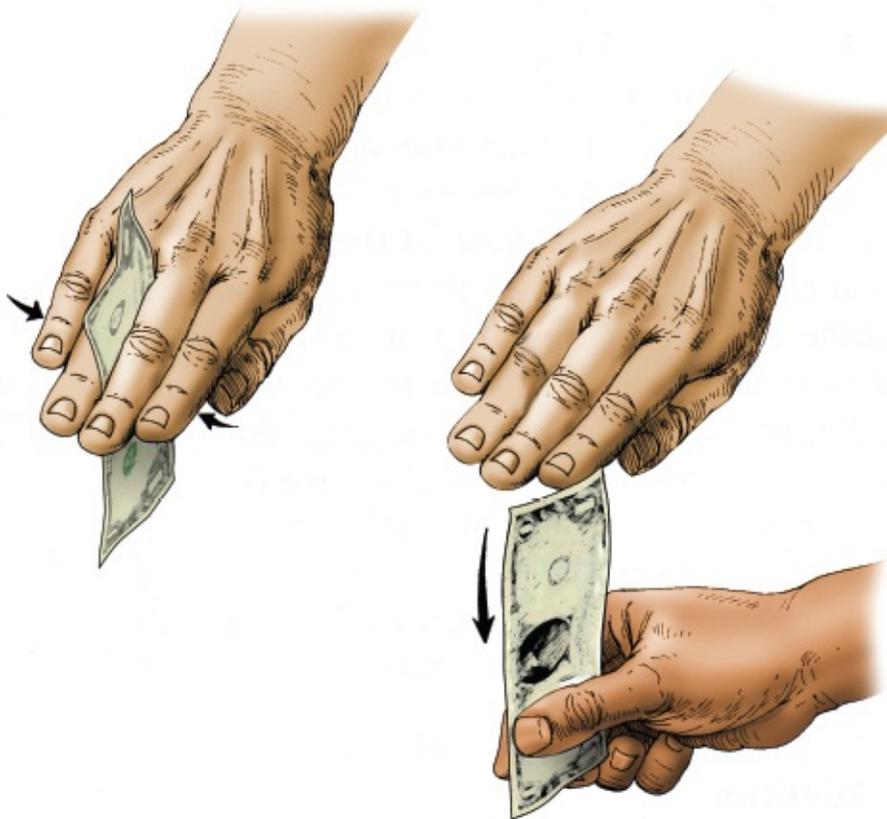

FIGURE 1-32 Muscle test for finger adduction.
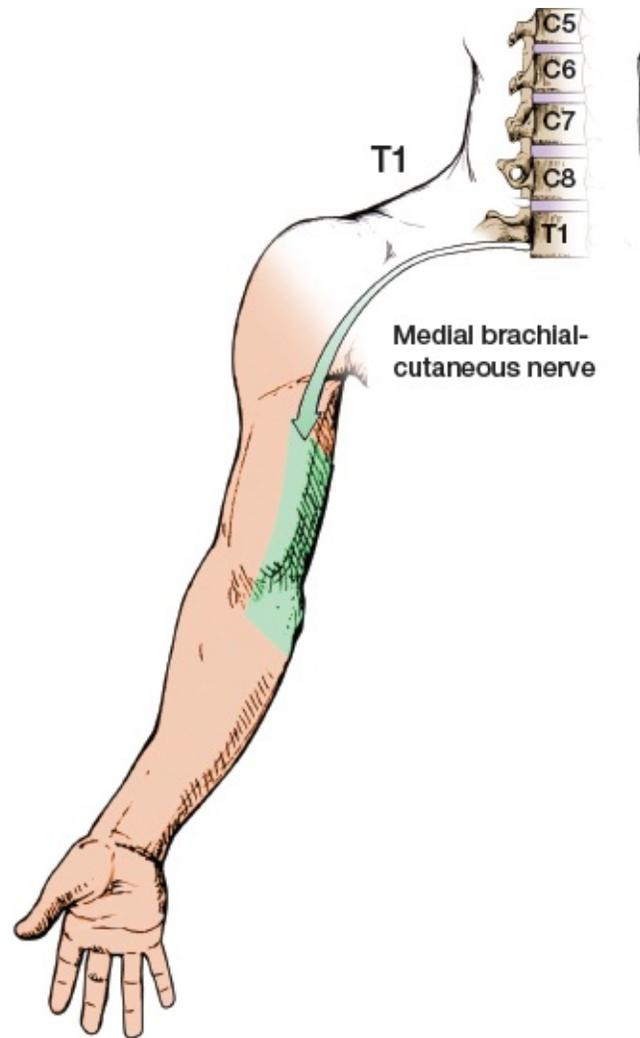

FIGURE 1-33 T1 sensory distribution.

Reflexes can all be obtained in a smooth pattern if the elbow and extremity are stabilized in one position. It is then easy to move the reflex hammer to tap the appropriate tendon—biceps (C5), brachioradialis (C6), and triceps (C7) (Fig. 1-35).

Sensation can also be tested in a smooth pattern. Start proximally on the outer portion of the extremity and move down the extremity (C5, arm; C6, forearm), then across the fingers (C6-C8). Finally, move up the inner border of the extremity (C8, forearm; T1, arm), to the axilla (T2) (Fig. 1-36).

    C7—Triceps

Clinical Application of Neurologic Levels

Herniated Cervical Disks

There are eight cervical nerves and only seven cervical vertebrae; thus, each cervical nerve leaves the spine adjacent to its corresponding vertebral body except C8, the first cervical nerve exits between the occiput and C1, the sixth between C5 and C6, and the eighth between C7 and T1 (Fig. 1-37). A herniated disk impinges upon the nerve root exiting above the disk and passing through the nearby neural foramen and results in the involvement of one specific neurologic level. For example, a herniated disk between C5 and C6 impinges upon the C6 nerve root (Fig. 1-38). When a disk herniates into a nerve root, pain radiates along the path of the nerve root being irritated.
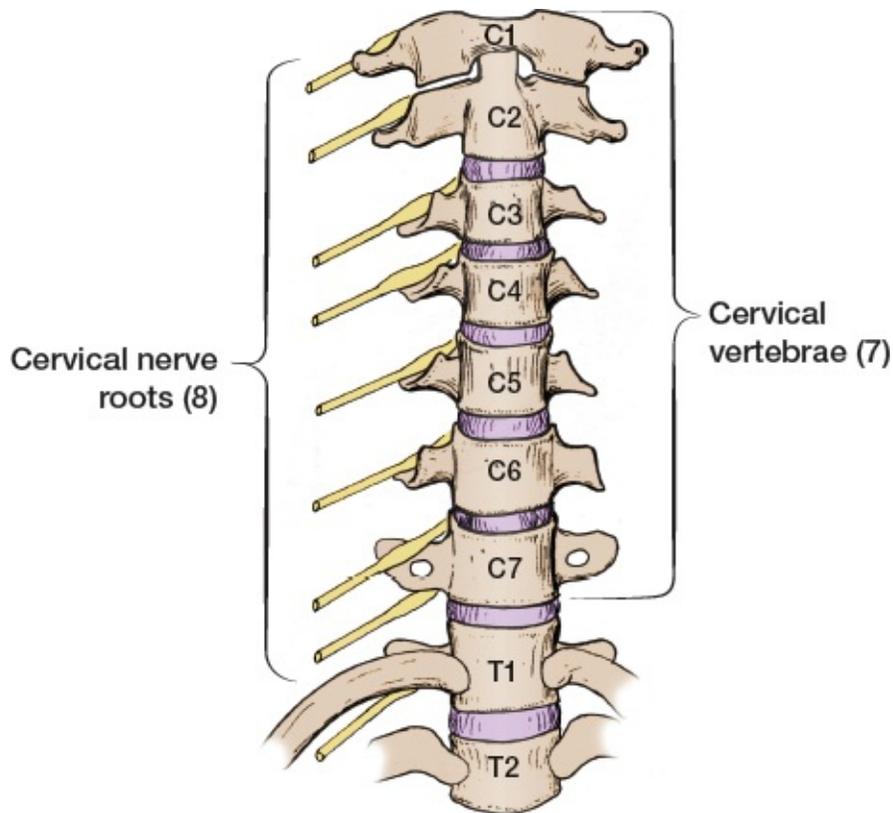

FIGURE 1-37 Cervical vertebrae and nerve roots.

There is slightly more motion between C5 and C6 than between the other cervical vertebrae (except for between the specialized articulations of the occiput and C1, and C1 and C2) (Figs. 1-39 and 1-40). Greater motion causes a greater potential for breakdown, and the incidence of herniated disks and osteoarthritis is greater at C5-C6 than at any of the other cervical disk spaces. The incidence of herniation increases at C6-C7 as the patient grows older; the reasons for this are not yet known.

To involve the nerve root, the disks must herniate posteriorly. They do so for two reasons: first, the annulus fibrosus is intact and strong anteriorly and defective posteriorly; second, the anterior longitudinal ligament is anatomically broader and stronger than the narrower posterior longitudinal ligament. Because a disk usually herniates under pressure, it breaks through in the direction of least resistance, posteriorly. Because of the rhomboidal shape of the posterior longitudinal ligament, the disk also tends to herniate to one side or the other (Fig. 1-41); it is less common to have a midline herniation, because the disk would then have to penetrate the strongest portion of the ligament.
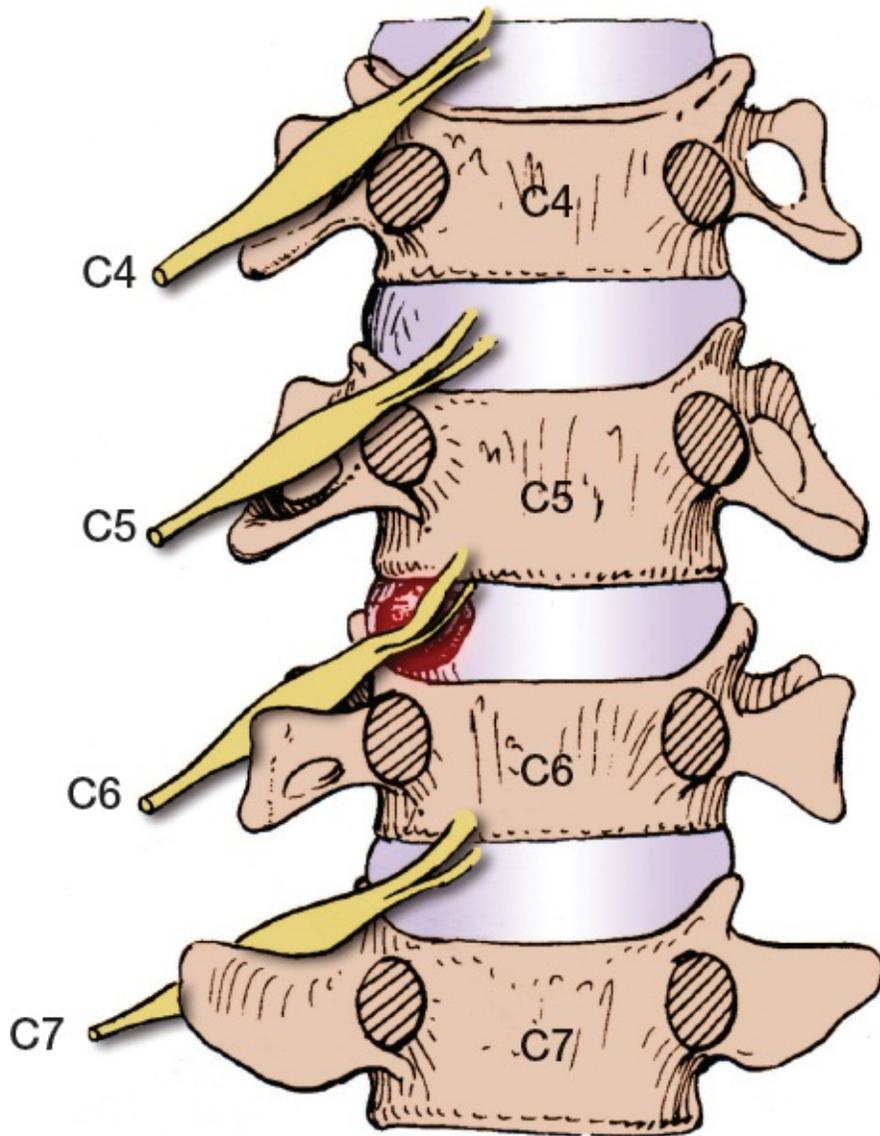

FIGURE 1-38 A herniated cervical disk.
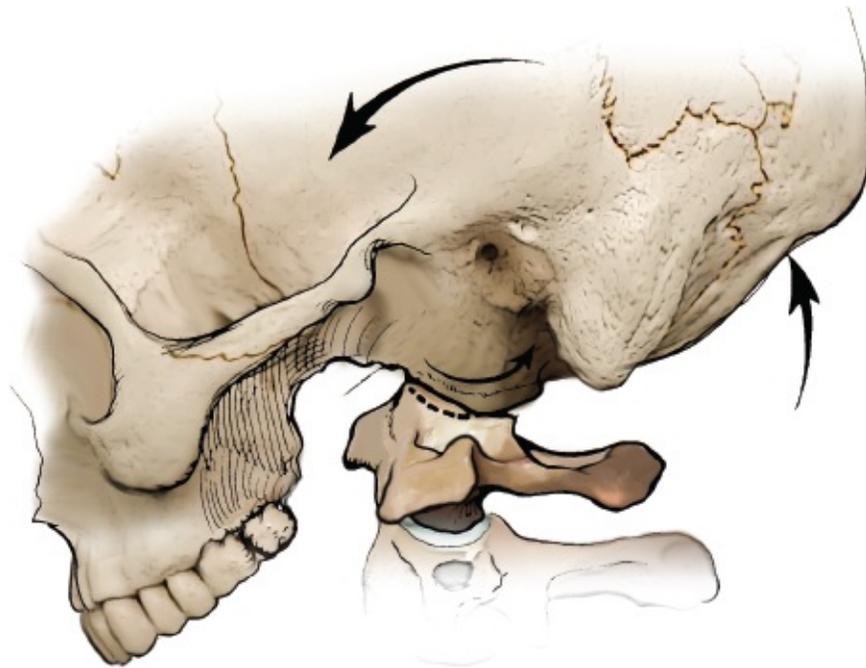

FIGURE 1-39 Specialized articulation between the occiput and C1 allowing for 50 percent of the flexion and extension in the cervical spine.
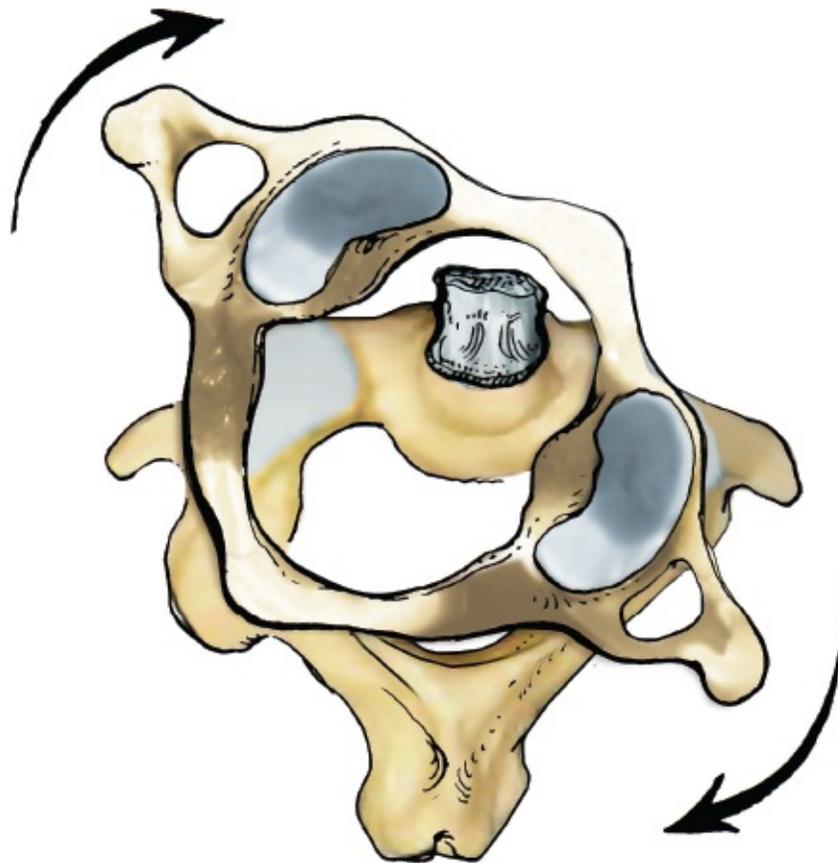

FIGURE 1-40 Specialized articulation between C1 and C2 allowing for 50 percent of the rotation in the cervical spine.

Pain in one arm or the other is symptomatic of herniated cervical disks; the pain usually radiates to the hand along the neurologic pathways of the involved root, although, occasionally, the pain may be referred only as far as the shoulder. Coughing, sneezing, or straining usually aggravates the pain and causes it to radiate throughout the involved neurologic distribution in the extremity.
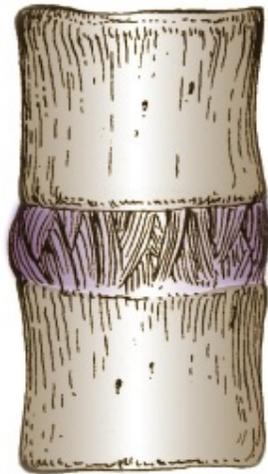

Ant. annulus fibrosis
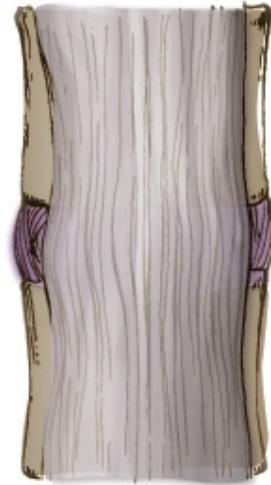

Ant. longitudinal ligament
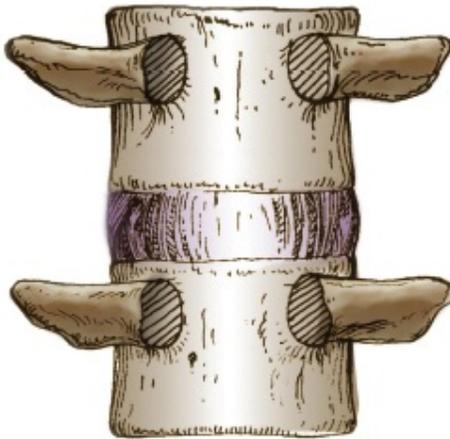

Post. annulus fibrosis
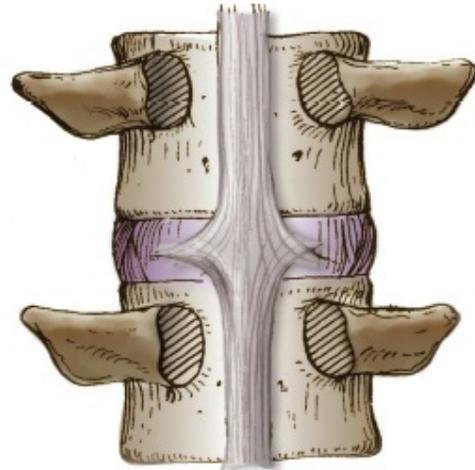

Post. longitudinal ligament
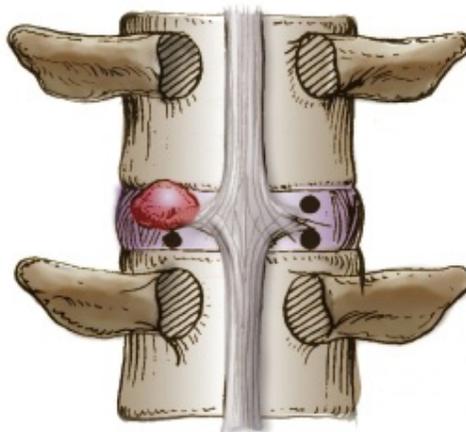

Herniated disk

FIGURE 1-41 The anatomic basis for posterior cervical disk herniation.

The symptoms and signs caused by a herniated disk vary depending on the location of the herniation. If the herniation is lateral, as is most common, it may impinge directly upon the nerve root, giving classical root-level neurologic findings. However, if the disk herniates in the midline, the symptoms may be evident in the leg and arm as well (Fig. 1-42). If the disk protrudes but does not herniate, pain may be referred to the midline of the back in the area of the superior medial portions of the scapulae (Fig. 1-43). Lateral protrusion may send pain along the spinous border of the scapula (most commonly to the superior medial angles), with radiation of pain down the arm, but usually without neurologic findings.

Occasionally, there may be inconsistent findings of neurologic level involvement during the examination. Sometimes the brachial plexus, which usually includes the nerve roots C5-T1, will begin a level higher (prefixed) or a level lower (postfixed), causing variations in the segmental innervation of the muscles; the findings will reflect this inconsistency in the innervation of the upper extremity. It is also possible that such major inconsistencies are due to brachial plexus or peripheral nerve injuries.
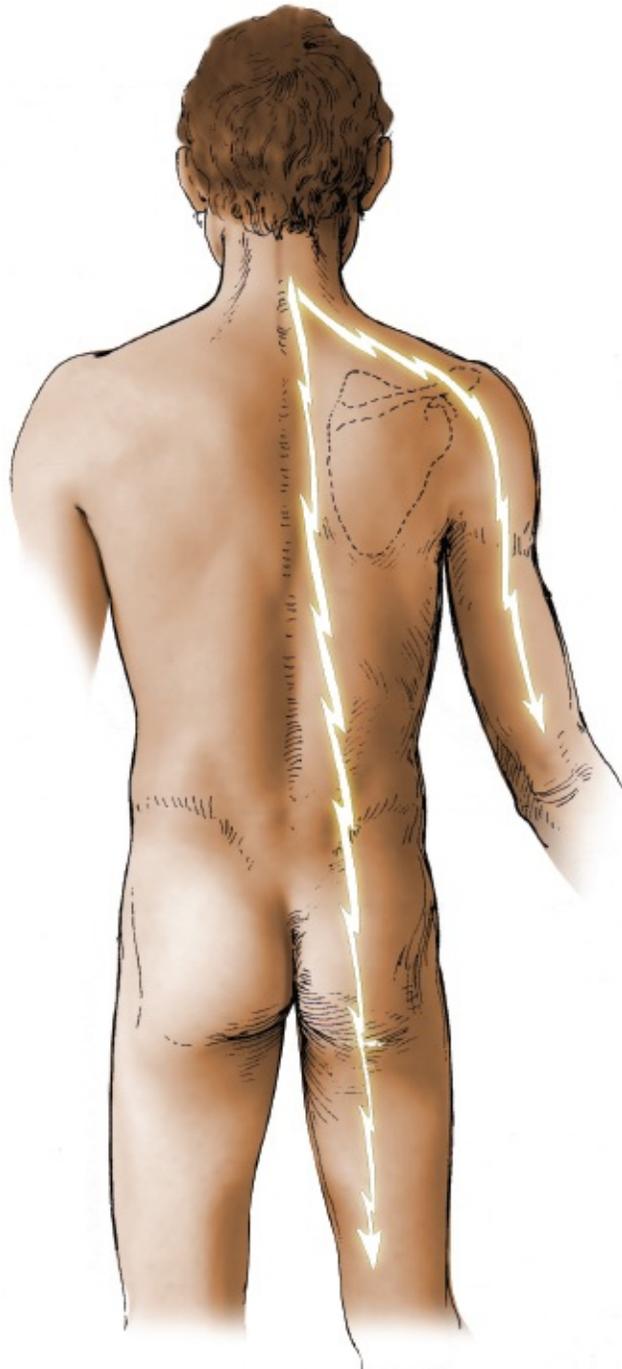

FIGURE 1-42 Pattern of pain radiation with a midline herniated cervical disk.

Specific Tests for Locating Herniated Cervical Disks

To establish the exact neurologic level of involvement secondary to a herniated disk, use the neurologic evaluation technique described earlier in this chapter (Figs. 1-44 to 1-48).

Table 1-1 summarizes the areas of neurologic level testing. In addition, it demonstrates the clinical application of neurologic level testing to pathology in the cervical spine, especially with regard to the evaluation of herniated disks. Other ways of locating herniated disks are through the following:

1. The magnetic resonance imaging (MRI), which reveals the abnormal protrusion of a herniated disk into the spinal cord, nerve root, or cauda equina at the involved level.

2. Myelogram, which is a test where contrast dye is injected into the spine, after which a computed tomography scan is performed to look for problems in the spinal canal, including spinal cord, nerve roots, and other tissue. The test is commonly reserved for patients who have previously had spine surgery or who cannot have an MRI (Fig. 1-49).

3. The electromyogram (EMG), which accurately measures motor potentials. Two weeks after injury to a nerve, abnormal spontaneous electrical discharges appear in the resting muscle (fibrillation potentials and positive sharp waves). These are evidence of a muscle denervation, which can result from herniated disks, nerve root avulsions, or cord lesions. (They can also occur in plexus and peripheral nerve lesions.) It is important that muscles representing each neurologic level (myotome) be sampled for a complete evaluation (see Table 1-1).
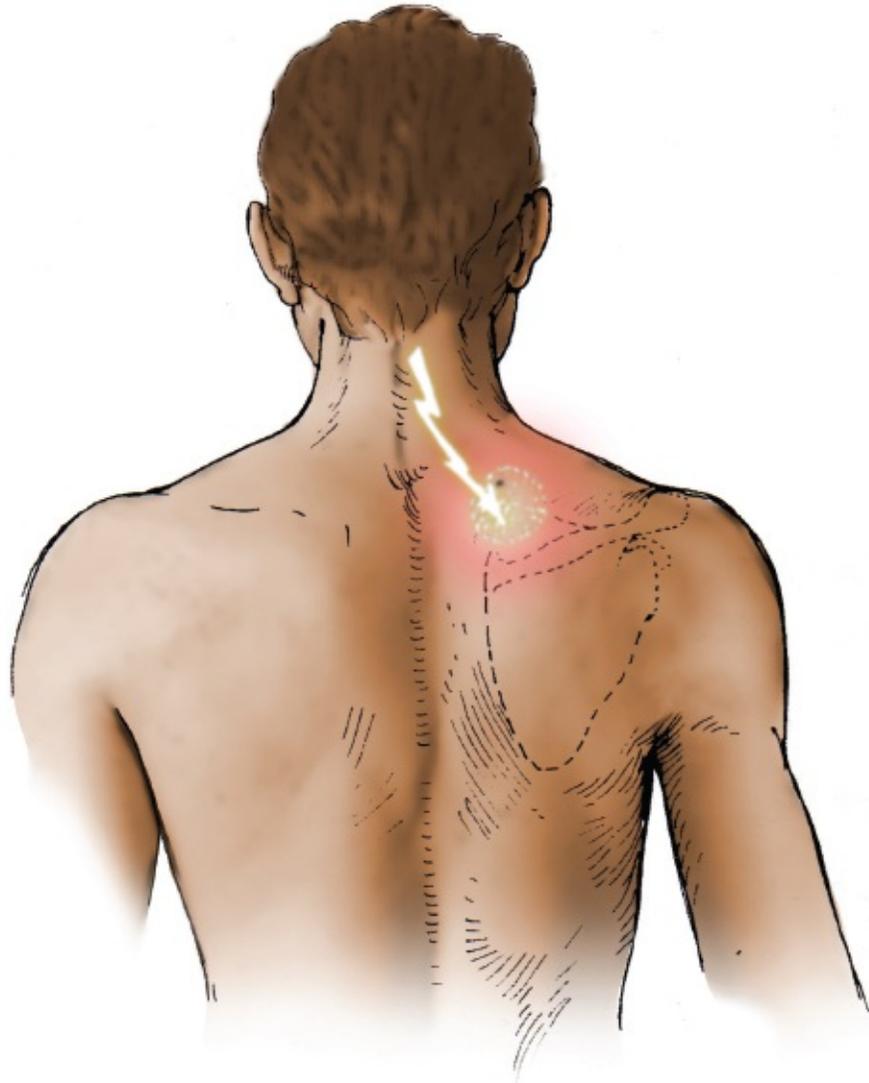

FIGURE 1-43 Pattern of pain radiation with a lateral protrusion of a cervical disk.
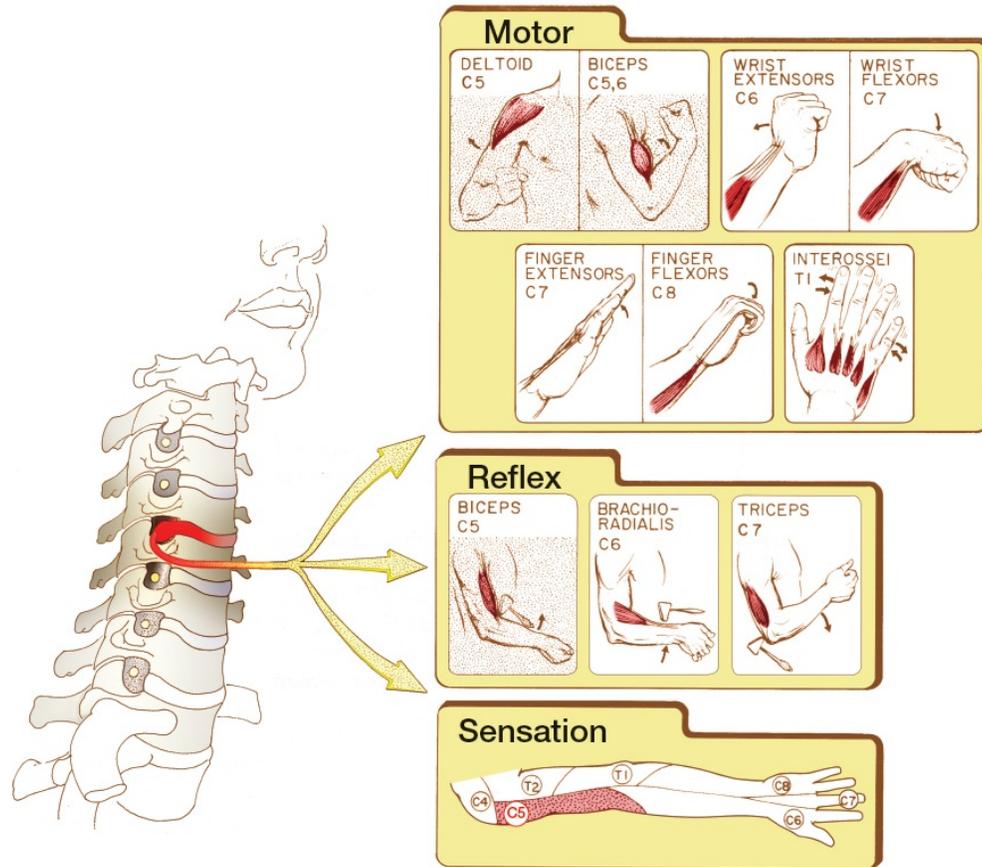

FIGURE 1-44 A herniated disk between vertebrae C4 and C5 involves the C5 nerve root.

General Test for Herniated Cervical Disks

The Valsalva test is a generalized test that indicates only the presence of a herniated disk. The tests of each neurologic level are more precise and can pinpoint the exact level of involvement.

Valsalva Test: The Valsalva test increases the intrathecal pressure. If there is a space-occupying lesion in the cervical canal, such as a herniated disk or a tumor, the patient will develop pain in the cervical spine secondary to the increased pressure. The pain may radiate to the neurologic distribution of the upper extremity that corresponds to the pathologically involved neurologic level.

To perform the Valsalva test, have the patient bear down as if moving the bowels while holding the breath. Then ask the patient if there is any increase in pain either in the cervical spine or, by reflection, in the upper extremity (Fig. 1-

). The Valsalva test is a subjective test that requires that the patient answer your questions appropriately; if the patient is either unable or unwilling to answer, the test is of little value.

Cervical Neck Sprain versus Herniated Disk

Patients frequently develop neck pain after automobile accidents that cause the cervical spine to whip back and forth (whiplash) or twist (Fig. 1-51A, B). The resulting injury may stretch an individual nerve root, cause a nerve root to impinge upon an osteoarthritic spur, or produce a herniated disk. Patients with neurologic involvement complain of neck pain referred to the medial border of the scapula and radiating down the arm to varying degrees, as well as of numbness and muscle weakness in the extremity. However, such an injury may simply stretch the posterior or anterior neck muscles, causing a similar neck pain with radiation to the shoulder and medial border of the scapula.
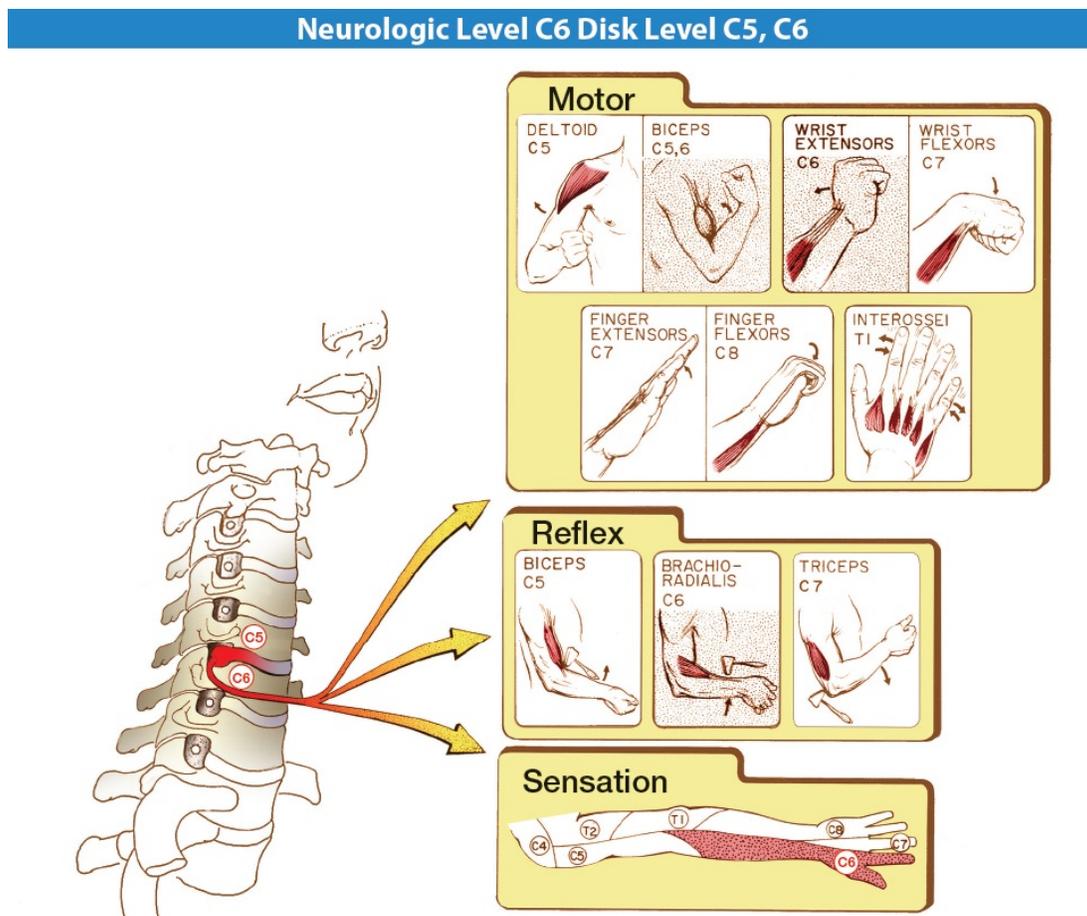

FIGURE 1-45 A herniated disk between vertebrae C5 and C6

involves the C6 nerve root. This is the most common level of disk herniation in the cervical spine.

Differentiation between generalized soft-tissue injury without neurologic involvement and injury with neurologic involvement can be made by testing the integrity of the neurologic levels innervating the upper extremities. With each patient visit, neurologic testing must be repeated, because an originally quiescent lesion may later clinically manifest itself. Note that the converse is also true: patients who are hospitalized for treatment of neurologic problems may show improved muscle strength, return of a reflex, or return of normal sensation to the involved dermatome.

Many patients continue to complain of cervical pain six months to a year after injury without evidence of either neurologic or objective MRI findings of pathology. The practitioner should have the confidence, despite patient pressure, to continue conservative (nonoperative) therapy, knowing that the patient may have a permanent soft-tissue injury not involving the anterior primary nerve roots or the intervertebral cervical disks.

Neurologic Level C7 Disk Level C6, C7
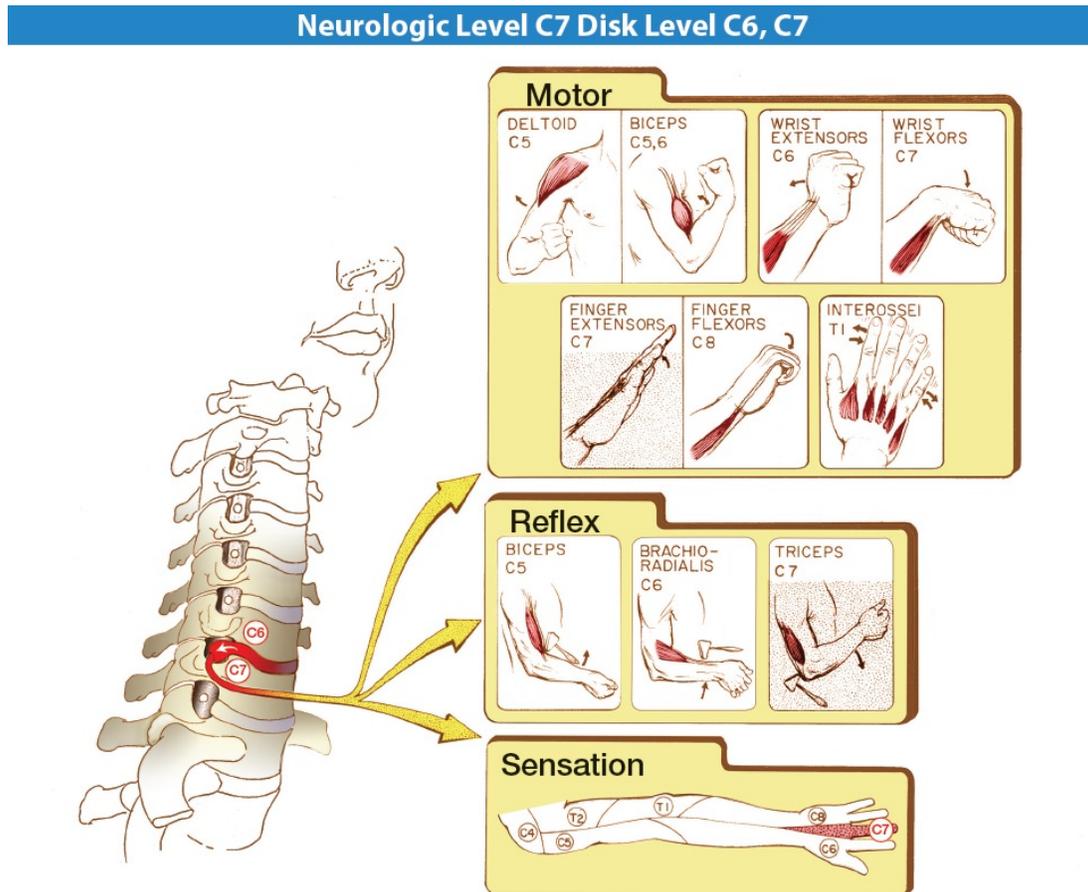

FIGURE 1-46 A herniated disk between vertebrae C6 and C7 involves the C7 nerve root.

The Uncinate Processes and Osteoarthritis

The uncinate processes are two ridges of bone that originate on the superior lateral surface of the cervical vertebrae. They help to stabilize the individual vertebra and participate in the formation of the neural foramen (Fig. 1-52). Enlargements or osteoarthritis involving the uncinate process may encroach upon the neural foramen and directly compress the exiting nerve root or limit the amount of room in which it can move (Fig. 1-53).

The neural foramen and portion of the uncinate process encroaching upon it can be seen on an x-ray (Fig. 1-54). Note that the nerve roots emerge at a 45° angle from the cord and vertebral body, the same angle that exists between the neural foramen and the vertebral body. An osteophyte from the uncinate process has little clinical significance unless it is accompanied by symptoms. Clinical problems may arise after an automobile accident, when a patient with a narrowed neural foramen may place excessive strain on the nerve root lying in it because of the extreme extension/flexion of the head and neck and the subsequent reactive edema of the nerve root. Note that the narrowed foramen frequently has the x-ray appearance of a figure 8, a configuration that does not allow room for the posttraumatic swelling of the nerve and results in pain. Pain and neurologic findings are naturally found in the involved neural distribution in the upper extremity. For example, trauma affecting the C6 nerve root may result in decreased sensation to the lateral forearm, muscle weakness to the wrist extensors, and an absent brachioradialis reflex (Fig. 1-40). It is also possible, however, that the only symptom referred is pain to the superior medial angle and medial border of the scapula.

Neurologic Level C8 Disk Level C7, T1
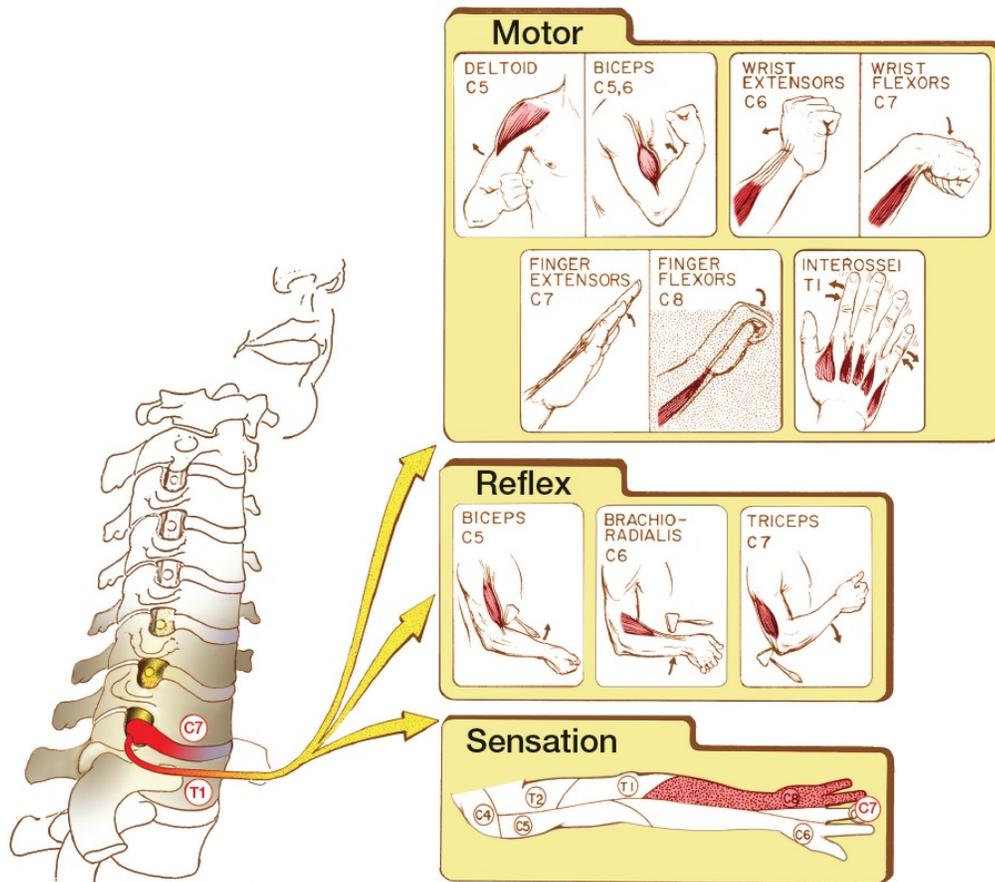

FIGURE 1-47 A herniated disk between vertebrae C7 and T1 involves the C8 nerve root.

Where there is more motion, there is a greater chance of breakdown, and uncinate process enlargement secondary to osteoarthritis is most often found at the C5-C6 bony level.

Spurling Test

The cervical spine compression test determines whether the patient's pain is increased when the cervical spine is compressed. Pain caused by narrowing of the neural foramen, pressure on the facet joints, or muscle spasm may be increased by compression. The compression test may also faithfully reproduce pain referred down the upper extremity from the cervical spine; in doing so, it may assist in locating the neurologic level of existing pathology.
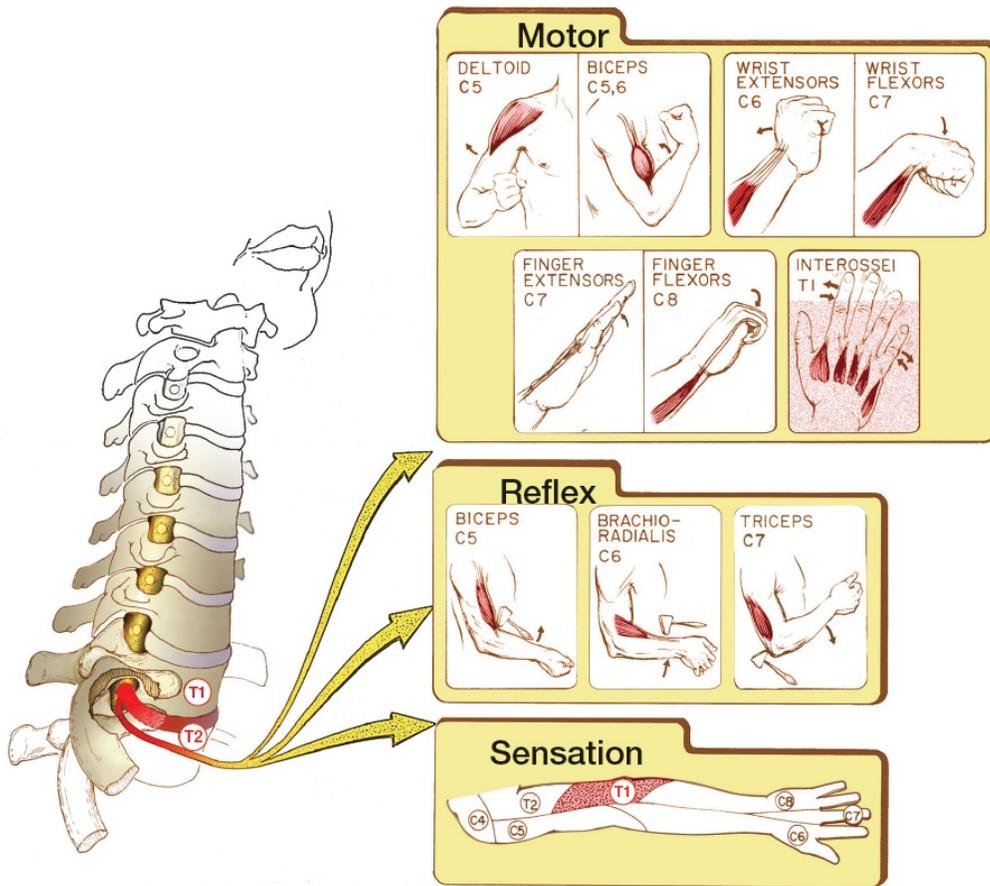

FIGURE 1-48 A herniated disk between vertebrae T1 and T2 involves the T1 nerve root. A herniated disk in this area is unusual.

To perform the compression test, have the patient turn their head to the affected side and slightly extend their head. Press on the top of the patient's head while the patient is either sitting or lying down; discover whether there is any corresponding increase in pain either in the cervical spine or down the extremity. Note the exact distribution of this pain and whether it follows any previously described dermatome (Fig. 1-55).

Nerve Root Avulsions

Cervical nerve roots are frequently avulsed from the cord during motorcycle accidents. When a rider is thrown from his cycle, his head and neck are forced laterally, and his shoulder is depressed by the impact with the ground, causing the cervical nerve roots to stretch and finally avulse (Fig. 1-56). The C5 and C6

nerve roots are the roots most commonly avulsed.

Physical examination shows the obvious results: with the loss of the C5 root, there is total motor paralysis along the C5 myotome and sensory deficit along the C5 dermatome. The deltoid muscle is paralyzed, sensation along the upper lateral portion of the arm is hypesthetic or anesthetic, and the biceps reflex (C5-C6) is diminished or absent. The MRI shows an avulsion, the origin of the C5 nerve root between the C4 and C5 vertebrae. Such a lesion is not amenable to surgical repair. The injury is permanent; no recovery is to be expected.

TABLE 1-1 UNDERSTANDING HERNIATED DISKS AND OSTEOARTHRITIS OF THE CERVICAL SPINE

Although C5 and C6 are the most commonly avulsed roots, the C8 and T1 may also be avulsed. If the cyclist strikes the ground with his shoulder hyperabducted, the lowest roots of the brachial plexus are usually the ones injured, whereas the C5 and C6 nerve roots remain intact.
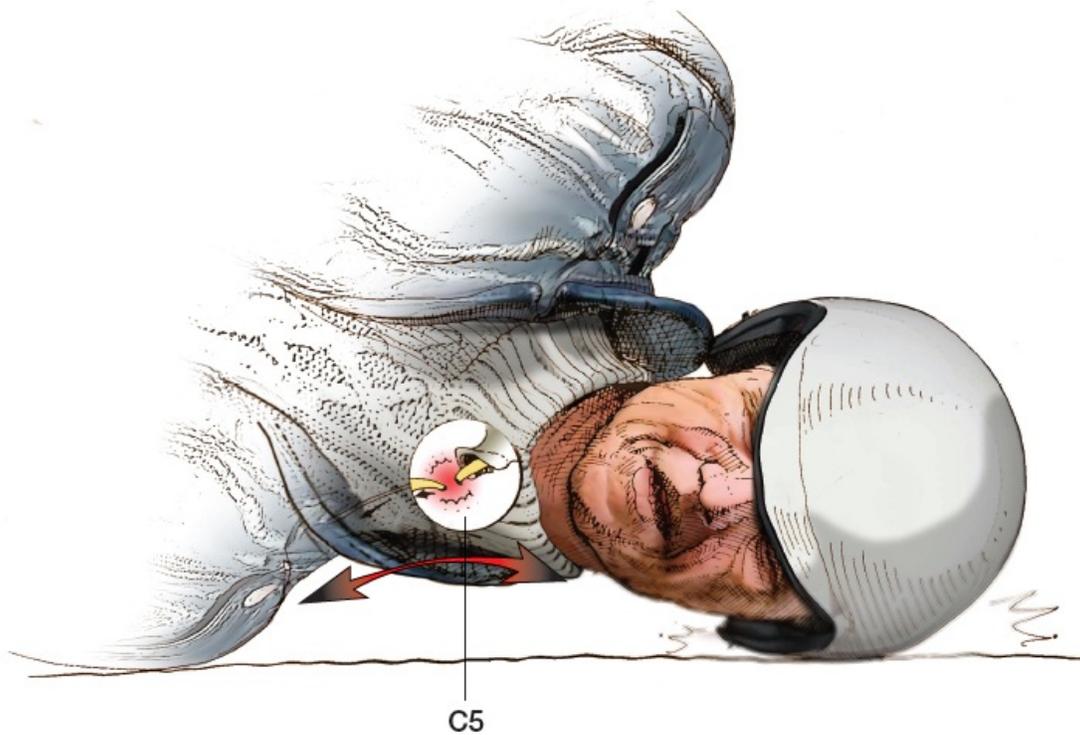

FIGURE 1-56 Avulsion of the C5 nerve root following a motorcycle accident.

2

Evaluation of Nerve Root Lesions Involving the Trunk and Lower Extremity

Manifestations of pathology involving the spinal cord and cauda equina, such as herniated disks, tumors, or avulsed nerve roots, are frequently found in the lower extremity. Understanding the clinical relationship between various muscles, reflexes, and sensory areas in the lower extremity and their neurologic levels (cord levels) is particularly helpful in detecting and locating spinal problems with greater accuracy and ease.

To make the relationship between the spine and the lower extremity clear, the neurologic examination of the lumbar spine is divided into tests of each neurologic level and its dermatomes and myotomes. Thus, for each neurologic level of the lower spinal cord, the muscles, reflexes, and the sensory areas that most clearly receive innervation from it is tested.

Testing of Individual Nerve Roots, T2-S4

Neurologic Levels T2-T12

Muscle Testing

Intercostals: The intercostal muscles are segmentally innervated and are difficult to evaluate individually.

Rectus Abdominis: The rectus abdominis muscles are segmentally innervated by the primary anterior divisions of T5-T12 (L1), with the umbilicus the dividing point between T10 and T11.

Beevor's sign (Fig. 2-1) tests the integrity of the segmental innervation of the rectus abdominis muscles. Ask the patient to do a quarter sit-up. While the patient is doing this, observe the umbilicus. Normally, it should not move at all when the maneuver is performed. If, however, the umbilicus is drawn up or down or to one side or the other, be alerted to possible asymmetrical involvement of the anterior abdominal muscles. Lesions of the spinal cord or roots between T10 and T12 will cause weakness of the lower part of the muscle, and thus a positive Beevor's side with the umbilicus moving upward during the quarter sit-up.
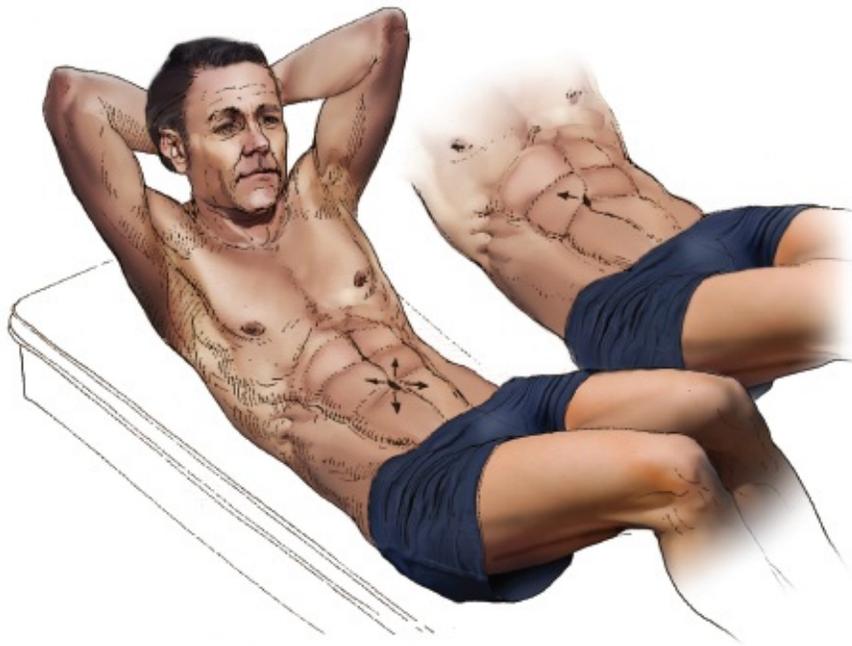

FIGURE 2-1 Beevor's sign.

Sensory Testing

Sensory areas for each nerve root are shown in Figure 4-1. The sensory area for T4 crosses the nipple line, T7 the xiphoid process, T10 the umbilicus, and T12 the groin. There is sufficient overlap of these areas for no anesthesia to exist if only one nerve root is involved. However, hypoesthesia is probably present.

Neurologic Levels T12-L3

Muscle Testing

There is no specific muscle test for each root. The muscles that are usually tested are the iliopsoas (T12-L3), the quadriceps (L2-L4), and the adductor group (L2-L4).

Iliopsoas: (Branches from [T12], L1-L3): The iliopsoas muscle is the main flexor of the hip (Fig. 2-2). To test it, instruct the patient to sit on the edge of the examining table with the legs dangling. Stabilize the pelvis by placing your hand over the patient's iliac crest and have the patient actively raise their thigh off the table. Now place your other hand over thedistal femoral portion of the knee and ask the patient to raise the thigh further as you resist (Fig. 2-3). Determine the maximum resistance the patient can overcome. Then repeat the test for the opposite iliopsoas muscle and compare muscle strengths. Because the iliopsoas receives innervation from several levels, a muscle that is only slightly weaker than its counterpart may indicate neurologic problems.
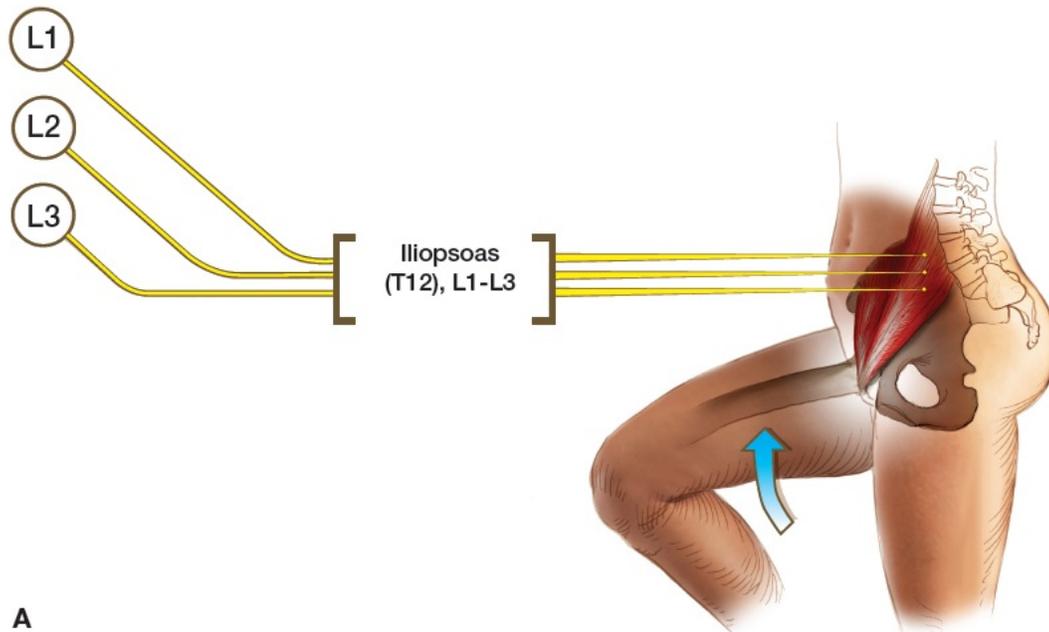

FIGURE 2-2A (T12), L1-L3—hip flexion.
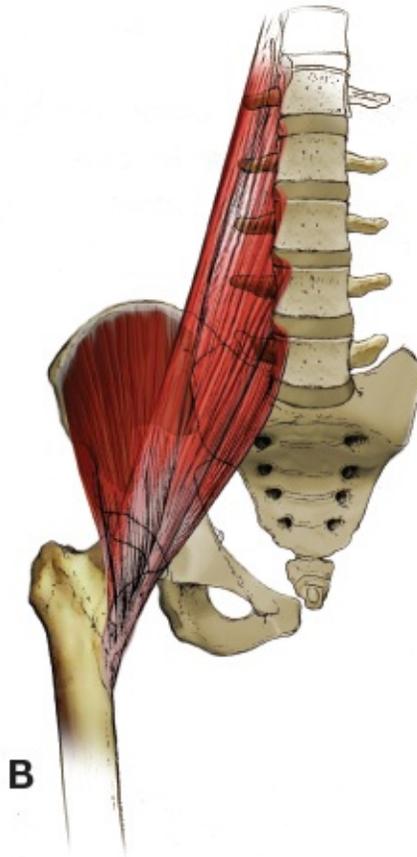

FIGURE 2-2B *Iliopsoas.*
Origin: Anterior surface of the bodies of all lumbar vertebrae and their transverse processes and corresponding intervertebral disks. Upper two-thirds of the iliac fossa.
Insertion: Lesser trochanter of femur.

FIGURE 2-3 Muscle test for the iliopsoas.

In addition to possible neurologic pathology, the iliopsoas may become weak as a result of an abscess within its substance; the patient may then complain of pain during muscle testing. The muscle may also become weak as a result of knee or hip surgery.

Quadriceps: L2- L4 (Femoral Nerve): To test the quadriceps functionally, instruct the patient to stand from a squatting position (Fig. 2-4). Note carefully whether the patient stands straight, with the knees in full extension, or whether one leg is used more than the other. The arc of motion from flexion to extension should be smooth. Occasionally, the patient may be able to extend the knee smoothly only until the last 10°, finishing the motion haltingly and with great

effort. This faltering in the last 10° of extension is called *extension lag*; it occurs because the last 10° to 15° of knee extension requires at least 50 percent more muscle power than the rest (according to Jacqueline Perry). Extension lag is frequently seen in association with quadriceps weakness. Sometimes, the patient may be unable to extend his knee through the last 10° with even the greatest effort (Fig. 2-5).
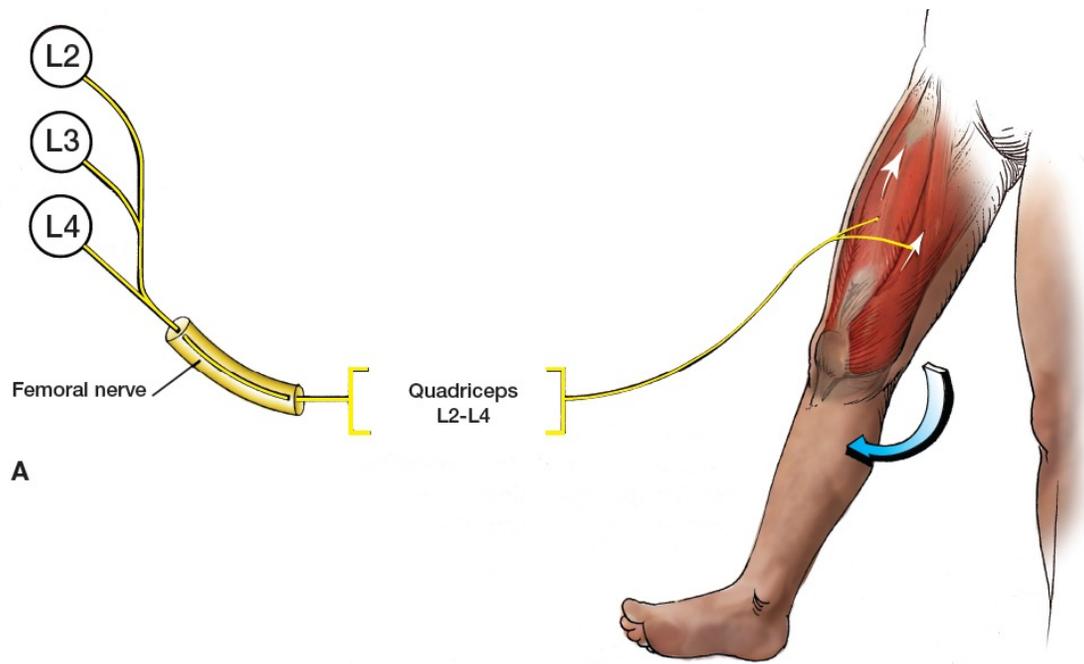

FIGURE 2-4A L2-L4—knee extension.
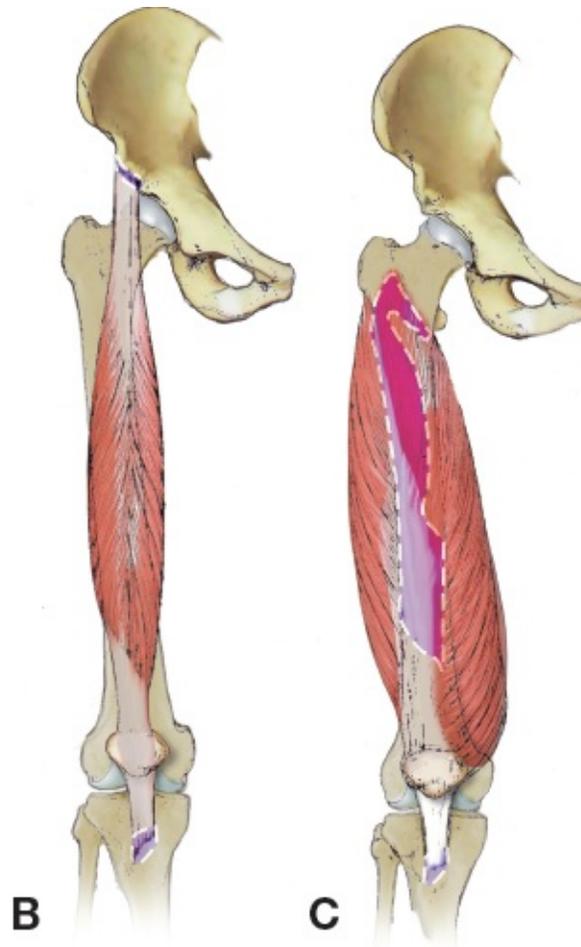

FIGURE 2-4B *Rectus femoris.*
Origin: Rectus femoris is a "two-joint" muscle that has two heads of origin. Straight head: from anterior inferior iliac spine. Reflected head: from groove just above brim of acetabulum.
Insertion: Upper border of patella, and then into the tibial tubercle via the infrapatellar tendon.

FIGURE 2-4C *Vastus intermedius.*
Origin: Upper two-thirds of anterior and lateral surface of femur.
Insertion: Upper border of the patella with the rectus femoris tendon and then via the infrapatellar tendon into the tibial tubercle.

Vastus lateralis.
Origin: Capsule of hip joint, intertrochanteric line, gluteal tuberosity, linea aspera.
Insertion: Proximal and lateral border of patella, and into tibial tubercle via the infrapatellar tendon.

Vastus medialis.
Origin: Lower half of intertrochanteric line, linea aspera, medial supracondylar line, medial intermuscular septum, tendon of adductor magnus.
Insertion: Medial border of patella and into tibial tubercle via the infrapatellar tendon.
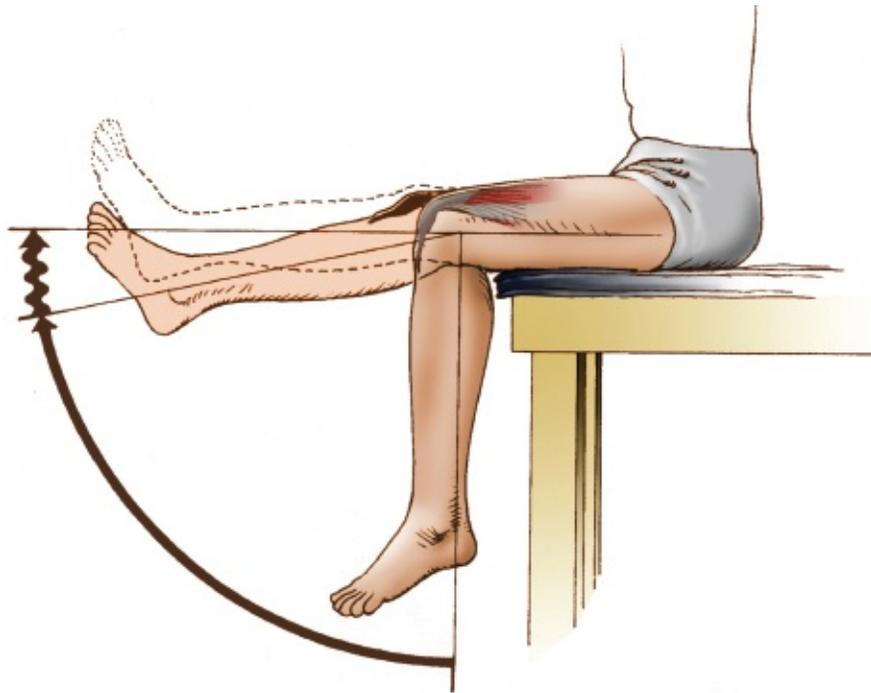

FIGURE 2-5 Extension lag. (Hoppenfeld, S.: *Physical Examination of the Spine and Extremities.* Norwalk, CT: Appleton-Century-Crofts, 1976.)

To test the quadriceps manually, stabilize the thigh by placing one hand just above the knee. Instruct the patient to extend his knee as you offer resistance just above the ankle joint. Palpate the quadriceps during the test with your stabilizing hand (Fig. 2-6). Note that the quadriceps weakness can also be due to a reflex decrease in muscle strength following knee surgery or to tears within the substance of the muscle itself.
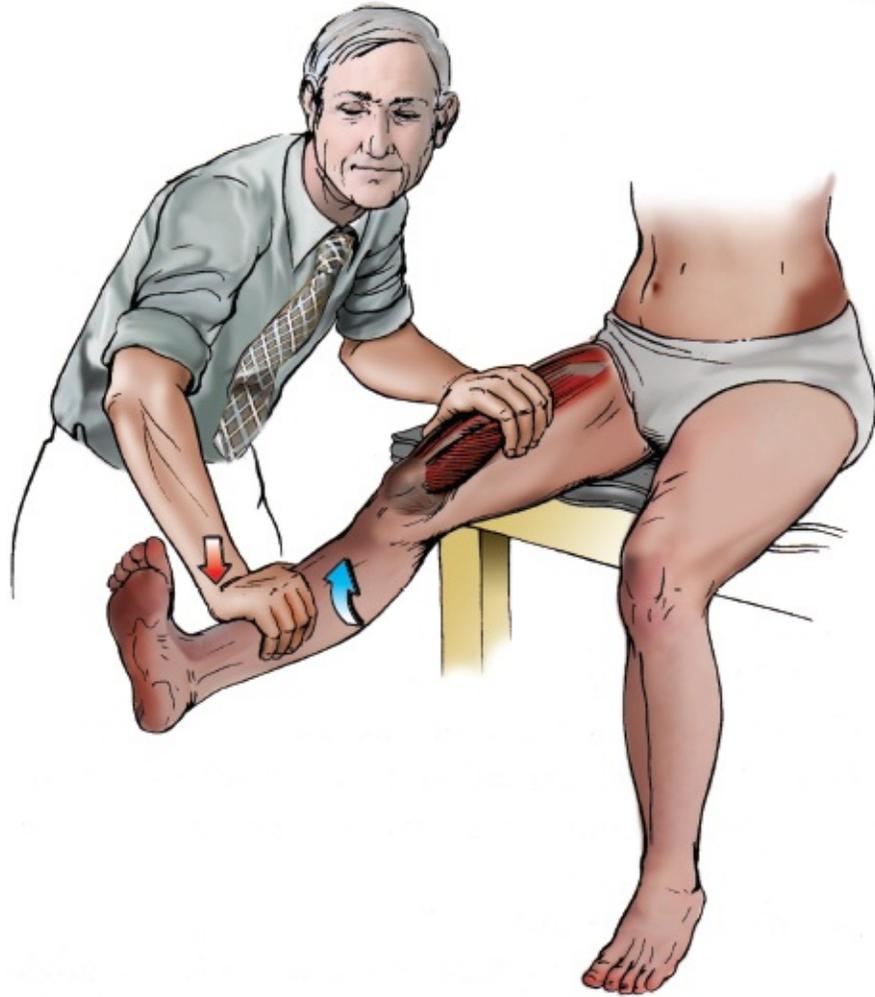

FIGURE 2-6 Muscle test for the quadriceps.

Hip Adductor Group: L2-L4 (Obturator Nerve): Like the quadriceps, the hip adductors can be tested as a massive grouping (Fig. 2-7). Have the patient lie supine or on their side and instruct the patient to abduct the legs. Place your hand on the medial sides of both knees and have the patient adduct their legs against your resistance (Fig. 2-8). Determine the maximum resistance they can overcome.

Reflexes

Although the patellar tendon reflex is supplied by L2-L4, it is predominantly L4 and will be tested as such.

Sensory Testing

Nerves from L1 to L3 provide sensation over the general area of the anterior

thigh between the inguinal ligament and the knee. The L1 dermatome is an oblique band on the upper anterior portion of the thigh, immediately below the inguinal ligament. The L3 dermatome is an oblique band on the anterior thigh, immediately above the kneecap. Between these two bands, on the anterior aspect of the mid thigh, lies the L2 dermatome (Fig. 2-9).
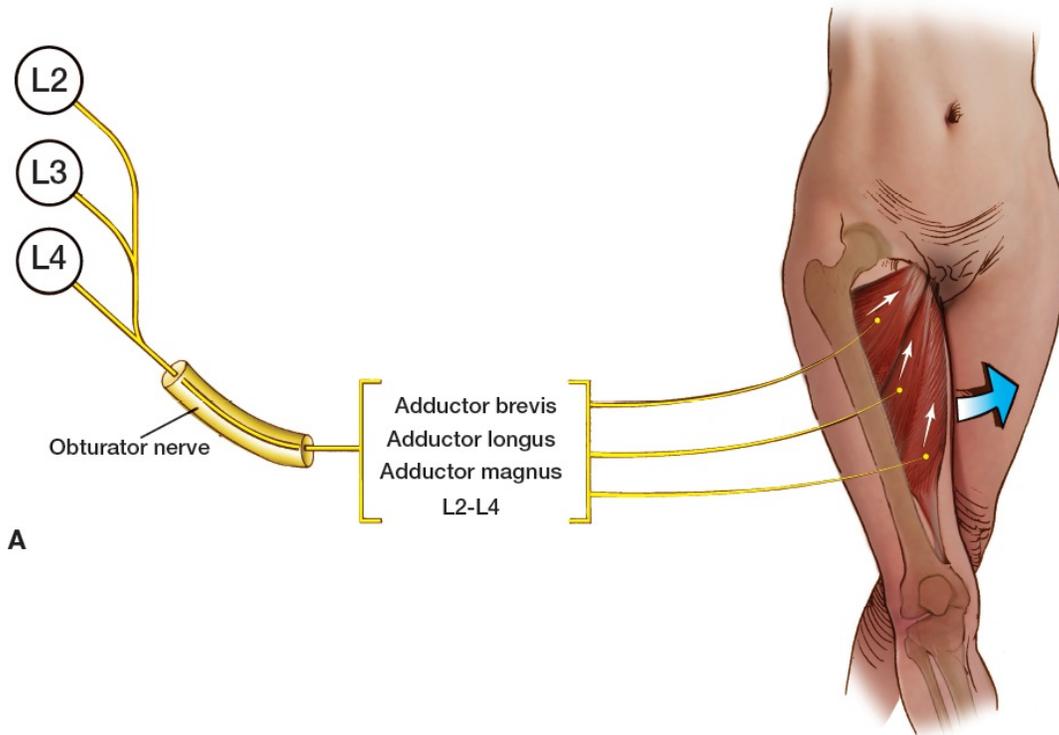

FIGURE 2-7A L2-L4—hip adduction.
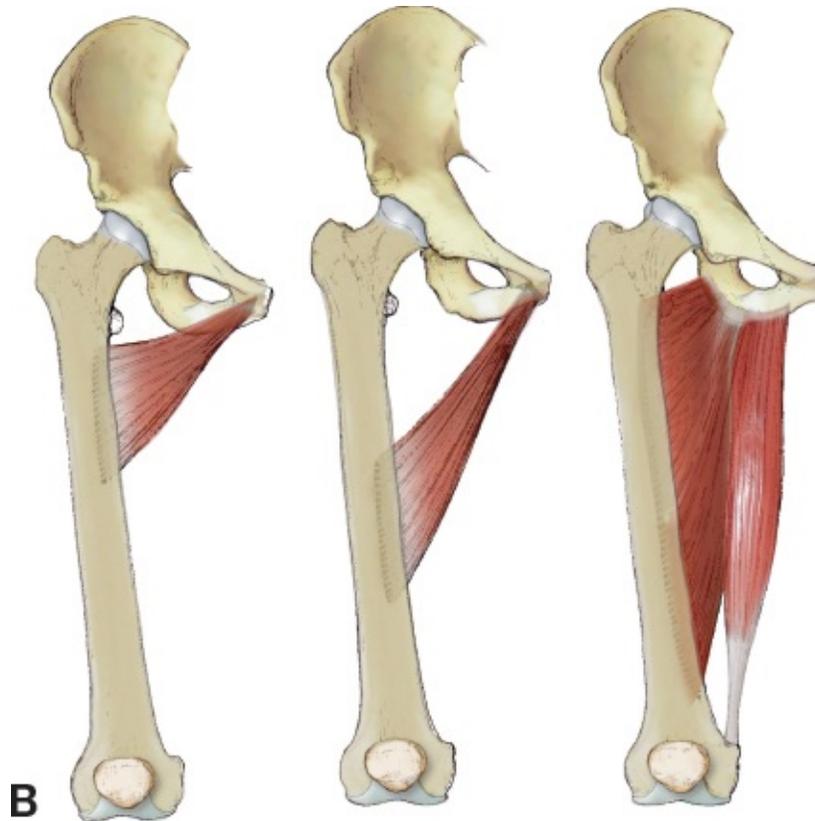

FIGURE 2-7B *Adductor brevis* (center).
Origin: Outer surface of inferior ramus of pubis.
Insertion: Line extending from lesser trochanter to linea aspera and upper part of linea aspera.
Adductor longus (left).
Origin: Anterior surface of the pubis in the angle between crest and pubic symphysis.
Insertion: Linea aspera, middle half of medial lip.
Adductor magnus (right).
Origin: Ischial tuberosity, inferior rami of ischium and pubis.
Insertion: Line extending from greater trochanter to linea aspera. The entire length of linea aspera, medial supracondylar line, and adductor tubercle of the femur.
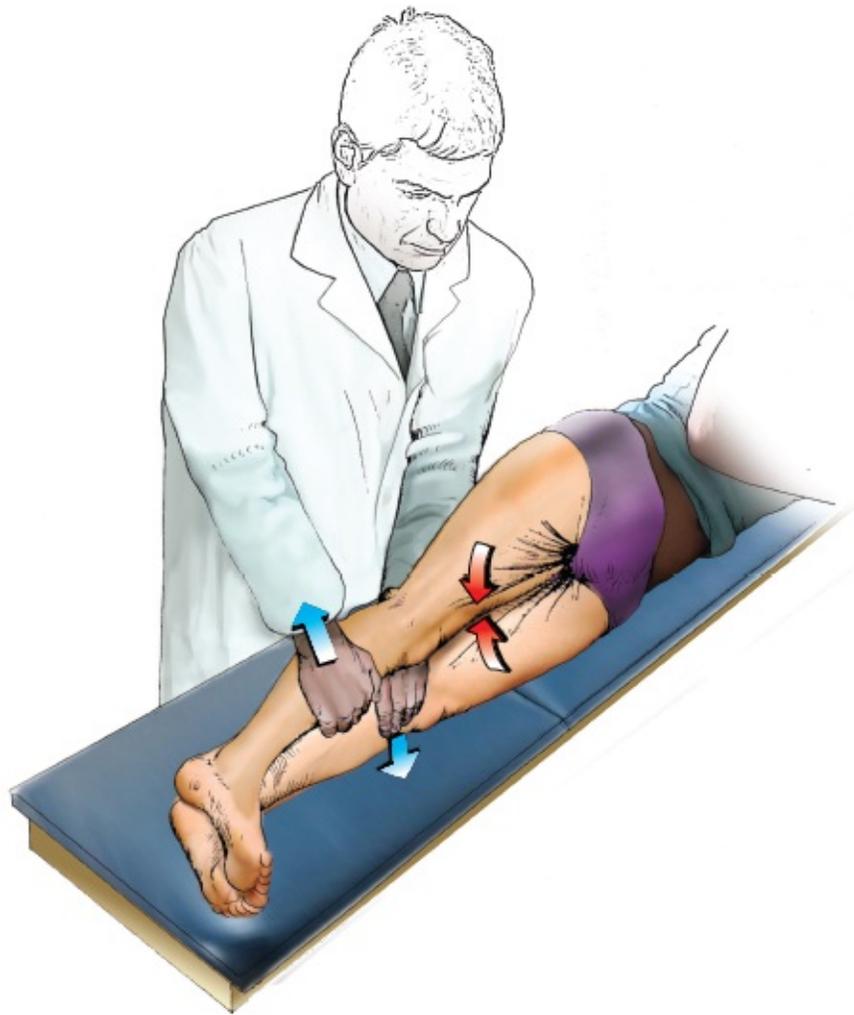

FIGURE 2-8 Muscle test for hip adductors.

Sensory testing, with its bands of individual dermatomes, is a more accurate way of evaluating neurologic levels T12-L3 than motor testing, which lacks individual representative muscles. There are also no representative reflexes for these levels, making it even more difficult to diagnose an exact neurologic level. Neurologic levels L4, L5, and S1 are represented by individual muscles, dermatomes, and reflexes, and are easier to diagnose.

Neurologic Level L4

Muscle Testing

Tibialis Anterior: L4 (Deep Peroneal Nerve): The tibialis anterior muscle is predominantly innervated by the L4 segmental level; it also receives L5

innervation (Figs. 2-10 and 2-11). To test the muscle in function, ask the patient to walk on his heels with his feet inverted. The tendon of the tibialis anterior muscle becomes visible as it crosses the anteromedial portion of the ankle joint and is quite prominent as it proceeds distally toward its insertion. Patients with weak tibialis anterior muscles are unable to perform this functional dorsiflexion-inversion test; they may also exhibit "drop foot," or steppage gait.
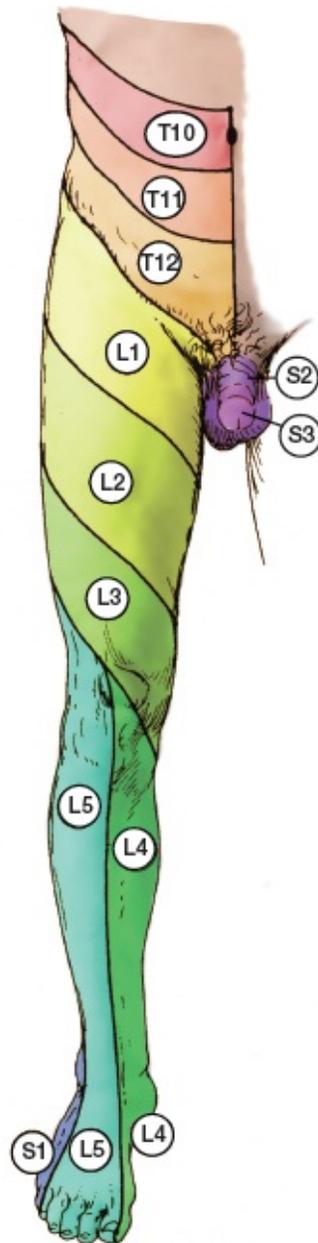

FIGURE 2-9 Dermatomes of the lower extremity.

To test the tibialis anterior manually, instruct the patient to sit on the edge

of the examining table. Support his lower leg, and place your thumb in a position that makes him dorsiflex and invert his foot to reach it. Try to force the foot into plantar flexion and eversion by pushing against the head and shaft of the first metatarsal; palpate the tibialis anterior muscle as you test it (Fig. 2-12).
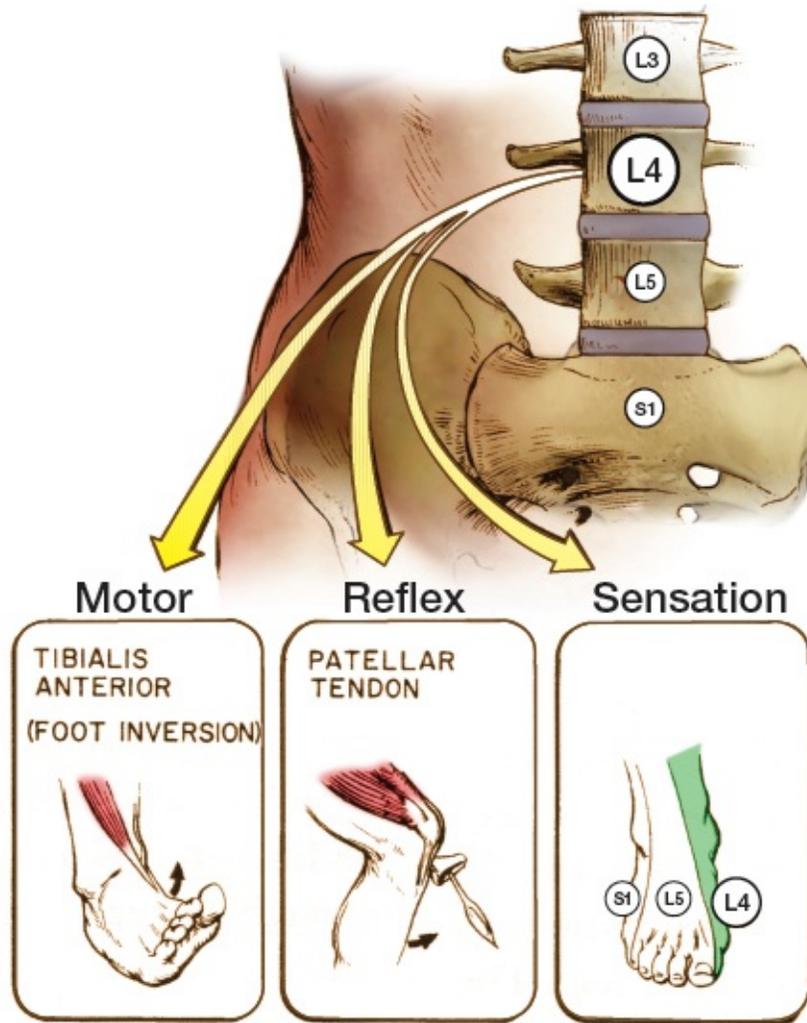

FIGURE 2-10 Neurologic level L4.
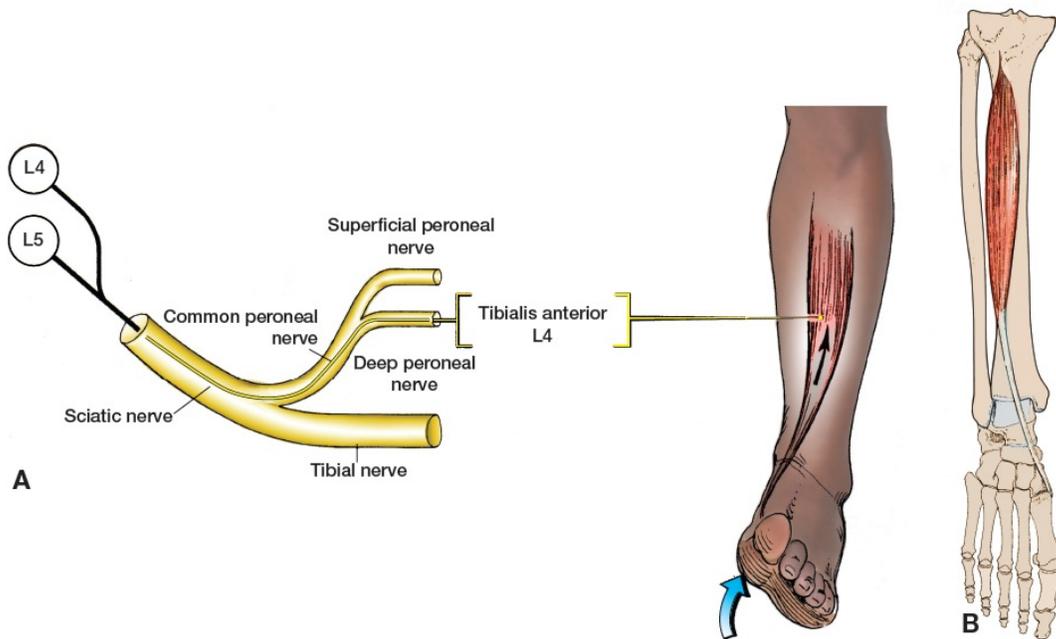

FIGURE 2-11A L4, L5—foot inversion.

FIGURE 2-11B *Tibialis anterior.*

Origin: Lateral condyle of tibia, upper two-thirds of the anterolateral surface of tibia, interosseusmembrane.

Insertion: Medial and plantar surfaces of medial cuneiform bone, base of 1st metatarsal bone.
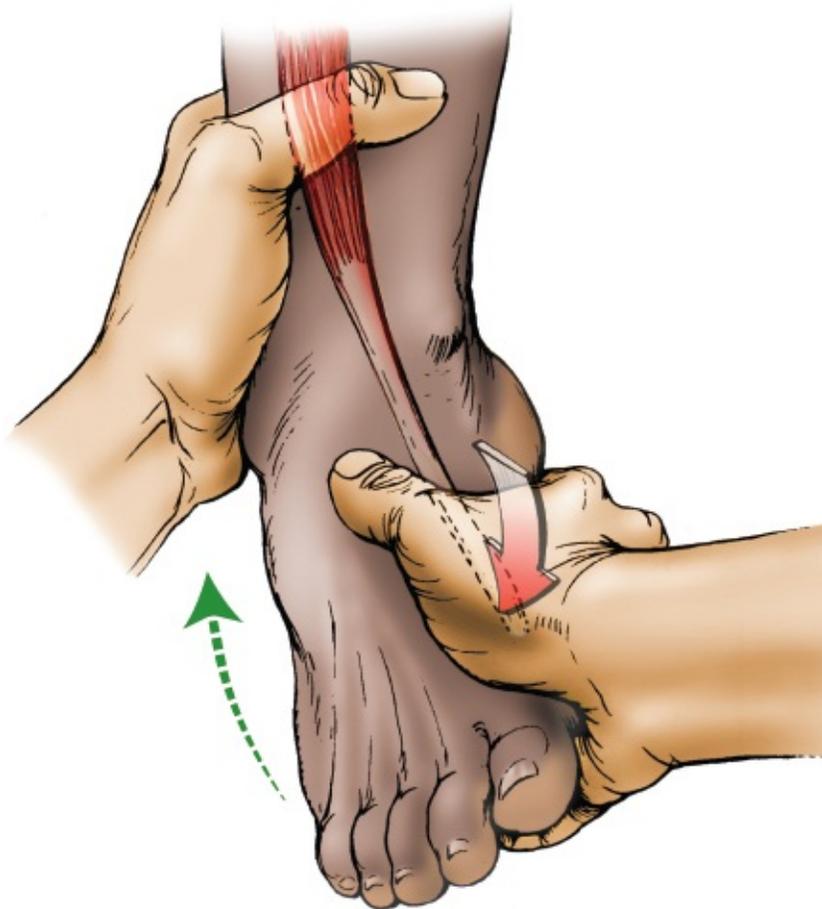

FIGURE 2-12 Muscle test for the tibialis anterior.

Reflex Testing

Patellar Tendon Reflex: The patellar tendon reflex is a deep tendon reflex, mediated through nerves emanating from the L2-L4 nerve roots (predominantly from L4). For clinical application, the patellar tendon reflex should be considered an L4 reflex; however, because it receives innervation from L2 and L3 as well as from L4, the reflex will still be present, although significantly weakened, even if the L4 nerve root is completely severed. The reflex is almost never totally absent. However, in primary muscle, nerve root, or anterior horn cell disease, the reflex can be totally absent.
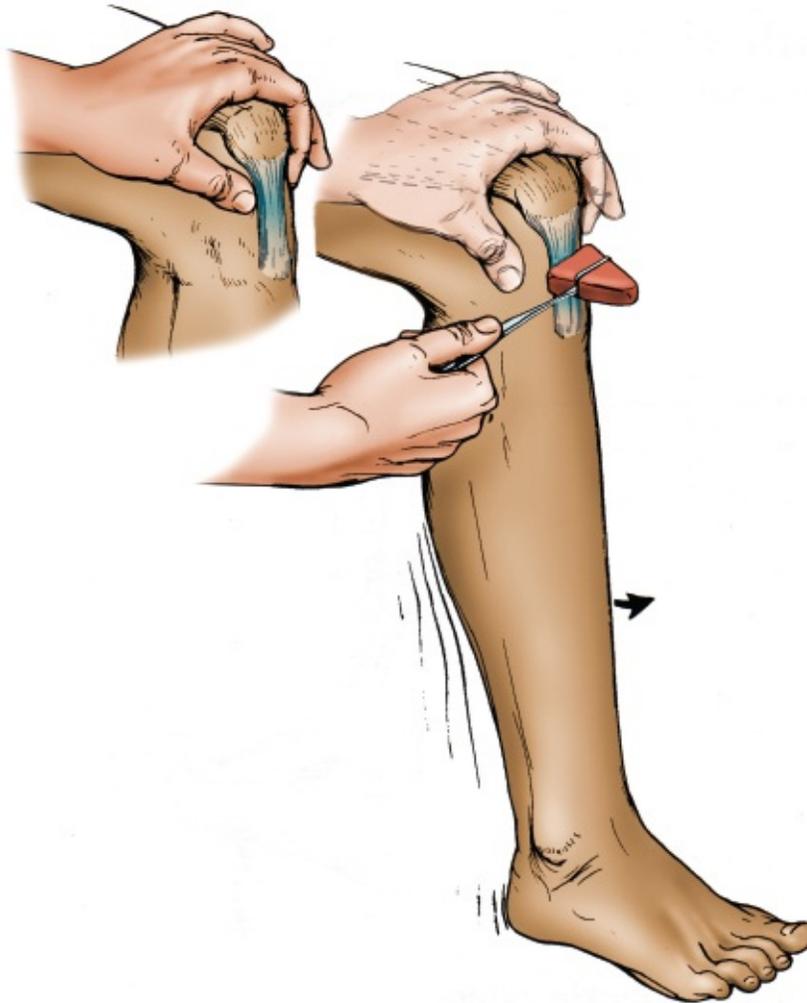

FIGURE 2-13 Patellar tendon reflex.

To test the patellar tendon reflex, ask the patient to sit on the edge of the examining table with the legs dangling. (The patient may also sit on a chair with one leg crossed over his knee or, if the patient is in bed, with the knee supported in a few degrees of flexion) (Fig. 2-13). In these positions, the infrapatellar tendon is stretched and primed. Palpate the soft tissue depression on either side of the tendon to locate it accurately, and attempt to elicit the reflex by tapping the tendon at the level of the knee joint with a short, smart wrist action. If the reflex is difficult to obtain, reinforce it by having the patient clasp his hands and attempt to pull them apart as you tap the tendon. This is known as the Jendrassik maneuver. It prevents the patient from consciously inhibiting or influencing his or her response to reflex testing. Repeat the procedure on the opposite leg, and grade the reflex as normal, increased, decreased, or absent. To remember the neurologic level of the reflex, associate the fact that *four* muscles constitute the

quadriceps muscle with the L4 of the patellar tendon reflex (Fig. 2-14).

The reflex may be affected by problems other than neurologic pathology. For example, if the quadriceps has been traumatized, if the patient has undergone recent surgery to the knee, or if there is knee joint effusion, the reflex may be absent or diminished.

Sensory Testing

The L4 dermatome covers the medial side of the leg and extends to the medial side of the foot. The knee joint is the dividing line between the L3 dermatome above and the L4 dermatome below. On the leg, the sharp crest of the tibia is the dividing line between the L4 dermatome on the medial side and the L5 dermatome on the lateral side (Fig. 2-15).
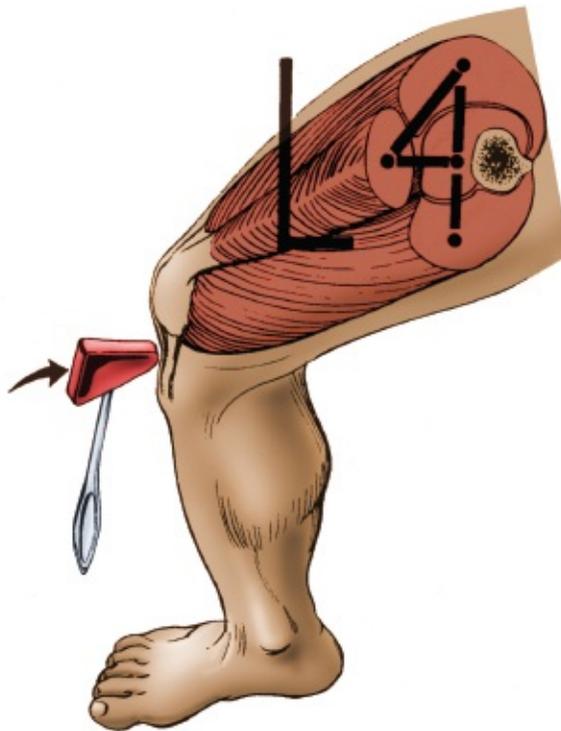

FIGURE 2-14 An easy way to remember that the patellar tendon reflex is innervated by L4 is to associate the *four* quadriceps muscles with the neurologic level *L4.*
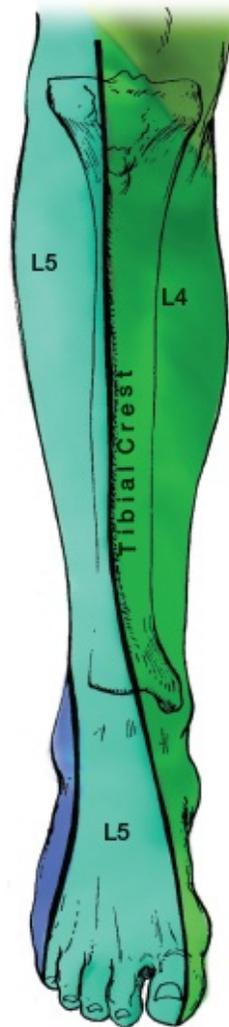

FIGURE 2-15 L4 and L5 sensory dermatome.

Neurologic Level L5

*Muscle Testing (*Figs. 2-16 *to* 2-18*)*

1. Extensor hallucis longus
2. Extensor digitorum longus and brevis
3. Gluteus medius
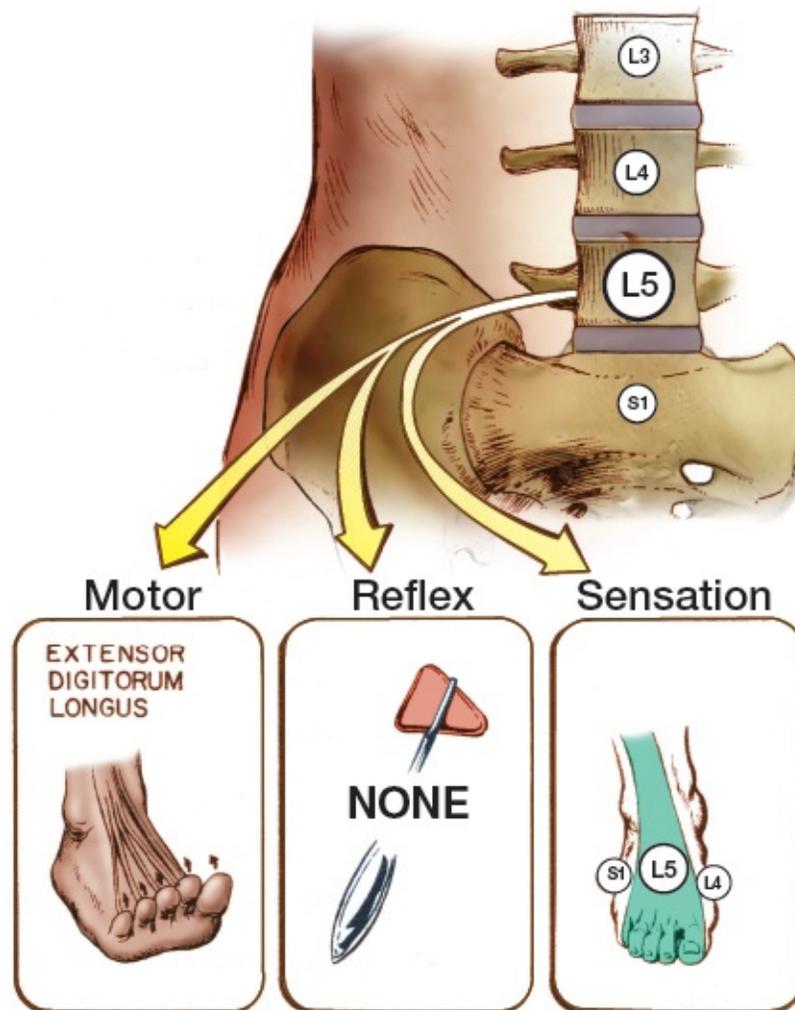

FIGURE 2-16 Neurologic level L5.

Extensor Hallucis Longus: L5 (Deep Branch of the Peroneal Nerve): The tendon of the extensor hallucis longus passes in front of the ankle joint lateral to the tibialis anterior, which is predominately innervated by L4. Test it functionally by having the patient walk on his heels, with his feet neither inverted nor everted. The tendon should stand out clearly on the way to its insertion at the proximal end of the distal phalanx of the great toe. To test the extensor hallucis longus manually, have the patient sit on the edge of the table. Support the foot with one hand around the calcaneus and place your thumb in such a position that the patient must dorsiflex his great toe to reach it. Oppose this dorsiflexion by placing your thumb on the nail bed of the great toe and your fingers on the ball of the foot; then pull down on the toe (Fig. 2-19A). If your thumb crosses theinterphalangeal joint, you will be testing the extensor hallucis

brevis as well as the longus; make certain that you apply resistance distal to the interphalangeal joint so that you are testing only the extensor hallucis longus. Note that a fracture of the great toe or other recent trauma will produce apparent muscle weakness in the extensor hallucis longus.

Extensor Digitorum Longus and Brevis: L5 (Deep Peroneal Nerve): Test the extensor digitorum longus in function by instructing the patient to walk on his heels, as he did for the extensor hallucis longus. The tendon of the extensor digitorum longus should stand out on the dorsum of the foot, crossing in front of the ankle mortise and fanning out to insert by slips into the dorsal surfaces of the middle and distal phalanges of the lateral four toes.

For the manual test, the patient may remain seated on the edge of the table. Secure the ankle with one hand around the calcaneus and place the thumb of your free hand in such a position that he must extend his toes to reach it. Oppose this motion by pressing on the dorsum of the toes and attempting to bend them plantarward (Fig. 2-19B). They should be virtually unyielding.
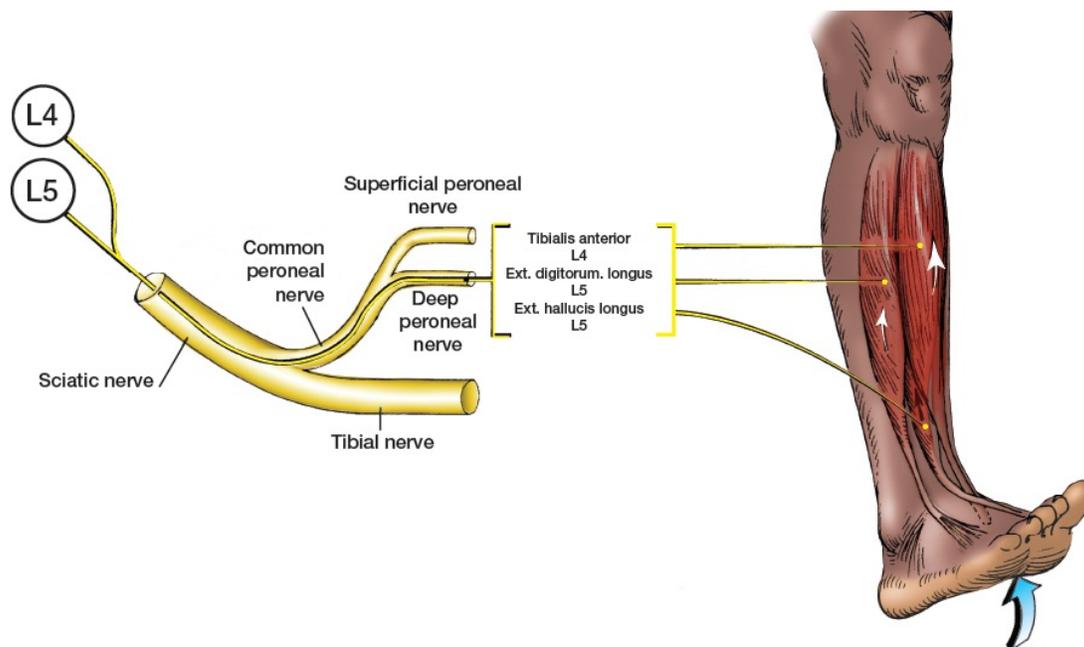

FIGURE 2-17 L4, L5—foot dorsiflexion (ankle extension).

Extensor hallucis
longus

Extensor digitorum
longus

Extensor digitorum

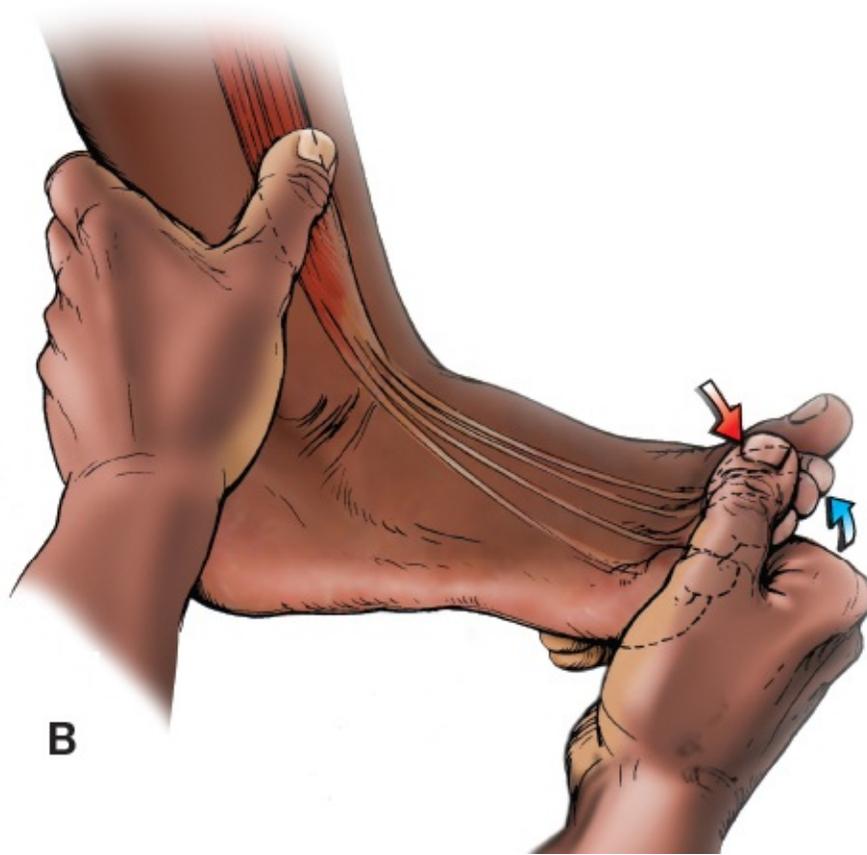

FIGURE 2-19B Muscle test for toe extensors.

FIGURE 2-19C An easy way to remember that the toe extensors are innervated by neurologic level L5.

Gluteus Medius: L5 (Superior Gluteal Nerve): To test the gluteus medius, have the patient lie on his side (Fig. 2-20). Stabilize the patient's pelvis with one hand and instruct the patient to abduct the leg. Allow the leg to abduct fully before you resist by pushing against the lateral thigh at the level of the knee joint

(Fig. 2-21). To prevent the muscle substitution that may take place if the hip is allowed to flex, make sure it remains in a neutral position throughout the test.

Reflex Testing

There is no easily elicited reflex supplied by the L5 neurologic level. Although the tibialis posterior muscle provides an L5 reflex, it is difficult to elicit routinely. If, after you have performed sensory and motor tests, you are not certain of the integrity of the L5 level, you should try to elicit the tibialis posterior reflex by holding the forefoot in a few degrees of eversion and dorsiflexion, and by tapping the tendon of the tibialis posterior muscle on the medial side of the foot just before it inserts into the navicular tuberosity. Normally, you should elicit a slight plantar inversion response.

Sensory Testing

The L5 dermatome covers the lateral leg and dorsum of the foot. The crest of the tibia divides L5 from L4. To make the distinction between L4 and L5 clearer, palpate the crest of the tibia from the knee distally as it angles toward the medial malleolus. All that is lateral to the crest, including the dorsum of the foot, receives sensory innervation from L5 (see Fig. 2-15).

Neurologic Level S1

Muscle Testing

1. Peroneus longus and brevis
2. Gastrocnemius-soleus muscles
3. Gluteus maximus

Peroneus Longus and Brevis: S1 (Superficial Peroneal Nerve): The peronei may be tested together in function (Figs. 2-22 and 2-23). Because they are evertors of the ankle and foot, ask the patient to walk on the medial borders of his feet. The peronei tendons should become prominent just before they turn around the lateral malleolus, pass on either side of the peroneal tubercle (the brevis above, the longus below), and run to their respective insertions.
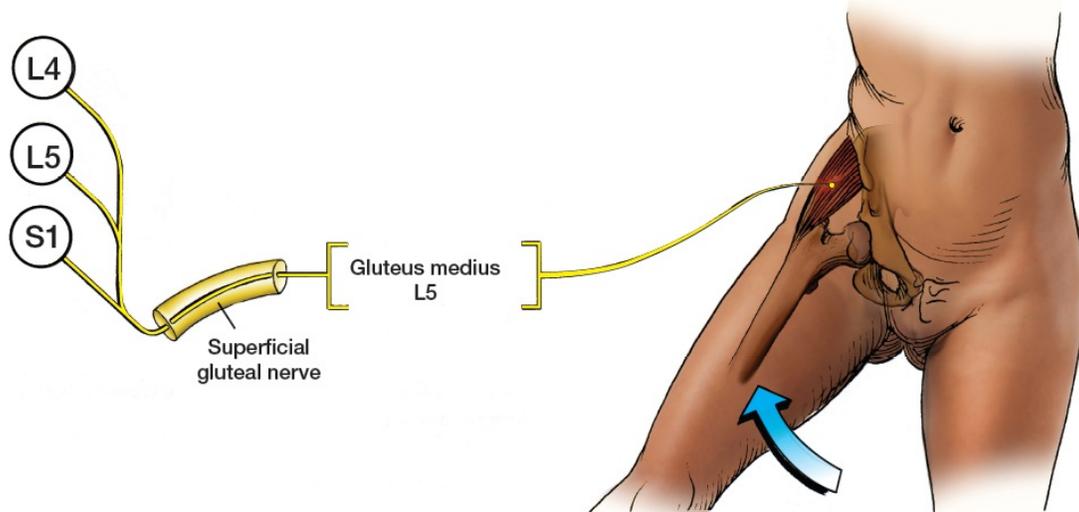

FIGURE 2-20 L4, L5, S1—hip abduction.
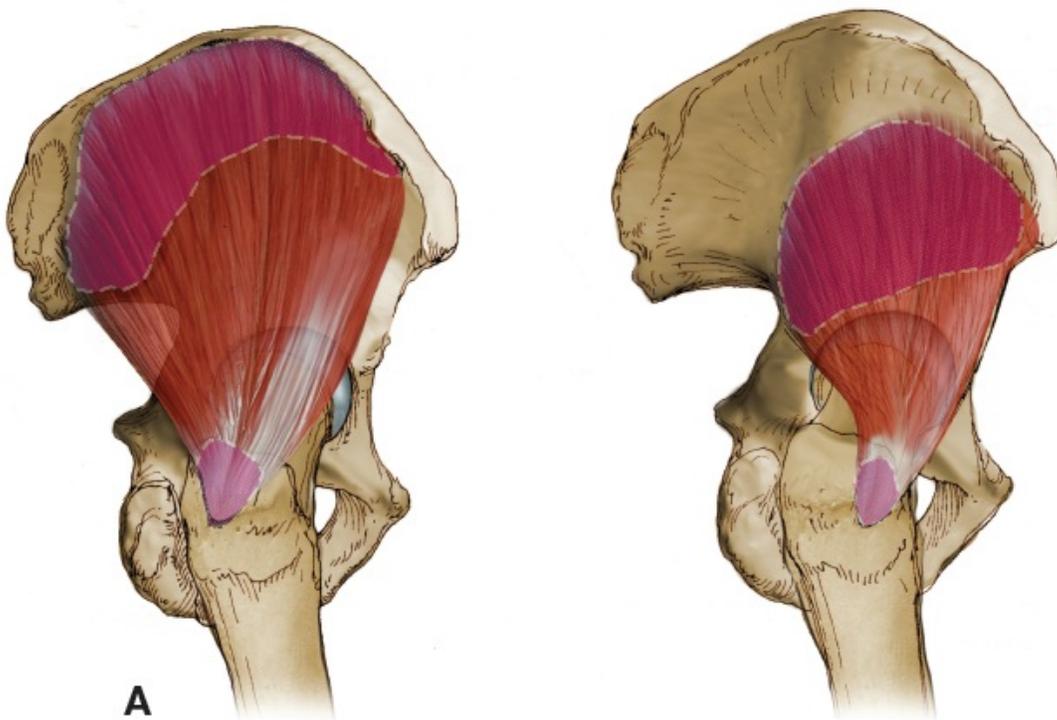

FIGURE 2-21A *Gluteus medius.*
Origin: Outer surface of ilium between iliac crest and posterior gluteal line above to the anterior gluteal line below, as well as the gluteal aponeurosis.
Insertion: Lateral surface of greater trochanter.
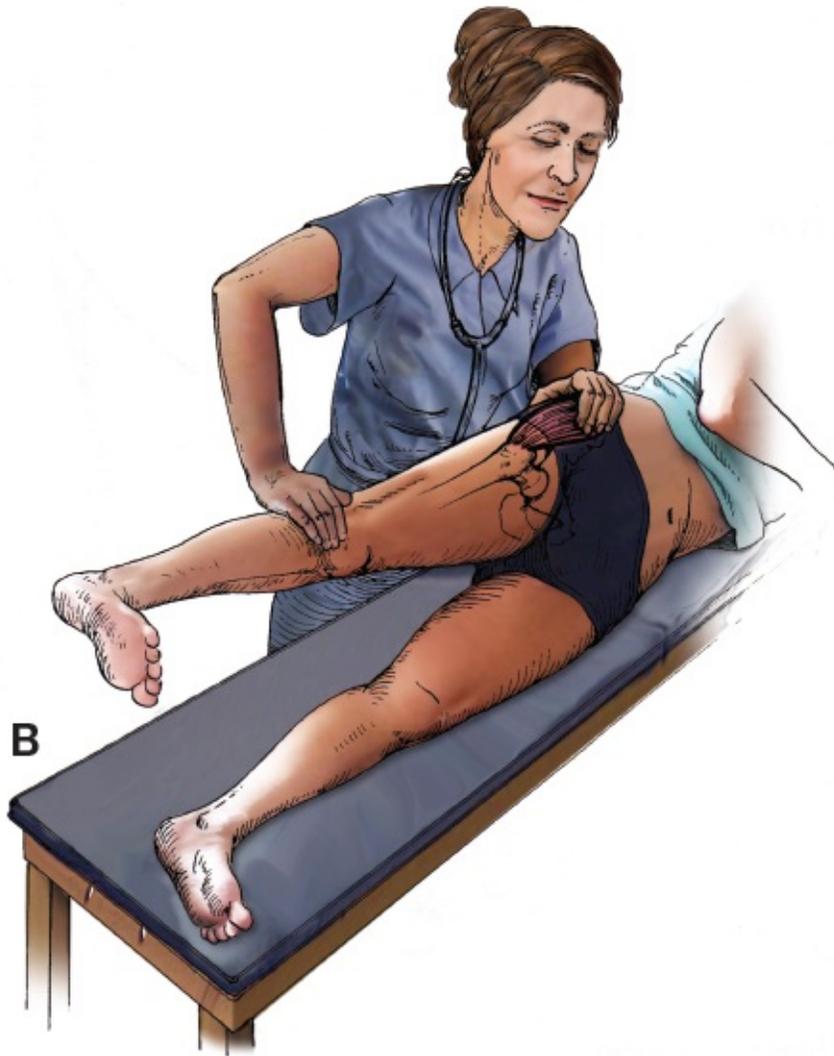

FIGURE 2-21B Muscle test for the gluteus medius muscle.
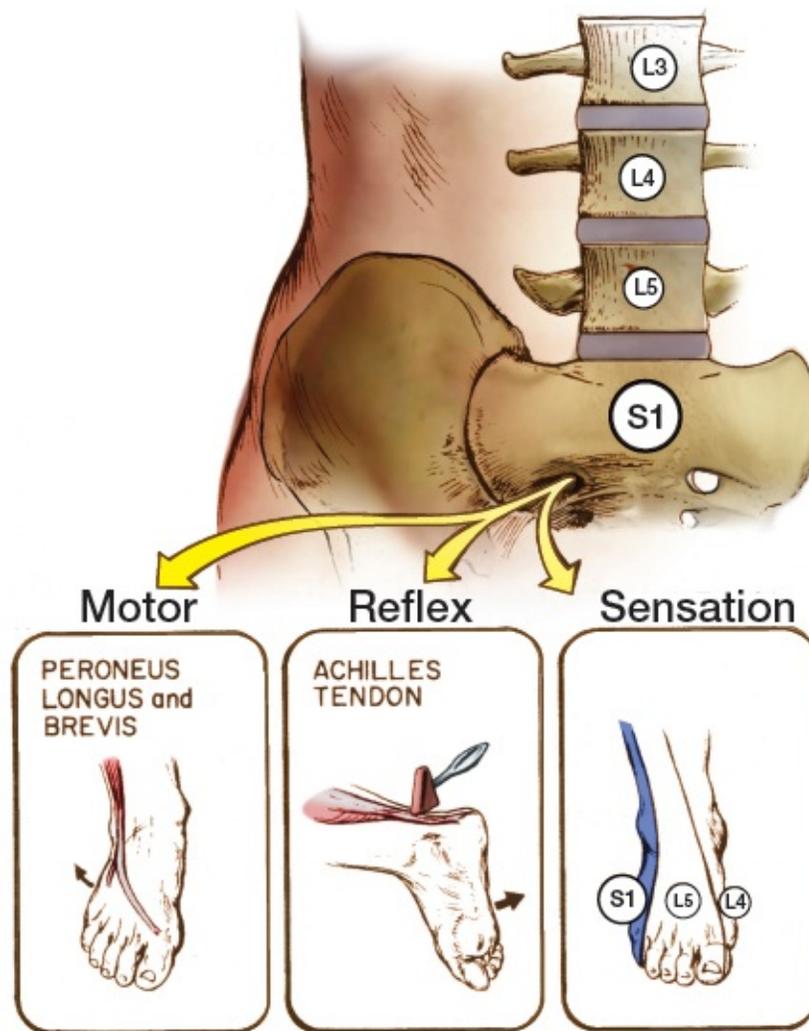

FIGURE 2-22 Neurologic level S1.

To test the peronei muscles manually, have the patient sit on the edge of the table. Secure the ankle by stabilizing the calcaneus and place your other hand in a position that forces him to plantarflex and evert his foot to reach it with his small toe. Oppose this plantar flexion and eversion by pushing against the head and shaft of the 5th metatarsal bone with the palm of your hand (Fig. 2-24); avoid applying pressure to the toes, because they may move.
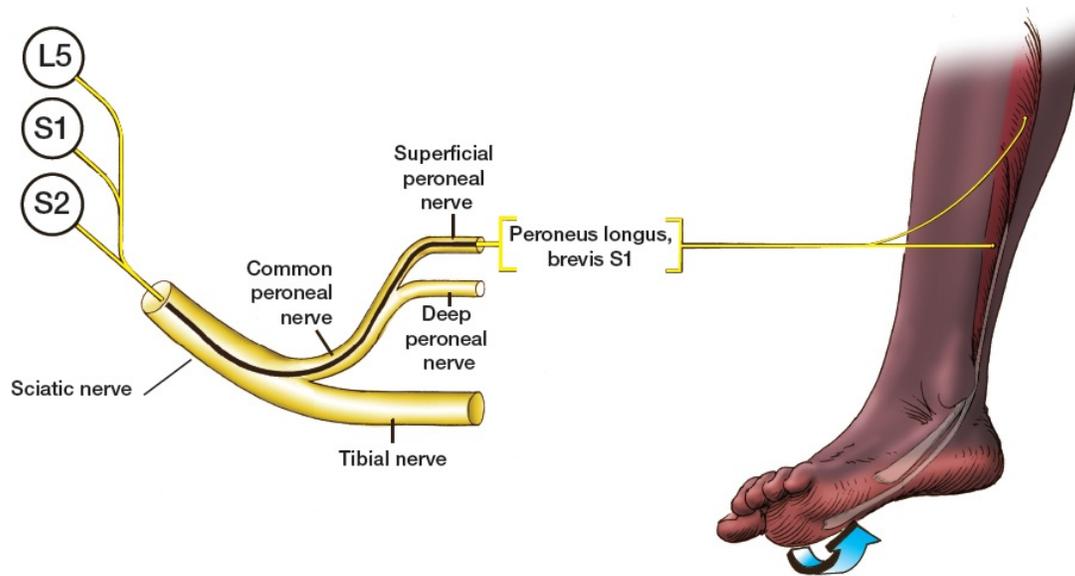

FIGURE 2-23 S1—foot eversion.

Peroneus brevis.
Origin: Distal two-thirds of lateral surface of fibula, adjacent intermuscular septa.
Insertion: Styloid process of base of 5th metatarsal bone.
FIGURE 2-24B Muscle test for the peronei muscles.

Gastrocnemius-Soleus Muscles: S1, S2 (Tibial Nerve): Because the gastrocnemius-soleus group is far stronger than the combined muscles of your

arm and forearm, it is difficult to detect small amounts of existing weakness; the group is thus a poor choice for manual muscle testing and should be observed in function (Fig. 2-25). Ask the patient to walk on his toes; the patient will be unable to do so if there is gross muscle weakness. If the test is normal, instruct him to jump up and down on the balls of his feet, one at a time, forcing the calf muscles to support almost two-and-a-half times the body's weight. If the patient lands flat-footed or is otherwise incapable of performing this test, there is weakness in the calf muscle (Fig. 2-26). Obviously, elderly people or patients with back pain cannot be expected to perform this portion of the functional test. Ask these patients to stand on one leg and rise up on their toes five times in succession. Inability to complete this test indicates calf muscle weakness.

Insertion: Into posterior surface calcaneus by calcaneal tendon.

FIGURE 2-26C Muscle test for the gastrocnemius-soleus muscle group.

Gluteus Maximus: S1 (Inferior Gluteal Nerve): To test the gluteus maximus functionally, have the patient stand from a sitting position without using his hands (Fig. 2-27). To test it more accurately for strength, ask him to lie prone on the examining table with his hips flexed over the edge and his legs dangling. Have the patient bend their knee to relax the hamstring muscles so that they cannot assist the gluteus maximus in hip extension. Place your forearm over his iliac crest to stabilize the pelvis, leaving your hand free to palpate the gluteus maximus muscle. Then ask him to extend his hip. Offer resistance to hip extension by pushing down on the posterior aspect of his thigh just above the knee joint; as you perform the test, palpate the gluteus maximus muscle for tone

(Fig. 2-28).

Reflex Testing

Achilles Tendon Reflex: The Achilles tendon reflex is a deep tendon reflex, mediated through the triceps surae. It is supplied predominantly by nerves emanating from the S1 cord level. If the S1 root is cut, the Achilles tendon reflex will be virtually absent.

To test the Achilles tendon reflex, ask the patient to sit on the edge of the examining table with the legs dangling. Put the tendon into slight stretch by gently dorsiflexing the foot. Place your thumb and fingers into the soft tissue depressions on either side to locate the Achilles tendon accurately, and strike it with the flat end of a neurologic hammer to induce a sudden, involuntary plantar flexion of the foot (Fig. 2-29). It may be helpful to reinforce the reflex by having the patient clasp his hands and try to pull them apart (or push them together) just as the tendon is being struck. To remember the S1 reflex more easily, associate "AchilleS'1 weak spot" with the reflex (Fig. 2-30).

There are various alternate methods of testing the Achilles tendon reflex, some of which are described here. Choose the appropriate method, depending on the condition of the particular patient you are examining.

If the patient is bedridden, cross one leg over the opposite knee so that movement of the ankle joint is unhindered. Prime the tendon by slightly dorsiflexing the foot with one hand on the ball of the foot and strike the tendon. If the patient is lying prone in bed, ask the patient to flex the knee to 90° and prime the tendon by slightly dorsiflexing the foot before performing the test. If the patients ankle joint is swollen, or if it is prohibitively painful to tap the Achilles tendon directly, have the patient lie prone with the ankle over the edge of the bed or examining table. Press the forepart of your fingers against the ball of the foot to dorsiflex it and strike your fingers with the neurologic hammer. A positive reflex is present if the gastrocnemius muscle contracts and the foot plantar flexes slightly. You should be able to detect this motion through your hand.

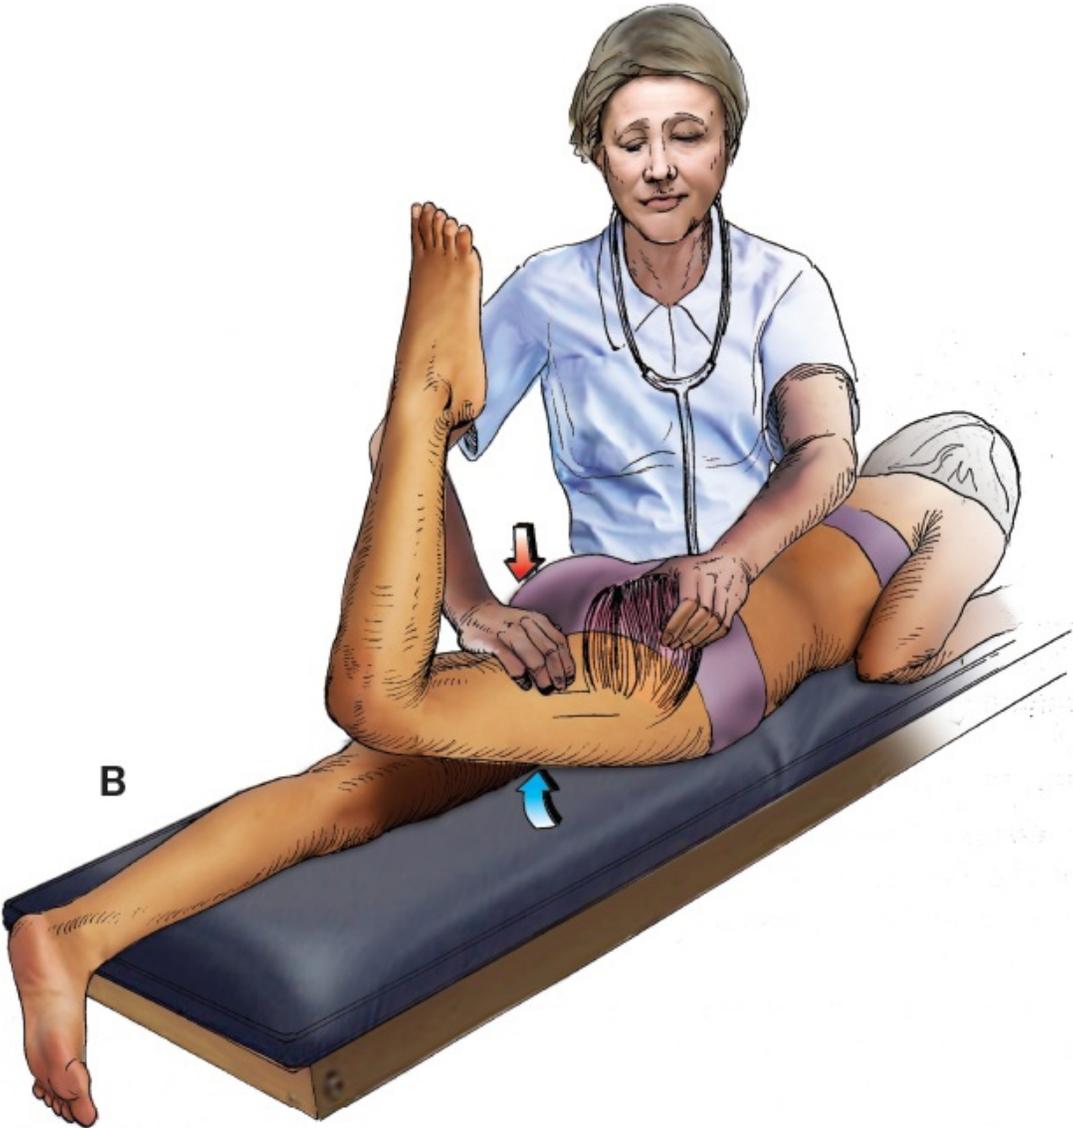

FIGURE 2-28B Muscle test for the gluteus maximus.
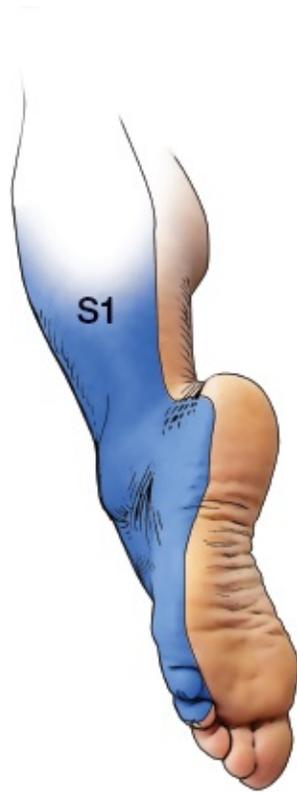

FIGURE 2-28C S1 dermatome.
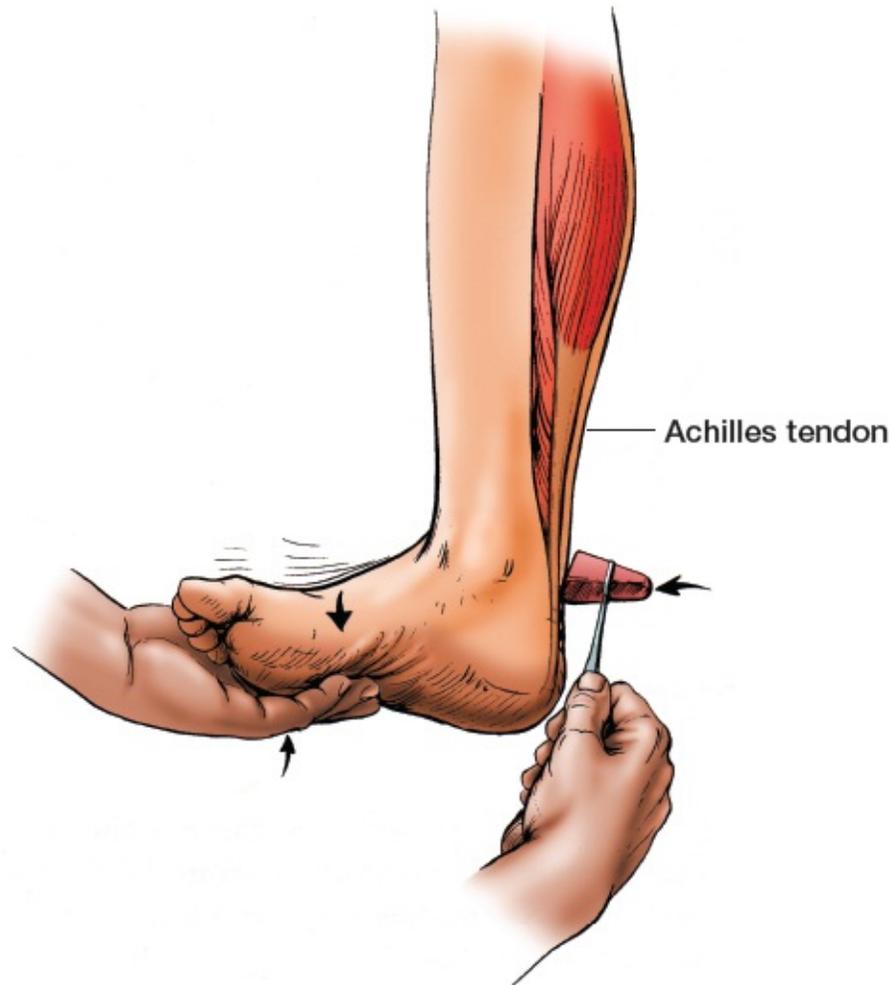

Achilles tendon

FIGURE 2-29 Test of the tendon of Achilles reflex.

Sensory Testing

The S1 dermatome covers the lateral side and a portion of the plantar surface of the foot (Fig. 2-28C).

Neurologic Levels S2-S4

Nerves emanating from the S2 and S3 neurologic levels supply the intrinsic muscles of the foot. Although there is no efficient way to isolate these muscles for testing, you should inspect the toes for clawing, possibly caused by denervation of the intrinsics. S2-S4 are also the principal motor supply to the bladder, and neurologic problems that affect the foot may affect it as well.

Reflex Testing

Note that there is no deep reflex supplied by S2-S4. There is, however, a superficial anal reflex. To test it, touch the perianal skin; the anal sphincter muscle (S2-S4) should contract (wink) in response.

Achille S' 1 Weak Spot

FIGURE 2-30 An easy way to remember that the tendon of Achilles reflex is an S1 reflex.

Sensory Testing

The dermatomes around the anus are arranged in three concentric rings,

receiving innervation from S2 (outermost ring), S3 (middle ring), and S4-S5 (innermost ring) (Fig. 2-31).

Summary

The following is a suggested clinical scheme for most neurologic level testing in the lower extremity. It is practical to evaluate all motor power first, then all sensation, and finally all reflexes.

Most **muscle testing** of the involved lower extremity can be performed with a minimum of effort and motion for examiner and patient if it is generally confined to the foot. Muscle test across the foot from the medial to the lateral side; the tibialis anterior on the medial side of the foot is innervated by L4, the extensor digitorum longus and brevis on the top of the foot by L5, and the peronei on the lateral side of the foot by S1.

FIGURE 2-31 Sensory dermatomes S2-S5.

Sensation can also be tested in a smooth, continuous pattern across the dorsum of the foot from medial to lateral. The medial border of the foot receives innervation from L4, the top of the foot from L5, and the lateral border of the foot from S1 (Fig. 2-32). It is practical to test sensation in each extremity simultaneously to obtain instant comparison. The skin over a muscle is usually

innervated by the same neurologic level as the muscle it covers.
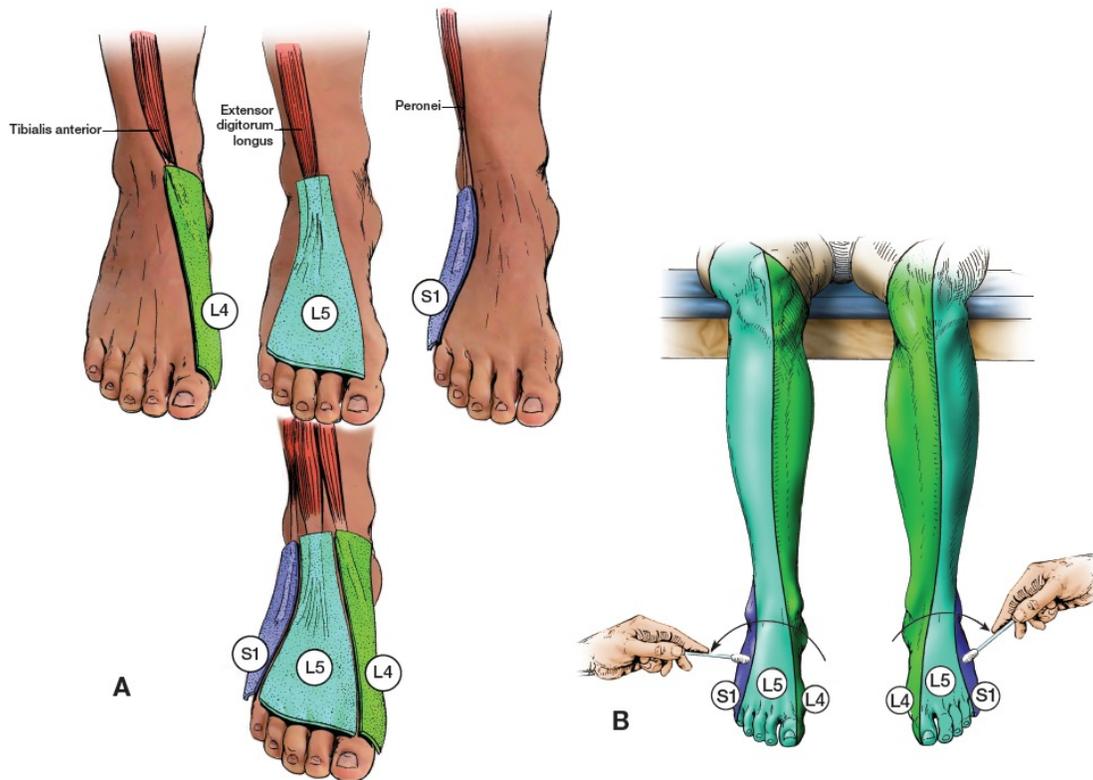

FIGURE 2-32 The sensory dermatomes **(A)** and **(B)** a practical method of testing sensation across the dorsum of the foot.

Reflexes can be tested smoothly as well. With the patient seated, the appropriate tendons—infrapatellar tendon, L4; tendon of Achilles, S1—are easily tested.

Clinical Application of Neurologic Levels

Herniated Lumbar Disks

Lumbar disks, like cervical disks, usually herniate posteriorly rather than anteriorly and to one side rather than in the midline; the anatomic reasons for each type of herniation are the same (see page 25), and the disk usually impinges only upon one of the two nerve roots at each level (Fig. 2-33). The patient usually complains of pain radiating to one leg or the other, and rarely of pain radiating to both legs at the same time.

     Note that there is a special relationship between the nerve roots of the cauda equina and the disk space. Before it exits through the neural foramen, the nerve root turns at approximately a 45° angle around the pedicle of its vertebra. Because the pedicle is situated in the upper third of the vertebral body, the nerve root, which is relatively tethered to it, never crosses the disk space below and thus is usually not involved in any herniations of the disk within that space (Fig. 2-34). A nerve root is commonly involved only in herniations of the disk located *above* its point of exit. For example, the L5 nerve root crosses the disk space between L4 and L5, then turns around the pedicle of L5, and leaves the spinal canal via the neural foramen before it reaches the L5-S1 disk space. It may be affected by an L4-L5 herniation, but not typically by one between L5 and S1(Fig. 2-35).Thus, a patient whose symptoms are manifested along the L5 distribution has a potential herniation in the disk space *above* the L5 vertebra.
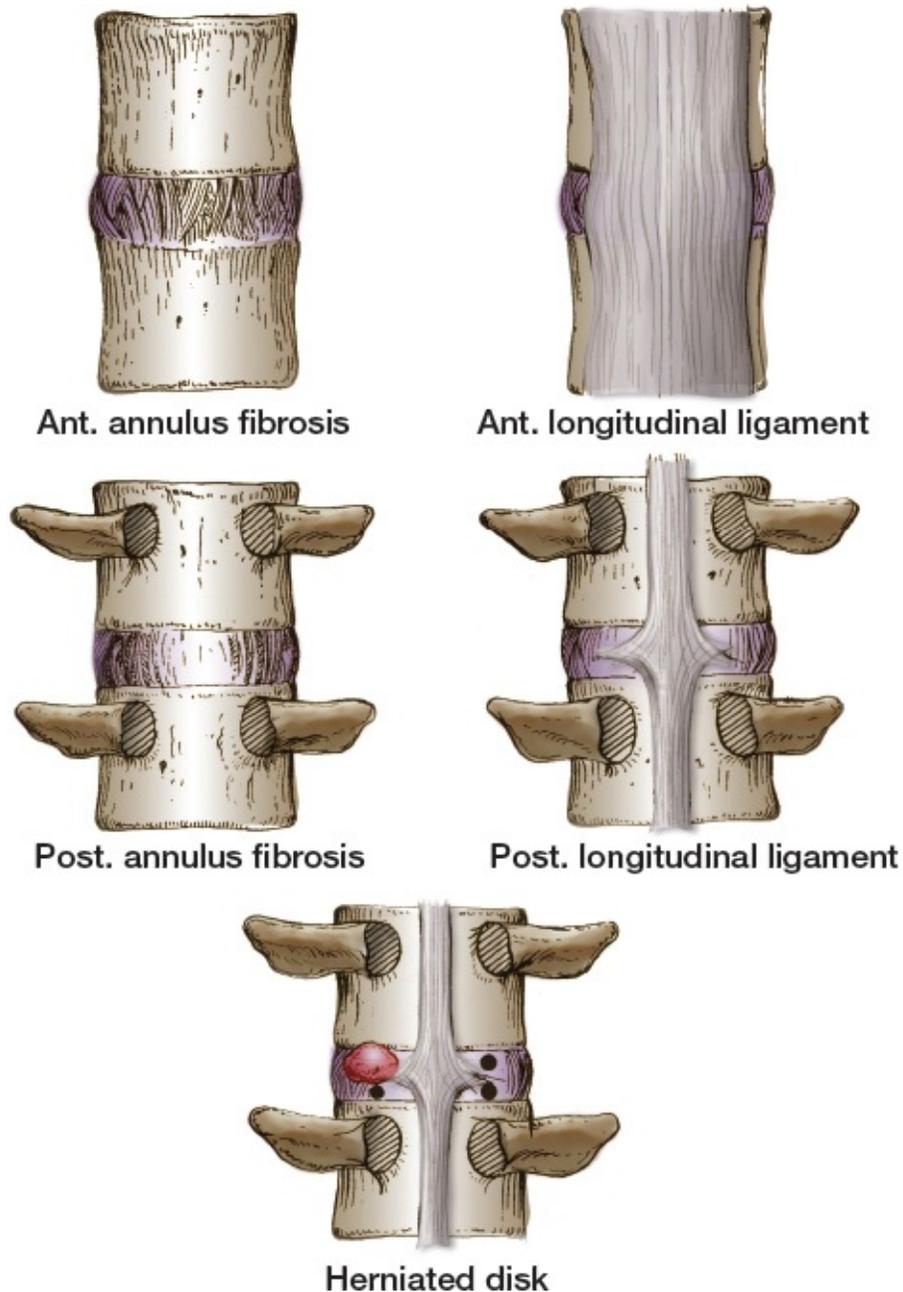

FIGURE 2-33 The anatomic basis for posterior lumbar disk herniation.

The L4-L5 and L5-S1 articulations have the greatest motion in the lumbar spine. Greater motion causes an increased potential for breakdown, and the incidence of herniated disks is greater at L4-L5 and L5-S1 than at any other lumbar disk space in the entire spine. Ninety percent of lumbar disk herniations occur at the two levels.
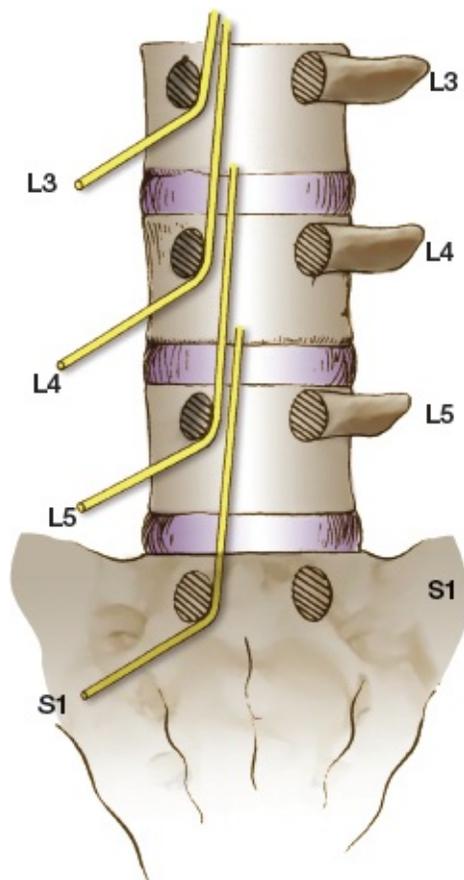

FIGURE 2-34 The anatomic basis for nerve root impingement by a herniated disk.

Table 2-1 delineates the applicable tests for the most clinically relevant neurologic levels. It applies most critically to problems of herniated disks (Figs. 2-36 to 2-39).

Although this table reflects precise neurologic levels, the clinical picture may not be as clear. The reasons for discrepancies are numerous. For example, a nerve root may occasionally carry elements of adjacent nerve roots. Thus, the L4 root may contain components of L3 or L5. In addition, a single disk herniation may involve two nerve roots. This applies particularly to the L4-L5 disk, which may compress not only the L5 root but also the S1 root, particularly if the herniation is in the midline. Disk herniation occasionally occurs at more than one level, giving an atypical neurologic pattern.
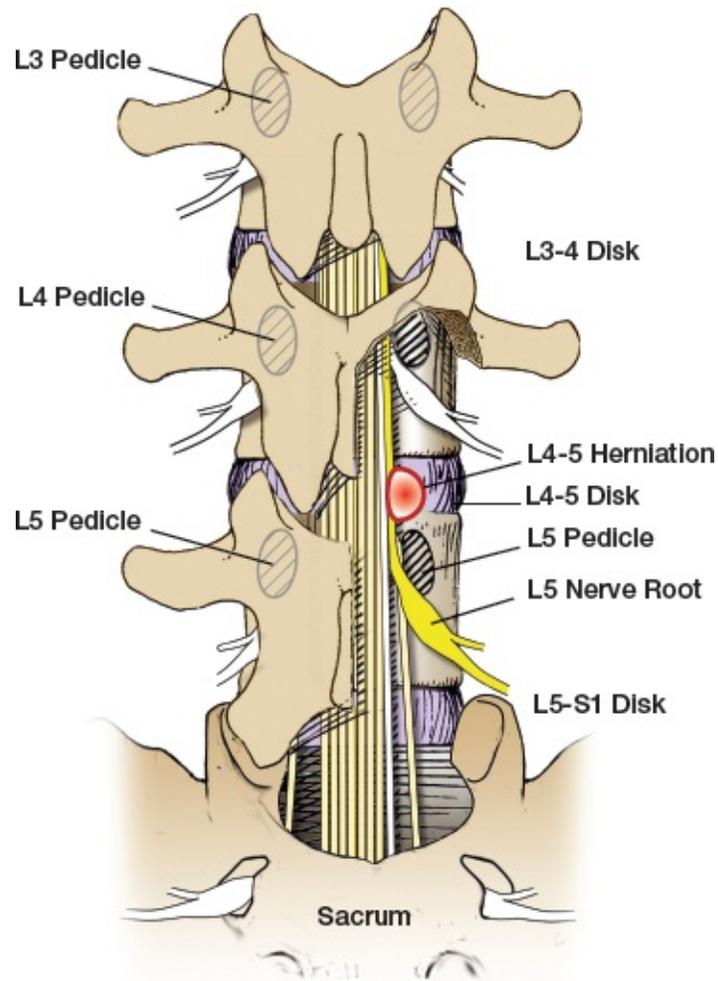

FIGURE 2-35 L4/L5 disk herniation compressing the L5 nerve.

TABLE 2-1 UNDERSTANDING HERNIATED LUMBAR DISKS

ROOT	DISK	MUSCLES	REFLEX	SENSATION	EMG	MYELOGRAM

[*]Most common level of herniation.
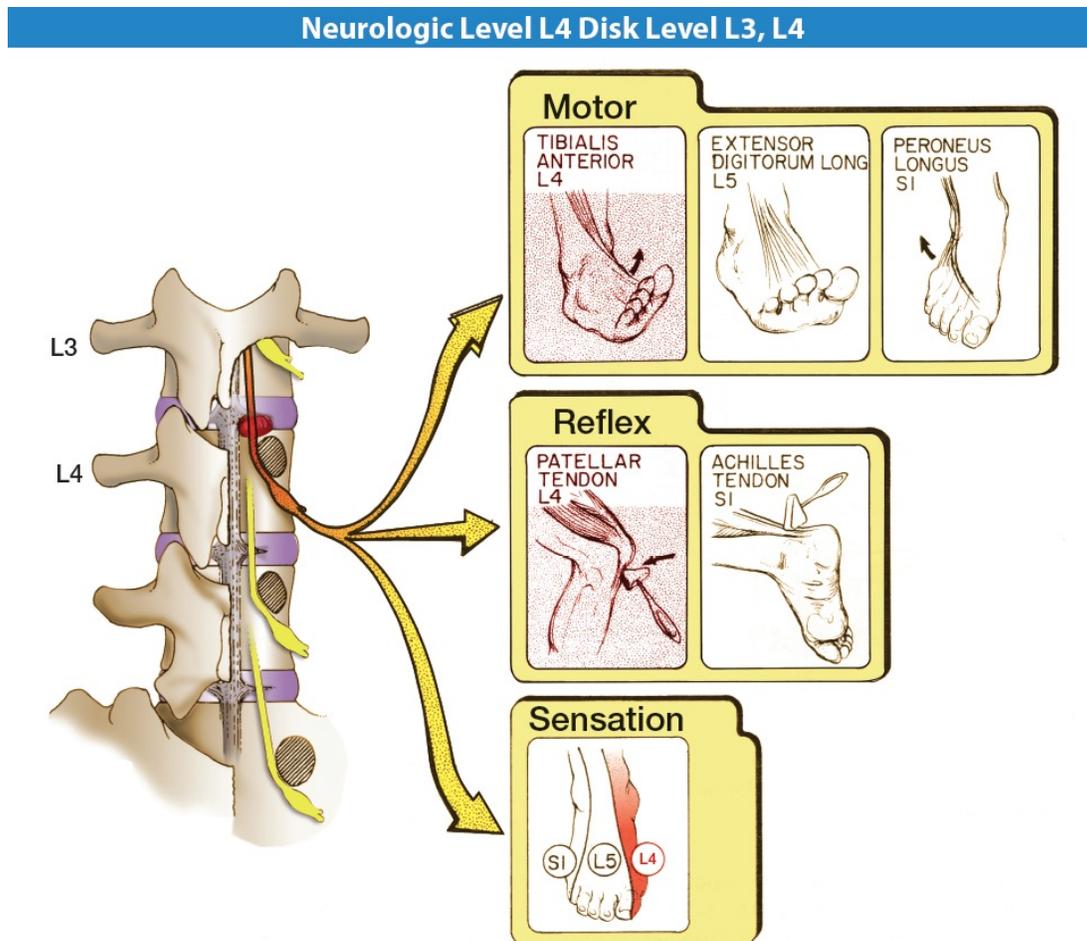

FIGURE 2-36 A herniated disk between vertebrae L3 and L4 involves the L4 nerve root.

Low Back Derangement versus Herniated Disk

Patients frequently develop "low back" pain after lifting heavy objects or falling, or after a violent automobile accident that throws or twists them around the interior of the car. These patients complain of back pain (point tenderness or pain across the lower lumbar spine) with radiation to varying degrees around the posterior superior iliac spines and down the back of the leg.

Complaints of a generalized backache or low back derangement without neurologic involvement can be differentiated from those with neurologic involvement by testing the neurologic levels innervating the lower extremity.

The tests should be repeated with each visit, because a loss of function not apparent in the initial examination; a further loss of muscle strength, reflex, or sensation in the involved neurologic level; or an improvement from the initial findings (as a result, perhaps, of treatment) may occur.

Unless there is evidence either of an alteration in reflex, sensation, or motor power or of positive findings on electromyogram, nonsurgical conservative therapy including physical therapy, injections, and medication management should continue despite patient pressure for a change in treatment.

Although neurologic involvement of a herniated disk is most often manifested by the alteration of only one or two signs, there should be enough information to help pinpoint the involved neurologic level. Certainly, the electromyogram and magnetic resonance imaging (MRI) can be used as further diagnostic tools. But your clinical judgment, based on the physical examination of the patient, will most often allow you to make the proper neurologic diagnosis and prescribe the correct treatment.
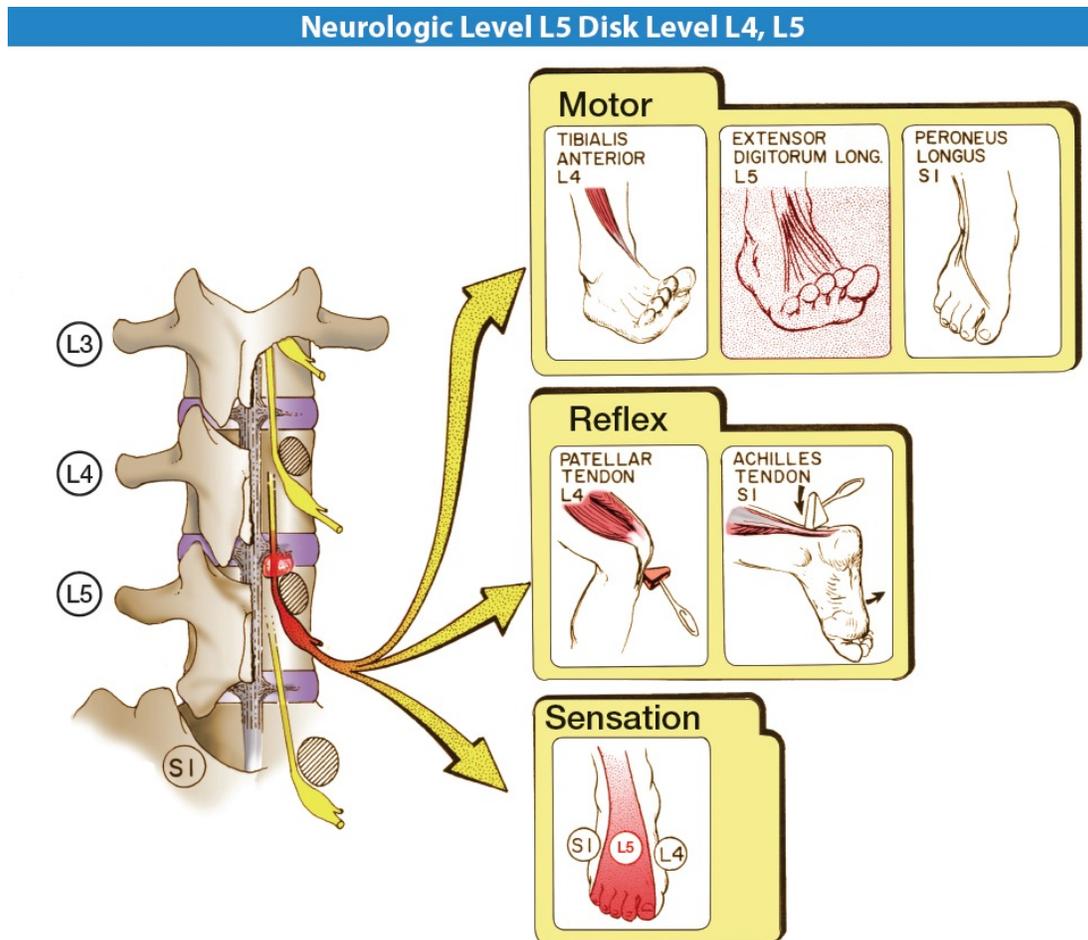

Neurologic Level L5 Disk Level L4, L5

Spondylolysis and Spondylolysthesis

Spondylolysis refers to the lytic line that crosses the pars interarticularis, the area between the superior and the inferior articulating processes, or, more precisely, the point at which the inferior articulating process approaches the pedicle (Fig. 2-40). As a result of this pathology, the involved vertebra may slip forward on the vertebra immediately inferior to it. This forward slippage is called spondylolysthesis. Although the etiology of the defect of the pars interarticularis is still unknown, it is commonly believed to be the result of a fracture due to repeated stress. Because of the frequency of L5-S1 spondylolysthesis with involvement of L5-S1 nerve roots, the hamstrings, supplied medially by L5 and laterally by S1, may well go into spasm. Both sensation and reflex usually remain normal, unless there is an associated herniated disk. Occasionally, spondylolysthesis may occur even with an intact pars interarticularis in patients with degenerative arthritis. However, this is very unusual.

The degree of forward slippage is measured clinically by the relationship of the superior vertebra to the inferior vertebra (the superior vertebra slips forward). A slip of up to 25 percent is termed a first-degree slip, 25 to 50 percent a second-degree slip, and 50 to 75 percent a third-degree slip. Any greater slippage is termed a fourth-degree slip. The vertebra most commonly involved in spondylolysis and spondylolysthesis is the L5 vertebra. The second most common is L4.

FIGURE 2-39 MRI: a herniated disk at L5, S1.
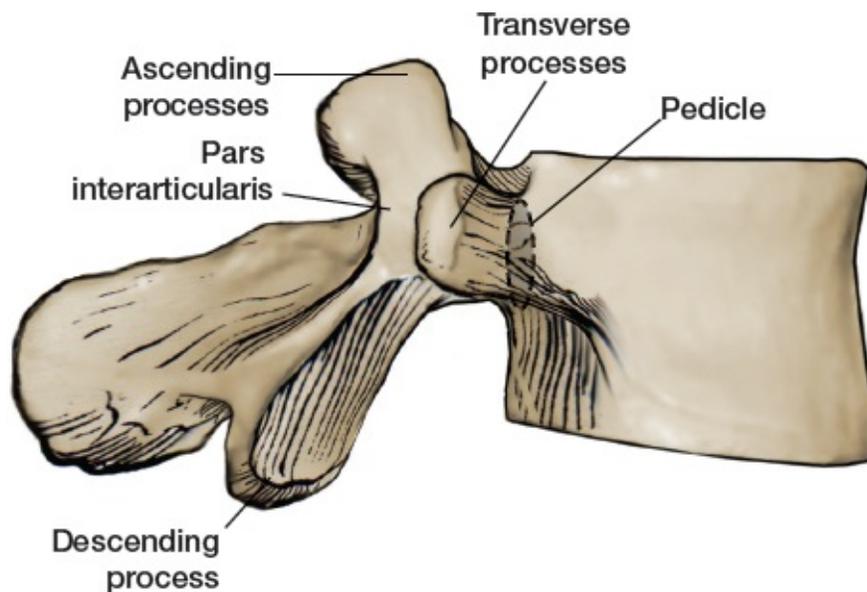

FIGURE 2-40 Pars interarticularis.

The degree of pain that the patient experiences is not necessarily related to

the degree of slippage, so a patient with a first-degree slip may feel greater pain than a patient with a fourth-degree slip, who may, in fact, feel no pain at all.

An increase of symptoms in patients with spondylolysis or spondylolysthesis can often be the result of an associated herniated lumbar disk. The incidence of a herniated disk is greater in patients with spondylolysthesis than that in the general population. The disk herniation usually occurs one level above the bony pathology. For example, if there is a bony defect at L5, the disk between L4 and L5 is the one most likely to herniate. The involvement of the L5 nerve root may produce associated neurologic findings, such as positive straight leg raising, toe extensor weakness, and diminution of sensation on the dorsum of the foot. Although such involvement usually stems from an associated herniation, the nerve root may also become impinged directly from a spondylolysthesis.

Spondylolysis and spondylolysthesis are frequent causes of teenage backache; the patient usually complains of back pain, particularly after sports activities.

Note that spondylolysis has a characteristic look on an x-ray (Figs. 2-41 and 2-42).
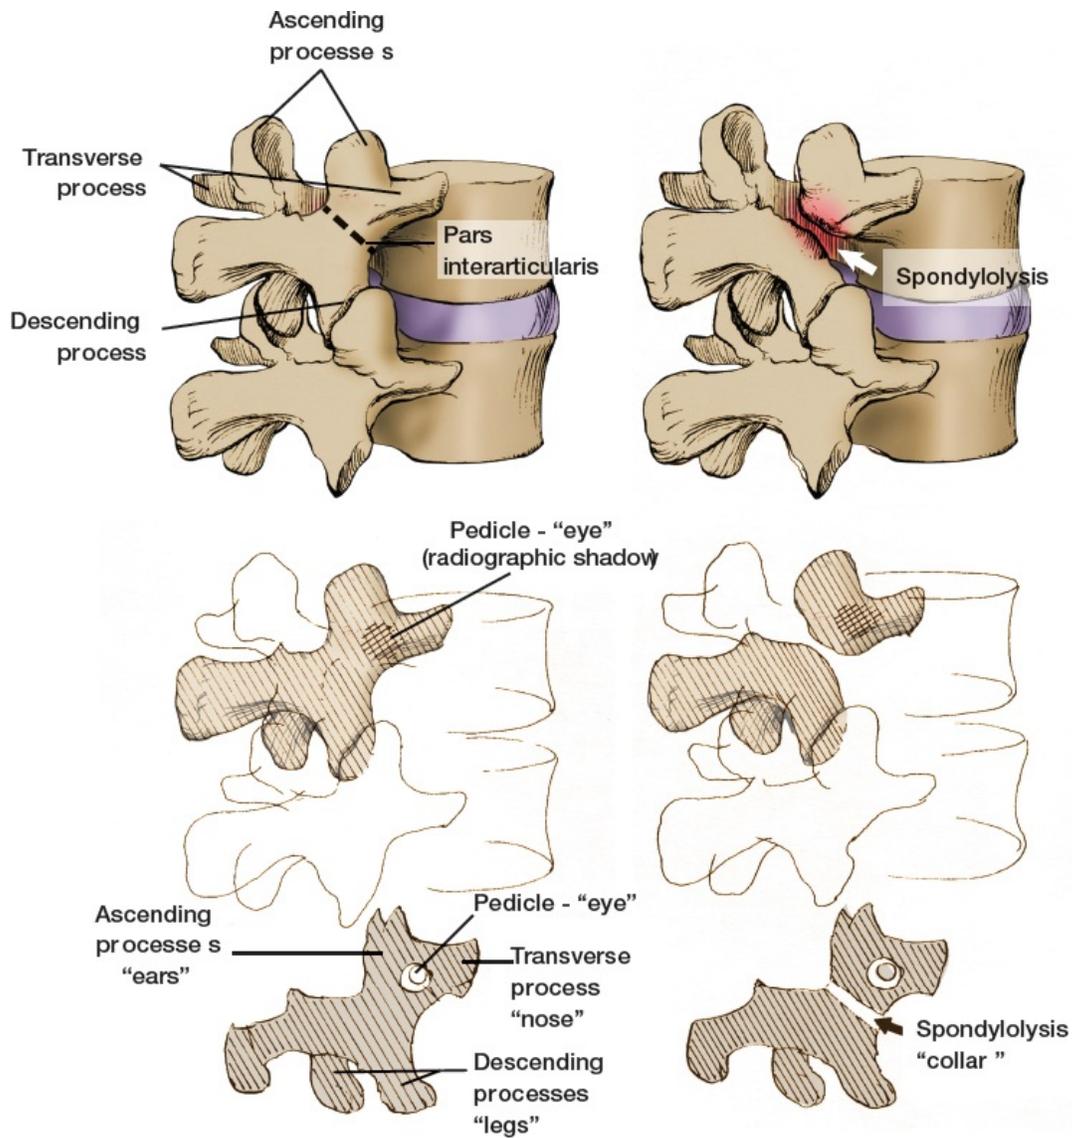

FIGURE 2-41 Schematic drawing of an oblique roentgenogram of the lumbar spine, showing the characteristic "scotty dog" look of its posterior elements. Note that the defect in the pars interarticularis appears to be a collar around the dog's neck.

FIGURE 2-42 Spondylolysis.

Herpes Zoster

Herpes zoster (shingles) is a viral disease that usually involves a single, unilateral dermatome. Thoracic roots are most commonly involved. Pain frequently precedes the appearance ofthe skin lesion and follows the distribution of thenerve root, without crossing the midline. The level involved can be located through appropriate sensory testing and evaluation of the level of the skin lesion.

Poliomyelitis

Poliomyelitis is an acute viral infectious disease that may inflict temporary or permanent destructive changes in motor function. It involves the destruction of the anterior horn cells of the spinal cord. Poliomyelitis usually attacks younger patients, causing motor paralysis and atrophy. It does not affect sensation, and reflexes, although diminished, are usually present, because the reflex arcs remain intact unless all the anterior horn cells are destroyed (Fig. 2-43).

Although its lesion lies in the cord, the clinical appearance of poliomyelitis may be similar to that of a nerve root lesion, because the virus destroys the cells of the nerve root. At least 50 percent of the anterior horn cells in the levels innervating a particular muscle must be involved before there is any clinical evidence of muscle weakness (according to W. J. W. Sharrard). Poliomyelitis attacks the anterior horn cells segmentally—it does not simply involve all levels in an area—and it may skip levels, leaving them free of pathology. This leads to a smaller degree of involvement for muscles that are innervated by several layers. For example, the quadriceps muscle, which is innervated by L2-L4, does not experience any significant weakness unless 50 percent of the anterior horn cells of all three levels are involved. Conversely, the tibialis anterior muscle, which is innervated mainly by L4, is affected by the involvement of 50 percent of the anterior horn cells of that level, causing the relatively common problem of foot drop. If the anterior horn cells of the 5th lumbar level are involved, weakness of the gluteus medius muscle, the medial hamstrings, and the toe extensors may occur. If the anterior horn cells of the 1st sacral level are involved, there may be weakening of the gluteus maximus muscle, the lateral hamstring, and the peronei and calf muscles.
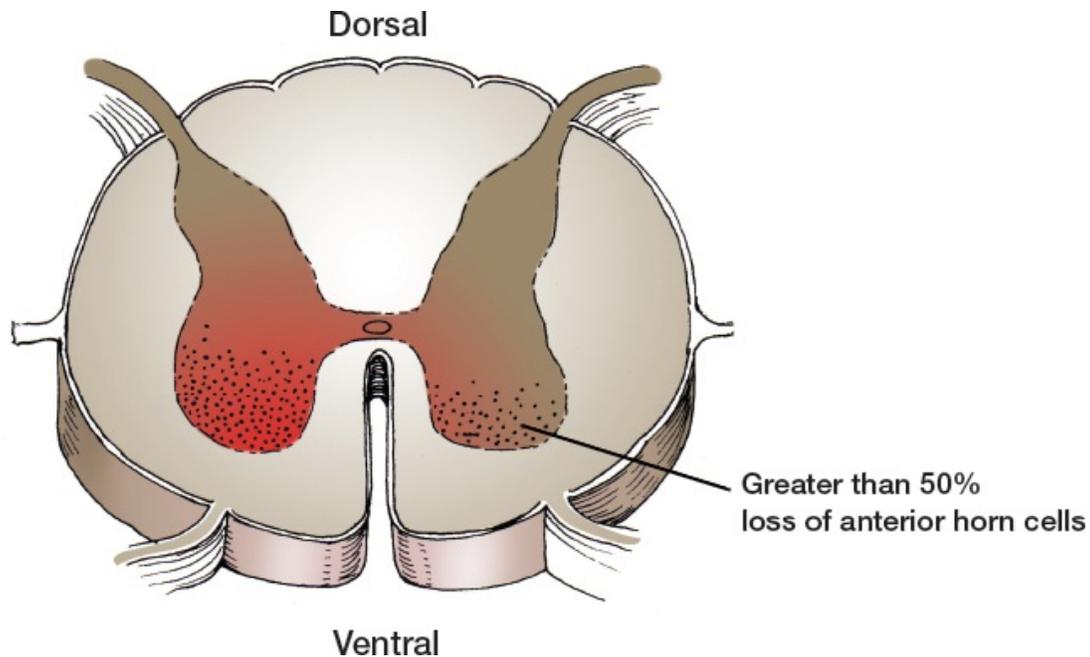

FIGURE 2-43 Anterior horn cell loss leading to clinical muscle weakness.

Through vaccination, poliomyelitis has been practically eliminated as a serious problem.

MUSCLE	NEUROLOGIC LEVEL*	NERVE

Spinal Cord Lesions by Neurologic Level

The acute injuries leading to tetraplegia and paraplegia present great problems in both early diagnosis of the levels of neural involvement and prognostication of future function. In today's society, where potentially debilitating occurrences, including war, auto and industrial accidents, and contact sports, are common, there is a need for a concise system of early neurologic examination. Traumatic pathology of any kind that affects the spine and spinal cord must be diagnosed immediately and must be accurately and promptly treated. The key to management of spinal injuries is immediate protection of the spinal cord, even if an immediate examination is not performed. Without immediate protection, incomplete lesions of the cord can progress to complete lesions, and partially contused nerve roots may be totally lost.

Spinal injuries may occur at any level. Each level at which an injury can occur gives special problems: acute injuries to the cervical spine may result in death or tetraplegia; injuries to the thoracic spine usually lead to spastic paraplegia; and injuries to the lumbar spine (cauda equina injuries) can result in varying degrees of flaccid lower extremity paralysis. The following discussion deals with these three zones and with methods of examination that help establish a precise level of neural involvement.

3

Cervical Cord Lesions: Tetraplegia

Tetraplegia, or quadriplegia as it is more commonly known, means paralysis involving all four extremities. The lesion that causes such paralysis occurs in the cervical spine.

In an analysis of tetraplegia, establishment of the level of neural involvement and evaluation of its degree (whether the cord lesion is complete or incomplete) are of primary concern. Both these factors must be known before there can be any attempt at prediction of recovery of neurologic function or before any effective program of therapeutic treatment and rehabilitation can be planned. The more rapid the rate of return of spinal cord function, the greater the amount of recovery and, conversely, the slower the rate of return, the smaller the amount of recovery. This rule of thumb makes it easier to estimate the future possibility of both ambulation and bladder and bowel function. Because, at the beginning, the patient may be in a state of spinal shock (diaschisis), from which some neural recovery may occur, a thorough neurologic examination, repeated every 2 to 4 hours for the first 48 hours, may begin to provide some answers about the potential for recovery. Each examination must include muscle testing, sensory testing, and reflex testing to permit a complete evaluation of the possibility of cord return.

Evaluation of Individual Cord Levels: C3-T1

If the cervical cord is completely transected, complete paralysis of the lower

extremities occurs, but the degree of paralysis of the upper extremities depends on the neurologic level involved. Although some cervical cord lesions are, in reality, incomplete or partial (so that some function remains below the level of the lesion), we shall discuss the signs as if each cord lesion is complete, because the real issue is to determine the level of injury.

Spinal shock and associated muscle flaccidity usually pass between 24 hours and three months after trauma. Spasticity and clonus set in and gradually increase in intensity. The deep tendon reflexes become exaggerated and pathologic reflexes appear.

Neurologic Level C3 (C3 Intact)

A neurologic level of C3 means that the third cervical root is intact, whereas the fourth is not. Neurologic level C3 corresponds to vertebral level C3, C4 (Fig. 3-1).

Motor Function

There is no motor function in the upper extremities; the patient is completely tetraplegic. Muscles are flaccid as a result of denervation and spinal shock. After spinal shock has worn off, the muscles will demonstrate varying degrees of spastic response. Because the diaphragm is supplied largely by C4, the patient is unable to breathe independently, and will die without artificial respiratory assistance. Sometimes, in what at first appears to be a C3 level, C4 later recovers, with a return of diaphragmatic function.

REFLEX

| BICEPS C5 | BRACHIO-RADIALIS C6 | TRICEPS C7 |

SENSATION

RESPIRATION

Permanent respiratory support
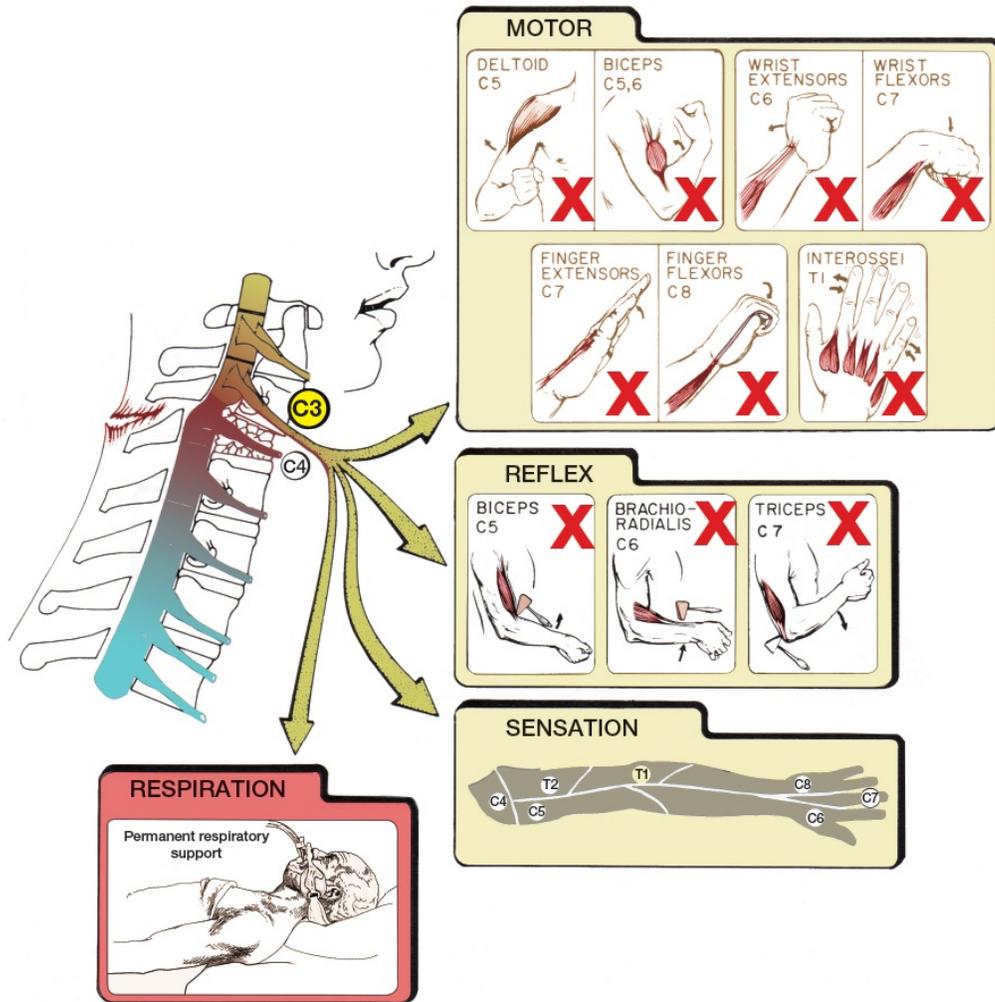

FIGURE 3-1 Tetraplegia: neurologic level C3.

Sensation

There is no sensation in the upper extremities or below a line three inches above the nipple on the anterior chest wall.

Reflexes

In the presence of spinal shock, all deep tendon reflexes are absent. When spinal shock has worn off, they will become brisk to exaggerated and pathologic reflexes may be evident.

Neurologic Level C4 (C4 Intact)

The 4th cervical cord segment remains intact. The lesion lies between the 4th and 5th cervical vertebrae (Fig. 3-2).

Neurologic Level C4 Bony Level C4, C5
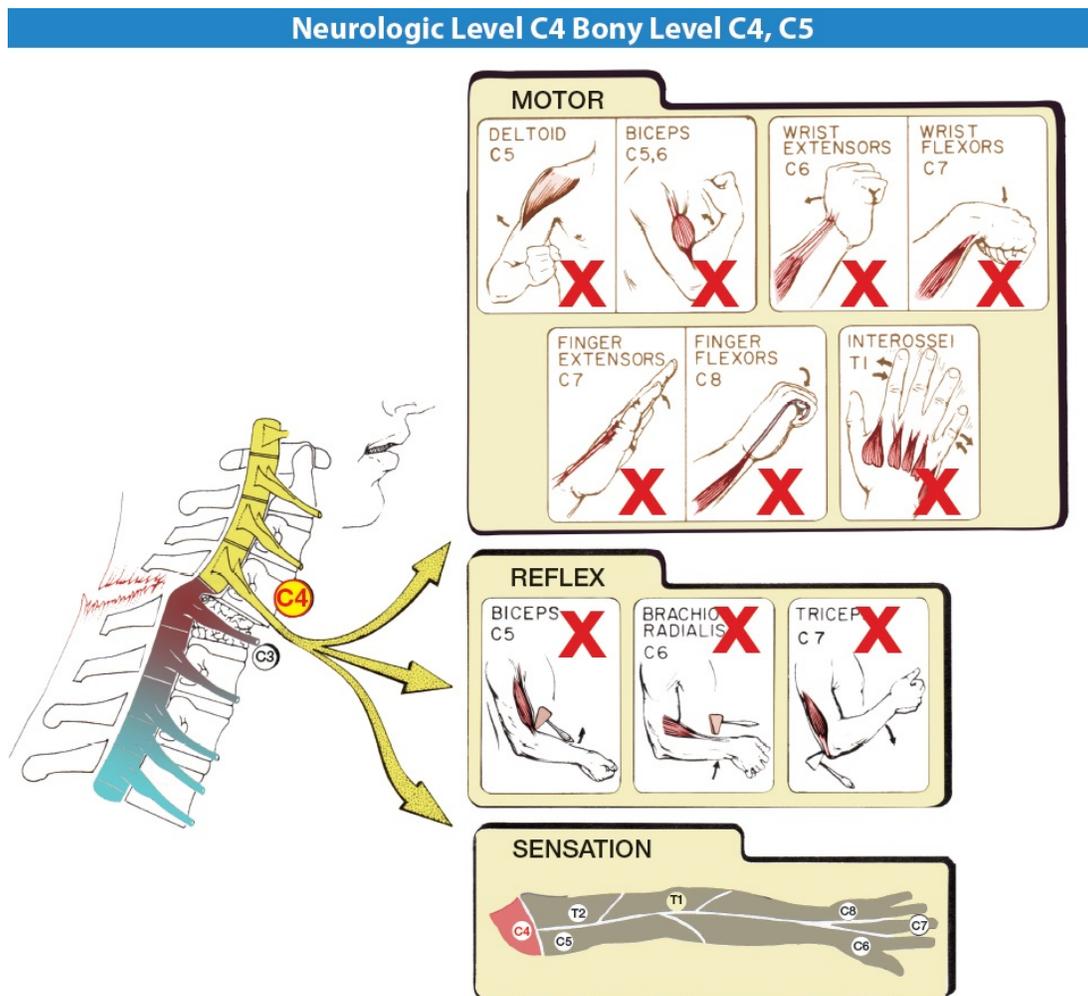

FIGURE 3-2 Tetraplegia: neurologic level C4.

Motor Function

The muscles of the upper extremity are nonfunctional. Because C4 is intact, the patient can breathe independently and shrug the shoulder. But the lack of functioning intercostal and abdominal muscles keeps the patient's respiratory reserve low, although probably adequate for the reduced level of function.

Sensation is present on the upper anterior chest wall, but not in the upper extremities.

Reflexes

Initially, all deep tendon reflexes are absent, but the passing of spinal shock may

bring changes.

Neurologic Level C5 (C5 Intact)

A lesion at this level leaves C5 intact. Because this is the first cord level to contribute to the formation of the brachial plexus, the upper extremity will have some function (Fig. 3-3).

Motor Function

The deltoid muscle and a portion of the biceps muscle are functioning. The patient is able to perform shoulder abduction, flexion, and extension, as well as some elbow flexion. However, all these motions are weakened because the muscles governing these movements usually have contributions from the C6 nerve root. The patients cannot propel a wheelchair by themselves and their respiratory reserve is low.

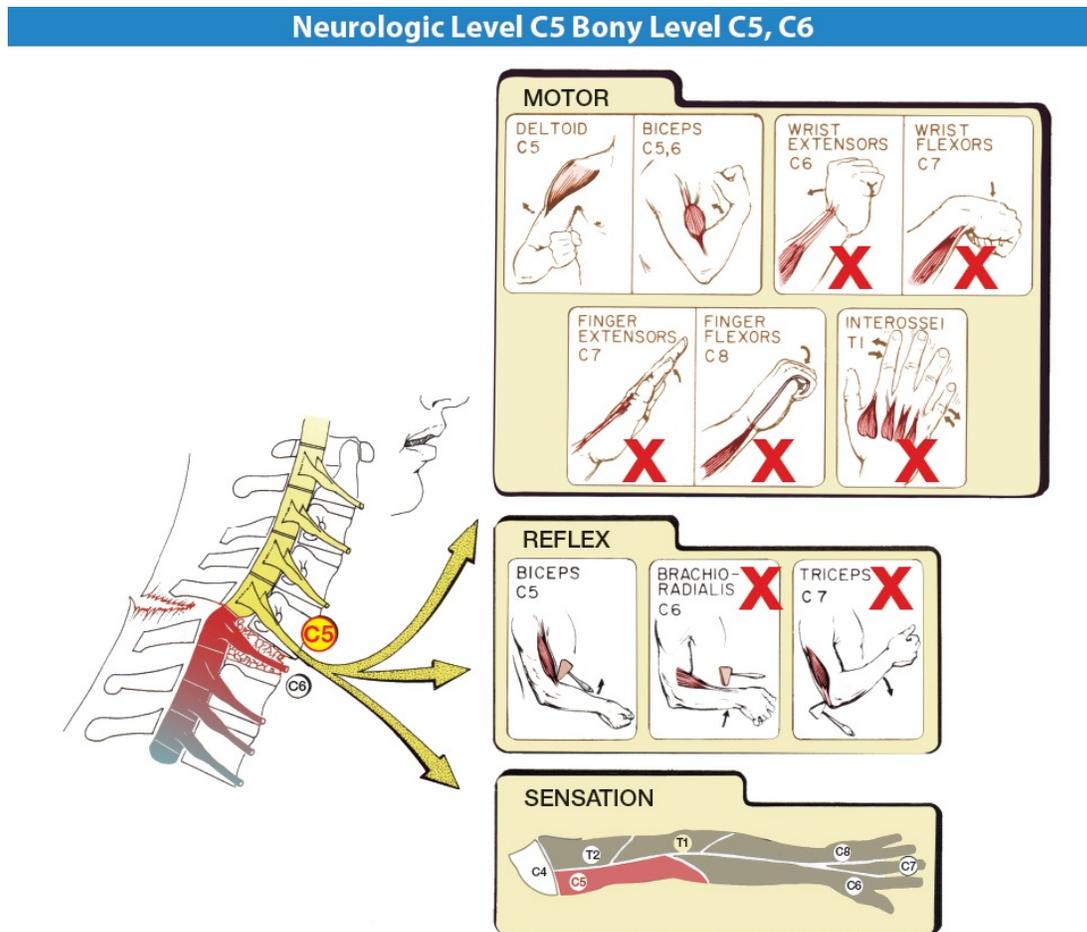

FIGURE 3-3 Tetraplegia: neurologic level C5.

Sensation is normal over the upper portion of the anterior chest and in the lateral aspect of the arm from the shoulder to the elbow crease.

Reflexes

Because the biceps reflex is primarily mediated through C5, it may be normal or slightly decreased. As spinal shock wears off and elements of C6 return, the reflex may become brisk.

Neurologic Level C6 (C6 Intact)

Involvement is at skeletal level C6-C7 (Fig. 3-4).

Motor Function

Because both C5 and C6 are intact, the biceps and the rotator cuff muscles function. The most distal functional muscle group is the wrist extensor group; the extensor carpi radialis longus and brevis (C6) are both innervated (although the extensor carpi ulnaris—C7—is still involved). The patient has almost full function of the shoulder, full flexion of the elbow, full supination and partial pronation of the forearm, and partial extension of the wrist. The strength of wrist extension is normal, because power for extension is predominantly supplied by the extensor carpi radialis longus and brevis.
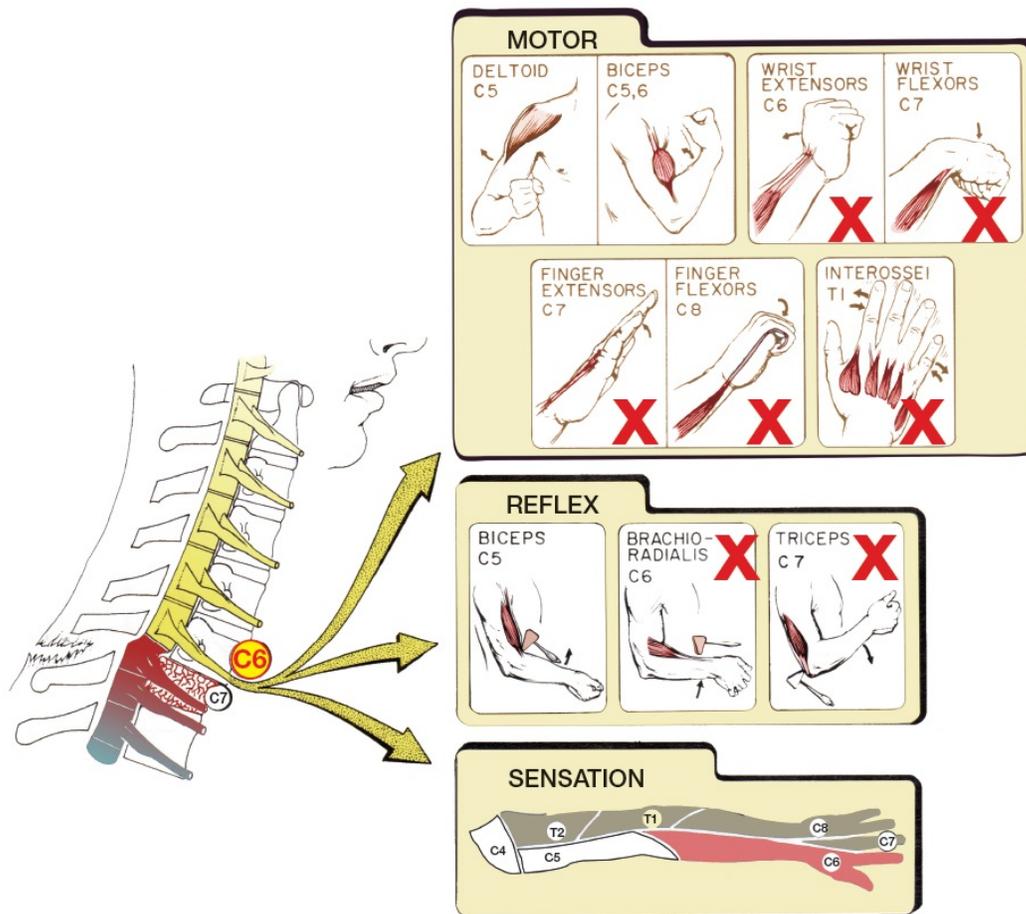

FIGURE 3-4 Tetraplegia: neurologic level C6.

Respiratory reserve is still low. The patient is confined to a wheelchair, which can be propelled over smooth, level surfaces.

Sensation

The lateral side of the entire upper extremity, as well as the thumb, the index, and half of the middle finger, has a normal sensory supply.

Reflexes

Both the biceps and the brachioradialis reflexes are normal.

Neurologic Level C7 (C7 Intact)

Involvement is at vertebral level C7-T1 (Fig. 3-5).

Motor Function

With the C7 nerve root intact, the triceps, the wrist flexors, and the long finger extensors are functional. The patient can hold objects, but grasp is extremely weak. Although he is still confined to a wheelchair, the patient may begin to attempt parallel bar and brace ambulation for general exercise.

Sensation

C7 has little pure sensory representation in the upper extremity. No precise zone for C7 sensation has been mapped.

Reflexes

The biceps (C5), brachioradialis (C6), and triceps (C7) reflexes are normal.
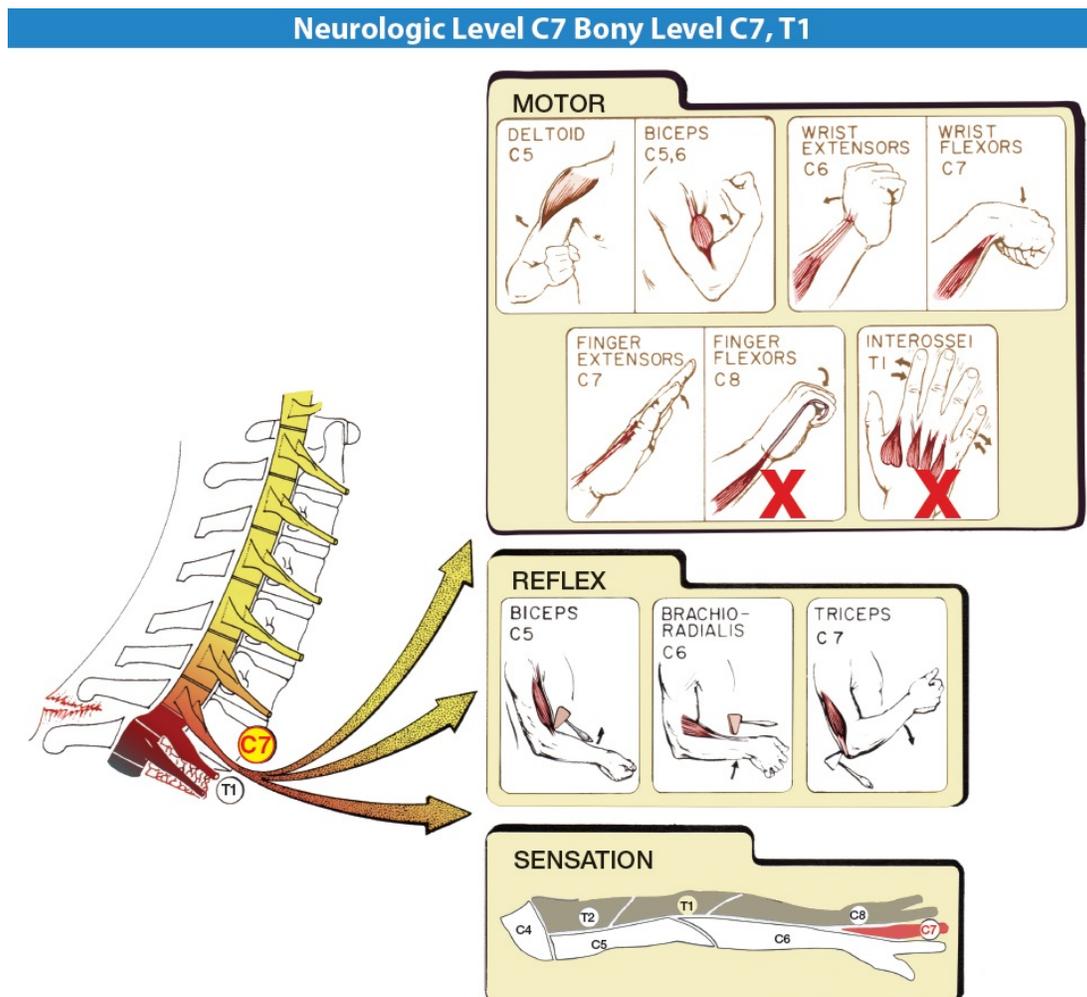

FIGURE 3-5 Tetraplegia: neurologic level C7.

Neurologic Level C8 (C8 Intact)

Involvement is at skeletal level T1-T2 (Fig. 3-6).

Motor Function

The upper extremity is normal, except for the intrinsics of the hand. Thus, all upper extremity motions except finger abduction, finger adduction, and the pinch mechanism of the thumb, index, and middle fingers are intact. Grasp is difficult, because the hand is intrinsic minus or clawed.

Sensation

The lateral aspect of the upper extremity and the entire hand has normal sensory awareness. Sensation on the medial side of the forearm is normal to several inches below the elbow.

Reflexes

All upper extremity reflexes are intact.

Neurologic Level T1 (T1 Intact)

Involvement occurs at skeletal level T2-T3.

Motor Function

Involvement at neurologic level T1 results in paraplegia. The upper extremity is fully functional. The brachial plexus' neurologic supply (C5-T1) is intact, whereas the lower extremities are partially or wholly paralyzed, depending on the degree of cord damage at that level. The patient can ambulate in a variety of ways with correct bracing, but a wheelchair is still the most practical means of moving about. A T1 paraplegic can drag-to with crutches and bracing but he cannot assume the erect position without some help. Trunk stability is absent, and the energy cost of ambulation is markedly increased. Therefore, ambulation is not functional, but is useful as exercise.

SENSATION

FIGURE 3-6 Tetraplegia: neurologic level C8.

Sensation

The anterior chest wall as low as the nipple and the entire upper extremity have normal sensation.

Reflexes

The reflexes in the upper extremity are normal.

Upper Motor Neuron Reflexes

Pathologic reflexes appear in the upper and lower extremities in association with tetraplegia. Hoffmann's sign can be elicited in the upper extremity and, if present, is an indication of an upper motor neuron lesion and can be elicited in

the upper extremity.

To test for Hoffmann's sign, nip the nail of the middle finger. Normally there should be no reaction at all. A positive reaction produces flexion of the terminal phalanx of the thumb and of the second and third phalanx of another finger (Fig. 3-7).

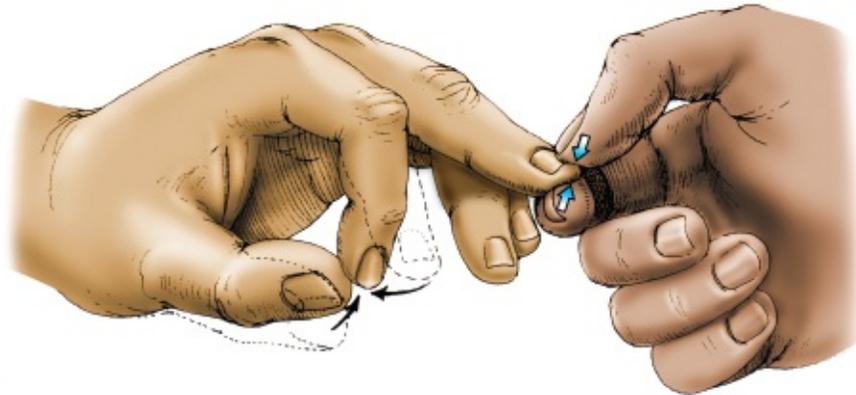

FIGURE 3-7 Hoffmann's sign, indicating an upper motor neuron lesion.

Clinical Application

Fractures and Dislocations of the Cervical Spine

Injuries to the cervical spine are a major cause of tetraplegia. The types of injury include flexion injuries (compression fractures), hyperextension injuries, and flexion-rotation injuries (cervical facet dislocations).

On occasion, the neurologic level involved does not correspond to the skeletal level. Thus, in a fracture-dislocation of the 5th and 6th cervical vertebrae, the C6 neurologic level may remain functional. Each patient must be evaluated on an individual basis.

Fracture of C1

The C1 or Jefferson fracture is a bursting fracture of the ring of C1, which usually decompresses the cord. The fracture commonly results from a fall, with the patient landing on the head. If the patient survives, there are usually no permanent neurologic findings (Figs. 3-8 and 3-9).
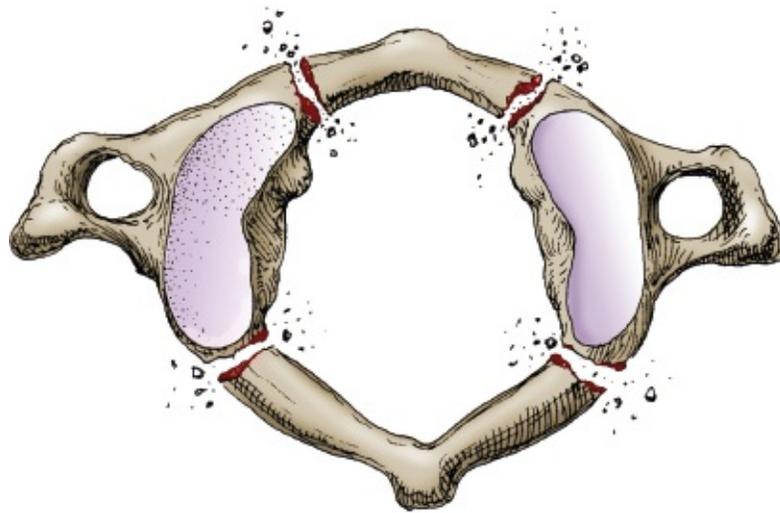

FIGURE 3-8 Jefferson fracture, a bursting fracture of the ring of C1.

FIGURE 3-9 Jefferson fracture.

Fracture of C2

The C2 or hangman's fracture is a bursting fracture that separates the body of C2 from its posterior elements, thereby decompressing the cord. If the patient survives, there are usually only transient neurologic findings (Figs. 3-10 and 3-11).

Odontoid Fracture

A fracture at the base of the odontoid commonly results from trauma. The patient usually survives. There may be transient neurologic findings, but without the establishment of the involvement of a specific neurologic level. On occasion, if the trauma is severe enough, the patient dies. However, there is usually enough space in the cervical canal to allow for partial displacement of the odontoid (Figs. 3-12 and 3-13).
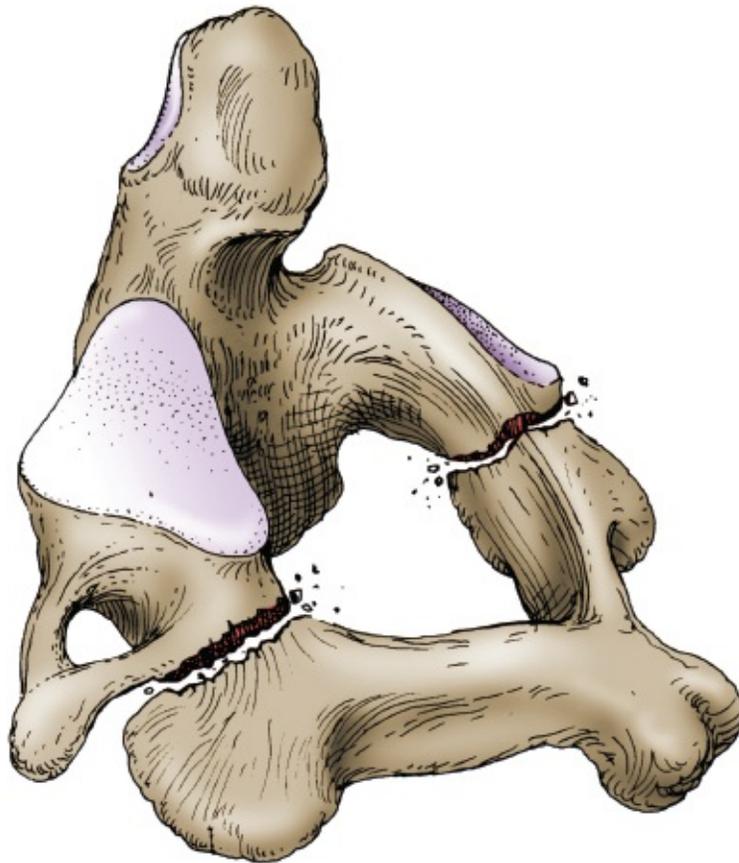

FIGURE 3-10 Hangman's fracture, a fracture that separates the body of C2 from its posterior elements.

Fractures of C3-C7

Compression fractures are caused by hyperflexion injuries of the neck when a

vertical force ruptures the end plates of the vertebra and shatters the body. This bursting fracture occurs in both the cervical and lumbar spines and may involve both the nerve root and the cord itself (Fig. 3-14). A compression fracture of the C5 vertebra, the most common fracture of the cervical spine, involves most of the brachial plexus and may result in tetraplegia. Compression fractures are easy to diagnose on x-ray (Fig. 3-15).

FIGURE 3-11 Hangman's fracture.

Hyperextension injuries of the neck are caused by hyperextension forces, such as the acceleration injury caused by a rear-end automobile collision. A hyperextension injury is essentially a soft tissue injury, unlike a compression injury, which fractures the body of the vertebra; the anterior longitudinal

ligament is usually ruptured and the cord may well become involved. Because it is a soft tissue injury, the hyperextension injury may not be obvious on x-ray (Fig. 3-16).

Cervical facet joint dislocations are flexion-rotation injuries that may cause neurologic problems. A unilateral facet dislocation produces some narrowing of the spinal canal and neural foramen. Because a unilateral facet dislocation usually results in less than 50 percent anterior dislocation of the vertebral body, approximately 75 percent of cases have no neurologic involvement, because the narrowing is not sufficient to affect the cord (Figs. 3-17 to 3-20).

Bilateral facet dislocations produce far greater narrowing of the spinal canal than unilateral dislocations because, with both facets dislocated, there is usually greater than 50 percent anterior dislocation of the vertebral body. Because of this greater degree of dislocation, approximately 85 percent of patients suffer neurologic lesions. Because the cervical spine depends primarily on ligaments for its stability, bilateral facet dislocations, which cause the ligaments to tear, rarely heal with sufficient strength to reinstate spinal stability; unless appropriate treatment is undertaken, there is a risk of further damage secondary to any number of possible accidents. Bilateral dislocations may occur at any level, but they are most common at C5-C6, the level around which the most movement takes place (except for the specialized articulation at C1-C2) (Figs. 3-21 and 3-22).

FIGURE 3-13 Odontoid fracture.
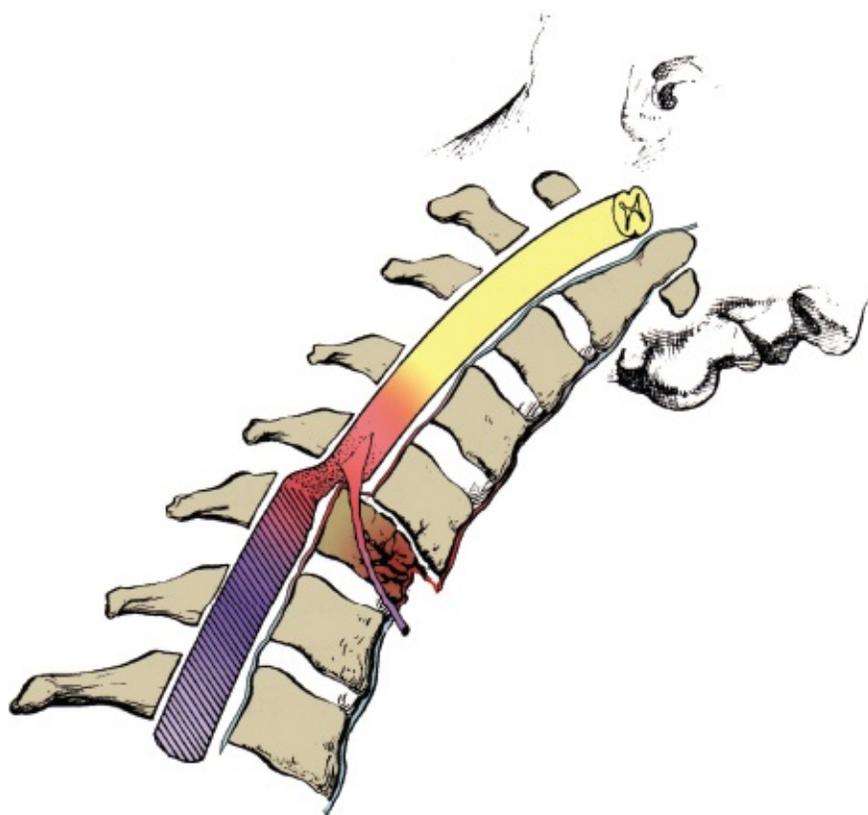

FIGURE 3-14 Cervical compression fracture, caused by hyperflexion of the neck.
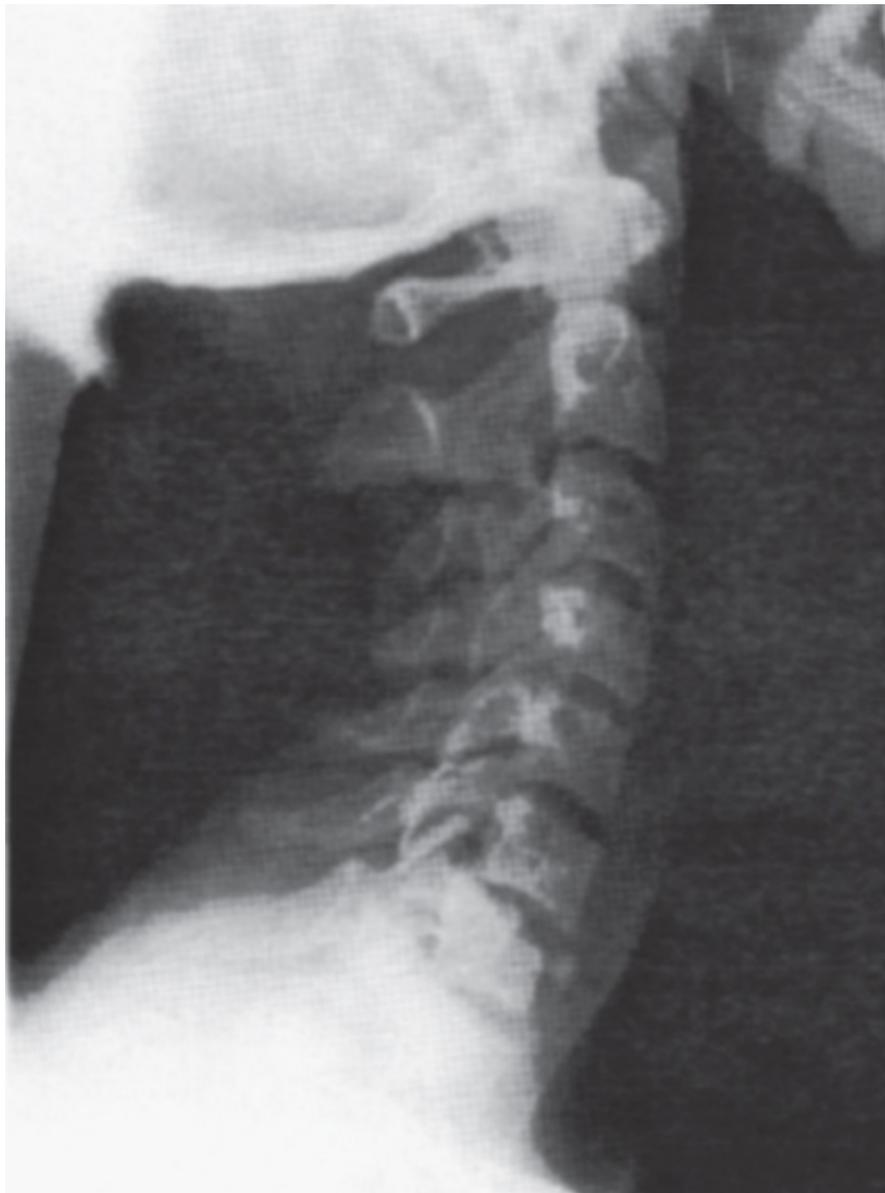

FIGURE 3-15 Cervical spine compression fracture.

Activities of Daily Living

Respiration

From this description of cord lesions, it should be apparent that a complete transection of the cord at neurologic level C3 or higher is incompatible with life,

unless the patient is permanently ventilated. Involvement at neurologic levels C4 to C5 may cause degrees of respiratory insufficiency that may threaten life in the presence of relatively mild pulmonary disease.
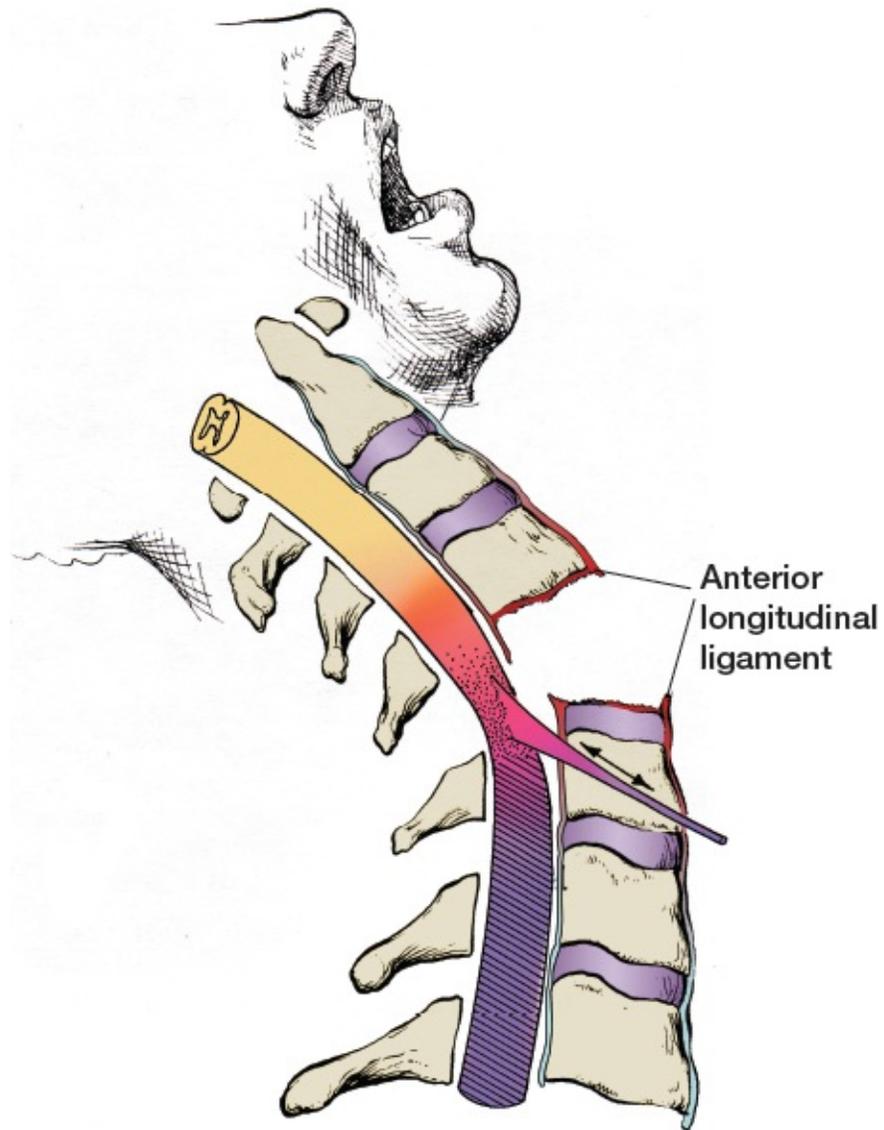

FIGURE 3-16 Hyperextension injury of the cervical spine.
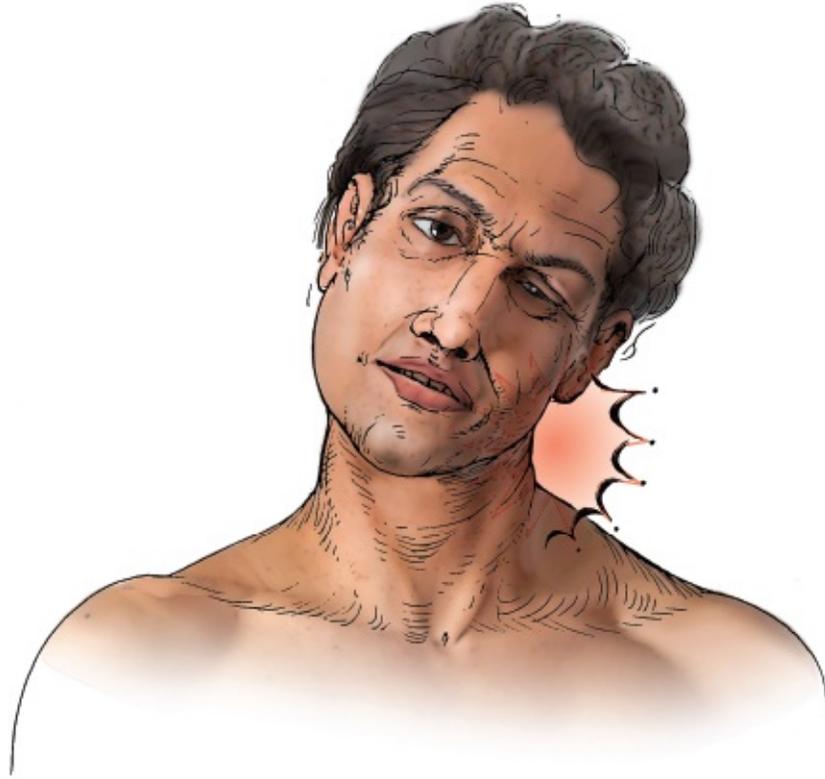

FIGURE 3-17 Pain associated with facet joint dislocation.

FIGURE 3-18 Unilateral facet joint dislocation. (Hoppenfeld, S.: *Physical Examination of the Spine and Extremities*. Norwalk, CT: Appleton-Century-Crofts, 1976.)

Wheelchair

C6 is the highest neurologic level that leaves sufficient innervation of the upper extremity to permit independent manipulation of a wheelchair. However, independent transfer into and out of the wheelchair is still difficult because of the lack of function of the triceps muscle. An active triceps is needed to help lift the body for transfer.

Crutches

Complete cord lesions at neurologic level C8 and above are incompatible with

the use of crutches because the intrinsic muscles of the hand, needed for strong grip on the crutches, are nonfunctioning. Functional walking with crutches is made more difficult both because of the need to expend two to four times more energy than in normal ambulation and because of a decreased respiratory reserve. Attempts to encourage walking with braces and other supports are also rarely successful.
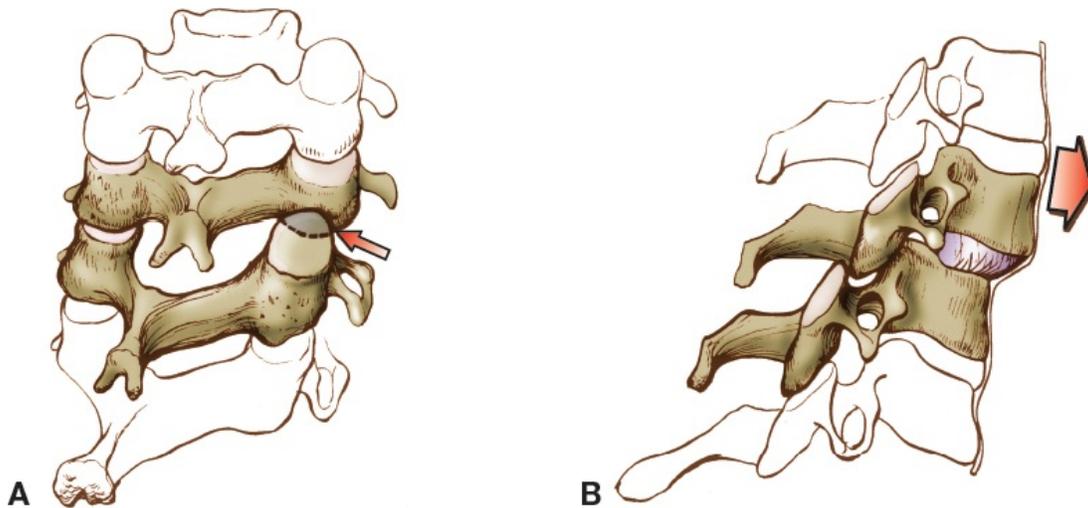

FIGURE 3-19 A, B In a unilateral facet joint dislocation, there is less than 50 percent anterior dislocation of the vertebral body.

Note that this is true of complete cord lesions; partial cord lesions show varying patterns of neurologic deficiency. Each patient must be assessed as an individual (Fig. 3-23).

FIGURE 3-20 Unilateral facet joint dislocation. Grade I anterior dislocation of the vertebral body.

Herniated Cervical Disks

Although herniated cervical disks often cause neurologic root involvement, the cervical canal is sufficiently large to accommodate the herniated disk without significant cord damage, and tetraplegia rarely occurs. However, minor degrees of cord damage—upper motor neuron lesions—may result from a large midline herniation. They are usually first recognized as a diminution in sensation of position and vibration in the lower extremities. In more advanced cases, there may be actual muscle weakness and an increase in the deep tendon reflexes, as well as early bladder symptoms.
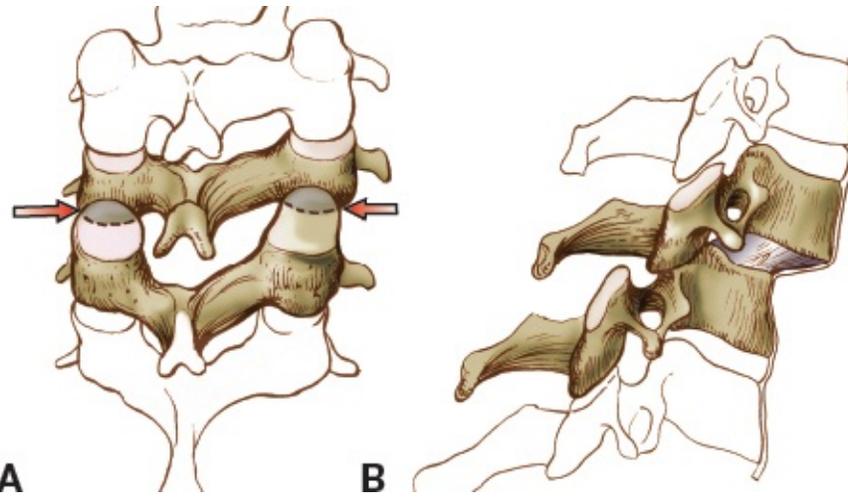

FIGURE 3-21 A, B Bilateral facet joint dislocation, resulting in greater than 50 percent anterior dislocation of the vertebral body.

FIGURE 3-22 Bilateral facet joint dislocation. Grade III anterior dislocation of the vertebral body.

Tumors of the Cervical Spine

Tumors of the cervical cord are space-occupying lesions. They may present as local pain in the spine, and may also radiate pain to the extremities. The anatomic location of the tumor can usually be ascertained by a neurologic evaluation of the extremity. For example, a tumor of the cervical cord involving the C6-C7 neurologic segment may cause anesthesia of the middle finger, an absence of the triceps reflex, and weakness of finger extension and wrist flexion. Primary tumors of the cord rarely give precise neurologic levels of involvement.

Metastatic tumors in the vertebrae of the cervical spine are not uncommon.

Primary breast and lung tumors frequently metastasize to the spine. As bone is destroyed, vertebral collapse and angulation take place and tetraplegia occurs. The neurologic level of involvement usually correlates with the x-ray findings.

Tuberculosis of the Spine

Tuberculosis of the spine causes gibbus formation through the destruction of bone. The spinal angulation may ultimately cause cord compression and tetraplegia, but the process is far slower than that of trauma. Frequently, neurologic recovery occurs after surgical decompression and chemotherapy.

Transverse Myelitis

Transverse myelitis refers to an inflammatory process in which a spinal cord lesion extending horizontally across the cord is limited longitudinally to one or, at most, a few spinal segments. Ascending myelitis occurs when the lesion spreads proximally.
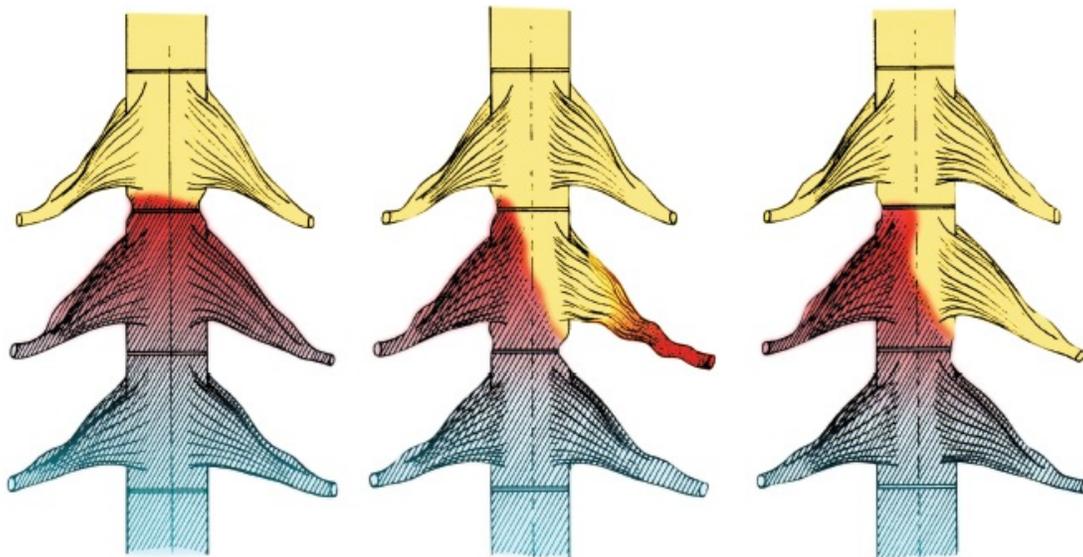

FIGURE 3-23 The findings resulting from a complete lesion depend on the anatomic configuration of the destruction of neural tissue at a particular level.

Transverse myelitis may occur spontaneously and rapidly following a vaccination, an infectious illness, or trauma. Although sensory and motor loss occurs below the lesion, complete anesthesia is rare. Flaccid paralysis occurs initially, but quickly reverts to spastic paralysis.

The neurologic level of involvement can usually be delineated by neurologic level testing of sensation, motor power, and reflexes. The highest level of sensory loss usually corresponds to the segmental site of the cord lesion.

4

Spinal Cord Lesions Below T1, Including the Cauda Equina

Paraplegia

Paraplegia is the complete or partial paralysis of the lower extremities and lower portion of the body. It is most frequently caused by traumatic injury to the spine, but may also derive from various diseases such as transverse myelitis, cystic lesions of the cord, and Pott's paraplegia (caused by tuberculosis), as well as a host of other pathologies. It occurs rarely from surgical correction of such thoracic problems as scoliosis, as a result of the loss of the appropriate blood supply to the spinal cord, and from the excision of a herniated thoracic disk.

The cauda equina comprises the roots of all spinal nerves below the first lumbar vertebra. Cauda equina is a descriptive Latin term because the nerves resemble a horse's tail, and rarely result in full paralysis of the lower extremities

The following descriptions assume that a complete lesion exists. Often, however, lesions are incomplete; the neurologic findings for each individual patient must be carefully determined, for involvement may vary considerably.

Neurologic Levels T1-T12

The level of neurologic involvement can be determined by tests of motor power and sensation. The latter is easier and more accurate.

Muscle Function

The intercostal muscles, as well as the abdominal and paraspinal muscles, are segmentally innervated. Intercostal motion during breathing implies neurologic integrity; a lack of motion implies involvement. The abdominal and paraspinal

muscles can be similarly evaluated, for they are both segmentally innervated by T7-T12 (L1). To test for the integrity of their innervation, have the patient do a half sit-up as you palpate the anterior abdominal wall. As the patient sits up, note whether the umbilicus is pulled toward any of the four quadrants of the abdomen. If the umbilicus is pulled in one direction, the opposing flaccid muscles are denervated (Beevor's sign) (Fig. 2-1). Note that the umbilicus is the dividing line between T10 above and T11 below. Obviously, this test should not be performed during the acute stages of thoracic lesions or with patients who have unstable spines.

Sensation

Sensory innervation may be determined in accordance with the chart (Fig. 4-1). Special skin landmarks that mark sensory areas are as follows:
1. Nipple line—T4
2. Xiphoid process—T7
3. Umbilicus—T10
4. Groin—T12

L1 Neurologic Level (L1 Intact)

Muscle Function

There is complete paralysis of the lower extremities, with the exception of some hip flexion from partial innervation of the iliopsoas (T12, L1-L3) (Fig. 4-2).

Sensation

There is no sensation below the L1 sensory band, which extends over the proximal third of the anterior aspect of the thigh.

Reflexes

The patellar and Achilles tendon reflexes are absent when spinal shock is present. As spinal shock wears off, the reflexes become exaggerated.

Bladder and Bowel Function

The bladder (S2-S4) does not function. The patient cannot urinate in a stream. The anus is initially patulous, and the superficial anal reflex (S2-S4) is absent.

As spinal shock wears off, the anal sphincter contracts and the anal reflex becomes hyperactive.
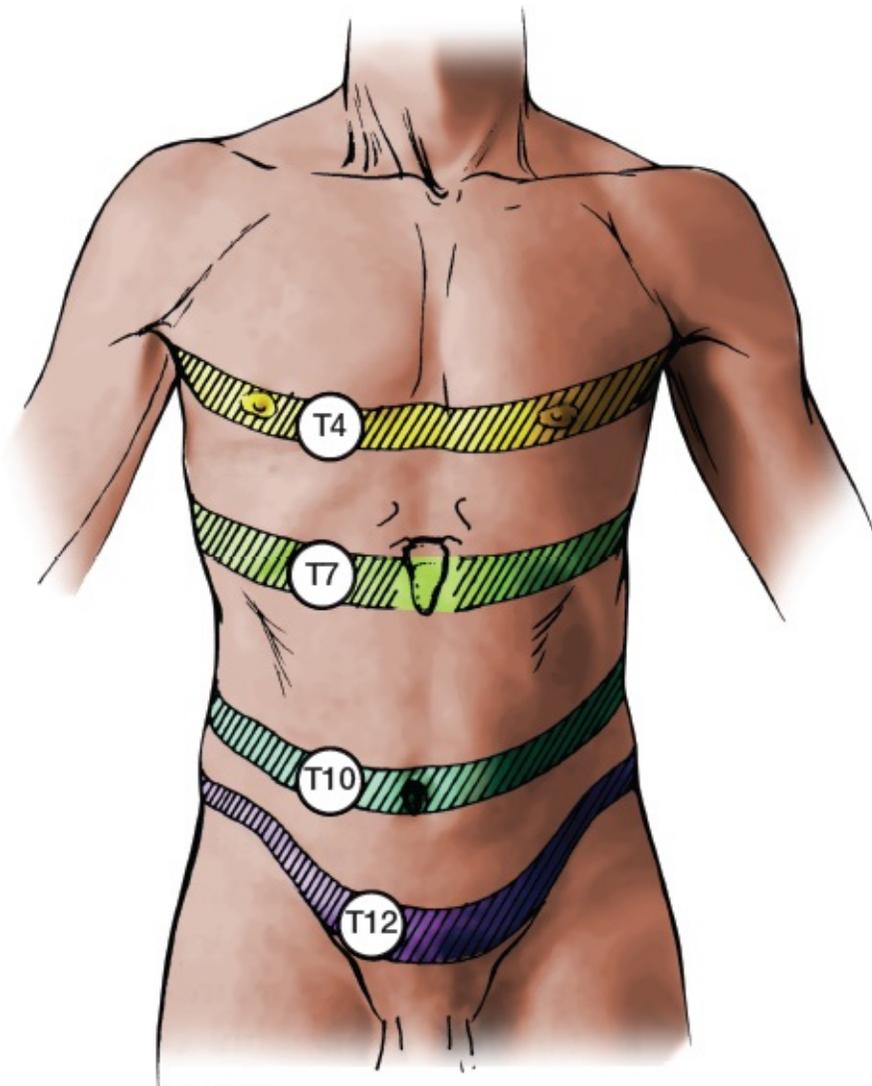

FIGURE 4-1 Sensory dermatomes of the trunk.

L2 Neurologic Level (L2 Intact)

Muscle Function

There is good power in hip flexion because the iliopsoas is almost completely innervated. The adductor muscles are partially innervated (L2-L4) and show diminished power. Although the quadriceps (L2-L4) are partially innervated, there is no clinically significant function. No other muscles in the lower extremity have innervation, and the unopposed action of the iliopsoas and

adductors tends to produce a flexion and slight adduction deformity.

Sensation

There is no sensation below the L2 sensory band, which ends two-thirds of the way down the thigh.

Reflexes

The patellar reflex receives innervation from L2 to L4, but the L2 contribution is small.

Bladder and Bowel Function

There is no voluntary control.

L3 Neurologic Level (L3 Intact)

Muscle Function

In addition to the iliopsoas and adductors, the quadriceps (L2-L4), although slightly weak, show significant power. No other muscle groups are functioning. Thus, the hip tends to become flexed, adducted, and externally rotated while the knee remains extended.

Sensation

Sensation is normal to the level of the knee (L3 dermatome band).

Reflexes

The patellar reflex (L2-L4) is present, but decreased. The Achilles tendon reflex is absent.

Bladder and Bowel Function

There is no voluntary control.

L4 Neurologic Level (L4 Intact)

Muscle Function

Muscle function at the hip and knee is the same as in L3 neurologic lesions except that quadriceps function is now normal. The only functioning muscle below the knee is the tibialis anterior (L4), which causes the foot to dorsiflex and invert.
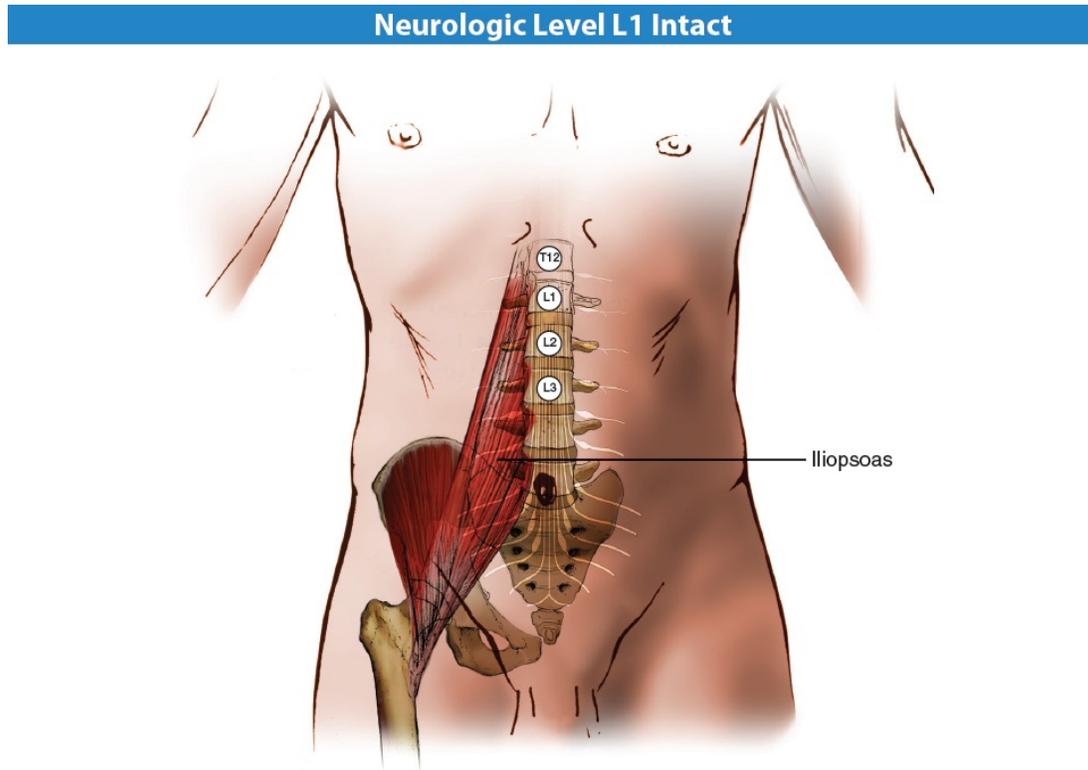

FIGURE 4-2 Innervation of the iliopsoas T12-L3.

Sensation

In addition to the entire thigh, the medial side of the tibia and foot has sensation.

Reflexes

The patellar reflex (predominantly L4) is normal; the Achilles tendon reflex (S1) is still absent.

Bladder and Bowel Function

There is no voluntary control of either function.

L5 Neurologic Level (L5 Intact)

Muscle Function

The hip still has a flexion deformity, because the gluteus maximus does not function. Innervation of the gluteus maximus is derived from L5, S1 and S2. The gluteus medius (L1-S1) has partial function; it counteracts the action of the adductors. The quadriceps are normal.

The knee flexors function partially with the medial hamstrings (L5) present and the lateral hamstrings (S1) absent.

The foot dorsiflexors and invertors function. Because the plantar flexors and evertors are still absent, the foot tends to develop a calcaneus (dorsiflexion) deformity.

Sensation

Sensation is normal in the lower extremity, with the exception of the lateral side and plantar surface of the foot.

Reflexes

The patellar reflex is normal. The Achilles tendon reflex is still absent.

Bladder and Bowel Function

There is no voluntary control of either function.

S1 Neurologic Level (S1 Intact)

Muscle Function

The hip muscles are normal, with the exception of slight gluteus maximus weakness. The knee muscles are normal. The soleus and gastrocnemius (S1, S2) are weak, and the toes show clawing as a result of intrinsic muscle weakness (S2, S3).

Sensation

Sensation in the lower extremity is normal. There is perianal anesthesia.

Reflexes

The patellar and Achilles tendon reflexes are normal, because the S2 contribution to the Achilles tendon reflex is small.

Bladder and Bowel Function

There is still no voluntary control of either function.

Upper Motor Neuron Reflexes

Pathologic Reflexes

Pathologic reflexes can be elicited in the lower extremities in association with paraplegia. Babinski's sign and Oppenheim's sign are two pathologic reflexes that indicate an upper motor neuron lesion.

Babinski's Sign

Elicit the plantar response by running a sharp instrument across the plantar surface of the foot, and along the calcaneus and lateral border of the forefoot. Normally, in a negative reaction, the toes plantarflex. A positive reaction (Babinski's sign) occurs when the great toe extends as the other toes splay (Fig. 4-3). This sign indicates an upper motor neuron lesion—a corticospinal tract involvement. To ascertain the level of the lesion, correlate this sign with other neurologic findings. In young infants, the presence of Babinski's sign is normal rather than pathologic. However, this response should disappear by 12 to 18 months of age.

Oppenheim's Sign

To elicit Oppenheim's sign, run your finger along the crest of the tibia. Normally there should be no reaction at all, or the patient should complain of pain. Under abnormal circumstances, the reaction is the same as it is in plantar stimulation: the great toe extends as the other toes splay (Oppenheim's sign) (Fig. 4-4). Oppenheim's sign is not as reliable as Babinski's sign and should be used as a confirmation of a positive Babinski's sign.

FIGURE 4-3 Babinski's sign.

Normal Superficial Reflex

Cremasteric

The lack of the cremasteric reflex may be due either to the loss of the reflex arc or to an upper motor neuron lesion. However, absence of the reflex in association with the presence of a pathologic reflex (Babinski's or Oppenheim's signs) supports the diagnosis of an upper motor neuron lesion.
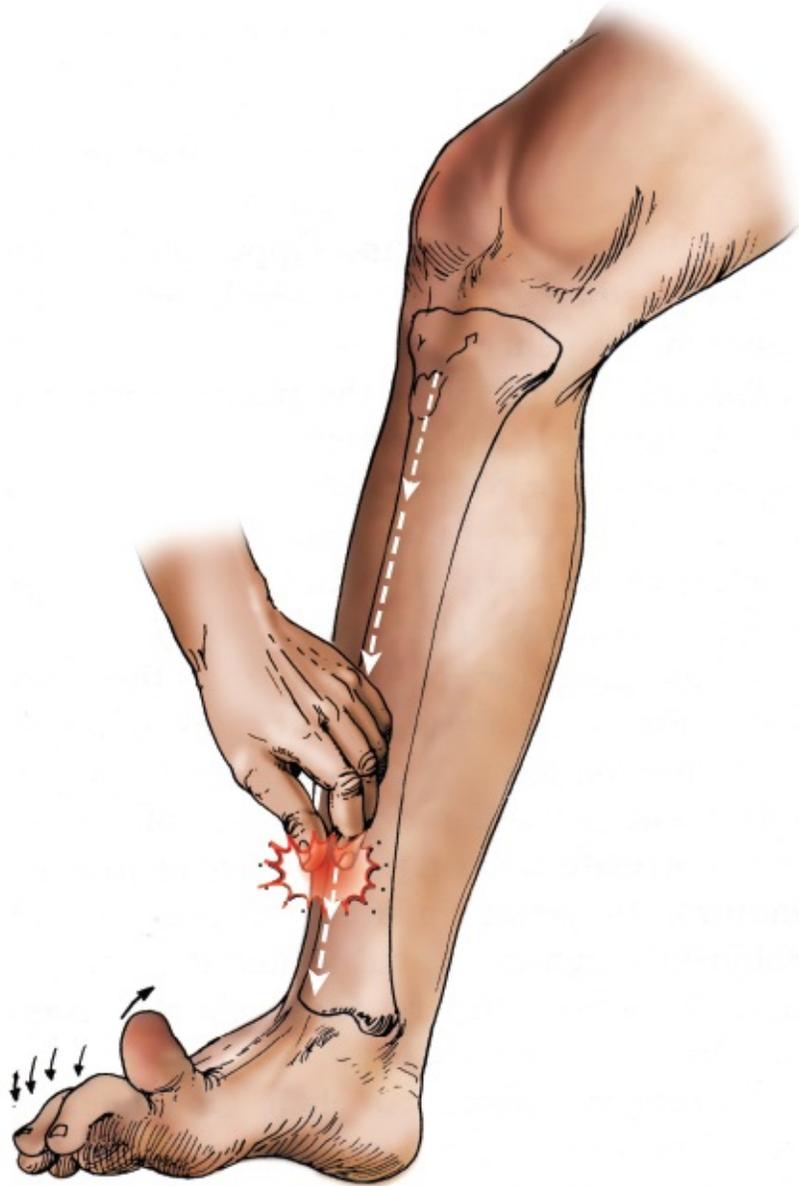

FIGURE 4-4 Oppenheim's sign.
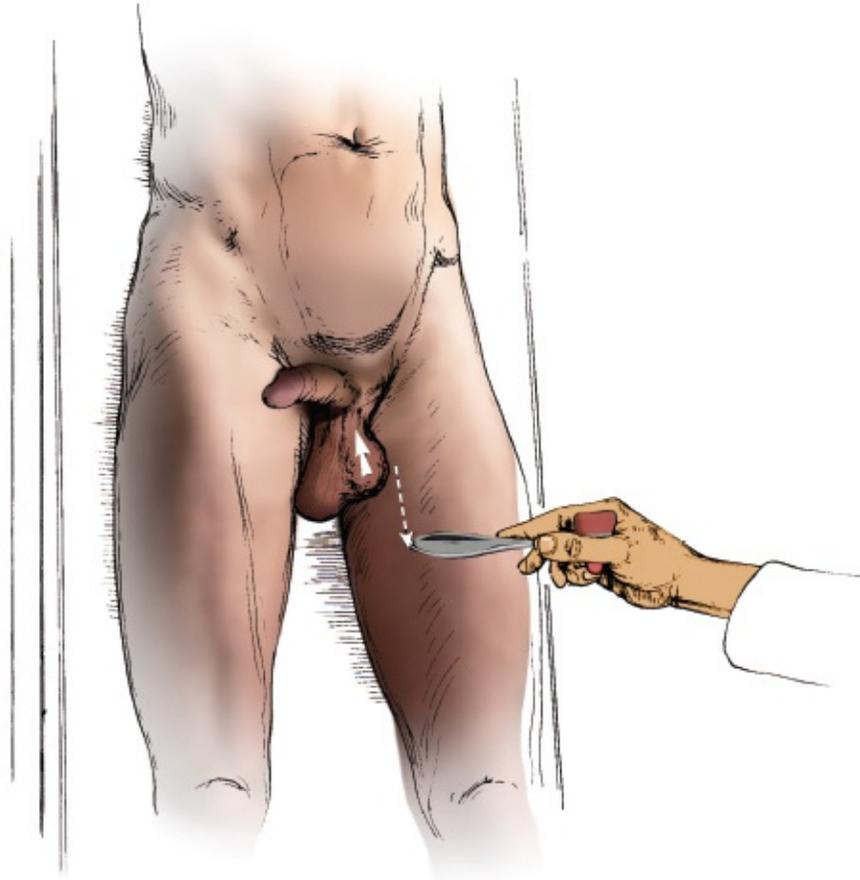

FIGURE 4-5 The cremasteric reflex. (Hoppenfeld, S.: *Physical Examination of the Spine and Extremities*. Norwalk, CT: Appleton-Century-Crofts, 1976.)

To elicit the superficial cremasteric reflex, stroke the inner side of the upper thigh with the sharp end of a neurologic hammer. If the reflex is intact, the scrotal sac on that side will be pulled upward as the cremaster muscle (T12) contracts. If the cremasteric reflex is unilaterally absent, there is probably a lower motor neuron lesion between L1 and L2 (Fig. 4-5).

Clinical Application

Further Evaluation of Spinal Cord Injuries

Complete or Incomplete Lesion

The possibility of cord return, and whatever partial functional recovery it may provide, depends on whether the lesion is complete or incomplete, whether the cord is completely severed or only partially severed or contused. Injuries in which no function returns over a 24-hour period are assumed to be complete lesions, where no return of cord function will occur. A complete neurologic examination is needed to confirm such a diagnosis. If, however, there is partial return of function in the initial period, the lesion is probably incomplete, and more function may eventually return. Function must return at more than one neurologic level to support such a diagnosis, however, because return at only one level may simply indicate that the nerve root at the level of the lesion has been partially damaged or contused. Such single-level return gives no indication as to whether the lesion below it is complete or incomplete. The recovery of this single nerve root is considered to be a root lesion (rather than a cord lesion) of the root originating just proximal to the injured portion of the cord. Functional return of muscle strength from such an injury may occur at any time; prognostication for root return is good as late as six months after the initial injury.

Sacral Sparing

The best indicator of the possibility of cord return is sacral sparing, in which the sacral nerves are partially or wholly spared injury because of their location on the periphery of the cord. Evidence of sacral sparing is evidence of an incomplete lesion. It enhances the possibility of partial or complete return of motor power as well as of bladder and bowel function.

Sacral sparing can be evaluated through three tests of motor, sensory, and reflex innervation:
1. Muscle testing of flexion of the great toe (S1 innervation)
2. Sensory testing of the perianal area (S2-S4)
3. Reflex testing of the anal sphincter muscle (S2-S4)

Because the bladder and bowel are innervated by the sacral nerves (S2-S4), testing of these three areas gives a valid indication of the degree of sacral sparing and the possibility of return of function (Fig. 4-6).

Flaccidity and Spasticity

Immediately after any trauma causing tetraplegia or paraplegia, the spinal cord experiences spinal shock, resulting in the loss of reflexes innervated by the portion of the cord below the site of the lesion. The direct result of spinal shock

is that all the muscles innervated by the traumatized portion of the cord and the portion below the lesion, as well as the bladder, become *flaccid*. Spinal shock wears off between 24 hours and three months after injury, and *spasticity* may replace flaccidity in some or all of these muscles. Spasticity occurs because the reflex arc to the muscle remains anatomically intact despite the loss of cerebral innervation and control via the long tracts. During spinal shock, the arc does not function; as the spine recovers from shock, the reflex arc begins functioning without the inhibitory or regulatory impulses from the brain, creating local spasticity and clonus. Initially absent deep tendon reflexes may therefore become hyperactive as spinal shock ends. Such spasticity may be useful in increasing function by, for example, assisting in emptying the bladder and bowel.
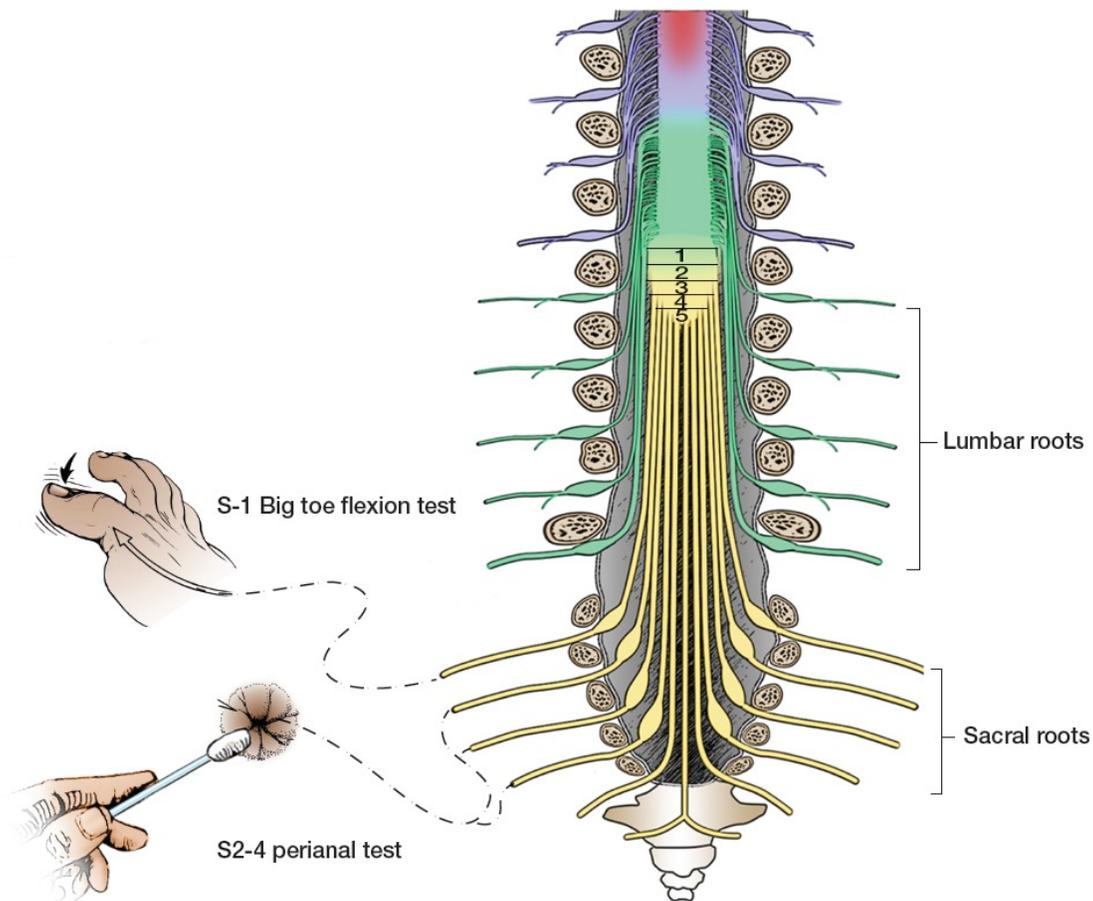

FIGURE 4-6 Sacral sparing.

Prognostication of Ambulatory Function

Thoracic lesions, if they are complete, create similar problems regardless of the

level of involvement. Because the thoracic cord does not supply innervation to any extremity, a complete thoracic lesion at any level leaves the patient paraplegic. The major diagnostic consideration in determining the neurologic level is that of sensory innervation to the trunk and, to a lesser extent, innervation of the abdominal musculature. In prognosticating the patient's future performance, it is important to assess the function of the segmentally innervated abdominal and paraspinal muscles that aid in balance for sitting, standing, and walking during rehabilitation.

T1-T8: In general, a paraplegic with a lesion anywhere from T1 to T8 can be independent in all wheelchair activities, whereas the more complex motions, such as getting up from the floor and curb jumping with a wheelchair, are more difficult for those with lesions from T1 to T4.

T6: A T6 paraplegic has complete upper extremity and thoracic musculature, and can stabilize himself against his pectoral girdle.

T9-T12: A paraplegic with a lesion from T9 to T12 can walk independently with long leg braces and crutches.

L1-L3: A paraplegic with a lesion from L1 to L3 and pelvic stability can ambulate with long leg braces and forearm crutches if the patient wishes.

L4-S2: A paraplegic with a lesion from L4 to S2 can exist independent of his wheelchair using short leg braces and forearm crutches. The patient is completely independent in all activities.

Although paraplegia may result from a lesion located anywhere from T1 to L1, the most common site for a lesion is between T12 and L1. The facet joints between T12 and L1 are lumbar in nature and face laterally, whereas those between the other thoracic vertebrae are thoracic in nature, and face vertically (Fig. 4-7). Thus, the angle between the facet joints of T12 and L1 is in the sagittal plane, permitting more flexion than the frontal alignment of the thoracic joints. Many of the other thoracic vertebrae are further limited in their motion by the rib cage. This greater concentration of motion at the T12-L1 articulations leads to a point of stress and a greater potential for fracture and subsequent paraplegia (see Fig. 4-15).

Note that there is very little room in the spinal canal at this level; any vertebral dislocation is almost certain to cause neurologic problems as a result of

direct pressure on the cord. Extreme flexion and rotation is the cause of fracture-dislocation of the thoracic spine, and usually leads to paraplegia.

Prognostication of Bladder and Bowel Function

Restoring useful function to the bladder and bowel and thus a catheter-free state is crucial for tetraplegic and paraplegic patients. A bladder that must be regularly emptied through a catheter is prey to repeated infections and excessive autonomous dysreflexia (resulting from distension of the bladder, among other peripheral stimuli) causing paroxysmal hypertension, bradycardia, and nonthermoregulatory sweating. Evaluating the extent of sacral sparing may give a clue to the possible return of function. Usually, when innervation of the bladder and its central mechanisms is intact, voiding function rapidly returns to normal. If function is only partially disrupted, a residual neurogenic disorder can be restored to useful function fairly quickly by retraining.

Incomplete Lesions: An incomplete lesion may affect the bladder and bowel in various ways. If voluntary flexion of the great toe is present, perianal sensation is intact, and there is voluntary contraction of the anal sphincter muscle, the entire sacral innervation to the bladder and bowel has probably been spared and voluntary bladder and bowel function will return, usually within a few days (Fig. 4-6).
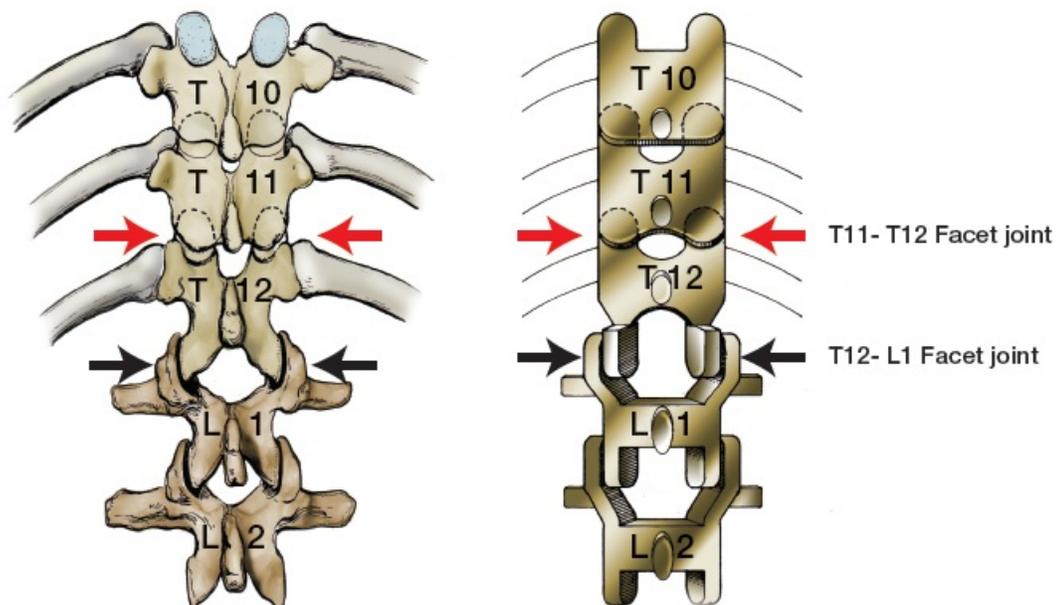

FIGURE 4-7 Differences in facet joint anatomy of the thoracic

and lumbar spines.

If perianal sensation is normal and there is no voluntary contraction of the anal sphincter, the sacral segments may have suffered partial damage (partial sacral sparing); bladder and bowel function may undergo only partial recovery.

Complete Lesion: A complete lesion with no sacral sparing has great influence on bladder and bowel functions. First, voluntary flexion of the great toe, perianal sensation, and voluntary sphincter control are absent, indicating permanent loss of central control of bladder and bowel function. Second, the perianal sphincter reflex (anal wink) and the bulbocavernosus reflex (in which a squeeze of the glans penis stimulates an anal sphincter contraction) (Fig. 4-8) may be present to indicate that reflex innervation of the bladder and bowel is intact. The bladder can be expected to contract on a reflex basis, and the bowel will empty as a result of a reflex induced by fecal bulb or by a rectal glycerin suppository.

It is rare that all reflexes remain absent after the initial period of spinal shock, resulting in an atonic bladder, constipation, and ileus. During the atonic period, the bladder cannot contract by reflex action and must be catheterized or emptied by manual pressure on the lower abdomen. To empty the bowel will require enemas as well as manual evacuation if the stool is inspissated. As the atonic phase passes, the bladder begins to contract reflexly, and the patient can be trained to empty it using its reflex action.
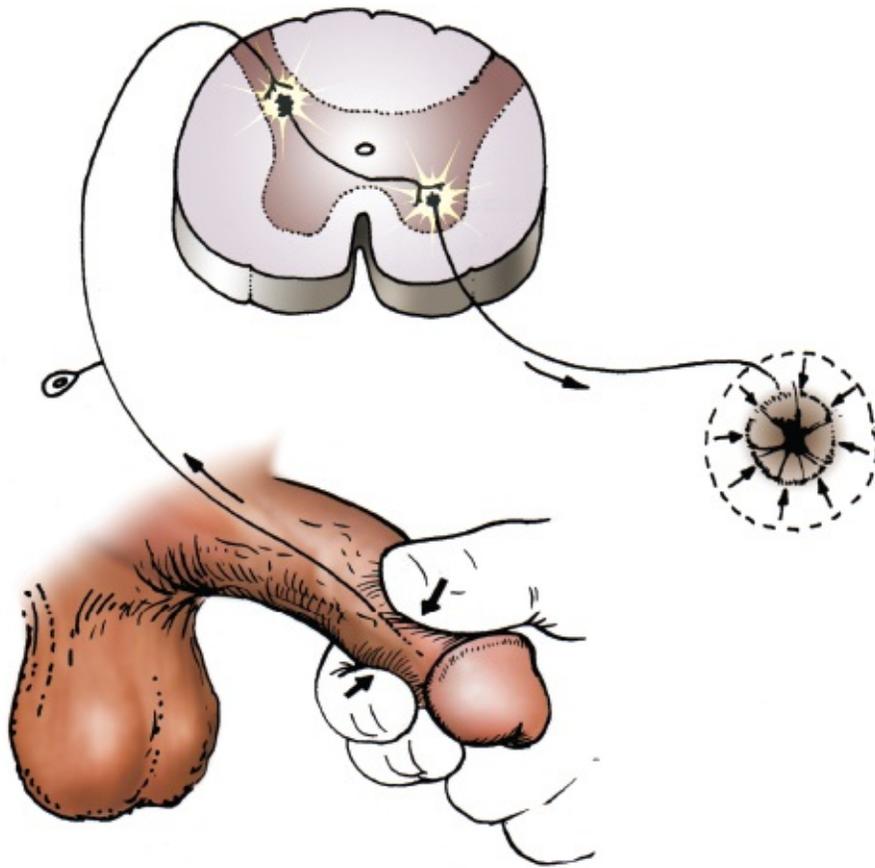

FIGURE 4-8 The bulbocavernosus reflex.

Herniated Thoracic Disks

The thoracic spine has the advantage of attachment to the ribs and sternal plate, which splint the vertebrae and provide added stability. With less motion, there is less chance for disk herniation and fracture and subsequent neurologic problems. Thus, thoracic herniated disks are rare in comparison to cervical and lumbar herniated disks.

Herniated thoracic disks usually produce *cord* involvement, whereas lumbar and cervical disks usually produce *nerve root* involvement. Because there is little extradural space in the thoracic spinal canal, a comparatively small disk protrusion may have pronounced effects on the neurology (Fig. 4-9). It is more difficult to make a clinical diagnosis of a herniated thoracic disk than a herniated cervical or lumbar disk. Although evaluation of muscle power, reflexes, sensation, and bladder and bowel function can assist in determining the level of involvement, magnetic resonance imaging (MRI) is the cornerstone for establishing the diagnosis. Note that with herniated thoracic disks, paraplegia

occasionally occurs.

Motor power is impaired, but not in a myotomal or neurologic pattern. Proximal and distal muscle groups are equally weak, and leg weakness may be unilateral or bilateral. Weakness of the lower abdominal muscles may be apparent, a situation that can be evaluated by Beevor's sign (see page 37). Muscle weakness may vary from mild paresis to complete paraplegia. Muscle tone is increased in most patients, as one would expect in an upper motor neuron lesion.
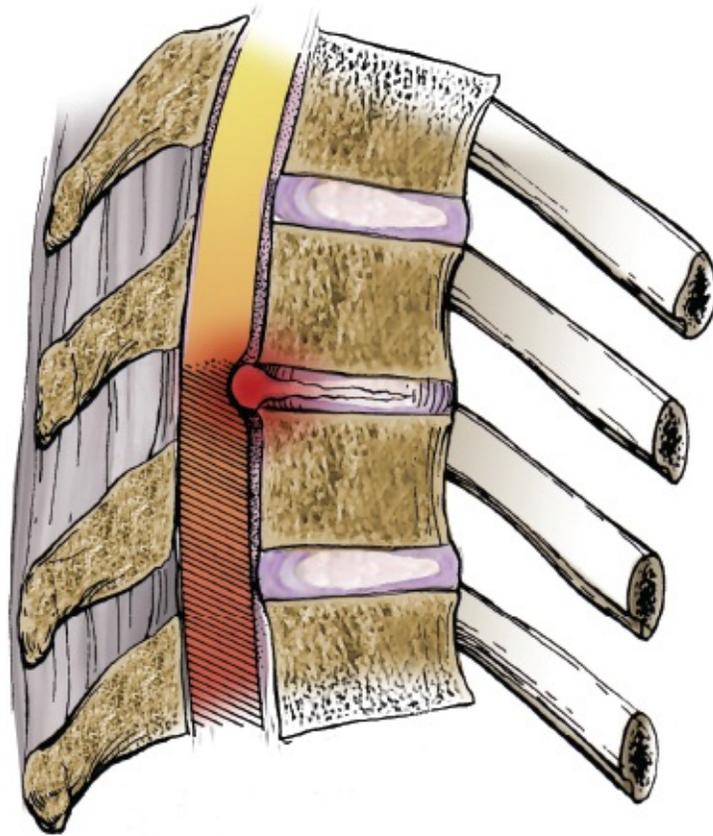

FIGURE 4-9 A herniated thoracic disk.

Sensation

Examination can determine the level of sensory involvement. Usually, it is one or two levels lower than the bony level depicted on the MRI.

Reflexes

Deep tendon reflexes: patellar and Achilles tendon reflexes are increased, brisk, or exaggerated.

Superficial reflexes: abdominal and cremasteric reflexes are absent.

Pathologic reflexes: Babinski's and Oppenheim's signs are usually present (Figs. 4-3 and 4-4).

Bladder and Bowel Function

Most patients have no bladder or bowel symptoms. Occasionally, a patient may experience urinary retention.

It should be clear from this discussion that the signs vary depending on the extent of the herniation. The variations themselves may be a tip-off to the diagnosis.

Evaluation of Spinal Stability to Prevent Further Neurologic Level Involvement

After spinal trauma, it is crucial to determine whether the spine is stable or unstable in order to protect the spinal cord. If the spine is unstable, it must be stabilized immediately to prevent further damage to the cord, and possible tetraplegia and paraplegia. The name of the game is to protect the spinal cord.

Diagnosis

The diagnosis of an unstable spine is based on the history of the mechanism of injury, the physical examination, and an x-ray examination. Stability depends essentially on the integrity of the posterior ligamentous complex, which consists of the following:

1. Supraspinous ligament
2. Interspinous ligament
3. Facet joint capsule
4. Ligamentum flavum (Fig. 4-10).

The breakdown of this ligamentous complex can be diagnosed by specific criteria, as shown in Table 4-1.

X-ray shows instability, shows whether there is separation of the spinous

processes, dislocation of the articular processes, and fracture.

Physical examination determines whether there is a palpable spinal defect (Fig. 4-11).

History may establish whether the injury was caused by flexion-rotation or excessive flexion. Direct longitudinal pull rarely ruptures fibers of the posterior ligamentous complex. However, direct longitudinal pull combined with rotation frequently ruptures fibers and results in spinal instability. Ligamentous healing is simply not strong enough to ensure spinal stability: a spine fusion is almost always necessary. If the fracture-dislocation does not disrupt the posterior ligamentous complex, bone healing is usually strong enough to ensure stability.

Flexion Injury

If, during flexion injury, the posterior ligament and complex remains intact, the force of flexion is spent on vertebral body, and a wedge compression fracture occurs. The vertebral end plates remain intact, and the spinous processes are only minimally separated. A wedge compression fracture is most often seen in the cervical and lumbar spines, and is considered a stable fracture; the bone fragments are firmly impacted and the posterior ligamentous complex, including the anterior and posterior longitudinal ligaments, remains intact (Fig. 4-12).

Excessive flexion results in tearing of the posterior ligamentous complex and disengagement of the posterior facet joints, leading to pure dislocation. The spinous processes are separated, and the vertebral bodies remain uncrushed because there is no fulcrum around which to compress them. This injury is more common in the cervical spine than in the lumbar spine; it does not occur in the thoracic spine because of the stability offered by the ribs and sternal plate. Pure dislocations such as these are unstable (Fig. 4-13,Table 4-2).
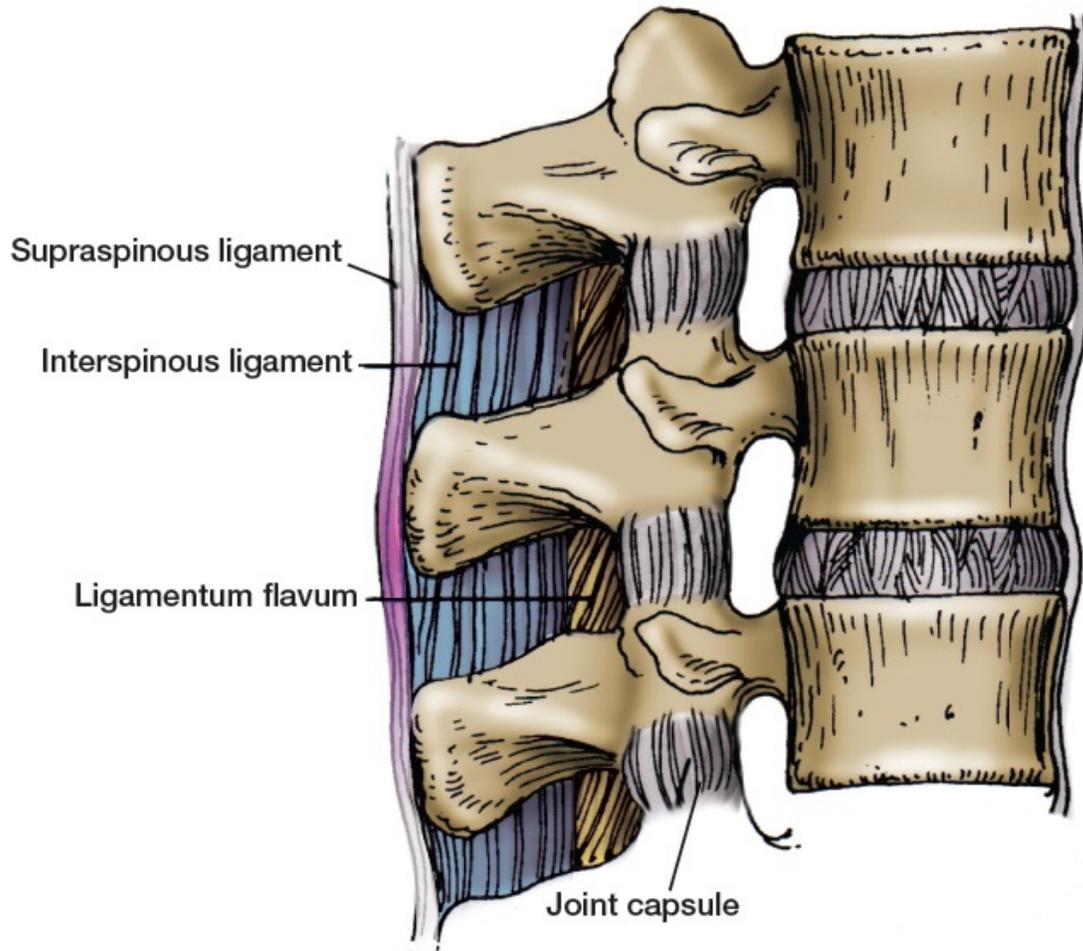

FIGURE 4-10 The posterior ligamentous complex.

TABLE 4-1 CRITERIA FOR STABILITY OF SPINE

HISTORY OF MECHANISM OF INJURY	PHYSICAL AND NEUROLOGIC EXAMINATIONS	X-RAY EXAMINATION SPECIFIC CRITERIA
Flexion-rotation Excessive flexion	Palpable spine defect Motor/reflex/sensation alteration Abrasions on the back	Spinous process separation Articular process dislocation and/or fracture
Disruption of posterior ligamentous complex	Disruption of posterior ligamentous complex	Disruption of posterior ligamentous complex
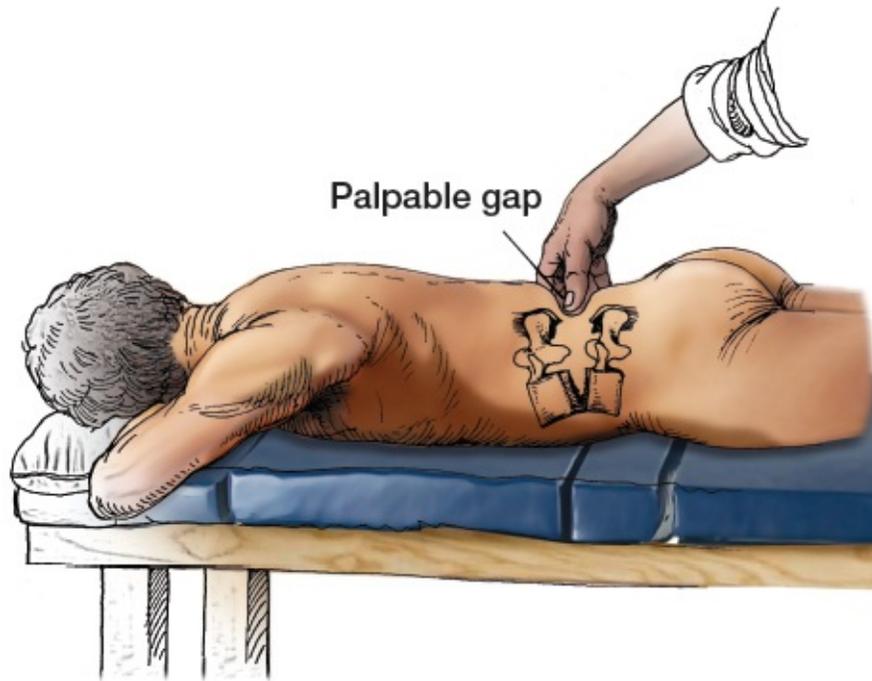

FIGURE 4-11 A palpable spinal defect indicating an unstable spinal injury.
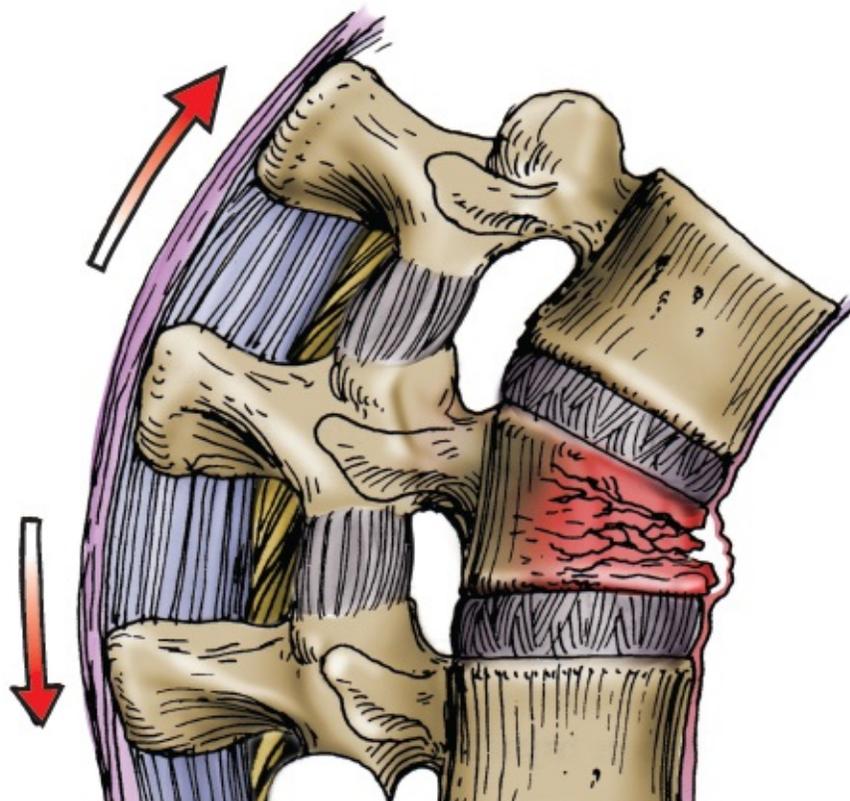

FIGURE 4-12 A stable flexion injury.
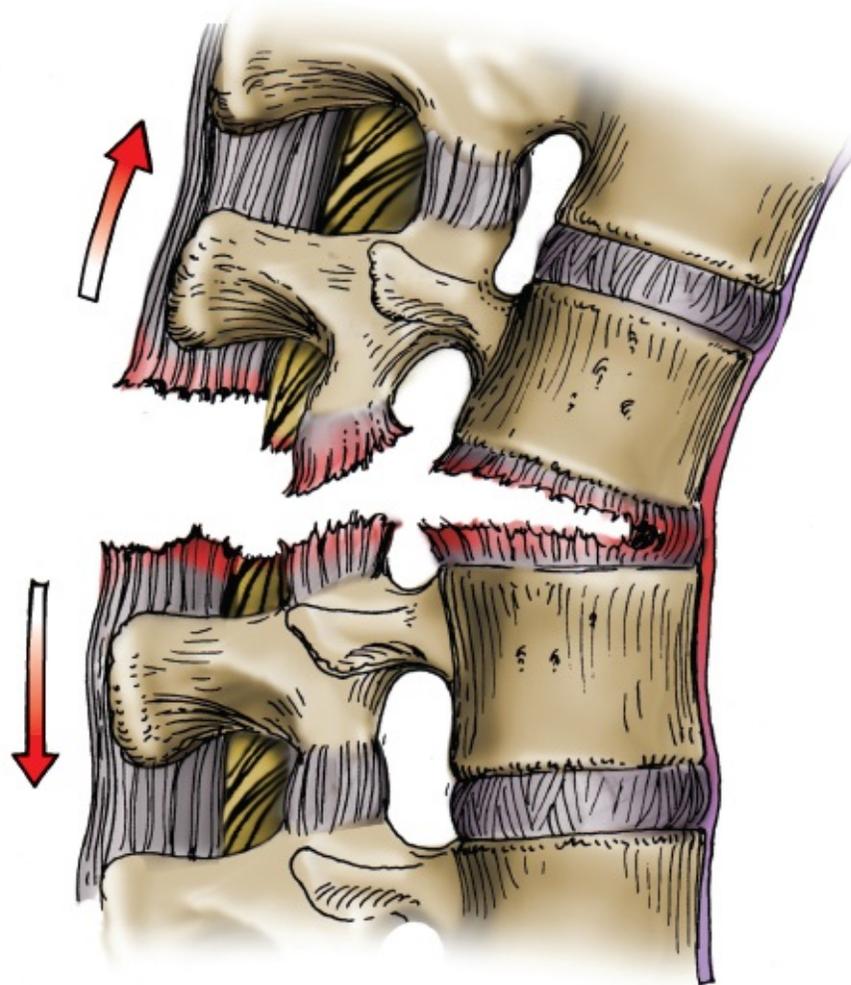

FIGURE 4-13 An unstable flexion injury.

Flexion-Rotation Injury

Flexion-rotation injury results in fracture-dislocations of the spine (Fig. 4-14). The posterior ligamentous complex ruptures, the rotating spine dislocates at the facet joints, and the articulating processes fracture. A slice fracture may also occur in the vertebra below the facet dislocation. In addition, the spinous processes are pulled apart and laterally displaced (Fig. 4-15). This type of injury is consistently associated with paraplegia. Injuries in the thoracolumbar area, it is very unstable and must be protected, for a partial lesion, or even a cord still untouched, can be converted into a complete lesion (Figs. 4-12 and 4-16, Table 4-3).

FIGURE 4-14 A flexion-rotation injury resulting in a fracture-dislocation of the spine.

Hyperextension Injuries

In hyperextension injuries (to the cervical spine), the anterior longitudinal ligament and annulus are disrupted and extension-dislocation occurs. The injury becomes stable if the neck is held in flexion. Frequently, x-rays taken with the neck in flexion are negative.

Compression Injuries

In compression injuries, the posterior ligamentous complex and the anterior and posterior longitudinal ligaments remain intact, and the spinous processes are not separated. The spine remains stable. However, a fragment that bursts posteriorly may compress the cord and cause tetraplegia in the cervical spine and paraplegia in the lumbar spine.

TABLE 4-2 CRITERIA FOR STABILITY OF CERVICAL SPINE

HISTORY OF MECHANISM	INTEGRITY OF POSTERIOR LONGITUDINAL	PHYSICAL EXAMINATION

5
Meningomyelocele

Determination of Level

Determining the level of neurologic involvement in meningomyelocele is crucial. It permits the evaluation of the following five major functional criteria:

1. Determination of the extent of muscular imbalance around each of the major joints of the lower extremity
2. Evaluation of the degree and character of any deformity
3. Assessment of remaining function and the need for bracing or surgery
4. Evaluation of bladder and bowel function
5. Baseline analysis for long-term follow-up

Although the defect frequently causes a total loss of innervation below it, this is not always so. In many cases, there will be partial innervation of several levels below the major level of involvement, or partial denervation of several levels above it. It is therefore necessary to determine not only the level that seems to be primarily involved but also the extent to which other levels may be affected. The level of involvement can be determined through muscle testing, sensory testing, reflex testing, examination of the anus, and evaluation of bladder function.

It is easier to test a newborn infant than a child. In the infant, the skin can be pinched to provide a painful stimulus and the muscle being tested can be palpated for contraction: the muscle will either react (positive indication of muscle function) or will remain inactive (indication of no muscle function). Although it is difficult to grade muscle strength accurately in an infant, it will be evident from palpation and observation whether the muscle is functioning at a minimum of grade 3: movement possible against gravity, but not against resistance by the examiner. The infant's muscular function can also be tested by appropriate electrodiagnostic studies such as electromyography and muscle

stimulation tests. Children are more difficult to test because they may refuse to respond, forcing the examiner to test many times to obtain an accurate evaluation. In addition, muscle grading is a necessity as soon as it is possible, especially when a child is old enough to cooperate, because the child may lose muscle power or the cord level of involvement may ascend, reducing functional capacity. As a result of such shifting involvement, further evaluation and surgical intervention may be necessary.

Deformities that result from meningomyelocele are usually caused by muscle imbalance. If the muscles around the joint are not working or if all muscles are functioning equally well, deformities seldom develop. It is usually when a muscle is working either unopposed or against a weakened antagonist that a deformity occurs. A mild muscle imbalance acting over a prolonged period of time may produce a deformity. Development of muscle imbalance after birth as a result of the involvement of additional neurologic levels may also lead to deformities. They may also appear as a result of postural problems if braces or splints are incorrectly applied, if the limbs remain constantly in one position until they become fixed, or if the patient is allowed to lie in one position in the crib (in most instances, the hips flex, abduct, and externally rotate; the knees flex; and the feet move into a few degrees of equinus).

Once a fixed deformity has developed, it tends to remain, even if the muscular imbalance disappears. For example, if nerve roots higher than the original lesion become involved, an existing deformity will usually not correct itself even though the previously unopposed muscle has ceased to function.

Evaluate the neurologic or cord level of involvement by motor testing each of the joints of the lower extremity. Then review the information within the broader concepts of neurologic levels to establish the diagnosis (Table 5-1).

The following meningomyelocele examination will evaluate each possible level of involvement from L1-L2 to S2-S3, its functional deficits, and its potential for causing deformity (Fig. 5-1).

L1-L2 Neurologic Level (L1 Is Intact, L2 Is Not)

Motor Function

Hip

Flexion: absent
Extension: absent

Adduction: absent

Abduction: absent

No function; there may be some hip flexion from the partial innervation of the iliopsoas (T12, L1-L3).

TABLE 5-1 MOTOR TESTING FOR NEUROLOGIC LEVEL

JOINT	ACTION	LEVEL
Hip	Flexion	T12, L1-L3
	Extension	S1
	Adduction	L2-L4
	Abduction	L5
Knee	Extension	L2-L4
	Flexion	L5,S1
Ankle	Dorsiflexion (ankle extension)	L4, L5
	Plantar flexion (ankle flexion)	S1, S2
	Inversion	L4
	Eversion	S1
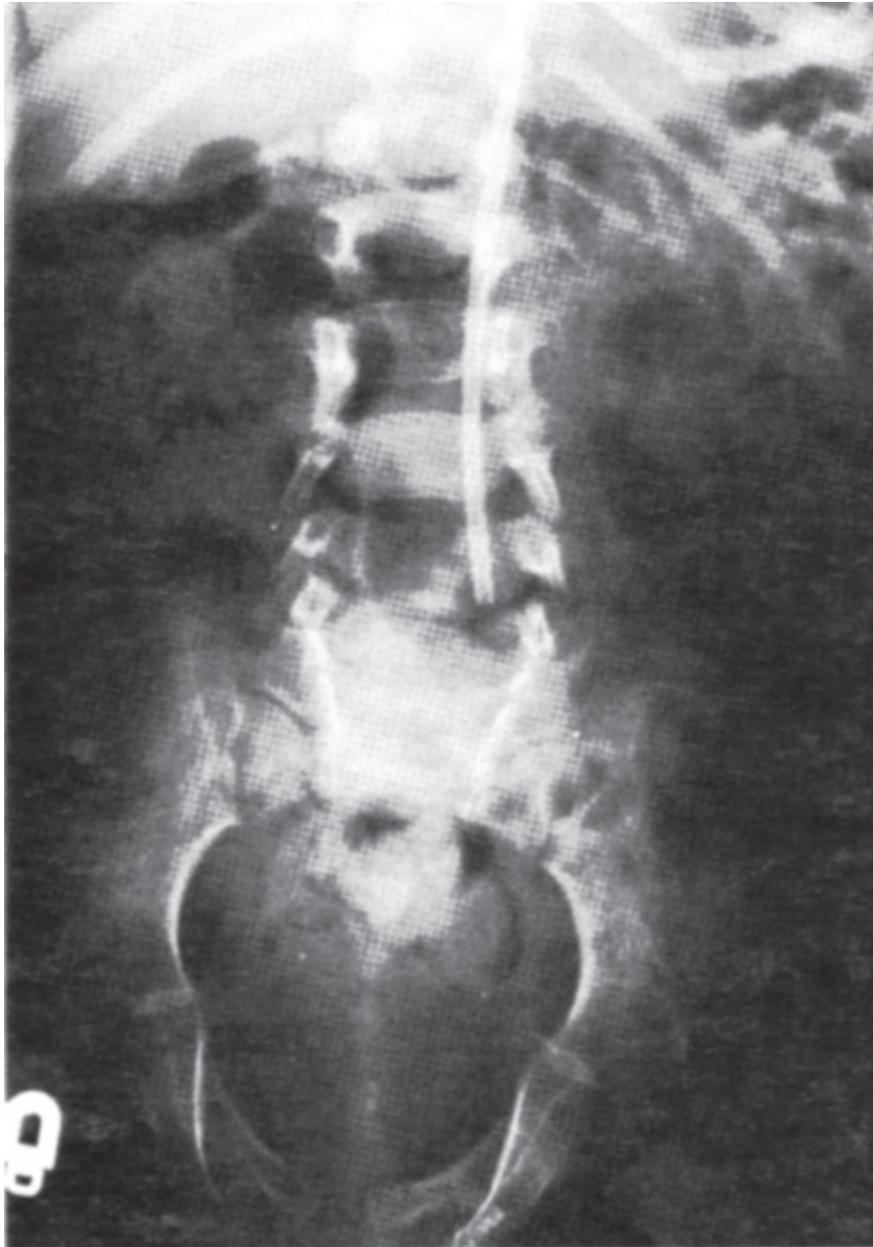

FIGURE 5-1 Meningomyelocele.

Knee
   Extension: absent
   Flexion: absent
   No function, no deformity

Foot
   Dorsiflexion: absent
   Plantar flexion: absent

Inversion: absent

Eversion: absent

No function; if there is any deformity, it may be a result of either the intrauterine position, a loss of function where there was once a muscle imbalance, or a crib position that has produced hip and knee flexion contractures and equinovarus deformity of the foot. The foot normally has a few degrees of equinus when at rest, a position that may become fixed.

Sensory Testing

There is no sensation below the L1 band, which ends approximately one-third of the way down the thigh (Fig. 5-2).
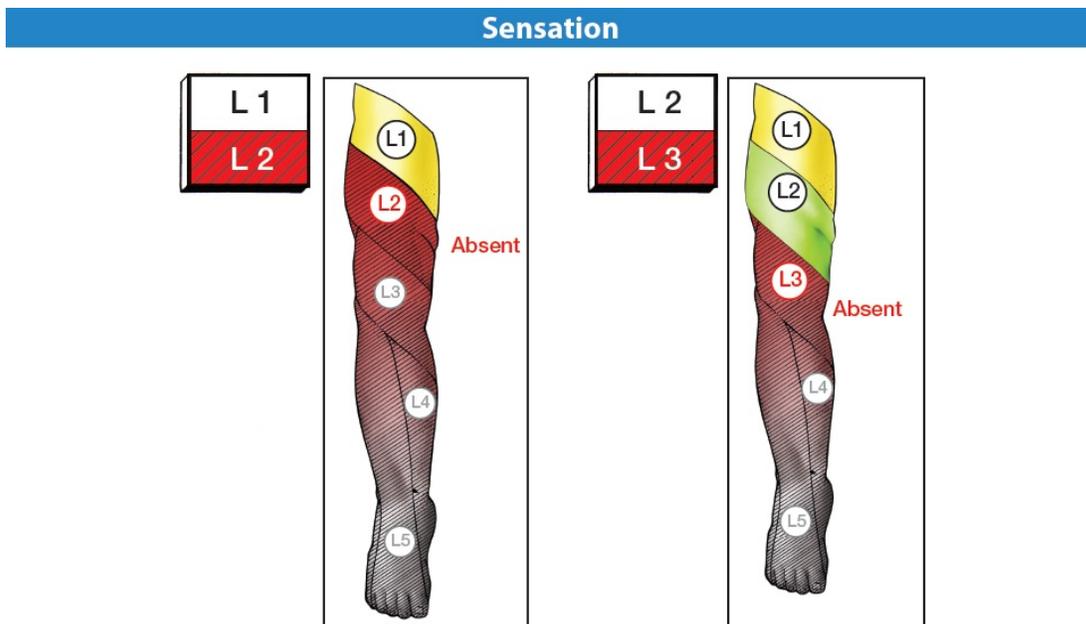

FIGURE 5-2 Lumbar sensory dermatome.

Reflex Testing

None of the deep tendon reflexes of the lower extremity function. Occasionally, reflex activity may occur as a result of the functioning of a portion of the cord below the involved neurologic level (intact reflex arc).

Bladder and Bowel Function

The bladder (S2-S4) is nonfunctioning, the patient is incontinent, the anus is patulous, and the anal wink (S3, S4) is absent. It should be noted that sacral sparing is not uncommon at any level. Lesions that give a pattern of

involvement in the sacrally innervated leg muscles but adequate innervation of the sphincter muscles are also common.

L2-L3 Neurologic Level (L2 Is Intact, L3 Is Not)

Motor Function

Hip

Flexion: partial
Extension: absent
Adduction: partial
Abduction: absent

Flexion is considerable, because the iliopsoas is almost completely innervated. There is, in addition, a hip flexion deformity because the iliopsoas is unopposed by the major hip extensor, the gluteus maximus (S1, S2). There is a small degree of hip adduction, with a corresponding slight adduction deformity because the adductor group (L2-L4) is partially innervated and is unopposed by the main hip abductor, the gluteus medius (L5, S1).

Knee

Extension: partial
Flexion: absent

The knee is not deformed in spite of the small amount of function of the knee extensor, the quadriceps (L2-L4). There is no significant clinical function.

Foot: No function, no muscular deformity, except as mentioned earlier.

Sensory Testing

There is no sensation below the L2 band, which ends two-thirds of the way down the thigh.

Reflex Testing

None of the lower extremity reflexes are functioning.

Bladder and Bowel Function

There is no function of the bladder and bowel. The patient cannot urinate in stream; the patient is only able to dribble urine. A stream may appear if the

patient is crying, as a result of the tightening of the rectus abdominus muscle and the corresponding increase in intra-abdominal pressure.

L3-L4 Neurologic Level (L3 Is Intact, L4 Is Not)

*Motor Function (*Fig. 5-3*)*

Hip
    Flexion: present
    Extension: absent
    Adduction: present
    Abduction: absent
    The hip has flexion, adduction, and lateral rotation deformities.
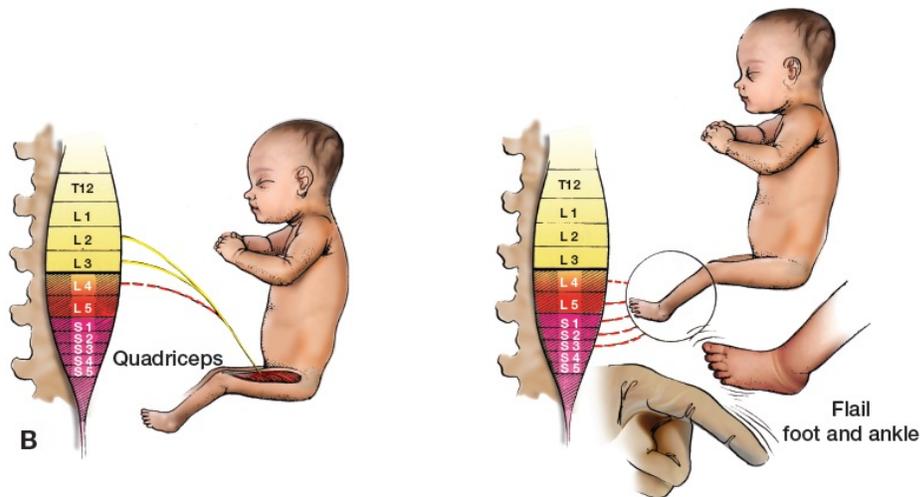

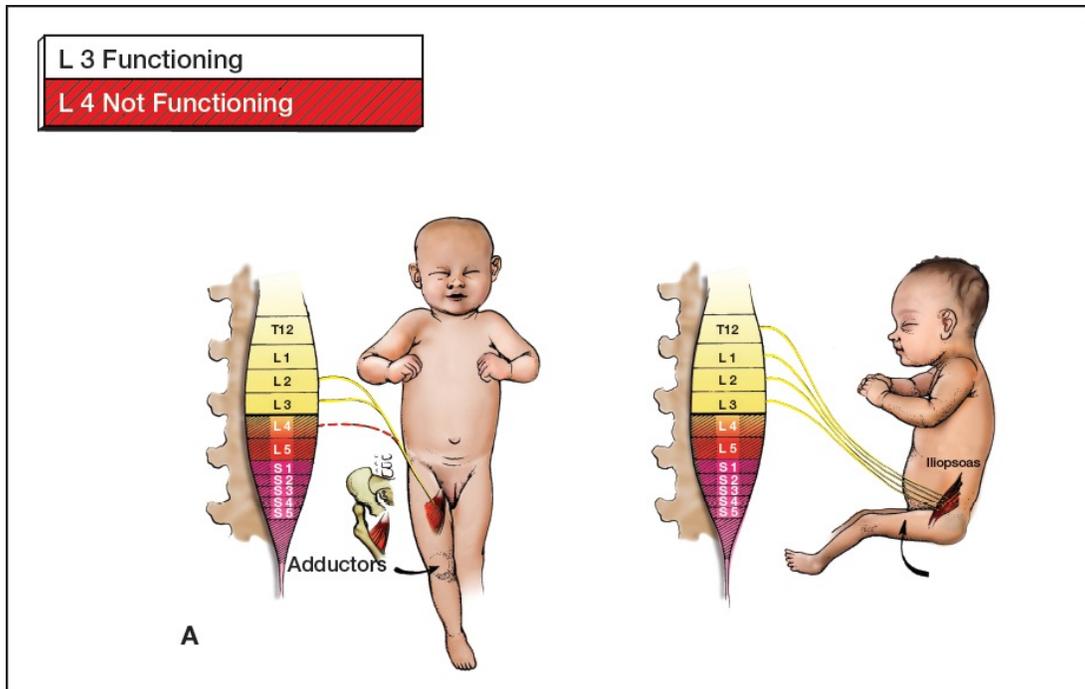

FIGURE 5-3 A, B Neurologic level L3-L4: motor function.

Knee
> Extension: present
> Flexion: absent
> The knee is fixed in extension by the unopposed quadriceps.

Foot
> Dorsiflexion: absent
> Plantar flexion: absent
> Inversion: absent

Eversion: absent

There are still no active muscles in the foot.

Sensation Testing

Sensation is normal to the knee. Below the knee, there is no sensation (Fig. 5-4).
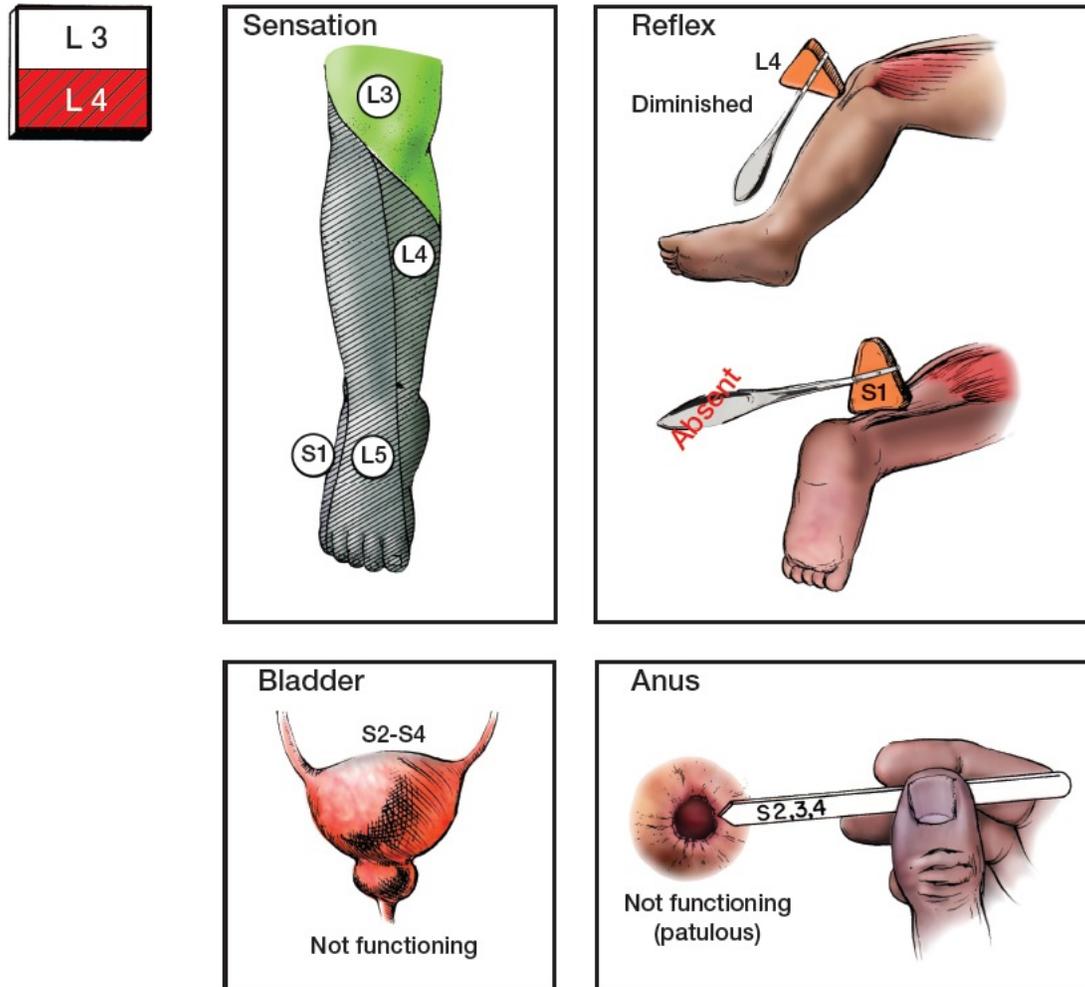

FIGURE 5-4 Neurologic level L3-L4: sensation, reflex, and bladder and bowel function.

Reflex Testing

There may be a slight, but obviously diminished, patellar reflex (L2-L4), because the reflex is primarily L4.

Bladder and Bowel Function

No function.

L4-L5 Neurologic Level (L4 Is Intact, L5 Is Not)

*Motor Function (*Fig. 5-5*)*

Hip

 Flexion: present
 Extension: absent
 Adduction: present
 Abduction: absent

 The hip has both flexion and adduction deformities, because the iliopsoas (T12-L3) and adductor muscles (L2-L4) are still unopposed. Such an unopposed adduction may over time result in a dislocated hip and, eventually, a fixed flexion-adduction deformity. For ambulation, full leg bracing will be necessary, including the use of a pelvic band, because the hip is unstable without extension and abduction. Surgery is also a possible solution.
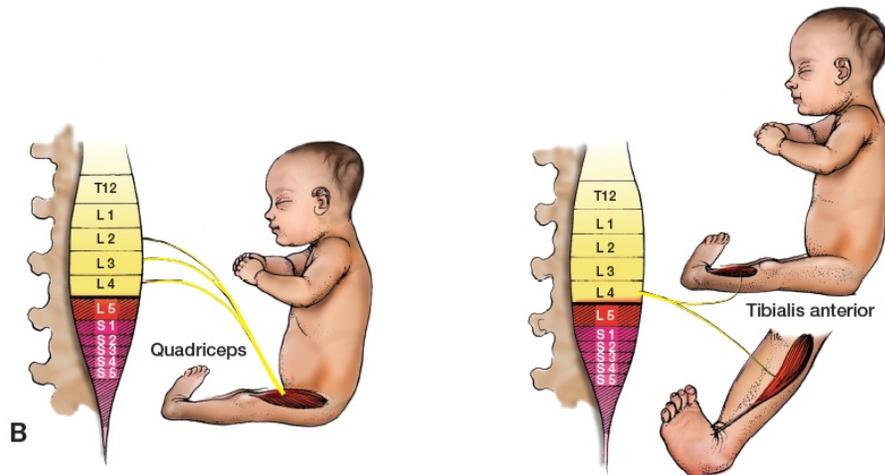

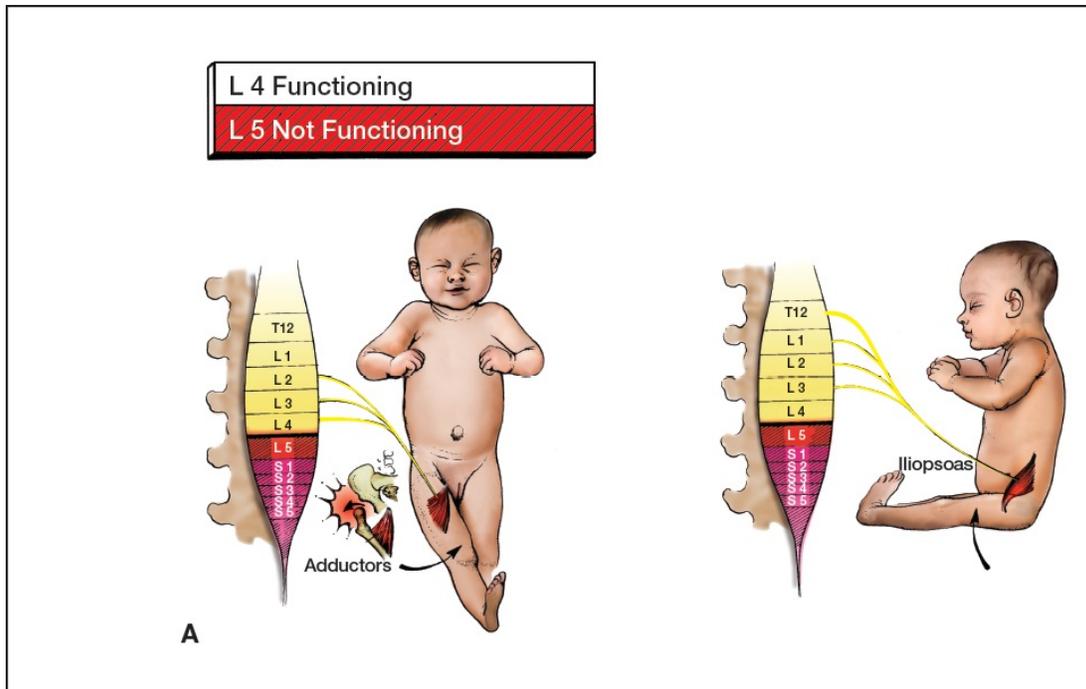

FIGURE 5-5 A, B Neurologic level L4-L5: motor function.

Knee

Extension: present

Flexion: absent

The knee has an extension deformity as a result of the unopposed action of the quadriceps. The main knee flexors, the medial and lateral hamstrings (L5 and S1), are denervated. An extended knee is relatively stable, and future bracing is not necessary. However, because the hip must be braced (unless surgery is performed), the knee is also braced.

Foot

> Dorsiflexion: partial
> Plantarflexion: absent
> Inversion: partial
> Eversion: absent

The only functioning muscle in the foot is the tibialis anterior (L4) because everything else is innervated by L5, S1-S3. The insertion of the tibialis anterior on the medial side of the foot at the first metatarsal–cuneiform junction causes the foot to be dorsiflexed and inverted. In this position, the foot is both unbalanced and unstable, and the tibialis anterior may have to be surgically released. The foot is not plantigrade and is without sensation; thus, skin breakdown may occur. Bracing is necessary, but fitting shoes and getting the foot into a brace may be difficult if some correction is not achieved.

Sensory Testing

Sensation extends to the medial side of the tibia and foot. The lateral aspect of the tibia (L5) and the middle and lateral portions of the dorsum of the foot are anesthetic (Fig. 5-6). A pinprick is the most effective way to test infants for sensation; if there is sensation, the child cries or moves the extremity. A triple response to the pinprick (flexion of the hip and knee, dorsiflexion of the foot) should not be confused with motor function at these joints. Such a general triple reflex response may occur even if the patient is completely paralyzed.

Reflex Testing

The patellar reflex (predominantly L4) functions, whereas the tendon of Achilles reflex (S1) does not. If there is hyperactivity in the tendon of Achilles reflex, a portion of the cord below the original lesion has developed with intact nerve roots, without connection to the rest of the cord. Thus, the S1 ankle reflex arc is intact, and only the inhibitory and controlling factor of the brain is missing.
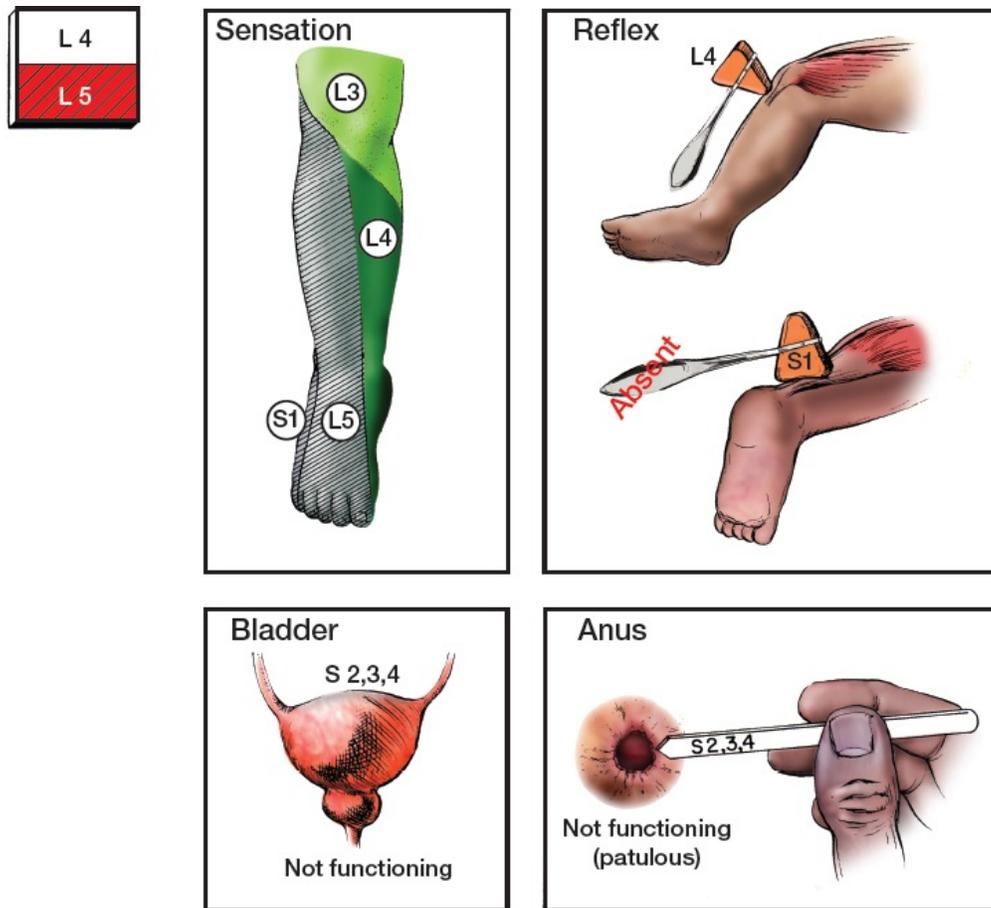

FIGURE 5-6 Neurologic level L4-L5: sensation, reflex, and bladder and bowel function.

Bladder and Bowel Function

Neither the bladder nor the bowel functions.

L5-S1 Neurologic Level (L5 Is Intact, S1 Is Not)

Motor Function (Fig. 5-7)

Hip

    Flexion: present
    Extension: absent
    Adduction: present
    Abduction: present
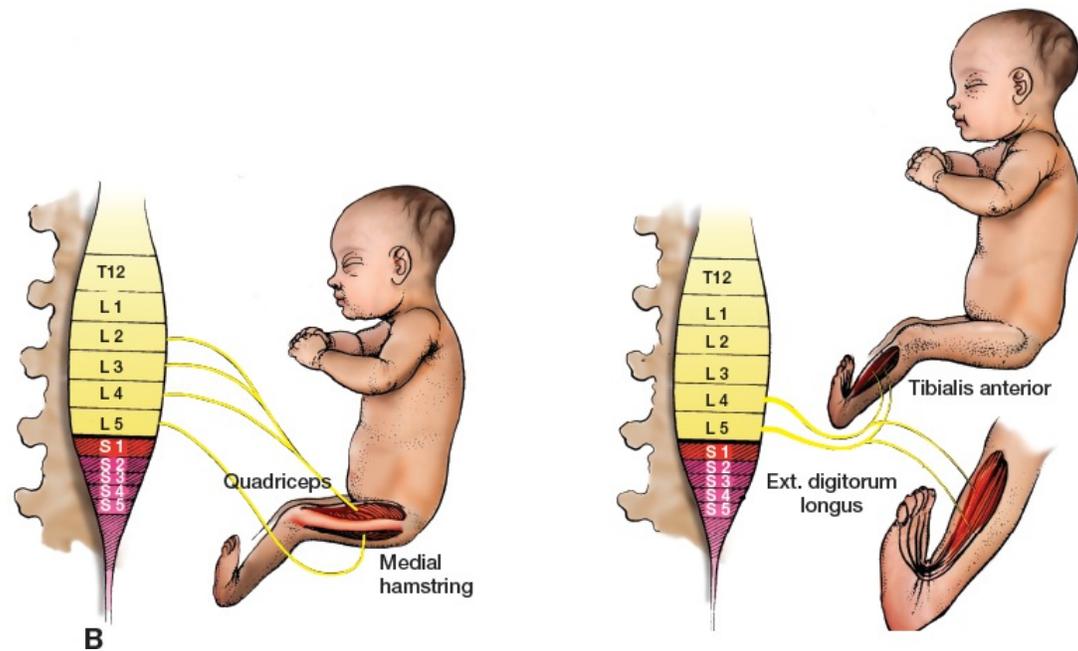

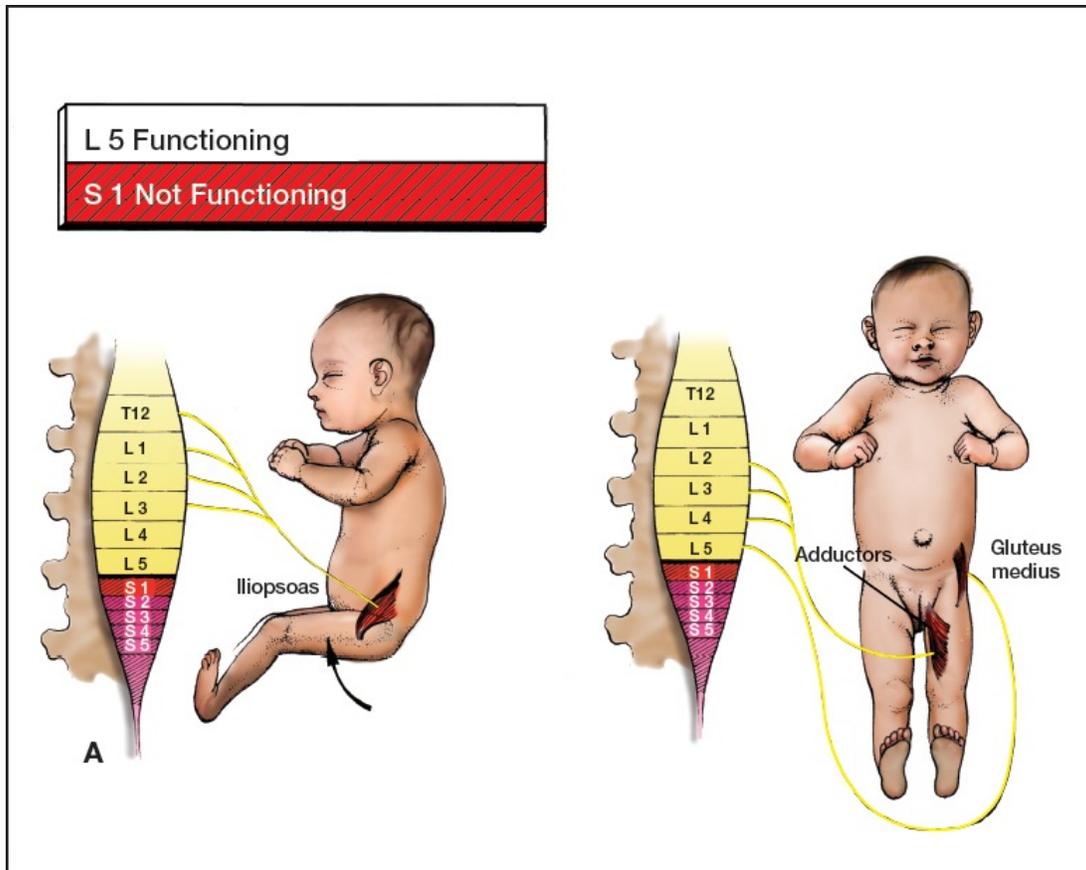

FIGURE 5-7 A, B Neurologic level L5-S1: motor function.

There is a flexion deformity of the hip, because the gluteus maximus is not

working. There is now a balance between adduction and abduction; however, a minimal adduction deformity may still exist because the gluteus medius, partially supplied by S1, is slightly weak. Because of this partial balance, there is usually no hip dislocation. However, if the gluteus medius is excessively weak, the hip may later sublux. For ambulation, bracing or surgery will be necessary to prevent severe fixed flexion deformity.

Knee

Extension: present

Flexion: partial

The knee is relatively well balanced, and there are no deformities. The extensors are working; the flexors are functioning in part, with the medial hamstrings (L5) in and the lateral hamstrings (S1) out. Because of this, there may be a slight weakness in flexion. Bracing will be unnecessary.

Foot

Dorsiflexion: present

Plantarflexion: absent

Inversion: present

Eversion: absent

The dorsiflexors all function. Therefore, the foot will have only a dorsiflexion deformity (calcaneal foot).

Sensory Testing

Sensation is absent on the lateral side and plantar surface of the foot (Fig. 5-8). Elsewhere, it is normal.

Reflex Testing

The tendon of Achilles reflex is still absent.
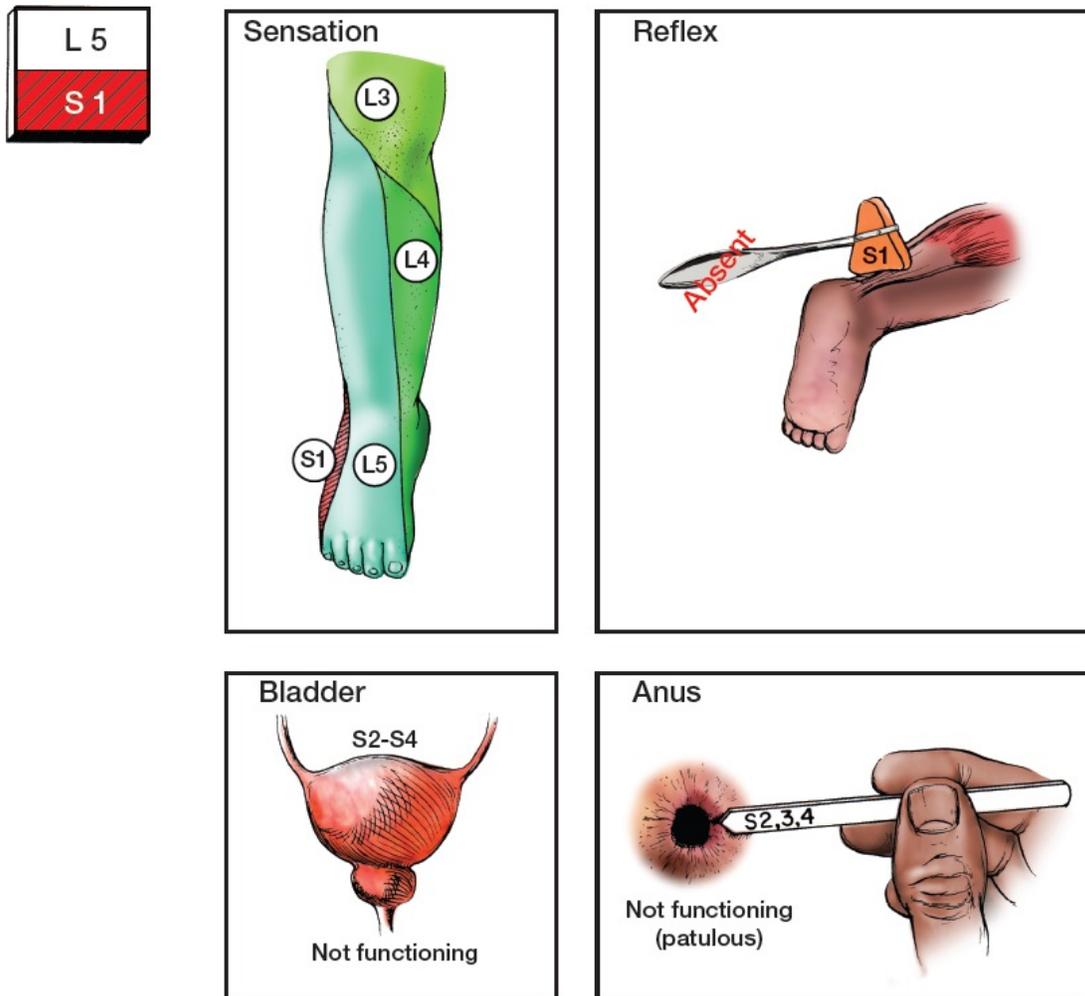

FIGURE 5-8 Neurologic level L5-S1: sensation, reflex, and bladder and bowel function.

Bladder and Bowel Function

The bladder and bowel are still nonfunctional.

S1-S2 Neurologic Level (S1 Is Intact, S2 Is Not)

*Motor Function (*Fig. 5-9*)*

Hip
 Flexion: present
 Extension: partial
 Adduction: present

Abduction: present

The hip is almost normal; there may be slight gluteus maximus weakness, which is innervated by L5, S1, and S2.

Knee

Extension: present
Flexion: present
The knee is normal and well balanced.
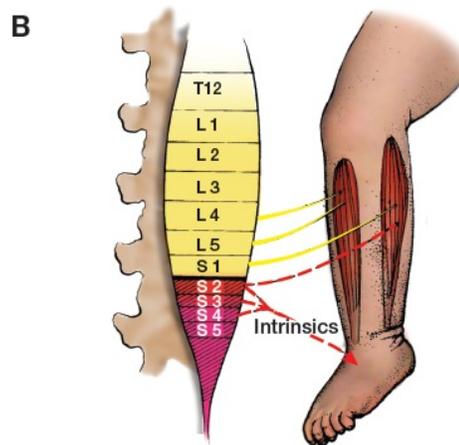

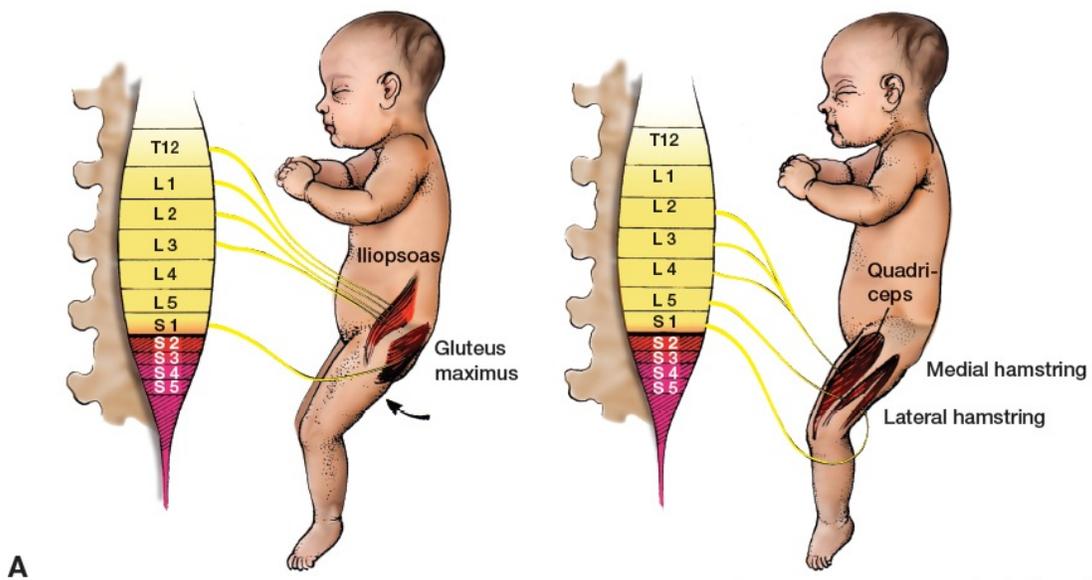

FIGURE 5-9 A, B Neurologic level S1-S2: motor function.

Foot

    Dorsiflexion: present
    Plantarflexion: partial
    Inversion: present
    Eversion: present
    The toes of the foot may become clawed, because the intrinsic muscles are still not functioning. In addition, plantar flexion is still weak. Future gait will show weakened or absent toe-off, and the forefoot may be broken on the hindfoot from muscle imbalance (calcaneovalgus of the forefoot). The foot may have a vertical or dislocated talus (convex pes valgus).

Sensory Testing

Sensation is normal except for the posterior strip in the thigh and leg and on the sole of the foot (S4) (Fig. 5-10).

Reflex Testing

The tendon of Achilles reflex, although it functions, may be slightly weakened. The reflex is predominantly an S1 reflex with elements of S2.

Bladder and Bowel Function

The bladder and bowel are still not functioning.

S2-S3 Neurologic Level (S2 Is Intact, S3 Is Not)

Motor Function

Hip: Normal.

Knee: Normal.

Foot: The toes of the foot may become clawed in time; there may also be a cavovarus deformity.
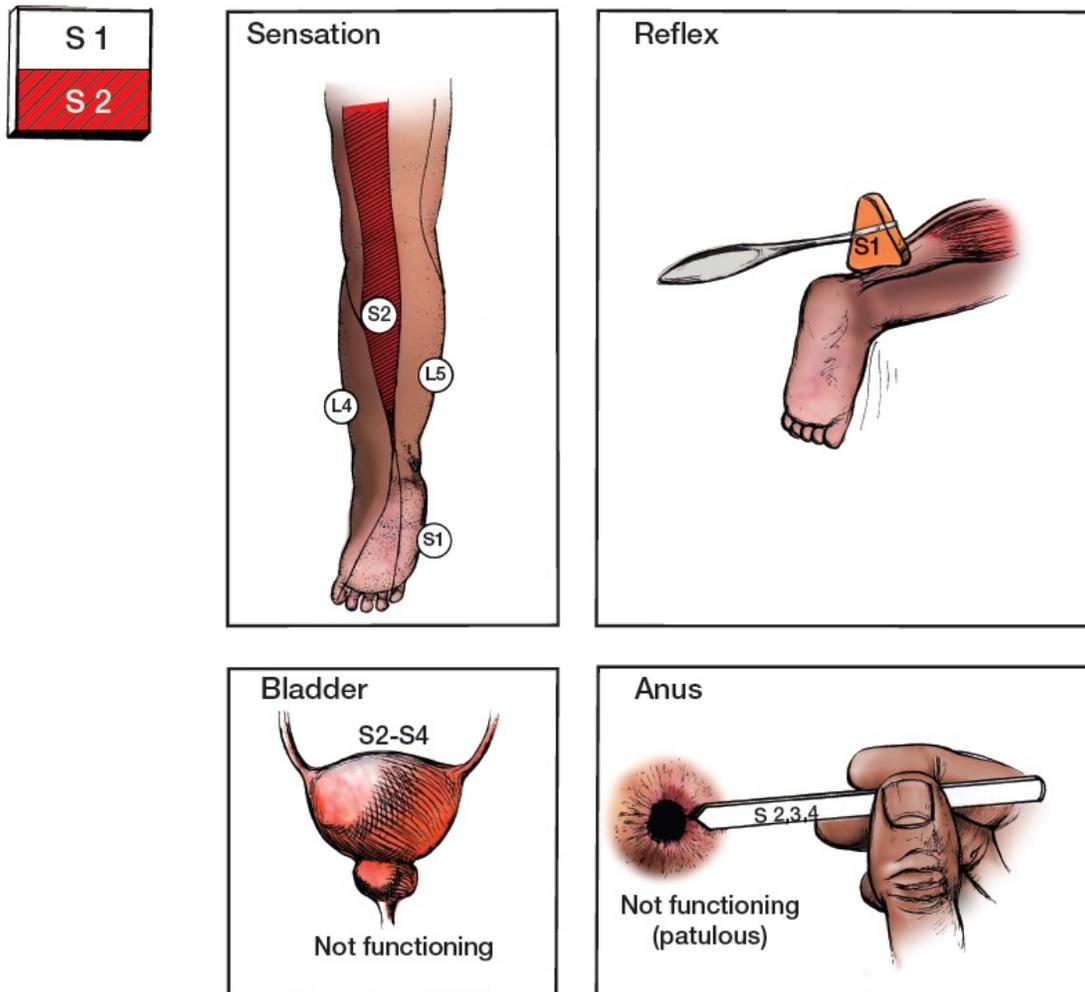

FIGURE 5-10 Neurologic level S1-S2: sensation, reflex, and bladder and bowel function.

Sensory Testing

Sensation is normal.

Reflex Testing

Reflex is normal.

Bladder and Bowel Function

There is often some bladder activity; a portion of the anal wink is present.

Milestones of Development

Sitting, standing, and walking are three developmental indicators that are useful in determining the future gross motor functional capacity of the patient. Most patients with meningomyelocele experience some delay in reaching these milestones; the amount of delay and degree of difficulty that they encounter provide valuable information as to the course of future rehabilitation.

Sitting

Normally, a child learns to balance himself while sitting at six months of age, and can pull himself to a sitting position at seven to eight months. A child with a lesion above L3 sits late—at approximately ten months—because of muscle weakness around the hips. A child with a high thoracic lesion may have spinal instability, forcing him to balance himself, with the help of his hands, in the tripod position. A spinal fusion stabilizes the spine, freeing the hands for activities of daily living.

Standing

A child is normally able to pull himself to a standing position at nine to ten months. A child with a thoracic meningomyelocele is unable to do this, no matter what the level of lesion. He should be offered bracing for stability; he may still experience some difficulty, however, because braces are both heavy and cumbersome.

Walking

Ambulation normally begins at 12 to 15 months (range; 8 to 18 months). Although almost all children with meningomyelocele have problems with ambulation, independent ambulation with the aid of appliances is possible for those with normal intelligence and involvement in the lumbosacral region. Children are usually more extensively braced than they would be as adults until they reach midadolescence (12 to 15 years). After that time, most patients with lesions higher than S1 will become limited ambulators because of the excessive energy that must be expended as a result of the weight their arms must bear; ambulation with braces and crutches requires as much energy as running at top speed.

Unilateral Lesions

Bifid cords with widely discrepant levels of function are not uncommon. There is a serious possibility that a bony or cartilaginous spur will cause tethering of the cord as the column grows (diastomatomyelia) (Fig. 5-11); any sign of such unilateral loss of function is an indication for a myelogram. Scoliosis, the lateral curvature of the spine, is a significant concomitant problem for those in this group.

Hydrocephalus

From 50 to 70 percent of children with meningomyelocele develop hydrocephalus, an abnormal increase in the ventricular size, resulting in enlargement of the head and abnormal prominence of the forehead. Hydrocephalus usually develops secondary to Arnold-Chiari malformation (caudal displacement of the brain stem). If it is left unattended, it can lead to spasticity that may further decrease already compromised muscle function on either marginally or normally innervated muscles. If hydrocephalus is treated early, ventricular size, and thereby head circumference, can be maintained within normal limits. The usual method of therapy is with a shunt and appropriate revisions, if necessary. The shunt is a tube that drains excess spinal fluid from the ventricles of the brain to the peritoneal cavity or heart.
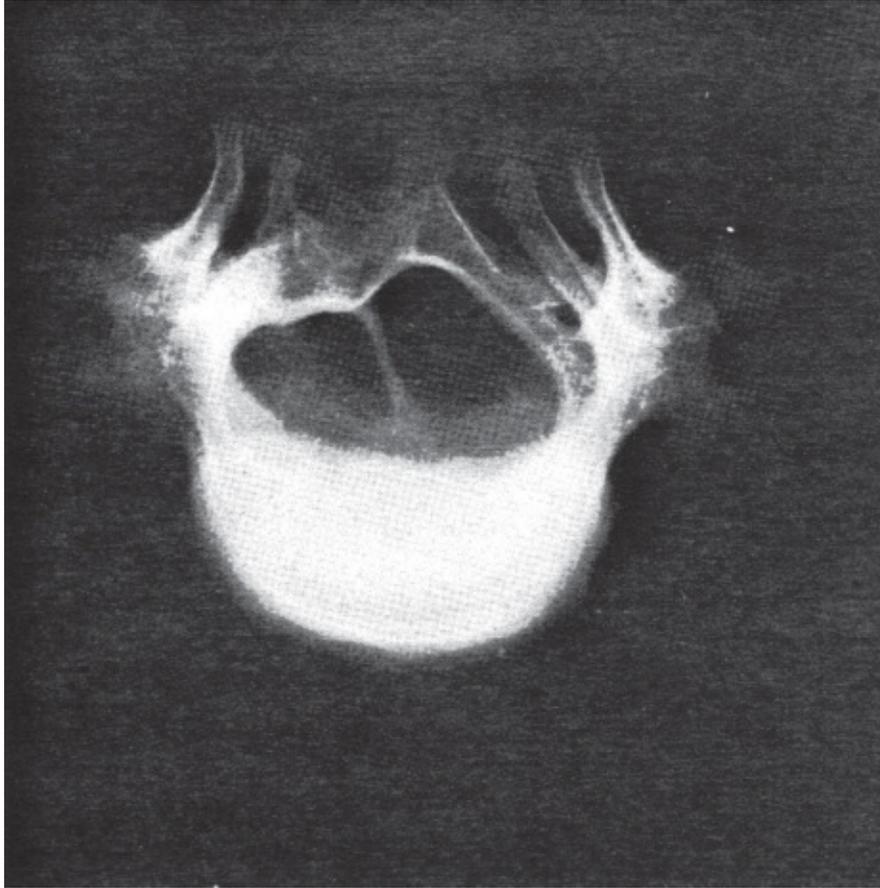

FIGURE 5-11 Diastomatomyelia (Hoppenfeld, S.: J *Bone Joint Surg*., 493:276, 1967).

Examination of the Upper Extremity

Although the great majority of meningomyelocele lesions occur in the lumbosacral region, higher lesions affecting the function of the upper extremity may occur in association with these lower lesions, necessitating a complete neurologic evaluation of the upper extremity. Hydromyelia (enlargement of the central canal of the spinal cord) and syringomyelia (liquid filling abnormal cavities in the substance of the spinal cord) of the cervical cord may also occur in association with meningomyelocele of the lumbar and sacral regions. Both these pathologies are progressive and require careful motor and sensory testing of the upper extremity with provisions for follow-up care. To patients with

meningomyelocele, the upper extremities are particularly important because of their use in crutch walking.

Suggestions for Examination of the Patient with Meningomyelocele

1. Do not mistake the withdrawal response for voluntary control of motor power. Even though a pinprick stimulus may cause withdrawal at three joints —hip flexion, knee flexion, and ankle dorsiflexion (the triple response)—the infant does not necessarily feel the noxious stimulus. It is necessary to watch the child for signs of crying and changes in facial expression to determine whether there exists a *central recognition* of pain.
2. To muscle test the hamstrings, position the patient face down on the edge of the examining table so that the hips and lower extremities hang freely (Fig. 5-12). Stabilize him. Then determine whether he can flex his knees. If the knee flexes, it is working against gravity and is acting with at least grade three strength (Fig. 5-13). During testing, palpate medially to determine activity of the semimembranosus and semitendinosus (L5) and laterally for the biceps femoris (S1).
3. To muscle test the gluteus maximus, continue to hold the patient in the same position and have the patient extend the hips, indicating gluteus maximus activity (S1) (Fig. 5-14).
4. It is by far easier to evaluate function in young children by playing with them than by conducting a formal examination.
5. Make certain that the patient is warm and comfortable during the examination.
6. Have the nursing staff record their observations of any spontaneous movements of the patient's extremities.
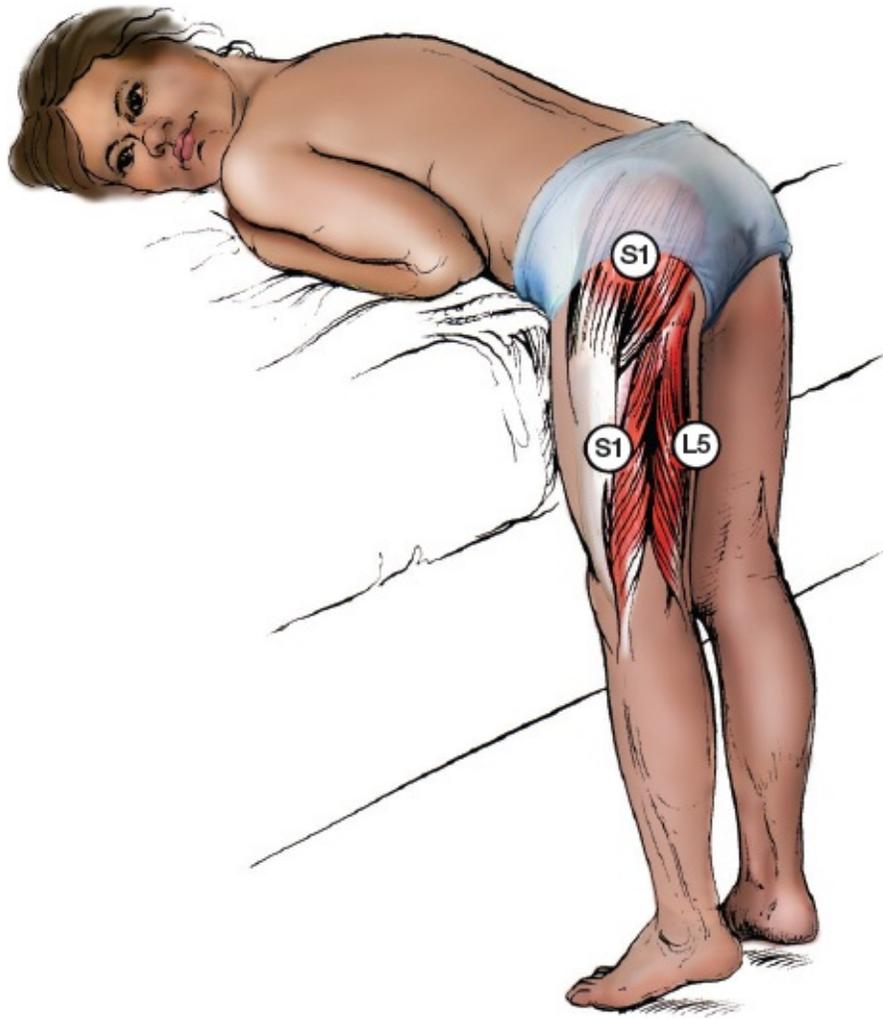

FIGURE 5-12 Position for testing the hamstring and gluteus maximus muscles.
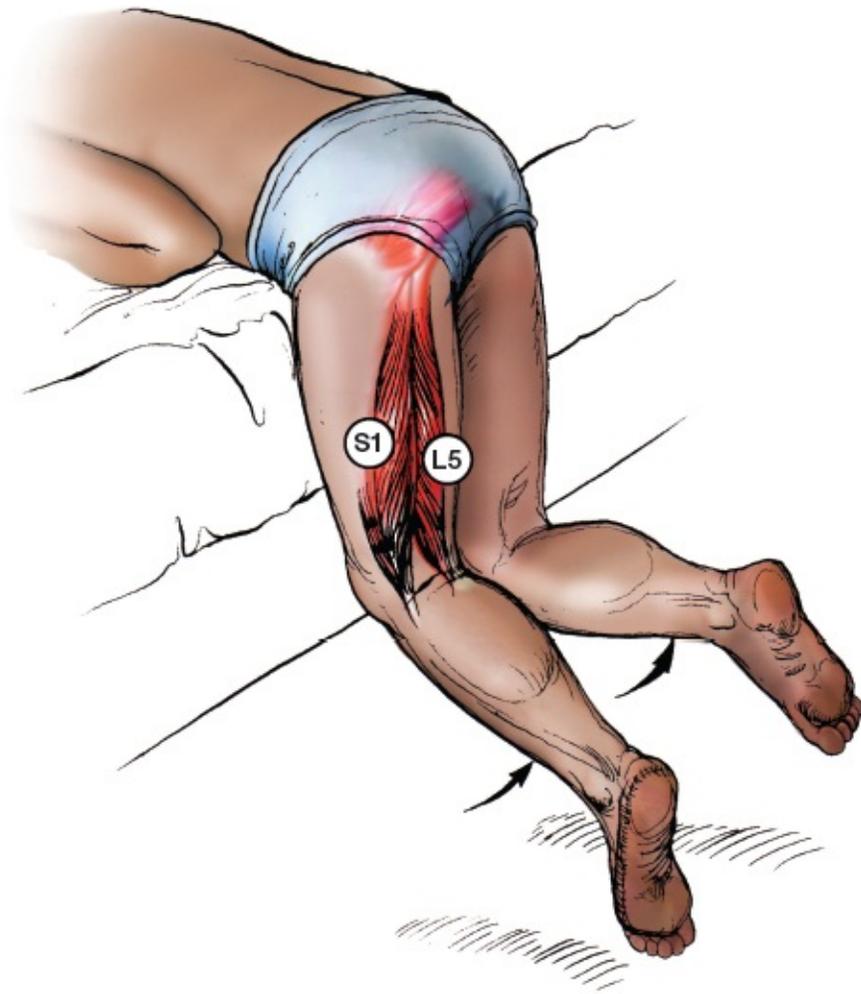

FIGURE 5-13 Contraction of the medial hamstring muscle indicates integrity of L5 neurologic level; contraction of the lateral hamstring muscle indicates integrity of S1 neurologic level.
